The notion EMBEDDING refers to all types of clauses occurring as subordinate parts of their superordinate clauses (which themselves may be either main or subordinate). The starting point will be the classical view of subordination as expounded in Quirk et al. (1989, Chapter 14). Typical finite sub-clauses are of three types: complement, relative, and adverbial. They are indicated by subordinators or relative pronouns, henceforth called sub/wh-elements.

CENTER-EMBEDDED clauses have words of the superordinate clause both to their left (excluding subordinators and coordinators) and to their right, as the relative clauses in (1, 2) and the *when*-clause in (3). SELF-EMBEDDING is multiple center-embedding invoking two or more clauses of the same type, e.g. two relative clauses as in (4). In the examples, the gross clausal structure is indicated by angular brackets prefixed by the character 'C' for center-embedding and an integer indicating dept of embedding.

- (1) Others [_{C-1} who are attracted to this Mecca of the beat generation] are heroin addicts and small hoodlums. (Brown Corpus)
- (2) Another frequent pioneer difficulty, [_{C-1} caused by wearing rough and heavy shoes and booths,] was corns (Brown).

- (3) On March 13, [_{C-1} when he preached a sermon on the text,] he told his congregation how disappointed he was (Brown).
- (4) For an analysis of the possible modifications [_{C-1} of which the pathological termination of an act [_{C-2} which is not according to law] are susceptible] we have therefore ... (Jeremy Bentham)

When a sentence contains multiple embeddings of the same type, e.g. two center-embeddings as in (4), the DEGREE OF EMBEDDING is equal to the number of embeddings and occasionally indicated by the character 'C' superfixed with the degree. Thus, (4) is an instance of C², double center-embedding.

A clause embedded after the initial subordinating (or coordinating) conjunction of the superordinate clause is not center-embedded but initially-embedded, e.g. the I-2-clauses in (5, 6):

- (5) [_{I-1} If [_{I-2} what is tantamount to dictatorship ...] continues in a union] it can ... (Lancaster-Oslo/Bergen Corpus = LOB))
- (6) c. [_{I-1} If [_{I-2} when I'm 38] Metallica ends] I don't think ...] (British National Corpus = BNC)

Here, the subordinating conjunctions of the respective I-1-clauses are not fully integrated syntactic constituents in their clauses and therefore a further clause embedded after them is not center-embedded but initially-embedded. The superordinate clause material preceding a center-embedding must consist of full syntactic constituents, as in (1-4).

Empirical data on multiple center-embedding

By systematically searching the Brown and LOB corpora, by checking the extant scarce empirically-minded literature on multiple center-embedding, by consulting more than 100 older grammars, style manuals and philological studies especially of older forms of German and Latin, and furthermore by manually analyzing 6000 sentences by three 19th century scholars known for their intricate and syntactically complex language use (Jeremy Bentham, John Stuart Mill, C. S. Peirce), Karlsson (2007) established a data pool of 13 triple center-embeddings, C³, and 104 double center-embeddings, C². As every C³ contains two C²s, the total number of C²s is 130. The languages concerned were English, German, Latin, Swedish, Finnish, French and Danish, from Antiquity to the 21st century.

Here are three of the C³s observed:

- (7) In an excellent article ... Salvini draws a parallel between the way [_{C-1} in which the spoken Latin of the men [_{C-2} with whom Gregory of Tours, [_{C-3} whom he has no reason to mention,] must have mixed] eventually became Old French ...,] and the comparable direct development of pre-Romanesque painting ... (L. Thorpe, *Gregory of Tours: The History of the Franks*, 1974; due to Geoffrey Sampson)
- (8) The Prime Minister [_{C-1} who at the height of the crisis had snapped to a junior minister [_{C-2} who, [_{C-3} not having seen him for some time,] had approached him in a Westminster corridor with a view to wishing him luck ...,] 'If you want to resign, put it in writing',] was unlikely to ... (Patrick Cosgrave 1979; De Roeck et al., 1982)
- (9) A person [_{C-1} who, [_{C-2} when riding a cycle, [_{C-3} not being a motor vehicle,] on a road or other public place,] is unfit to ride through drinks or drugs,] shall be guilty of an offence. (*British Road Traffic Act*, 1972; Hiltunen, 1984)

Here are four C^2 s ('F' = finally-embedded clause; '&' coordinated clause):

- (10) And yet a widow, [_{C-1} whose pension, [_{C-2} for which her husband paid,] is wiped out [_{F-2} because she works for a living wage,]] will now ... (LOB)
- (11) At one point in the game [_{C-1} when the skinny old man in suspenders [_{C-2} who was acting as umpire] got in the way of a thrown ball] [&_{C-1} and took it painfully in the kidneys,] he lay there ... (Brown)
- (12) ... the girl ... [_{C-1} who was clothed in the tightest-fitting pair of slacks [_{C-2} I had ever seen on a woman] and a sweater [_{F-2} that showed everything [_{F-3} there was]]] wanted to be sociable.] (Brown)
- (13) But the idea [_{C-1} that the fact [_{C-2} that some pain is heading my way] gives me no special reason to avoid it] seems so at odds with ...] (Internet)

On the basis of the material collected, Karlsson (2007) induced the following generalizations:

- (14) The maximal degree of multiple center-embedding is three in written language, but C^3 is so rare as to be practically non-existing (only 13 instances found).
- (15) The maximal degree of multiple center-embedding is two in spoken language, but it is so rare as to be practically non-existing (only three instances found).
- (16) Only clauses that postmodify nouns (i.e. relative clauses as in (7, 8, 10 12), complement *that*-clauses as in (13), and indirect questions allow central self-embedding.
- (17) A C^2 must contain at least one postmodifying clause.
- (18) The typical C^3/C^2 contains a pair of relative clauses, and is located at the end of the grammatical subject immediately before the main verb. Its main function

is to aid in the specification of the topic of the sentence.

- (19) A/the lower clause in a multiple center-embedding must contain at least one overt pronoun, preferably as grammatical subject.
- (20) Direct objects must not be multiply relativized in C^2 s or C^3 s.

In practice, constraint (15) rules out multiple center-embedding in spoken language. This means that genuine rested syntactic recursion under no circumstances can be considered an important design feature of natural language syntax.

Constraint (18) is explicable by the fact that the S-V junction is the major natural syntactic break in SVO-languages, between the topic (the grammatical subject) and the comment.

Constraint (20) rules out the classical sentence (21), even if (21) is in conformance with constraint (14). Sentence (21) has often been used in the literature as supposed proof of the absence of constraints on the degree of multiple center-embedding.

- (21) The rat_j [_{C-1} the cat_k [_{C-2} the dog_m chased _┐_k] killed _┐_j] ate the malt.

Not a single genuine example of double object relativization was found in Karlsson's (2007) corpus, nor are there any in the literature known to me. (In (21), the traces of the preposed objects are indicated.)

Gibson's processing theory

Edward Gibson's (1998) Syntactic Prediction Locality Theory (SPLT) has been influential in accounting for the relationship between the sentence processing mechanism and the available (mental) computational resources.

The theory has two components: an INTEGRATION COST component and a component for the MEMORY COST associated with keeping track of obligatory syntactic requirements. The type of memory concerned is, of course, working memory (WM). WM cost is quantified in terms of the number of syntactic categories that are necessary to complete the current input as a grammatical sentence. Both memory cost and integration cost depend on LOCALITY. The longer a predicted category must be kept in WM before the prediction is satisfied, the greater is the memory cost for maintaining that prediction. The greater the distance is between an incoming word and the most local head or dependent to which it attaches, the greater the integration cost.

When a syntactic prediction has been made, a WM cost of one memory unit (MU) is taxed every time a new discourse referent is encountered until the prediction is satisfied. The operational definition of 'new discourse referent' is either introduction of a referent not so far mentioned, or a tensed verb. Because several syntactic predictions may be active

simultaneously, several WM taxation counts may be running simultaneously, consuming WM resources. The main verb is assumed to be cost-free because its existence is taken for granted in every sentence.

SPLT explains the processing difficulties associated with an impressive number of difficult structures, including the unacceptability (I would say: ungrammaticality) of multiple center-embeddings such as the double object relativization (21).

To illustrate, first consider Gibson's examples (23, 24)

- (22) The reporter [_{C-1} who attacked the senator] admitted the error.
 (23) The reporter [_{C-1} who the senator attacked] admitted the error.

In the subject-relativized sentence (22), *who* predicts the occurrence of a predicate and a pronoun gap in the relative clause. When the next word *attacked* is encountered, both predictions are satisfied and no costs incur. *Attacked* next predicts an object but this occurs as the next constituent and therefore no costs incur for this prediction either. The total WM taxation for (22) is therefore 0 MUs.

Next, consider the object relativization in (23). *Who* makes the same predictions as in (22), but the next constituent is the new referent expressed by *the senator*, whereupon both predictions incur a cost of 1 MU, totaling 2M(1) (two predictions having passed one new referent). Next *attacked* resolves the pending predictions and the analysis proceeds as in (22). Thus the correct analysis is made that object relativization is more complex by consuming more WM resources than subject relativization, a fact well established in psycholinguistics.

Now consider Gibson's (made-up) equivalent of (21), sentence (24) with double object relativization:

- (24) The administrator [_{C-1} who the **intern** [_{C-2} who the **nurse supervised**] had bothered] lost the medical reports.

The syntactic predictions (i.e. the predicate and the relative pronoun gap) of the first *who* will not be satisfied until *had bothered* is encountered, yielding a WM expenditure of 2M(3) MUs, the relevant three crossed new referents pending in WM storage being *intern*, *nurse* and *supervised* (bolded in (24)).

Gibson infers the following generalization "...structures which include a parse state with at least two long unresolved predicted categories in addition to the top-level verb are unacceptable, and those without such a state are usually acceptable. Under the memory cost function assumed here, a 'long' unresolved prediction is one spanning at least three intervening new discourse referents. Thus, sentences whose parses include parse states whose memory cost is 2M(3) MUs or greater are generally not acceptable, while sentences whose parses do not include such a costly parse

state are generally acceptable. A reasonable conclusion from this analysis is that linguistic working memory capacity is somewhere around 2M(3) MUs or just below".

Gibson based his analysis on a handful of invented examples. The rest of this paper evaluates Gibson's ACCEPTABILITY LIMIT in the light of my empirical data on multiple center-embeddings. A characterization is also offered of the overall processing complexity of these constructions.

Triple center-embeddings

Of the thirteen observed triple center-embeddings, only one, (25), is clearly below the acceptability limit, by Gibson defined as 2M(3) MUs. (25) consumes only 1M(3) for satisfaction of the prediction at *weil* that C-1 needs a predicate. This prediction is satisfied at the word *verzichtet*, having crossed three new discourse referents, one in each of the embedded clauses (*Mitbewerber*, *angenommen*, *überlegen*). At *angenommen wird* there is a parse state with a cost of 1M(2)+2M(1) MUs, also clearly below the acceptability limit. (Note the use of the plus notation to indicate the sum of differing simultaneous prediction costs.) The consumption of WM resources is low in (25) because all three embedded clauses are short, C-2 contains two pronouns, and C-3 an impersonal passive construction which disposes of its grammatical subject.

- (25) Er hat den Preis nur, [_{C-1} weil ein Mitbewerber, [_{C-2} welcher ihm, [_{C-3} wie allgemein angenommen wird,] überlegen ist,] verzichtet hat,] bekommen. (Literal gloss: 'He has the price only, (C-1) because a competitor, (C-2) who over him, (C-3) as is generally presumed, (C-2) is superior, (C-3) gave up, (Main) got.') (Blatz 1896: 1274)

There are two C³s reaching a maximum of 1M(4), with all prior parse states < 2M(3). Gibson does not discuss instances where only one prediction crosses more than three referents. Assuming for the moment that the effort invested in one syntactic prediction would be equal in WM cost to that of crossing one new referent, we obtain the value 6 for the TOTAL EFFORT invested at Gibson's acceptability limit (2 syntactic predictions * 3 referent crossings = 6). We shall assume that all multiple center-embeddings with a maximal total effort smaller than 6 are below the acceptability limit, in particular 1M(4), 1M(5) and 3M(1), all of which exist, provided they have no prior parse state exceeding 2M(3). Thus three C³s out of 13 are clearly below the limit, when redefined in terms of total effort = 6.

Sentence (9) is exactly at (or, according to Gibson, perhaps slightly above) the acceptability limit 2M(3), which is reached at the verb *is* in C-1, after crossing of the three referents *riding*, *cycle*, and *road*. In C-3 neither the bleak copula nor the classificatory NP *motor vehicle* were included in the count because C-3 expresses a property, not an independent referent. Note the non-finiteness of the verbs in C-2 and C-3 and the consequent suppression of two

grammatical subjects by sharing them with the upper clause. There is one more C³ in the corpus at 2M(3) with an additional parse state at 1M(4):

- (26) Der Landvogt ... fand, [C₋₁ als er, [C₋₂ von dem, [C₋₃ was vorgefallen,] benachrichtigt,] in bestürzten Märschen zurückkehrte,] die Stadt in allgemeinen Aufruhr. ('The governor found, (C-1) as he, (C-2) about that, (C-3) which [had] happened, (C-2) notified, (C-1) returned in fast march, (Main) the city in general uproar'. (H. von Kleist, Michael Kohlhaas; Hoffmann-Krayer 1925: 131)

Sentence (8) above requires maximally 1M(6) MUs and is on the same level of processing complexity as those needing 2M(3) MUs when analyzed in terms of total effort.

The remaining seven C³s are further beyond the acceptability limit. Sentence (7) above and one more claim exactly 2M(4) MUs, one claims 2M(4) with a later parse stage of 1M(5). These sentences were produced by well-known writers and do not intuitively feel (much) more complex than (9, 26), suggesting that 2M(3) MUs is just one point on a more continuous slope of decreasing acceptability. Still more convoluted is the following sentence from von Kleist:

- (27) Der Ritter von Malzahn, [C₋₁ dem der Junker sich als einen Fremden, [C₋₂ der bei seiner Durchreise den seltsamen Mann, [C₋₃ den er mit sich führe,] in Augenschein zu nehmen wünschte,] vorstellte,] nötigte ihn ... ('(M) The rider from Malzahn, (C-1) to whom the Junker himself as a stranger, (C-2) who upon his journey (through) the strange man, (C-3) whom he brought with himself, (C-2) to judge by appearance wanted, (C-1) introduced, (Main) forced ... (H. von Kleist, *Michael Kohlhaas*; Schneider 1959: 469)

The more verbose the embedded clauses are, and the more full (non-pronominal) constituents they contain, the greater will be the WM expenditure as new referents are crossed.

(27) has a parse state peak at *in Augenschein* requiring 1M(5)+2M(4) MUs, where the prediction of the predicate in C-1 (*vorstellte*) has crossed (at least) five referents (it is not always clear what should be counted as a referent, what not), and the predictions of a predicate and subject relative in C-2 have consumed 2M(4) MUs. When the prediction of *vorstellte* in C-1 finally is satisfied, its parse state has risen to 1M(6): the referents crossed are *Junker – Durchreise – Mann – führe – Augenschein – nehmen*.

The three most complex C³s in my corpus are a Swedish one from 1863 reaching 2M(6), a German one from 1893 peaking at 2M(6)+2M(4) with a later local maximum at 2M(7), and a Danish sentence from a court decision in 1892 containing a maximum of 2M(6)+2M(4) with a later local peak 1M(11), cf. examples (3, 12, 13) in Karlsson (2007b). Such monster sentences are of course incomprehensible.

The conclusion of the analysis of C³s must be that few of them, only three, are below Gibson's acceptability limit. If the limit reflects a foundational WM restriction, this corroborates the marginality of C³s as a structural option, already expressed in (14). But the extant C³s rather seem to populate a gradual slope, where the value 2M(3) MUs does not stand out as being of particular significance.

Double center-embeddings

The 104 C²s in my corpus distribute themselves over WM cost as shown in Table 1. Columns 1a-b give the WM costs and numbers of those C²s that clearly are below Gibson's limit 2M(3) MUs (total effort less than 6). Columns 3a-b lists the instances which are above the acceptability limit with a total effort equal to or greater than 6.

Table 1: Working memory cost in 104 C²s.

1a	1b		2a	2b	Total
Cost	N		Cost	N	
M(0)	1		1M(6)	4	
1M(1)	9		1M(7)	1	
1M(2)	12		1M(8)	2	
1M(3)	10		2M(3)	11	
1M(4)	5		2M(4)	6	
1M(5)	3		2M(5)	1	
2M(1)	13		2M(6)	1	
2M(2)	17		2M(9)	1	
3M(1)	4		3M(2)	1	
			3M(3)	2	
Sum	74			30	104
%	71			29	100

More than two thirds of the C²s are below the limit and many of them are far from causing overflow in working memory. Here is an assortment, listed according to growing complexity, of those C²s that are easiest to process and understand, with the WM cost indicated at the end in angular brackets.

- (28) The girl ... [C₋₁ who was clothed in the tightest-fitting pair of slacks [C₋₂ I had ever seen on a woman] and a sweater [F₋₂ that showed everything [F₋₃ there was]]] wanted to be sociable. [M(0)]
- (29) We yet looked forward to a time ... [F₋₁ when the rule [C₋₂ that they [C₋₃ who do not work] shall not eat,] will be applied not to paupers only. [1M(1)]
- (30) It's ironic [F₋₁ that I'm here, [F₋₂ where the man [C₋₃ the trophy [C₋₄ I won] is named after] coached. [1M(2)]
- (31) The reason [C₋₁ why this question of [C₋₂ when the copy was made] is of some interest] is that ... [1M(3)]
- (32) He knows ... [F₋₁ that, for example, [C₋₂ whereas in 1908 the proportion of his students at Leeds [C₋₃ who were drawn from within 30 miles] was 78 %,] it was, by 1955, reduced to 40 %. [1M(4)]

- (33) Laughland's assertion [_{C-1} that the presence of Delors – 14 years old [_{C-2} when the war began –] in the Compagnons de France, the Vichy youth movement, meant [_{F-2} that he supported fascism]] is ridiculous. [1M(5)]
- (34) The two most difficult skills [_{C-1} that everyone [_{C-2} I know] has to learn when they join a team] are... [2M(1)]
- (35) All the concern [_{C-1} which he [_{C-2} to whom it belongs by adoption] has in the matter] is the being ... [2M(2)]
- (36) But the general principle [_{C-1} that every thing [_{C-2} to which such and such sensation belongs,] has such and such a complicated series of predicates,] is not one determined by reason but... [3M(1)]

In contradistinction to C³, C² is obviously a well-established even if rare construction type especially in written language: there is no question of the grammaticality and acceptability of (28-36) even if it is clear that overall acceptability has a tendency to decrease as the number of constituents pending in WM and the number of new referents crossed increases.

Note that there even are C²s like (28) that invoke no WM cost at all. This situation is possible in (28) because the subject and predicate of C-1 (*who was clothed*) are immediately available and therefore they do not need to be entered as pending predictions in WM. The predicate of C-1 predicts the occurrence of an adverbial prepositional phrase, but it too (*in the tightest-fitting pair of slacks*) is completed immediately, as the first part of a coordinated construction. C-2 is beneficially inserted before the second, optional part of the coordinated construction in C-1 and therefore does not tax WM at all. – (The C-3 of (7) is also inserted at a coordination junction, corroborating conclusion (18) that multiple center-embedding is preferred at natural syntactic breaks.)

The following sentences exemplify those 30 sentences (29 %) of Table 1 that are at or beyond the acceptability limit, consuming 1M(6) or 2M(3) MUs or more. The examples are listed according to growing complexity.

- (37) For the remainder of his industrious life (apart from during the second world war [_{C-1} when he worked in the Ministry of Information [_{C-2} – where he was banished to Belfast [_{F-3} for being lazy and unenthusiastic –]] and the Auxiliary Fire Service)] Quennell ... [1M(6)]
- (38) And in particular [_{C-1} when the motives [_{C-2} which are applied] are of the nature of those [_{F-2} which result from a change [_{F-4} made in the condition of the body,]]]] the power may be said to ... [1M(8)]
- (39) Neither, however, [_{C-1} as their critics and all of those [_{C-2} who subsequently complained about their assault on Heath] always stress,] felt moved to resign. [2M(3)]

- (40) The occasion [_{C-1} on which in the nation [_{C-2} of whose language I am writing] the word *repugnancy* has been most frequently made use of] is that where ... [2M(4)]
- (41) A number of speeches [_{C-1} into which a great deal of thought and preparation on a level a great deal higher [_{C-2} than is common in modern politics] have gone] are not reported at all ... [2M(5)]
- (42) Es wird allgemein angenommen, [_{F-1} dass die Militärs, [_{C-2} die das Land dreizehn Jahre lang mit Unterschiedlichem Erfolg und — mit Ausnahme Murtala Muhammeds, [_{C-3} der erst sieben Monate an der Macht war, [_{F-4} als er im Februar 1976 ermordet wurde]] — ohne Popularität zu erlangen geführt haben,] von sich aus eine Rückkehr an die Macht nicht anstreben. 'It is normally surmised (F-1) that the soldiers (C-2) who ruled the country thirteen years with variable results and – with the exception of Murtala Muhammed, (C-3) who first was seven months in power (F-4) until he was murdered in February 1976 – without achieving popularity, do not themselves strive for a return to power.' [2M(9)]
- (43) For an analysis of the possible modifications [_{C-1} of which the pathological termination of an act [_{C-2} which is not according to law] are susceptible] we have therefore only to ... [3M(2)]
- (44) (Swedish:) Helt säkra på [_{C-1} vad blandningen, [_{C-2} som de insjuknade har druckit] består av,] var läkarna inte.] '(M) Quite sure of (C-1) what the mixture, (C-2) that the patients had drunk (C-1) consisted of, (Main) the doctors were not'. [3M(3)]

Table 2 displays the data of Table 1 recounted in terms of total effort.

Table 2. Data of Table 1 recalculated in terms of total effort.

Total effort	N
0	1
1	9
2	25
3	14
4	22
5	3
6	16
7	1
8	8
9	2
10	1
10+	2
Sum	104

Recall Gibson's definition of the acceptability limit: "... linguistic working memory capacity is somewhere around 2M(3) MUs or just below". Table 2 shows that there are no less than 16 instances of 2M(3) and its equivalents of a total

effort of 6. These instances cannot all be declared unacceptable by intuition alone. This suggests at least that the acceptability limit rather is above than below 2M(3) MUs and its equivalents.

Discussion

The analysis of C³s and C²s has shown that the conjecture of a demarcation line at 2M(3) MUs, or slightly below, between acceptable and unacceptable multiple center-embeddings does not find clear support in real language data drawn from genuine written texts or, rarely, from natural spoken discourse. If there is such a demarcation line, it is rather above than below 6 total effort units. But most likely, the overall data speak in favor of a cline of asymptotically decreasing complexity.

There might be systematic flaws in the design of the procedure counting MUs. For example, the Swedish sentence (44) has a WM cost of 3M(3) which is huge. All ten native informants (including myself) I have consulted on the acceptability of (44) confirm that there is nothing weird about this sentence, which appeared in 2001 in the main Swedish newspaper of Finland, *Hufvudstadsbladet*. It is perfectly grammatical, acceptable and understandable. Its WM expenditure is high just because the prediction of its main clause subject is satisfied only after the doubly center-embedded relative clauses have been passed. That is, the prediction of a postposed main clause grammatical subject (here, *läkarna* ‘doctors’) turns out to be overly costly. The model needs revision.

A similar problem occurs in sentences with an initial modal or frame adverbial and a postposed grammatical subject, like (38, 39). The late grammatical subject causes the WM cost to become unrealistically high.

Overall, the data of this paper are in good conformance with current theories of the nature of working memory, e.g. Cowan’s (2000, 2005) theory of the storage limit on WM being around four chunks, or the well-known capability of humans to be able to simultaneously register some four elements in the focus of visual attention. Recall that even C² is next to non-existing in spoken language (15). Sentence (30) above is one of the few documented ones from spoken language. Its WM cost is only 1M(2), far below Gibson’s acceptability limit. Of course one should not let the most extreme instances of written language, such as (44), define what the bottom line of (spoken) language WM consumption is.

Department of Psychology, University of Notre Dame
Notre Dame, IN 46556 USA

Abstract

We report the results of a study investigating speakers' and addressees' coordination of understanding in face-to-face narrative dialogue. Analyses of the occurrence of addressees' acknowledgments and exemplifications of understanding showed that nonverbal forms consistently coincided with the speakers' gaze on their face. In contrast, there was less consistent correspondence between the addressees' verbal evidence of understanding and the speakers' gaze on their face. Evidence that speakers gaze off addressees' faces because of the demands of utterance planning or encoding comes from a correspondence between their gaze off the addressee's face and their production of pause fillers (*uh* and *um*), especially at the beginning of clauses.

Keywords: spoken dialogue; disfluency; gaze patterns

Introduction

Conversation is the quintessential form of language use. It is a purposeful activity requiring the coordination of two or more people. The aim of the research presented here was to examine the coordination process in a face-to-face storytelling situation by examining speakers' gaze patterns relative to delays in speaking signaled by pause fillers and relative to addressees' signals of understanding.

According to Clark (1996), language use is a joint project consisting of 4 hierarchical levels of speaker-addressee coordinated actions, which he refers to as an action ladder. Consider the case of a speaker asking an addressee, "What time is it?". At the first level, the speaker is executing a behavior that consists of producing the sounds of the utterance. The addressee, in turn, attends to the behavior (speech). At the second level, the speaker is presenting words and phrases, which the addressee identifies as such. At the third level, the speaker is signaling an intended meaning (requesting the current time), and the addressee is understanding the meaning. At the fourth level, the speaker is proposing a joint project, namely that the addressee inform him of the current time, and the addressee considers accepting the proposal. There are two essential properties of this hierarchy of actions. The first is upward causality: The actions at a lower level cause the actions at the next level up. The second property is downward evidence: Evidence of successful completion of the actions at a higher level constitutes evidence of success at all levels below it.

As Clark (1996, p. 222) states, "A fundamental principle of any intentional action is that people look for evidence that they have done what they intended to do." Furthermore, people strive to provide evidence that is

sufficient for current purposes, in a timely manner, and with the least effort. In the example above, the valid, timely, and sufficient evidence of success comes from the addressee responding with the current time soon after the end of the speaker's utterance. In doing so, the addressee provides positive evidence of her acceptance of the speaker's proposed joint project at level 4 as well as positive evidence of her understanding the meaning of the speaker's utterance (level 3), her identification of the speaker's words (level 2), and her attending to the speaker's speech (level 1).

In contrast to interactive conversation, in narrative dialogues, the speaker produces sequences of utterances across an extended time, resulting in minimal turn-taking. Thus, the joint project at level 4 is an extended proposal consisting of multiple iterations through the lower 3 levels. In this situation, the highest level of evidence of successful completion is level 3 (signaling and understanding of meaning). There are two main forms of evidence that are provided by addressees. One form is *acknowledgments*, which are assertions of understanding, also referred to as backchannels (Yngve, 1970) and generic listener responses (Bavelas, Coates, & Johnson, 2000). They may be verbal, e.g., *mhm*, *okay*, *uh huh*, or non-verbal head nods. The second form of evidence is *exemplifications* of understanding, also referred to as specific listener responses (Bavelas et al, 2000). Exemplifications are reactions to the meaning of the speaker's utterance, and, as such, they constitute more valid evidence. They can be verbal, e.g., *wow*, *oh*, *that's awful*, or non-verbal, e.g., facial gestures, such as wincing, grimaces, looks of surprise or sadness. Both acknowledgments and exemplifications are brief, requiring little planning and they often overlap with or occur at the end of the speaker's utterance (e.g., Goodwin, 1981).

Evidence that the addressee is attending to the speaker's execution of a communicative behavior (level 1) is provided by his or her maintaining gaze on the speaker's face (e.g., Argyle & Cook, 1976; Ehrlichman, 1981; Goodwin, 1981; Kendon, 1967). In contrast, the speaker often exhibits a pattern of gazing on and off the addressee's face (e.g., Ehrlichman, 1981, Goodwin, 1981; Kendon, 1967). In interactive conversation, this asymmetry in mutual gaze is considered one cue to turn-taking (Duncan, 1974; Kendon, 1967; Maclay & Osgood, 1959). That is, speakers typically gaze at the addressee at the end of their turn, thereby relinquishing the floor.

However, the asymmetry in speaker's and addressee's gaze on the other's face is also observed in narrative dialogues. In this situation, the speaker's gaze on and off the addressee's face is likely to reflect other aspects of

coordination than turn-taking. In particular, following Kendon (1967), Bavelas, Coates, and Johnson (2002) proposed that in narrative dialogue, speakers gaze at addressees for evidence of their understanding. Support for this proposal comes from their finding that addressees' acknowledgments and exemplifications occurred more often when speakers gazed at them than when they gazed away, and, the speakers' gaze away occurred shortly after the occurrence of this evidence of understanding.

The current study sought to replicate and extend Bavelas et al.'s (2002) findings. Specifically, like Bavelas et al., the current study tested the hypothesis that speakers gaze at their addressee's face for evidence of successful understanding (level 3), which is provided by the addressee producing verbal and/or nonverbal acknowledgments and exemplifications. The current study extends Bavelas et al.'s work by investigating the additional hypothesis that speakers gaze away from their addressee when the resource demands for utterance planning or encoding are high. This second hypothesis was tested by examining the co-occurrence of speakers' gaze off their addressee's face and their production of pause fillers such as *uh* or *um*, which signal a delay in speaking due to planning or encoding difficulties (Bortfeld, Leon, Bloom, Schober, & Brennan, 2001; Brennan & Schober, 2001; Clark & Fox Tree, 2002; Fox Tree, 2001). Studies investigating interactive dialogues with frequent turn-taking provide some evidence for this latter hypothesis by showing that speakers often gaze away from their addressee at the beginning of their turn at talk (Kendon, 1967; Beattie, 1978), which is the point at which speakers produce pause fillers when the high demands of utterance planning and encoding cause a delay in speaking (Smith & Clark, 1993).

As mentioned above, the speaker's gaze away from the addressee at the beginning of a turn in interactive dialogues may also be a procedure by which the speaker establishes his or her turn to talk. The limited turn-taking in narrative dialogue eliminates this possible role of gaze patterns. Furthermore, we examined whether there is a co-occurrence of the speaker's gaze off an addressee's face with pause fillers that occur before a clause/discourse segment, when the demands of utterance planning should be high, as well as within a clause, where the delay may reflect lexical retrieval difficulties.

The speakers in the current study read an obscure Brothers Grimm story, which they then told to an addressee. The story involves three main characters and several subordinate characters. It also has four main scenes, corresponding to different time periods and settings. To ensure that the speakers understood the story and that they would tell it in a relatively uniform way, they completed a quiz after reading it and before telling it to the addressees. The addressees completed the same quiz after listening to the speakers tell the story to them.

Experiment

Method

Participants Seven same sex dyads participated in the experiment in exchange for payment of \$10.00 each or extra credit in a course. All were native American English speaking adults with an average age of 21 years. Five dyads were female, two of which were familiar with each other prior to the experiment. One male dyad were familiar with each other prior to the experiment.

Procedure The members of the dyads signed up for an hour-long session with one person, designated as the Speaker, arriving 30 minutes before the other person, who was designated as the Addressee. Upon arriving at the lab, the Speaker was given a consent form to read and sign. Then, he or she read a printed copy of the Brothers Grimm story *Faithful John* in a quiet room. All of the participants were unfamiliar with the story prior to the experiment. After reading the story, the Speaker completed a quiz consisting of 14 multiple-choice questions about the main events and characters in the story. The questions were presented one at a time on a computer screen, and the Speaker was given as much time as needed to select a response, which was made by pressing a key on the keyboard. The Speaker was allowed to consult the printed copy of the story when answering the questions, and the correct response for each question was displayed after the Speaker made his or her response. The Speaker was then seated at a table and fitted with a free-head eye-tracker.

After the Addressee read and signed the consent form, he or she was seated at the table opposite to the Speaker. For the four dyads who were unfamiliar with each other, the Speaker and Addressee were introduced, and each was asked to tell the other about themselves (e.g., where they were living, what year they were in college, and what their major was). The dyads were then given instructions for the task. Specifically, they were told that the experiment investigates conversational interactions between two individuals, and that the Speaker was to tell a Brothers Grimm story, which she or he had just read, to the addressee. The Addressee was told that the Speaker had answered a set of comprehension questions about the story and that he or she would receive the same set of questions after listening to the Speaker tell the story to him or her. Thus, the goal was for the Addressee to understand the story sufficiently well to be able to answer the questions correctly. The Speaker and Addressee were told that they could talk to each other and that the important thing was for them to interact as naturally as possible.

The Speaker and Addressee were informed that the experimenter would remain in the room to monitor the recording equipment. However, she would have her back to them and would listen to music over headphones to prevent her from participating as an "overhearer". The Addressee was instructed to tap the experimenter on the shoulder when the speaker had finished telling the story. The entire story-

telling session was video-taped, and after it was over, the Addressee completed the quiz.

Apparatus The Speaker was fitted with an eye-tracker (Applied Science Laboratories, Model 501) consisting of a lightweight eye camera attached to an adjustable headband. The eye camera was positioned above the Speaker's left eye, and it captured an infrared image of the eye at a 60 Hz sampling rate. The distance between the centers of the corneal and pupil infrared reflections were used to calculate the relative eye-in-head position. The head band also contained a scene camera that captured an image of the Addressee's head and torso across the table. The scene camera's image was displayed on a TV monitor along with a record of the Speaker's eye movements in the form of cross hairs that were superimposed over the scene image. A brief calibration routine was conducted to map nine eye-position coordinates onto nine corresponding scene-image coordinates. The accuracy of the resulting eye fixation record was approximately 0.5° over a range of $\pm 20^\circ$. Lapel microphones were attached to the Speaker's and Addressee's shirts and connected to a Hi8 VCR, which also recorded the scene image and eye-movement record displayed on the TV. A Hi8 video camera, which was positioned to the side of the Addressee, recorded an image of the Speaker's head and torso. Responses on a survey administered at the end of the experimental session indicated that the eye-tracking apparatus was not distracting or only minimally distracting to the Speakers, and it was minimally to moderately distracting to the Addressees.

Video Coding The two video-taped recordings of each dyad's experimental session were digitized at a 60Hz NTSC sampling rate and aligned with each other using Final Cut Express (Apple, Inc.). The project files were annotated using frame-by-frame playback of the synchronized audio and video tracks (each frame = 33 msec). Labeled markers were inserted on the first frame of events of interest and extended to the last frame. All coding was done independently by two individuals, with a third individual (KE) reconciling any disagreements. Categories of events of interest that were marked included the following:

(1) *Speaker's gaze*: The Speakers' gaze on and off the Addressee's face was coded in a binary fashion such that the frame that marked the last consecutive fixation on the Addressee's face was followed by the frame that marked the first fixation off the face. The Speaker's gaze on the Addressee's face consisted of two or more consecutive fixations anywhere on the face. The Speaker's gaze off the Addressee's face consisted of one or more fixations in the region surrounding the face, including the Addressee's neck and torso as well as the wall behind the Addressee. In addition, the gaze off the Addressee's face included instances in which there was a loss of the eye-tracking record due to the Speaker looking down or closing his or her eyes for a period longer than a blink.

(2) *Addressee's gaze*: The first and last frames of the Addressee's gaze away from the Speaker's head were marked based on the direction of the Addressee's eye gaze available from the eye-tracker's scene image. The Addressee's gaze away typically involved looking down at the table or to the left or right of the Speaker.

(3) *Addressee's nonverbal responses*: The beginning and end frames of the Addressee's head nods (acknowledgments) and facial gestures (exemplifications) were marked. Facial gestures displayed reactions to the story's content such as surprise or disbelief in the form of eye flashes or raised eyebrows, grimaces, wincing, and frowns. Smiles were not included as a nonverbal response.

Utterance Coding The Speakers' and Addressees' utterances were orthographically transcribed using Praat (Boersma & Weenink, 1996). Transcriptions of the Speaker's and Addressee's utterances were created on separate tiers in the textgrid files, with the tiers time-aligned with the digitized audio track (48 kHz sampling rate). Transcriptions were completed independently by two individuals and checked by a third (HN). The Addressee's transcriptions contained boundaries that marked the utterances' onset and offset. The utterances consisted of acknowledgments (e.g., *okay, mhm, hmmm, oh, uh huh*) and exemplifications (e.g., *wow, that's weird, crazy*), as well as requests for clarification.

Two duplicate tiers contained the transcriptions of the Speakers' utterances. One tier contained boundaries that marked intonational phrases, which typically consisted of one or two clauses. The other tier contained boundaries for individual words, which included pause fillers (e.g., *uh, um*) as well as silent pauses. A third tier was used to label the pause fillers with respect to whether they occurred at the beginning of a clause, within a clause, or embedded in a larger disfluency involving a repair. As shown in examples (a) and (b) below, clause-initial fillers preceded or followed one or more discourse markers (e.g., *so, and, then, etc.*). Examples (c) and (d) show fillers that occurred within a clause, and example (e) shows a filler that occurred in the middle of a larger disfluency. The numbers in square brackets show the location of a silent pause and its duration in seconds.

- a.) *Clause-initial*: [0.494] um so he knows what his inheritance is except for this one [0.635]
- b.) *Clause-initial*: [0.334] and [0.596] um so they know that this princess really likes gold
- c.) *Within-clause*: and they take a ship across the um [0.109] sea or something
- d.) *Within-clause*: and she's like wow can I [0.426] um get some of that
- e.) *Mid-disfluency*: if someone sticks [0.383] um [0.227] if someone makes her lip bleed

Analyses: The markers coding the video recordings were exported from Final Cut Express and imported into Praat as labeled tiers in the textgrid files that were time-aligned with

the transcription tiers and the digitized audio track. Scripts were used to extract frequency and duration information from the tiers. The analyses of the pause fillers and gaze patterns excluded fillers that were part of a larger disfluency (i.e., the mid-disfluency fillers).

Results

As shown in Table 1, the Speakers took an average of 659 seconds, or about ten minutes, to tell the story, and they did so with an average speaking rate of 192 words per minute. The Speakers' accuracy on the quiz was slightly higher than the Addressees (average of 95% vs. 91%, respectively). For three dyads in which both the Speaker and Addressee scored less than 100%, the questions that were responded to inaccurately by the Speaker differed from the questions that were responded to inaccurately by the Addressee.

Table 1: Total time, speech rate, and quiz scores

Dyad	Total time (sec)	Words per min	S's quiz score	A's quiz score
F1	591	202	100%	100%
F2	773	175	100%	86%
F3	531	205	93%	93%
F4*	1047	178	100%	100%
F5*	627	249	93%	86%
M1	551	155	93%	100%
M2*	491	181	86%	75%
Mean	659	192	95%	91%

Note: S = Speaker, A = Addressee, F = female, M = male,
* = friends prior to experiment

Table 2 shows the number and mean duration of the Speakers' gaze on and off the Addressee's face for each dyad, as well as the percentage of the total time that the Speakers' gazed off the Addressee's face. Five of the seven Speakers' exhibited the commonly reported pattern of spending more time gazing off their Addressee's face than gazing on their Addressee's face. The other two Speakers, one male (M2) and one female (F5), spent less time gazing off their Addressee's face than on it. As for the Addressees, all five female Addressees gazed at their Speaker's face 97% or more of the storytelling time. The two male Addressees gazed at their Speaker's face 79% (M1) and 46% (M2) of the storytelling time, respectively.

Table 2: Number and average duration (sec) of Speakers' gaze on and off the Addressee's face

Dyad	# Gaze on	Duration gaze on	Duration gaze off	% Total time gaze off
F1	127	1.271	3.380	73%
F2	285	1.209	1.499	55%
F3	211	1.066	1.449	58%
F4	379	0.991	1.805	65%
F5	107	5.405	0.451	8%
M1	189	0.634	2.580	78%
M2	132	2.519	1.203	32%
Mean	204	1.871	1.724	53%

Gaze and Addressees' Responses: Table 3 shows the number of the Addressees' nonverbal and verbal acknowledgments (e.g., head nods, saying *mhm*, *okay*, etc.) and exemplifications of understanding (e.g., looks of surprise, grimaces, saying *wow*, *oh my*, etc.). There was variability across the dyads in the frequency of providing evidence of understanding, with the total number of all forms ranging from 17 (M2) to 201 (F2). However, all 7 Addressees produced more acknowledgments than exemplifications as well as more nonverbal responses than verbal responses.

Table 3: Number of Addressees' acknowledgments and exemplifications and the percentage that overlapped with the Speaker's gazed on their face

	Acknowledgments		Exemplifications	
	Nonverbal	Verbal	Nonverbal	Verbal
F1	40 (75%)	9 (44%)	14 (79%)	6 (17%)
F2	111 (86%)	64 (55%)	21 (95%)	5 (60%)
F3	11 (73%)	5 (80%)	6 (83%)	0
F4	157 (60%)	28 (54%)	4 (100%)	0
F5	76 (99%)	38 (97%)	10 (100%)	11 (100%)
M1	15 (80%)	2 (0%)	0	0
M2	51 (90%)	8 (88%)	1 (100%)	5 (100%)
Mean	66 (80%)	22 (60%)	8 (93%)	4 (69%)

On average 80% of the Addressees' non-verbal acknowledgements (head nods) overlapped with the Speaker's gaze on the Addressee's face (range 60% to 99%), and 93% of their non-verbal exemplifications overlapped with the Speaker's gaze on the their face. In contrast, the average percentages of the Addressees' verbal acknowledgments and verbal exemplifications that overlapped with the Speaker's gaze on their face were less, i.e., 60% and 69%, respectively. For each dyad, the number of the Addressee's non-verbal responses and verbal responses that overlapped with the Speaker's gaze on his or her face was compared to the numbers expected to overlap by chance using the procedure described by Bavelas et al. (2002). Specifically, when the total number of nonverbal

responses or verbal responses was greater than 20, a z-value was calculated and evaluated with the normal distribution using the formula:

$$z = \frac{O - E - .5}{\sqrt{npq}}$$

where, n is the total number of responses, O is the observed number of responses overlapping with the Speaker's gaze on the face, p is the percentage of total time the Speaker spent gazing on the Addressee's face, q is $1-p$, and E is the expected number of responses overlapping with a gaze on face by chance ($p*n$). The subtraction of .5 is a correction for continuity. When the total number of verbal or nonverbal responses was less than or equal to 20, then the combination of n , p , and O were tested for significance using the binomial distribution. The results of the tests for each dyad are given in Table 4.

Table 4: Tests of the significance of the observed number of Addressees' responses occurring with gaze on their face

Dyad	n total responses	O # with gaze on face	p % total time gaze on face	z	p-value ^a
<i>Addressees' Nonverbal Responses</i>					
F1	54	41	0.27	7.95	< .0001
F2	132	116	0.45	9.81	< .0001
F3	17	13	0.42		< .002
F4	161	98	0.35	6.80	< .0001
F5	86	85	0.92	2.14	< .02
M1	15	12	0.22		< .002
M2	52	47	0.68	3.31	< .0001
<i>Addressees' Verbal Responses</i>					
F1	15	5	0.27		n.s
F2	69	38	0.45	0.56	= .06
F3	5	4	0.42		< .05
F4	28	15	0.35	1.86	< .05
F5	49	48	0.92	1.27	n.s
M1	2	0	0.22		n.s
M2	13	12	0.68		< .05

^aOne-tailed test was used for binomial tests when $n \leq 20$.

Table 4 shows that the number of the Addressees' nonverbal responses that overlapped with the Speaker's gaze on their face was significantly greater than the number expected by chance for all seven dyads. In contrast, the number of the Addressees' verbal responses that coincided with the Speaker's gaze on their face was significantly greater than the number expected by chance for only three of the seven dyads, and it was marginally significant for one other dyad. The results for the nonverbal responses replicates Bavelas et al.'s (2002) findings. The current finding that the Addressees' verbal evidence of understanding less consistently overlaps with the Speaker's gaze on their face is likely due to Speaker's gaze being unnecessary for conveying this form of evidence.

Gaze and pause fillers: The Speakers produced an average of 41 pause fillers (range 15 - 76), at an average rate of 1.87 per 100 words (range 1.0 - 3.4). The correlation between the Speakers' pause filler rate and the average duration of their gaze off the Addressee's face is 0.45. As shown in Table 5, the Speakers produced more clause-initial pause fillers than within-clause ($t(6) = 4.05$, $p < .02$, two-tailed); however, clause-initial fillers were not significantly longer in duration ($t(6) = 2.08$, $p = .08$, two-tailed).

Table 5: Filled pause rate per 100 words, % of all pause fillers (number) and average duration (sec) that were clause-initial or within-clause

Dyad	Rate	Clause-initial		Within-clause	
		Total	Dur. (sec)	Total	Dur. (sec)
F1	2.57	53% (27)	0.439	33% (17)	0.378
F2	3.37	67% (51)	0.399	25% (19)	0.362
F3	0.99	61% (11)	0.438	11% (2)	0.519
F4	1.45	71% (32)	0.406	20% (9)	0.340
F5	1.67	52% (22)	0.378	21% (9)	0.307
M1	2.81	55% (22)	0.422	43% (17)	0.349
M2	1.01	53% (8)	0.449	33% (5)	0.355
Mean	1.98	59% (25)	0.419	27% (11)	0.373
SD	0.94	8% (14)	0.026	11% (7)	0.068

For 6 of the 7 Speakers, all or all but one of their clause-initial pause fillers coincided with their gazing off their Addressee's face. The Speaker (F5) who spent most of the storytelling time (92%) gazing on her Addressee's face had fewer clause-initial pause fillers (23%) coinciding with a gaze off her Addressee's face than with a gaze on. Nevertheless, a binomial test of the number of the clause-initial pause fillers that coincided with her gaze off the Addressee's face was significantly greater than expected by chance ($p = .02$, two-tailed). Thus, there was a clear correspondence between the occurrence of the Speakers' gaze off their Addressee's face and their production of pause fillers at the beginning of clauses, when the demands of utterance planning and encoding are likely to be highest.

An examination of the within-clause pause fillers also provided evidence that these signals of production difficulty coincided with the Speakers' gaze off their Addressee's face in a narrative situation. Specifically, except for the Speaker (F5) who spent most of the storytelling time gazing on her Addressee's face, the number of within-clause pause fillers produced by the other six Speakers that coincided with their gaze off their Addressee's face was greater than the number expected by chance, which was calculated by multiplying the percentage of the Speaker's total time gazing off the Addressee's face by the Speaker's total number of within-clause pause fillers. Binomial tests were significant for four of the six Speakers (p -values $\leq .05$, one-tailed), and marginally significant for one Speaker (M1) ($p = .08$, one-tailed). The test was nonsignificant for the remaining Speaker (F3) due to a small number of observations i.e.,

only 2 within-clause pause fillers, both of which overlapped with the Speaker's gaze off the Addressee's face. For the Speaker (F5) who spent most of the time gazing on her Addressee's face, only 1 of her 9 within-clause pause fillers coincided with her gaze off the Addressee's face, which was equal to the number expected by chance, albeit not significant by a binomial test ($p > .05$).

Discussion

The results of the current study demonstrated coordination of understanding between Speakers and Addressees during a face-to-face narrative dialogue. Specifically, consistent with Bavelas et al.'s findings, Addressees produced nonverbal acknowledgments and exemplifications of their understanding more often when the Speaker gazed on their face than when the Speaker gazed off their face. However, across all seven dyads, there was less consistent co-occurrence of the Addressees' verbal acknowledgments and exemplifications (e.g., *mhm*, *wow*) with the Speaker's gaze on their face. This finding is likely due to the Speaker's gaze on the Addressee's face being unnecessary for conveying this evidence verbally. The results extended previous findings by providing evidence that Speakers gaze off their Addressee's face in narrative dialogues when they experience a delay in speaking due to utterance planning or encoding. Specifically, for six Speakers, nearly 100% of their pause fillers (*um*, *uh*) that occurred before a clause, when the demands of utterance planning are high, coincided with their gazing off their Addressee's face. For all seven Speakers, the number of their clause-initial pause fillers that coincided with a gaze off was significantly greater than expected by chance. There was some evidence that pause fillers that occurred within a clause also coincide with the Speaker's gaze off the Addressees' face, however this relationship was significant for only four of the six Speakers. Future research will examine the relationship between the Speaker's gaze off the Addressee's face and longer disfluent intervals, such as a syllable prolongation followed by a pause, then pause filler, etc. In addition, coordination may also be reflected in Speakers seeking and Addressees providing evidence that a disfluency involving a repair did not impede the Addressee's understanding.

Conclusion

Although there are a number of studies investigating coordination via gaze patterns, signals of understanding, and disfluencies in interactive conversation (e.g., Bard, Anderson, Chen, Nicholson, Havard, Dalzel-Job, 2007), few studies have investigated coordination in narrative dialogue. The research presented here extends previous findings by demonstrating that Speakers' gaze on and off their Addressee's face when telling a story reflect the demands of encoding meaningful messages in speech, and evidence of its success.

The Interpretation of Null and Overt Pronouns in Japanese: Grammatical and Pragmatic Factors

Abstract

Pronoun interpretation in English has been demonstrated to be sensitive to an interaction between grammatical and pragmatically-driven factors. This study investigated the interpretation of pronouns in Japanese, which has both null and overt forms. Thirty-two native speakers of Japanese participated in a passage completion experiment with transfer-of-possession contexts, varying prompt type, aspect, and topic/nominative-marking of the previous subject. Two judges annotated the referents of the matrix subjects and coherence relations in the completed passages. Japanese overt pronouns were revealed to pattern closely with English overt pronouns in their sensitivity to pragmatic factors, whereas Japanese null pronouns were predominantly governed by grammatical position. Somewhat surprisingly, topic-marking did not influence reference or coherence relations. The data suggest distinctive patterns of interactions between grammatical and pragmatic factors in the interpretation of null and overt pronouns in Japanese, and cast doubt on the existence of a division of labor between the two forms.

Keywords: Japanese pronoun interpretation, discourse processing, cross-linguistic language processing

Introduction

Previous work (Stevenson, Crawley, & Kleinman, 1994; Arnold, 2001; Rohde, Kehler, & Elman, 2006, 2008) has shown that pronoun interpretation in English is driven by the interaction of grammatical and pragmatic biases. For instance, Rohde et al. (2006) showed that pronoun interpretation differs in transfer-of-possession passages that vary by verbal aspect between perfective (1) and imperfective (2).

(1) John_{SOURCE} handed a book to Bob_{GOAL}
He _____

(2) John_{SOURCE} was handing a book to Bob_{GOAL}
He _____

The context sentences in (1) and (2) contain two possible referents for the pronoun, one that appears in subject position and fills the Source thematic role (*John*), and one that appears as the object of a prepositional phrase and fills the Goal thematic role (*Bob*). The results of a passage completion experiment revealed significantly more interpretations of pronouns to the Source referent (the grammatical subject) in the imperfective condition as compared to the perfective condition. Rohde et al. also

found that the influence of aspect in pronoun interpretation was correlated with certain relationships inferred to hold between the two clauses (henceforth ‘coherence relations’), suggesting that a shift in the distribution of coherence relations induced the shift in the distribution of pronoun interpretations.

Following Stevenson et al. (1994), Rohde et al. (2008) ran passages with pronoun prompts like (1) against those with ‘free’ prompts (3).

(3) John handed/was handing a book to Bob.

Results showed more references to the Source and more Source-biased coherence relations in the pronoun condition than in the free condition, indicating that pronouns overlay a grammatical subject bias on top of the pragmatic biases that were revealed by the aspect manipulation.

Present Study

Null pronouns in Japanese occur most commonly in subject position, but occasionally in object positions as well (Ueno & Polinsky, 2009). Overt pronouns also exist, but occur less commonly than the null forms (Martin, 1976).¹

The interpretation of Japanese null pronouns has been claimed to be analogous to the interpretation of overt pronouns in other languages without a null form (e.g., Kuroda, 1965; Kameyama, 1985; inter alia). The GIVENNESS HIERARCHY (GH) of Gundel, Hedberg, and Zacharski (1993) makes this claim as well, and further predicts that the Japanese null and overt forms should display a ‘division of labor’ effect whereby the preferred referents of the two forms fall into complementary distribution. These predictions result from the fact that the six cognitive statuses that comprise the GH participate in an implicational hierarchy, and are thus expected to give rise to scalar implicatures. According to the GH, English overt pronouns and Japanese null pronouns require referents of the highest status (IN FOCUS), whereas Japanese overt pronouns occupy the second highest status (ACTIVATED).

¹ The Japanese third person overt pronouns (e.g., *kare* ‘he’, *kanojo* ‘she’) are generally considered to be direct translations of their English counterparts, and appear to be becoming incorporated into daily Japanese at an increasing rate. A corpus count of *Asahi Shimbun* (popular Japanese newspaper) articles shows that out of 11,073,167 sentences, *kare* was used 28,795 times and *kanojo* 14,209 times (Amano & Kondo, 2000).

Whereas overt pronouns are compatible with both ACTIVATED and IN FOCUS referents, Grice's (1975) Maxim of Quantity ('say as much as you need to say') predicts that the informationally-stronger null form should be used for IN FOCUS referents, in turn predicting that overt pronouns will be used only for referents that are ACTIVATED but not IN FOCUS, creating the division-of-labor effect.

A relatively small number of experimental studies have been performed on the interpretation of null pronouns. Working within Centering Theory, Walker, Iida, and Cote (1994) reported an influence of grammatical/information-structural factors found in a referent-choice experiment, including higher salience for topic-marked (*-wa*; cf. Kuno, 1973) than nominative/subject-marked (*-ga*) referents. A recent study by Christianson and Cho (2009) suggests that topical arguments in Odawa are more likely to be realized as null pronouns than non-topical arguments. Experiments performed by Alonso-Ovalle et al. (2002) offered mixed support for a division-of-labor effect between null and overt pronouns in Spanish. In a written questionnaire study, for instance, null pronouns referred to the previous subject 73.2% of the time whereas overt pronouns did 50.2% of the time; while null pronouns clearly incorporated a stronger subject bias, the referents of the two forms were not strictly in complimentary distribution. Further, whereas an acceptability judgment task found that participants rated sentences with unambiguous references to the previous subject as being more acceptable when a null pronoun was used (4.19 on a 5-point scale) as compared to when an overt pronoun was used (3.57), the overt pronoun cases were still deemed to be relatively acceptable.

Taken together, the foregoing work gives rise to a series of questions that the present study seeks to answer. First, we ask whether the behavior of Japanese null and/or overt pronouns patterns with that of English overt pronouns in displaying sensitivity to pragmatic subsequent-mention biases, or whether their interpretation is determined primarily by other (e.g., grammatical) factors. This question can be addressed by employing a passage completion task that uses the same aspect manipulation employed by Rohde et al. (2006). The second question is whether null and overt Japanese pronouns exhibit a division-of-labor effect such that, for instance, a demonstrated subject bias for null pronouns corresponds to a commensurate non-subject bias for overt pronouns. This question will be answered using a manipulation that varies prompt type between null pronoun, overt pronoun, and free. Third, we ask whether topic-marked antecedents attract more pronominal references than subject-marked antecedents. We will answer this question by varying the morphological marking on the first mentioned referent of the preceding clause, specifically between subject/nominative marking (*-ga*) and topic marking (*-wa*). Lastly, we ask whether any grammatical biases that are revealed to be associated with these referential forms affects the distribution of ensuing coherence relations, as Rohde et al. (2008) found for English. This question will be answered by having judges

annotate the completions with respect to coherence relations and comparing the resulting distributions across prompt types.

Methods

We followed the passage completion task design used by Rohde et al. (2006, 2008) using Japanese stimuli.

Participants

Thirty-two native speakers of Japanese recruited from the San Diego area participated in the study. Participants were reimbursed for their time.

Materials

The experiment employed a 3x2x2 design that varied prompt type (Null-pronoun²/Overt-pronoun³/Free), aspect (Perfective/Imperfective⁴), and topic/nominative-marking of the context sentence subject (*-wa/-ga*), as shown in (4).

(4) Stimuli

太郎は/が 次郎に 本を渡した/渡している ところだった。

Taro-wa/ga Jiro-ni hon-o watashita/watashi-te-iru tokoro-datta.

Taro-TOP/NOM Jiro-to book-ACC handed/hand-INF-ASP scene-was

'Taro handed/was handing a book to Jiro.'

主語省略/彼は/自由 _____

shugo-shoryaku/kare-wa/jiyu

subject-omission(Null)/he-TOP(Overt)/free(Free)

The 60 experimental stimuli each had context sentences with different transfer-of-possession verbs. The Source referent ('Taro' in (4)) always appeared in subject position, and the Goal referent ('Jiro') was the dative/'to'-marked indirect object of the sentence. All verbs described physical transfer events (e.g., 'hand', 'throw').

Fillers consisted of 40 context sentences, containing transitive or intransitive non-transfer verbs in the perfective

² The 'subject-omission' prompt was used to indicate the presence of a null pronoun. A pilot study revealed that most participants were capable of continuing such prompts appropriately, which was confirmed in the actual study.

³ All overt pronoun prompts were topic-marked. This was done because the pilot study revealed that nominative-marked overt pronouns tend to be used to express an embedded subject of a complex sentence rather than a matrix subject. Topic-marking the pronoun resolved the issue.

⁴ Imperfectivity is not as straightforward to encode in Japanese as in English, since *-teita* 'was ~ing' is ambiguous between a perfective and imperfective reading depending on the verb (or VP) with which it co-occurs. Because transfer-of-possession verbs typically express achievement events as a default, the more natural interpretation of *-teita* with these verbs is perfective. We therefore use *tokoro* ('was in the scene of') to 'stretch out' instantaneous events and make an imperfective reading of achievement events possible, in a manner similar to what the English progressive does to achievement events.

or imperfective aspect. The transitive verbs varied between active and passive voice, and adverbs, names, and gender-unambiguous overt pronouns served as prompts. The 100 sets of sentences instantiating the 12 (3x2x2) experimental conditions were placed in a Latin square design to create 12 parallel lists of 100 sentences, such that no one participant saw more than one sentence from each set.

Task

Using a web-based interface, participants were asked to write continuations for the 100 passages. They were instructed to imagine a natural continuation to the story, writing the first continuation that came to mind and avoiding humor.

Data Analysis

Following previous studies on English, we focused our analysis on the interpretation of matrix subjects. Identifying the matrix subject can be less straightforward in Japanese than in English, however, since Japanese clauses may contain multiple null elements, and are characterized by flexible and head-final word order. It therefore proved useful to translate the continuations into English, thereby recovering the referents of null elements. For instance, if the original sentence in Japanese said ‘felt happy because passed exam’, detectable null pronouns were postulated, as in ‘(s/he) felt happy because (s/he) passed (her/his) exam’ in the relevant English translation. The first author (who is a native speaker of Japanese) then underlined the likely matrix subject of the given sentence for the subsequent annotation processes.

Two trained judges, who were native speakers of Japanese but were blind to the experimental hypotheses, annotated the referent of the matrix subject of each continuation sentence with respect to five categories: Source (‘Taro’ in (4)), Goal (‘Jiro’), Theme (‘book’), Other, and Unsure. The judges were instructed to do the annotation separately, without talking to each other. The first author compared their annotations and discarded the cases the judges did not agree on, as well as the cases in which participants did not omit a subject even though they were given a null pronoun prompt. The tokens discarded in this way constituted about 15% of the data.

The remaining tokens were then given back to the judges for annotating the coherence relations that held between each context sentence and continuation, as shown below (Hobbs, 1990; Kehler, 2002; Rohde, 2008).⁵

Elaboration: continuations that provide additional details about the eventuality described in the context sentence

e.g., *Taro handed a book to Jiro. He did so slowly and carefully.*

⁵ Although there are several other coherence relations which sometimes occurred – e.g., ‘Violated Expectation’ and ‘Parallel’ – we analyzed only these four.

Explanation: continuations that describe the cause of the eventuality described in the context sentence

e.g., *Taro handed a book to Jiro. He no longer had a use for it.*

Occasion: continuations that describe an eventuality that initiates from the end state of affairs of the eventuality described in the context sentence

e.g., *Taro handed a book to Jiro. He began reading it.*

Result: continuations that describe the effect or result of the eventuality described in the context sentence

e.g., *Taro handed a book to Jiro. He thanked him for the gift.*

The judges resolved disagreements through discussion.

Results

Reference

ANOVAs were run on the percentage of Source referents as a function of the total number of Source and Goal referents. Prompt type, aspect, and topic/nominative marking were used as factors. There was a significant main effect of prompt type [$F_1(2, 31) = 74.11, p < .0001$; $F_2(2, 59) = 64.10, p < .0001$]. Subsequent Tukey HSD posthoc comparisons found significant differences in order of Null > Overt > Free by both participants and items, i.e., Null pronouns were most Source-biased, followed by Overt pronouns, followed by Free prompt continuations. There was also a significant main effect of aspect [$F_1(1, 31) = 15.81, p < .0001$; $F_2(1, 59) = 21.02, p < .0001$], indicating that Imperfectives yielded more Source referents than Perfectives. Figure 1 shows the proportion of Source and Goal referents for each prompt type and aspect (collapsed over topic/nominative-marking) averaged across participants. The null pronoun conditions had about 80% Source referents irrespective of aspect, while Overt and Free conditions varied by aspect. Pairwise comparisons between Imperfectives and Perfectives within each prompt type revealed significant differences for Overt pronoun [$t_1(31) = 3.70, p = .0008$; $t_2(59) = 3.95, p = .0002$] and Free [$t_1(31) = 1.59, ns$; $t_2(59) = 3.47, p = .0011$]⁶ conditions, but not for Null conditions.

⁶ Some degrees of freedom vary due to missing cells.

⁷ The lack of significance by subjects in the Free prompt condition was due in part to the fact that the analysis included all continuations, as opposed to only those in which participants started their continuation with something other than a pronoun (i.e., a proper name). When name continuations only were compared, the aspect distinction yielded a marginal effect by participants [$t_1(23) = 2.02, p = .0551$] and remained significant by items [$t_2(43) = 2.56, p = .0141$].

Figure 1: Proportion of Source and Goal referents for all conditions (collapsed over topic-marking).

Mirroring Rohde et al. (2008), overt pronouns led to significantly more subject mentions of the Source than free prompts. We further divided the free prompt continuations according to their matrix subject type, namely, Null pronouns, Overt pronouns, and Names, and performed the same ANOVA as above. The results yielded significant main effects of aspect [$F_1(1, 31) = 4.01, p=.0462$; $F_2(1, 59) = 6.02, p=.0149$] and subject type [$F_1(2, 31) = 67.59, p<.0001$; $F_2(2, 59) = 43.40, p<.0001$]. Subsequent Tukey HSD posthoc comparisons found significant differences in order of Null > Overt > Free by participants and Null > Overt, Free by items, which shows the highest proportion of Goal referents for Name continuations, again consistent with Rohde et al.

Unlike aspect, however, there were no significant main effects or interactions involving topic-marking. Figure 2 shows the proportion of Source and Goal referents for each prompt type and topic/nominative-marking (collapsed over aspect) averaged across participants. Pairwise comparisons between Topics and Nominatives within each prompt type revealed no significant differences for any prompt type, but there was a marginal difference in Null continuations [$t_1(30) = 1.70, p=.0989$; $t_2(57) = 1.87, p=.0665$] that favored subject referents in the topic condition.

Figure 2: Proportion of Source and Goal referents for all conditions (collapsed over aspect).

Coherence Relations

Figure 3 shows the Source/Goal referent count for each coherence relation (collapsed over 12 experimental conditions) averaged across participants.

Figure 3: Mean Source/Goal referent count for each coherence relation (collapsed across conditions).

Figure 4 shows the referent biases as proportions between Source- and Goal-referential completions. As has been previously reported for English (Rohde et al., 2006), Elaboration and Explanation are highly Source-biased whereas Occasion and Result are highly Goal-biased.

Figure 4: Proportion of Source/Goal referents for each coherence relation (collapsed over conditions).

For our statistical analysis, we collapsed the proportion of Elaboration and Explanation (Source-biased relations) on the one hand and Occasion and Result (Goal-biased relations) on the other hand for each participant's continuations, and conducted repeated measures ANOVAs on the proportion of Source-biased relations over Source- and Goal-biased relations. There was a significant main effect of prompt type [$F_1(2, 31) = 25.94, p<.0001$; $F_2(2, 59) = 22.34, p<.0001$; Tukey HSD: Null > Overt > Free by participants, and Null > Overt, Free by items], suggesting that Null prompt conditions were most Source-biased. There was also a significant main effect of aspect [$F_1(1, 31) = 9.75, p=.0018$; $F_2(1, 59) = 9.54, p=.0021$], suggesting that Imperfectives yielded more Source-biased relations than Perfectives (Figure 5). Pairwise comparisons between Imperfectives and Perfectives within each prompt type revealed significant differences for Overt pronoun prompt conditions [$t_1(31) = 3.68, p=.0009$; $t_2(59) = 3.82, p=.0003$] and marginal by-item significance for Free prompt

conditions [$t_1(31) = 1.64$, ns; $t_2(44) = 1.90$, $p=.0637$]⁸, but non significance for Null conditions.⁹

Figure 5: Proportion of coherence relations for all conditions (collapsed over topic-marking).

As was the case for reference, ANOVAs revealed no main effects or interactions involving topic marking. While Figure 6 indicates a small numerical trend of more Source-biased relations for topic-marked than nominative-marked Overt and Free continuations, pairwise comparisons between Topics and Nominatives within each prompt type revealed no significant or marginal differences.

In summary, the distribution of coherence relations generally followed the pattern found for reference, being consistent with previous studies in English (Rohde et al., 2006, 2008).

⁸ As was the case for reference, the mixed results for the Free prompt condition were due in part to the fact that the analysis included all continuations, as opposed to only those in which participants started their continuation with something other than a pronoun (i.e., a proper name). When only Name continuations were compared, there was a marginal difference between Imperfectives and Perfectives by participants [$t_1(20) = 1.98$, $p=.0619$] and a significant one by items [$t_2(32) = 2.05$, $p=.0483$].

⁹ Posthoc observation revealed that the proportion of Elaborations within the Source-biased relations was consistently higher for Imperfectives than Perfectives for all prompt types. ANOVAs run on the proportion of Elaboration over Elaboration and Explanation relations revealed a significant main effect of aspect [$F_1(1, 31) = 28.29$, $p<.0001$; $F_2(1, 59) = 30.63$, $p<.0001$] with no other statistically-supported main effects or interactions. Imperfective conditions had a uniformly higher proportion of Elaboration than Explanation relations across prompt types; pairwise comparisons between Imperfectives and Perfectives within each prompt type revealed significant differences for all types except for Free prompts by subjects [Null: $t_1(23) = 2.42$, $p=.0240$; $t_2(39) = 2.54$, $p=.0151$; Overt: $t_1(24) = 3.36$, $p=.0026$; $t_2(39) = 3.06$, $p=.0040$; Free: $t_1(17) = 1.70$, $p=.1069$; $t_2(28) = 2.36$, $p=.0256$]. Participants were therefore more likely to elaborate an event described as ongoing (imperfective) than one described as completed (perfective), indicating an effect of aspect on coherence that is independent of the choice of subsequently mentioned entity.

Figure 6: Proportion of coherence relations for all conditions (collapsed over aspect).

Discussion

We are now in a position to answer the four questions posed in the introduction to the paper. First, we asked whether the behavior of Japanese null and/or overt pronouns patterns with that of English overt pronouns in displaying sensitivity to pragmatic subsequent-mention biases, or whether their interpretation is determined primarily by other (e.g., grammatical) factors. The results indicate that Japanese null pronoun interpretation is not analogous to English overt pronoun interpretation as previous researchers have suggested. Instead, null pronouns were most strongly and uniformly Source-biased for both interpretation and coherence relations, apparently being driven predominantly by grammatical position and without showing sensitivity to the aspect manipulation. Instead, overt Japanese pronouns patterned with English in demonstrating such sensitivity, with Imperfective conditions yielding more Source referents and Source-biased coherence relations. Further, overt pronouns led to significantly more mentions of the Source than free prompts, demonstrating that, like English overt pronouns, Japanese overt pronouns overlay a subject bias on top of pragmatically-driven ones. Indeed, the results for Japanese overt pronouns mirrored those of Rohde et al. (2006, 2008) for English pronouns quite closely.

The second question we asked is whether null and overt Japanese pronouns exhibit a division-of-labor effect such that a demonstrated subject bias for null pronouns would correspond to a commensurate non-subject bias for overt pronouns. The answer is no; both null and overt pronouns displayed a subject bias, and hence their referents were not in complimentary distribution. Although the nature of the biases were different – overt pronouns overlay a subject bias on top of pragmatically-driven subsequent-mention biases as measured in the free prompt condition, whereas null pronouns appear to have a more grammaticalized subject bias that is impervious to pragmatic expectations – both pronominal forms were used to refer to Sources more often

than Goals. It therefore appears that the use of an overt pronoun does *not* implicate that the referent is an entity other than what the preferred referent would have been if a null pronoun had been used (i.e., the subject). At first blush, these patterns nonetheless appear consistent with those found for Spanish by Alonso-Ovalle et al. (2002), although further comparison is difficult since the experimental tasks and manipulations carried out were very different.

The third question we asked was whether topic-marked antecedents attract more pronominal references than subject-marked antecedents. The answer again was no. Perhaps surprisingly, there was no significant influence of topic marking across prompt types.

Lastly, we asked whether any grammatical biases that are revealed to be associated with these referential forms affects the distribution of ensuing coherence relations, as Rohde et al. (2008) found for English. This is clearly the case. Although the null and overt pronouns were always fully ambiguous between the available Source and Goal referents, their appearance in a prompt biased the continuation toward mentioning the previous subject referent first, which in turn biased the participants toward continuing the story using a Source-biased coherence relation. Further, while the aspect manipulation in the null pronoun condition created differences in the distribution of Source-biased relations – imperfectives resulted in a greater number of Elaborations, at the expense of Explanations (see footnote 9) – it did not change the allocation between Source- and Goal-biased relations, in accord with the fact that the aspect manipulation resulted in no difference in the distribution between Source and Goal referents.

Several experiments suggest themselves as ways of confirming the conclusions arrived at in this paper. One is to see whether the lack of effect of pragmatic bias for null pronouns holds across different verb types. Whereas we manipulated aspect on a single type (transfer of possession), we could also vary the verbs themselves, choosing types that are known to yield substantially different subsequent-mention biases. Contexts employing object-biased implicit causality verbs, for instance, would offer strong test for the subject bias associated with null pronouns. Likewise, the lack of effect of topic-marking could be further examined by comparing reference in contexts in which nominative-marked subject referents compete with topic-marked object referents. Such studies remain for future work.

Acknowledgments

This research was supported by a grant from the UCSD Academic Senate. We thank Shin Fukuda for helpful discussion and his insights in Japanese syntax, Ria Abe and Sho Nakamura for data annotation, and Ryo Goto, Emiko Nakamura, and Susanne Mari Sakai for help in conducting the experiment.

Novel Words in Novel Contexts: The Role of Distributional Information in Form-class Category Learning

Abstract

One major aspect of successful language acquisition is the ability to organize words into form class categories and generalize from properties of experienced items to novel items. Furthermore, learners must often determine how to use a new word, when there is very sparse information regarding its acceptable contexts. In this work we employ an artificial language learning paradigm to explore how adult learners, under circumstances of varying distributional cues to category boundaries, apply their knowledge of category properties to a new word. We find that in cases of strong category cues and strong category learning, adults readily generalize all of the distributional properties of the learned category to a word that shares just one context with the other category members. However, as the distributional cues regarding the target category become sparser and contain more systematic gaps, learners show more conservatism in generalizing the allowable distributional properties to the novel word. Taken together, these results show striking flexibility in learners' tendency to generalize, depending on the distributional properties of the input corpus, in a probabilistically rational way.

Introduction

The problem that learners face when they attempt to categorize items in the environment is deciding when they should treat instances as a category (thus generalizing from properties of experienced items to novel ones) and when they should treat instances separately (with no generalization from properties of experienced items to predicted properties of novel items). This problem cannot always be solved on the basis of perceptual similarity, as membership in some categories is independent of the surface features of the members.

The acquisition of grammatical categories is an example of this type of problem, but has some additional complicating factors. We hear individual words in a limited number of specific contexts. However, the rules that languages are built on involve patterns defined over categories of words, not the individual words themselves. Language input is serially presented, so we need to predict the proper contexts for words we have not yet heard. Furthermore, learners never see the entire input corpus, so they must figure out the proper contexts for new words, keeping in mind that sometimes there are lexically specific restrictions on words (such as *give* versus *donate*: despite similar meaning, Joe can *give David a book*, but Joe cannot **donate David a book*). In acquiring grammatical

categories, the learner must ask whether contexts are absent by accident, or because they are ungrammatical. This question is particularly difficult to resolve when a new item is encountered in a single context and therefore overlaps only minimally with previously encountered words. For example, consider hearing the sentence: *I remembered to nerk yesterday*. Should one generalize from this context to another context where words of the category 'verb' are grammatical, such as *She will make him nerk tomorrow*, or *I saw the cat nerk earlier*?

One hypothesis about how learners handle this situation is that they have innately defined linguistic categories with featural and contextual information predefined, so that minimal exposure to language is needed to sort out which words belong to each category (e.g., McNeill, 1966). Another hypothesis is that learners use semantic categories to bootstrap the syntactic categories (e.g., Grimshaw, 1981). A third possibility is that learners exploit distributional information in the input to discover the category structure of natural languages (e.g., Braine, 1987). This third hypothesis is what we investigate in the present experiments.

A number of researchers have asked whether there is adequate distributional information in the input to form linguistic categories. This work uses hierarchical clustering and a computational learning mechanism to attempt to deduce grammatical categories from corpora of child-directed speech based solely on distributional analyses of the input (e.g., Mintz, Newport, & Bever, 2002; Redington, Chater, & Finch, 1998). These models have been able to use co-occurrence statistics among words to achieve relatively good categorization performance for frequent target words. To explore whether human learners can actually use this information during language learning, Mintz (2002) tested categorization in an artificial language learning environment, showing evidence that learners did engage in distributional analyses of the input in order to generalize their knowledge of previously encountered strings to grammatical novel strings. Hunt and Aslin (2010) showed that adults could learn categories embedded in sequences of visual symbols during a serial reaction time task when the only cue to category structure was distributional information among the symbol strings.

Building off of these findings on the importance of distributional information for category formation, we have proposed a systematic set of computational variables that can explain the types of distributional information that are

important for categorization. Deciding whether to generalize across words or preserve lexical specificity appears to be determined by (at least) 3 distributional variables: the *number* of linguistic contexts in which each word in the input set occurs, the *density* or proportion of these contexts that are present in the input, and the degree of *overlap* of contexts across words. In previous work (Reeder et al., 2009) we showed that learners are remarkably sensitive to these cues, which interact with each other to determine how basic category and subcategory structure are acquired. To do this, we manipulated the distribution of contexts for a target category in the exposure set to examine how adults determine when to generalize (deciding whether gaps in their input are accidental or systematic). When participants were exposed to a dense sampling of the language where there was rich coverage of contexts for a target category and high overlap in contexts across words, adult learners showed complete generalization to all possible grammatical contexts, even those that were never heard before for particular words. But as the input to the learner became more sparse with less overlap, participants became more conservative in their generalizations. Furthermore, as we increased the frequency of recurring gaps in the input, participants became more certain that the gaps were not accidental but rather part of the structure of the language, and they decreased their generalizations to unseen grammatical contexts. In the present work we ask how, under these same varying circumstances of category strength and category learning, learners will extend their knowledge of the target category to a *novel* word, one for which they have only minimal context information. In particular, is there a point in category learning where hearing one context for a novel word is enough to obtain full category privileges for that word? Or does every novel word need to be heard in a number of overlapping contexts in order to be treated as a member of the category?

Experiment 1

In Experiment 1 of Reeder et al. (2009), the learner was exposed to a very dense sampling of the language space, with all the words in the target category appearing in many highly overlapping contexts. Under these conditions, learners represented the words as a true category, generalizing fully across the gaps in the exposure corpus. In Experiment 1 we ask whether, under the same circumstances, the target category’s distributional properties will also generalize to a novel word that they have only heard in a single context. The logic of this paradigm is that, if learners acquire a strong category (called X), then novel sentences which observe even a bit of the category structure of the language might be perceived to be just as grammatical (or familiar) as sentences that have actually been heard during training.

An artificial grammar with the structure (Q)AXB(R) was used, similar to that used in Reeder et al. (2009), where each letter represents a set of 2, 3, or 4 words. In Experiment 1, the Q and R categories had 2 words each, the A and B

categories had 3 words each, and the X category had 4 words. The words of the grammar were *spad*, *klidum*, *flairb*, *daffin*, *glim*, *tomber*, *zub*, *lapal*, *fluggit*, *mawg*, *bleggin*, *gentif*, *frag*, and *sep*. The words were not mapped on to any referential world, so there were no semantic cues to categorization. All studies were run with two languages that differed only in which words were assigned to each of the categories in the language, to ensure that obtained results were not due to coincidental preferences for specific sound combinations. As in Reeder et al. (2009), X was the target category of interest, A and B were “context” categories that formed the distributional cues to the category X, and Q and R were optional flanker categories that allowed strings to range from 3 to 5 words in length.

Table 1: Possible AXB strings in Exp. 1-4. Items presented in Exp 1 are denoted *; items presented in Exp 2 are denoted ♦; items presented in Exp 3 & 4 are denoted ◊.

A ₁ X ₁ B ₁ *	A ₁ X ₂ B ₁	A ₁ X ₃ B ₁ * ♦ ◊	A ₁ X ₄ B ₁ * ♦ ◊
A ₁ X ₁ B ₂	A ₁ X ₂ B ₂ * ♦	A ₁ X ₃ B ₂ * ◊	A ₁ X ₄ B ₂
A ₁ X ₁ B ₃ * ♦ ◊	A ₁ X ₂ B ₃ *	A ₁ X ₃ B ₃	A ₁ X ₄ B ₃
A ₂ X ₁ B ₁	A ₂ X ₂ B ₁ * ♦ ◊	A ₂ X ₃ B ₁ *	A ₂ X ₄ B ₁
A ₂ X ₁ B ₂ * ♦ ◊	A ₂ X ₂ B ₂ *	A ₂ X ₃ B ₂	A ₂ X ₄ B ₂
A ₂ X ₁ B ₃ * ◊	A ₂ X ₂ B ₃	A ₂ X ₃ B ₃ * ♦	A ₂ X ₄ B ₃
A ₃ X ₁ B ₁ * ♦	A ₃ X ₂ B ₁ * ◊	A ₃ X ₃ B ₁	A ₃ X ₄ B ₁
A ₃ X ₁ B ₂ *	A ₃ X ₂ B ₂	A ₃ X ₃ B ₂ * ♦ ◊	A ₃ X ₄ B ₂
A ₃ X ₁ B ₃	A ₃ X ₂ B ₃ * ♦ ◊	A ₃ X ₃ B ₃ *	A ₃ X ₄ B ₃

Method

Participants 16 monolingual native English-speaking students at the University of Rochester participated in Experiment 1, eight in each of the two languages created by different assignments of words to categories. Subjects had not participated in any other categorization experiment and were paid for their participation.

Stimulus Materials Of the possible 36 AXB sentence types in the language, 19 were presented to participants, and the remainder were withheld for testing generalization (see Table 1). The presence of the 2 Q and 2 R words was varied evenly such that the exposure set was expanded to 76 possible (Q)AXB(R) sentences. The exposure set contained only four X₄ strings: A₁X₄B₁, Q₁A₁X₄B₁, A₁X₄B₁R₁, and Q₂A₁X₄B₁R₂, which presented the X₄ word in only one context (A₁X₄B₁); the remaining 72 sentences included equal numbers of sentences containing X₁, X₂, and X₃. Training consisted of 4 times through this exposure set, forming 22 minutes of exposure. Importantly, every X₁, X₂, and X₃ was seen with every A and every B word, but X₄ was only seen in one context. Thus, the training set for Experiment 1 was dense for X₁-X₃ such that participants were exposed to a high proportion of the possible strings for those three X words, but very sparse for X₄. Additionally, there was complete overlap of contexts among X₁, X₂, and X₃, but X₄ shared only one context with X₁-X₃.

A female native English speaker recorded the words in isolation with both non-terminal and terminal intonation. Words were then adjusted in Praat such that pitch, volume, and duration were roughly consistent. Sentences were constructed by splicing words sequences in Sound Studio such that all words except the last had non-terminal intonation, with 50ms silence between each word. The final word in each sentence had terminal intonation contour. The order of sentences in the exposure set was randomized for each subject and presented via a custom software package on a Dell PC. Each sentence was separated by 1.5s of silence. Participants wore headphones and passively listened to the exposure sentences during training.

Immediately after exposure, participants heard a series of test strings and were asked to rate each on a scale from 1 to 5, where 1 meant it definitely did *not* come from the language they were exposed to, and 5 meant it definitely *did* come from the exposure language. All test strings were 3-word sentences of one of the following forms: a grammatical familiar string (10 AXB strings presented during training), a grammatical novel string (13 AXB strings withheld during training), or an ungrammatical string (of the form AXA or BXB). Of the grammatical novel test strings, 4 of the 13 were strings testing generalization of X_4 : $A_2X_4B_2$, $A_2X_4B_3$, $A_3X_4B_2$, and $A_3X_4B_3$. With these strings we can ask whether learners have generalized X_4 to the full range of grammatical contexts for X-words, judging the familiar and novel grammatical sentences for X_4 to be equivalent, even though they have only seen X_4 in one of these contexts. These strings can then be compared to the 6 ungrammatical strings that contain X_4 (3 AX_4A , 3 BX_4B).

Results

A repeated measures ANOVA with condition (familiar, novel, ungrammatical) as the within subjects factor and language as the between subjects factor showed no significant effects of language ($F < 1$). For test items without X_4 , the mean rating of grammatical novel strings was 3.87 ($SE = 0.14$), the mean rating of grammatical familiar strings was 3.85 ($SE = 0.13$), and the mean rating of ungrammatical strings was 2.89 ($SE = 0.15$). We found no significant difference between ratings of grammatical novel items and grammatical familiar items ($F(1,14) = 0.24$, $p = 0.63$). These items were rated significantly higher than ungrammatical test strings ($F(1,14) = 26.40$, $p < 0.005$). For the test items that contained X_4 , the mean rating of grammatical novel strings was 3.28 ($SE = 0.18$), the mean rating of grammatical familiar strings was 3.59 ($SE = 0.24$), and the mean rating of ungrammatical strings was 2.61 ($SE = 0.21$). These items showed the same pattern as the without- X_4 items: there was no significant difference between ratings of grammatical novel X_4 items and familiar X_4 items ($F(1,14) = 1.71$, $p = 0.21$), however there was a significant difference between

these items and ungrammatical X_4 strings ($F(1,14) = 13.10$, $p < 0.01$).¹

Discussion

As in Reeder et al. (2009), learners strongly preferred familiar and novel grammatical sentences to ungrammatical sentences. Learners also showed generalization to the novel grammatical X_4 strings, but not to the ungrammatical X_4 strings. Thus they generalized X_4 to the full range of grammatical contexts for X words, even though they heard X_4 in only one of these contexts. These results show that, when learners are exposed to a dense sampling of the language space for words in the target category (X_1 - X_3) and presented with many overlapping contexts, they generalize their knowledge within the category X_1 - X_3 and also extend it to X_4 . Importantly, the generalized contexts are novel contexts for X_4 , but are strongly represented by the learner's exposure to the permissible contexts for X_1 - X_3 . Learners did not require semantic or perceptual cues to indicate that the X words form a category.

Experiment 1 provided the learner with a dense sampling of the language space for most of the words in the target category. In the remaining experiments we systematically manipulated the density, overlap, and number of contexts for X_1 - X_3 in the exposure set while restricting exposure to contexts for X_4 , in order to explore the impact of these distributional variables on the generalization of category knowledge.

Experiment 2: Sparseness

In Experiment 2, we decrease the density of the contexts for X_1 - X_3 words, but we keep the number and overlap among X_1 - X_3 contexts the same. We still present only one context for X_4 and explore what the increase in sparseness for X_1 - X_3 does to learners' generalizations to the novel X_4 item.

Method

Participants 16 monolingual native English-speaking students at the University of Rochester participated in Experiment 2 for payment, eight in each of the two possible languages. Subjects had not participated in any other categorization experiment.

Stimulus Materials The strings of the language were constructed in the same manner as Experiment 1, with two languages that had different assignments of words to categories. Here, however, the exposure set contained only 10 (versus 19 in Exp. 1) of the 36 possible AXB combinations (see Table 1). As in Experiment 1, every X_1 - X_3 word was heard in combination with every A and every B. With the addition of AXB strings with optional Q and R

¹ We did not compare ratings of the X_1 - X_3 test items with the X_4 items because of the lower statistical power of the X_4 means. For all experiments, we take the pattern of learning for familiar and novel grammatical items to be more informative than the size of the differences between X_1 - X_3 and X_4 .

flanker words, there were 40 sentences in the exposure set. The exposure set was repeated 4 times through so that each sentence type was presented with the same frequency as in Experiment 1, for an exposure of about 12 minutes. The test phase was the same as described for Experiment 1.

Procedure The procedure was the same as in Experiment 1.

Results

A repeated measures ANOVA with condition as the within subjects factor and language as the between subjects factor revealed no difference between the two languages ($F < 1$). For test items without X_4 , the mean rating of grammatical novel strings was 3.55 ($SE = 0.09$), the mean rating of grammatical familiar strings was 3.54 ($SE = 0.10$), and the mean rating of ungrammatical strings was 2.63 ($SE = 0.14$). Just as in Experiment 1, as well as Experiments 1 and 2 from Reeder et al. (2009), we found no significant difference between ratings of grammatical novel items and grammatical familiar items without X_4 ($F(1,14) = 0.008$, $p = 0.93$), but grammatical sentences were rated significantly higher than ungrammatical test strings ($F(1,14) = 25.37$, $p < 0.001$). For the test items that contained X_4 , the mean rating of grammatical novel strings was 3.27 ($SE = 0.15$), the mean rating of grammatical familiar strings was 3.53 ($SE = 0.22$), and the mean rating of ungrammatical strings was 2.55 ($SE = 0.16$). This is the same trend as demonstrated by the without- X_4 items and the analyses in Experiment 1. While there was a significant difference between grammatical X_4 strings and ungrammatical X_4 strings ($F(1,14) = 9.87$, $p < 0.01$), there was no significant difference between ratings of grammatical novel X_4 items and familiar X_4 items ($F(1,14) = 1.59$, $p = 0.23$).

Discussion

These results mirror those in Experiment 1, demonstrating that reduced density does not greatly affect learners' performance when there is full overlap of contexts among X_1 - X_3 words. The generalization to X_4 is maintained despite greatly reduced exposure due to a sparser sampling of the language space. We next explore how learners behave when there is reduced overlap of X_1 - X_3 word contexts.

Experiment 3: Overlap

Similar to Experiment 2, we present the learner with only 10 of the 36 possible AXB combinations. However, in order to test how overlap in contexts influences generalization of category knowledge to new X-words, we now reduce the overlap of contexts among members of X_1 - X_3 . Individual X-words do not fully share all of their contexts with other X-words, though the set of X-words as a whole occurs in all A and B contexts. By reducing the overlap in contexts across X words, we can assess the degree to which learners restrict generalization within X_1 - X_3 , and also how they extend the category knowledge to X_4 .

Method

Participants 16 monolingual native English-speaking students at the University of Rochester participated in Experiment 3, eight in each of the two possible languages. Participants had not been in any other categorization experiment and were paid for their participation.

Stimulus Materials Strings were assembled in the same way as Experiment 1, with two languages that had different assignments of words to categories. Exposure consisted of only 10 of the 36 possible AXB combinations, as in Experiment 2; however now X_1 , X_2 , and X_3 were heard with 2 of the 3 A-words and 2 of the 3 B-words each. X_1 occurred with A_1 , A_2 , B_1 , and B_2 , but not A_3 or B_3 ; X_2 was heard with A_2 , A_3 , B_2 , and B_3 , but not A_1 or B_1 ; X_3 was heard with A_1 , A_3 , B_1 , and B_3 , but not A_2 or B_2 . Thus, the overlap among contexts is maintained over the X_1 - X_3 category as a whole, but individual X-words do not have the degree and type of overlap in distributional contexts that they do in Experiments 1 and 2, where each X word occurs with every A and every B. X_4 was still only seen with one context (see Table 1).

Procedure The procedure was the same as in Experiment 1.

Results

A repeated measures ANOVA with condition as the within subjects factor and language as the between subjects factor showed no significant difference between the two languages ($F < 1$). For test items without X_4 , the mean rating of grammatical novel strings was 3.71 ($SE = 0.12$), the mean rating of grammatical familiar strings was 3.91 ($SE = 0.09$), and the mean rating of ungrammatical strings was 2.55 ($SE = 0.15$). Unlike Experiments 1 and 2, but in line with results from Reeder et al. (2009), we found significant differences between ratings of grammatical novel items and grammatical familiar items ($F(1,14) = 9.12$, $p < 0.01$). Additionally, both of these items were rated significantly different from ungrammatical test strings ($F(1,14) = 26.82$, $p < 0.001$). For the test items that contained X_4 , the mean rating of grammatical novel strings was 3.25 ($SE = 0.16$), the mean rating of grammatical familiar strings was 3.66 ($SE = 0.24$), and the mean rating of ungrammatical strings was 2.21 ($SE = 0.16$). Unlike the without- X_4 items, we do not see any significant difference between novel grammatical X_4 strings and familiar X_4 strings ($F(1,14) = 2.98$, $p = 0.11$), perhaps due to the lower statistical power for these test items; there is still a significant difference between ratings of grammatical and ungrammatical X_4 items ($F(1,14) = 26.21$, $p < 0.001$).

Discussion

In Experiment 3, we reduced the overlap among contexts in the exposure set by a third, but we kept the number of contexts in the input the same as in Experiment 2. The results indicate that despite full coverage of contexts across lexical items, the incomplete overlap between X_1 - X_3 -words

led to decreased generalization. However, learners still showed a much higher rating for grammatical novel items than ungrammatical items, indicating that they were still willing to generalize, though more conservatively than in Experiments 1 and 2. Additionally, learners were much less likely to generalize their knowledge of grammatical X_1 - X_3 contexts to X_4 given the systematic gaps in the Experiment 3 exposure set. Thus, as we move along the dimensions of sparseness and overlap explored in Experiments 2 and 3, we can see how learners weigh the likelihood that X_4 shares the same contexts as X_1 - X_3 and use this as a diagnostic for how strongly the X category has been formed.

Experiment 4: Overlap with extended exposure

The decision to generalize over a gap in the input or maintain lexical distinctness may also be influenced by the frequency of contexts (and gaps) in the input. If a context is consistently absent as in Experiment 3, learners start to show conservatism in their generalizations. If this gap is made even more prominent by creating an exposure set that has repeated instances of sparse contextual information, learners might develop even more certainty that gaps in the input are systematic and not accidental (e.g., Wonnacott, Newport & Tanenhaus, 2008; Xu & Tenenbaum, 2007). This will be particularly important with regard to X_4 , where we can explore how an increase in the exposure to the one context for X_4 (and potentially a perceived increase also in the gaps at the non-occurring contexts for X_4) affects how learners generalize their knowledge of the category X_1 - X_3 . If the category X_1 - X_3 is strongly defined (as in Experiment 1), we would expect that a very large increase in frequency of the one context of X_4 (and perceived increase in exposure to gaps for X_4) might be required before there is a decrease in generalization and a lessening of X_4 membership in the X -word category. However, if the X -category is weakly defined as in Experiment 3, the small increase in the number of repetitions in Experiment 4 might be enough to make learners conservative in their generalizations.

Method

Participants 16 monolingual native English-speaking students at the University of Rochester participated in Experiment 2, eight in each of the two possible languages. Participants had not been in any other categorization experiment and were paid for their participation.

Stimulus Materials The language was the same as in Experiment 3, except that exposure to the language was tripled by presenting the corpus 12 times rather than 4. Training lasted for approximately 22 minutes (as in Experiment 1), but contained only 10 contexts (as in Experiments 2 & 3). Test strings were the same as in Experiment 3.

Procedure The procedure was the same as in Experiment 1.

Results

A repeated measures ANOVA with condition as the within subjects factor and language as the between subjects factor showed no significant difference between the two languages ($F < 1$). For test items without X_4 , the mean rating of grammatical novel strings was 3.86 ($SE = 0.12$), the mean rating of grammatical familiar strings was 4.05 ($SE = 0.10$), and the mean rating of ungrammatical strings was 2.61 ($SE = 0.21$). These results show a significant difference between ratings of grammatical novel items and grammatical familiar items ($F(1,14) = 8.60$, $p = 0.01$). Additionally, these items were rated significantly higher than ungrammatical test strings ($F(1,14) = 35.83$, $p < 0.001$). For the test items that contained X_4 , the mean rating of grammatical novel strings was 3.44 ($SE = 0.19$), the mean rating of grammatical familiar strings was 4.06 ($SE = 0.21$), and the mean rating of ungrammatical strings was 2.37 ($SE = 0.21$). Similar to the without- X_4 items, we now find a significant difference between novel grammatical X_4 strings and familiar X_4 strings ($F(1,14) = 8.33$, $p = 0.011$), along with a significant difference between these and ungrammatical X_4 items ($F(1,14) = 31.04$, $p < 0.001$).

Figure 1: Experiment 1-4 difference scores of ratings of grammatical familiar items and grammatical novel items (for X_1 - X_3 words and X_4), and grammatical familiar items and ungrammatical items (for X_1 - X_3 words and X_4).

Discussion

These results indicate that, when we increase exposure to the same sparse data (with recurring gaps that may also become more prominent), learners act rationally and are even less likely to generalize over such gaps. Furthermore, learners apparently view the category formed by X_1 - X_3 as weakly defined due to the sparse sampling of the language and incomplete overlap among words, which also seems to increase learners' uncertainty about the status of the withheld grammatical X_4 items. While we still see that novel grammatical test strings are judged more grammatical than the ungrammatical strings, we hypothesize that increasing exposure to the sparse input set even longer might push learners to judge all novel items as ungrammatical. In contrast, if we increased the number of

unsystematic gaps in the input, we expect that learners would show more generalization, especially for the X_4 word.

General Discussion

The present experiments add grammatical category learning to a large literature showing that learners are highly sensitive to many types of distributional information in their input. We have replicated Experiments 1-4 of Reeder et al. (2009), demonstrating that learners are able to extract the category structure of an artificial language based on distributional information alone, and we show that learners are quite rational, statistically speaking, in how much and when they generalize across gaps in the input. Importantly, the current experiments also show that learners can skillfully transfer their knowledge of category structure and category cues to a novel item that is only weakly represented in the input. When given a dense sampling of the language space with almost complete overlap of contexts for many words in a target category X , learners generalize a novel word (X_4) to the full range of grammatical contexts of the other X -words, even when they have only seen X_4 in one of those contexts. This willingness to add X_4 to the strongly established X_1 - X_3 category is strongest when the X_1 - X_3 contexts are dense and overlapping; when contexts are more sparse and less overlapping across different X words, we also see more conservative generalization to a new X_4 word. The most extreme case is when we increase the number of times the learner hears the sparse exposure set, thus increasing also the frequency of recurring gaps in the input for X_1 - X_3 : learners in this situation rate the withheld X_4 contexts as more unfamiliar, while rating as highly familiar only the one context in which X_4 was actually heard. These findings are in line with results from Wonnacott, Newport and Tanenhaus (2008) in the area of verb-argument learning, where if the language is generally lexically specific, participants do not show generalization of the minimal exposure item (i.e., X_4) to other contexts. In contrast, if the language has the same contexts permitted for all verbs, then participants show strong generalization for the minimal exposure item.

We are in the process of modeling these results to determine the type of information learners might encode in order to accomplish these outcomes; storing any simple statistics – such as word, bigram, or trigram frequencies – would not be adequate to account for generalization to the novel X_4 strings. Instead, learners must be forming a more abstract representation of the data in order to generalize their knowledge to novel strings.

In contrast to our experiments, as learners face the problem of inferring category membership from sparse and incomplete data in natural languages, there are a number of correlated cues that they could use to help them extract category information, such as phonological, prosodic, or semantic cues as well as distributional cues. Indeed, many studies have shown that category learning is enhanced when category membership is correlated with such surface cues

(e.g., Monaghan, Chater, & Christiansen, 2005). But an important question in this literature has been whether category learning can utilize distributional information, either alone or when very poorly correlated with other cues. While natural languages do sometimes contain multiple cues to grammatical categories, our work indicates that learners are able to skillfully employ a statistical learning mechanism as a primary tool with which to extract category information from the input, even in cases where other correlated cues are incomplete or absent.

Optimal Language Learning: The Importance of Starting Representative

Abstract

Child-directed speech has a distinctive structure and may have facilitatory effects on children's language learning. We consider these facilitatory effects from the perspective of Marr's levels of analysis: could they arise at the computational level or must they be located at the algorithmic or implementation levels? To determine if the effects could be due to computational level benefits, we examine the question of what samples from a language should best facilitate learning by identifying the optimal linguistic input for an ideal Bayesian learner. Our analysis leads to a mathematical definition of the "representativeness" of linguistic data, which can be computed for any probabilistic model of language learning. We use this measure to re-examine the debate over whether language learning can be improved by "starting small" (i.e. learning from data that have limited complexity). We compare the representativeness of corpora with differing levels of complexity, showing that while optimal corpora for a complex language are also complex, it is possible to construct relatively good corpora with limited complexity. We discuss the implications of these results for the level of analysis at which a benefit of starting small must be located.

Keywords: language learning; child-directed speech; Bayesian models; representativeness; starting small

Introduction

Child-directed speech is an important source of information for children's language acquisition. Hoff and Naigles (2002) found that the amount of child-directed speech produced by mothers was predictive of the vocabulary of their children, and Cameron-Faulkner, Lieven, and Tomasello (2003) found correlations between the grammatical frames mothers used in speech to their children and the grammatical frames used by the children. Child-directed speech also differs from adult-directed speech in a number of ways. For example, Snow (1972) found that speech to two year olds by caregivers has simplified structure and involves more repetitions than speech to older children or adults, and Sherrod, Friedman, Crawley, Drake, and Devieux (1977) found that the mean length of utterances spoken to a child changed in response to changes in the child's understanding. Overall, child-directed speech tends to be simplified, more grammatically correct, and more repetitive than adult-directed speech (Pine, 1994). This raises an important question: Does the structure of child-directed speech facilitate language acquisition?

There is some evidence for a facilitatory effect of child-directed speech. Furrow, Nelson, and Benedict (1979) found that children's language development was positively correlated with mothers' use of simple constructions, and Newport, Gleitman, and Gleitman (1977) found that acquisition of certain syntactic features was facilitated by characteristics of mothers' speech, such as placement of particular

syntactic structures early in sentences. However, Newport et al. (1977) also found that many measures of acquisition were unaffected by characteristics of caregivers' speech, and Huttenlocher, Vasilyeva, Cymerman, and Levine (2002) found that exposing children to more complex speech resulted in the children using more complex syntax.

Previous work has used specific computational models such as associative learning and artificial neural networks to explore the effects of simplified input on language learning (Goldowsky & Newport, 1993; Elman, 1993; Rohde & Plaut, 1999). Elman (1993) found that training a simple recurrent neural network to predict the next word in a sequence using a corpus of limited complexity resulted in better generalization than beginning with the full corpus. However, the effects of "starting small" are far from clear: Rohde and Plaut (1999) subsequently found a disadvantage for language learning that begins with data of limited complexity when using similar models and corpora.

Demonstrating an effect of starting small under specific assumptions about learning leaves open the question of the level of analysis at which there might be an advantage for child-directed speech. Marr (1982) defined three levels at which information processing systems can be analyzed: the *computational* level, where the analysis aims to identify the abstract problem being solved and its ideal solution; the *algorithmic* level, where the focus is on the representation and algorithm being used to implement this solution; and the *implementation* level, which emphasizes the physical hardware on which the algorithm is executed. Facilitatory effects of the structure of child-directed speech could be caused by considerations at any of these levels. At the computational level, data of this kind could provide more statistical evidence for the structure of the language. Alternatively, constraints at the algorithmic or implementation levels might limit the information-processing capacities of children, making simplified input necessary despite the lack of a computational level benefit.

We try to identify the level of analysis at which a benefit from simplified input could be located by asking what characteristics a sample of language should have in order to be most useful for an ideal learner. If simpler corpora are better for this ideal learner, then we can provide a computational-level account of the benefit of starting small. If not, such an effect must be located at a lower level. It is necessary to consider the performance of ideal learners in order to rule out the possibility that starting small provides a computational-level advantage. If this were the case, it would not be necessary to assume algorithmic level constraints are the cause of an

advantage for starting small, as has been done in previous research.

We identify the optimal input for an ideal Bayesian language learner by asking what data maximize the posterior probability such a learner ascribes to the target language. This is a special case of the problem of defining a “representative” sample analyzed by Tenenbaum and Griffiths (2001). Consequently, we define a Bayesian measure of representativeness, and use this measure to give a mathematical characterization of an optimal corpus. We present a general mathematical result characterizing representativeness for discrete probability distributions, which are the basic component of any probabilistic model of language. This result provides the basis for a more detailed exploration of whether language of limited complexity might be as good or better for learning than language of full complexity. We explore the implications of this result by identifying the optimal input for four different learning scenarios, involving estimating probabilistic grammars with varying degrees of knowledge about the structure of a language and estimating n-gram models.

Identifying Optimal Corpora

To understand the characteristics of an optimal sample of language, we formalize the problem of language learning in terms of Bayesian inference. Learning a probabilistic model of language requires estimating the value of a set of parameters θ from observed linguistic data d . Assuming the learner has some initial beliefs about the value of θ , expressed through a *prior* probability distribution $p(\theta)$, the beliefs of a rational learner after observing d are given by the *posterior* distribution $p(\theta|d)$ obtained by applying Bayes’ rule,

$$p(\theta|d) = \frac{p(d|\theta)p(\theta)}{\int p(d|\theta)p(\theta)d\theta} \quad (1)$$

where the *likelihood* $p(d|\theta)$ indicates the probability of d under the probabilistic model with parameters θ .

A Measure of Representativeness

Formalizing language learning in this way now allows us to consider what corpora will most strongly support learning. Assume that the true structure of the language is characterized by parameters θ^* ; we consider a learner that is simply learning this structure, although more complicated models that also learn other parts of the language, such as semantics, are possible. To maximize the probability of a learner inferring θ^* over other values of θ , a teacher should provide data d that maximize $p(\theta^*|d)$. Examination of the right hand side of Equation 1 shows that this can be done by maximizing

$$R(d, \theta^*) = \frac{p(d|\theta^*)}{\int p(d|\theta)p(\theta)d\theta} \quad (2)$$

with respect to d , as the prior probability $p(\theta^*)$ is constant and thus unaffected by the choice of d . Tenenbaum and Griffiths (2001) suggested that $R(d, \theta^*)$ be considered a measure

of the “representativeness” of d relative to θ^* , being an indicator of the strength of evidence that d provides in favor of θ^* relative to other values of θ . Intuitively, a sample is more representative if it is both very probable under the true model (the numerator of Equation 2) and not as probable under a model selected at random (the denominator of Equation 2).

Representativeness for Discrete Distributions

In general, we may not be able to solve the integral in the denominator of Equation 2 exactly. However, we can solve this integral in the case where the model $p(d|\theta)$ is a discrete probability distribution, as is often true with probabilistic models of language. For a multinomial with ordered outcomes, the likelihood is $p(d|\theta) = \prod_{i=1}^t (\theta_i^{k_i})^{k_i}$, where t is the number of possible outcomes, θ_i^* is the probability of outcome i , and k_i is the number of times the outcome i occurred. We place a uniform Dirichlet prior on the distribution θ , reflecting no strong expectations about the probabilities of different rules. Thus, the integral in Equation 2 is in this case:

$$\int_{\Delta} \prod_{i=1}^t \theta_i^{k_i} d\theta = \frac{(\prod_{i=1}^t k_i!)}{(t-1 + \sum_{i=1}^t k_i)!} = \frac{(\prod_{i=1}^t k_i!)}{(t-1+n)!} \quad (3)$$

where Δ is the simplex of values such that $\sum_{i=1}^t \theta_i = 1$, and n is the total number of observations. The representativeness of a corpus with respect to this model with a particular value of θ is then:

$$R(d, \theta) = \frac{(t-1+n)! \prod_{i=1}^t \theta_i^{k_i}}{(\prod_{i=1}^t k_i!)} \quad (4)$$

The optimal corpus is that which maximizes this quantity.

We can find an exact expression for the frequencies an optimal corpus would have by maximizing the quantity in Equation 4 with respect to k_i . Since the logarithm is monotonic, the corpus that maximizes $R(d, \theta)$ is also the corpus that maximizes $\log R(d, \theta)$, so we perform our maximization with this transform. Additionally, this is a constrained optimization problem since n must equal $\sum_{i=1}^t k_i$. We enforce this constraint with a Lagrange multiplier, and replace the factorials using Stirling’s approximation to obtain the objective function:

$$L = (t-1+n) \log(t-1+n) + 1 - t + \sum_{i=1}^t k_i \log(\theta_i) - k_i \log(k_i) + \lambda(n - \sum_{i=1}^t k_i) \quad (5)$$

where λ is the Lagrange multiplier. To determine the optimum of this objective function, we differentiate with respect to k_i , set the derivative to zero, and solve for k_i . This shows that the optimal value is $k_i = n\theta_i$. Rounding to the nearest integer, this corresponds to what one might intuitively expect: The most representative corpus is that in which the relative frequencies of the outcomes match their probabilities under the target multinomial.

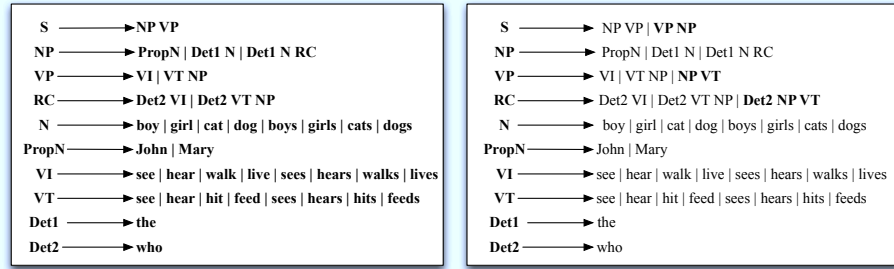

Figure 1: The context-free grammars used in our simulations. On the left, the true grammar; on the right, the overly general grammar with added rules, used in the third simulation. Bolded expansions are those present in the expanded grammar but not in the true grammar. In addition to these rules, subject-verb agreement is enforced, resulting in a much larger PCFG.

Representativeness for Probabilistic Grammars

The results for the representativeness of samples from multinomial distributions can be used to characterize optimal corpora for any probabilistic language model with discrete elements, such as an n-gram model. These results also generalize naturally to a representativeness measure for more sophisticated probabilistic models of language, such as probabilistic grammars. A *probabilistic context-free grammar* (PCFG; Baker, 1979) defines a probability distribution over sentences via a set of expansion rules for non-terminals (e.g. a noun phrase consists of a determiner followed by a noun) and distributions over those rules indicating the probability of a given non-terminal being expanded to a particular sequence (see Figure 1). The distributions over rules are independent multinomials, allowing us to build on the representativeness analysis above. In this case, the parameters θ describe the multinomial distributions associated with each expansion rule.

When the structure of sentences (i.e. the sequence of expansion rules used in generating each sentence) is known, the representativeness of a corpus follows directly from our result for multinomials. Since each rule is associated with an independent multinomial, the representativeness is the product of the representativeness for each multinomial. Thus, a representative corpus is one in which the relative frequencies with which expansion rules are used match the probabilities associated with those expansion rules in the grammar.

When the structure of sentences is unknown, $p(d|\theta)$ is obtained by marginalizing over possible structures. For PCFGs, this can be done efficiently using a dynamic program; in our simulations, we used Mark Johnson’s implementation of this algorithm.¹ However, since there is not a closed form for this marginalization, we cannot calculate the denominator of Equation 2 exactly. In this case, we can use a Monte Carlo method to approximate the integral and obtain an estimate of the representativeness of a corpus.

Starting Small

As described in Elman (1993), “starting small” involves showing a learner only a limited number of “complex” sentences from a language first, and gradually exposing the

learner to the full language. A sentence is complex if it contains a recursive rule; for example, in both Elman (1993) and Rohde and Plaut (1999), complex sentences are those that contain relative clauses. Both Elman (1993) and Rohde and Plaut (1999) used neural networks that learned to predict the next word in the sentence. Elman (1993) found that starting small was essential for his model; when a corpus of full complexity was used, the learner was never able to predict the next word with satisfactory accuracy. Rohde and Plaut (1999) found, in contrast, that in most cases starting small resulted negative impacts on performance, and none of their simulations showed any advantage to starting small.

We use the analysis of representativeness for an ideal language learner given in the previous section to explore the locus of a potential effect of starting small. Since our analysis focuses solely on the statistical evidence a corpus provides in favor of a particular language, we can examine whether a potential benefit of starting small could arise at the computational level, or must be a consequence of specific information-processing constraints associated with human learning. Thus, we consider two questions: First, does starting small result in particularly good corpora for language learning? And second, can a corpus of limited complexity be as good as a corpus without limited complexity? Clearly, if a starting small corpus is optimal, then such a corpus is as or more representative than a more complex corpus. However, even if a limited complexity corpus is non-optimal, it might be as representative as corpora generated by other means. In particular, we compare corpora of different complexity generated by maximizing representativeness and generated randomly.

As in the analysis in the previous section, we consider two types of corpora: those in which sentence structure is known and those in which structure is unknown. In two simulations, we assume that the learner knows the rules of the grammar, but does not know the frequencies with which they occur. Our third simulation introduces ambiguity about the rules of the grammar, and the fourth considers the possibility that children are not learning a grammar but simply distributions over which words follow one another. We used a PCFG similar to that in Elman (1991). The only instance of recursion was in the relative clause, which occurred in 75% of sentences generated from the grammar, and the grammar enforced the

agreement of subjects and verbs². Figure 1 shows the grammar prior to integrating the constraint of verbal agreement; the final grammar consisted of 63 rules and 23 nonterminals.

Representativeness with Known Structure

We first considered the problem of learning from a corpus in which the structures of the sentences are known, allowing us to use the closed form given in Equation (4) to exactly compute the representativeness of the corpus. We sought to quantify how representative a corpus could be given the constraint on complexity and discover how this compared to randomly generated corpora as well as more complex corpora.

To investigate this question, we generated several types of corpora. All corpora were created by choosing a subset of sentences from a large corpus generated by the grammar. *Random* corpora were generated by selecting this subset randomly, subject to a constraint on the number of complex sentences. *Optimized* corpora were collections of sentences chosen to maximize representativeness. An ϵ -greedy perturbation process was used to maximize representativeness. First, an initial corpus of the target complexity was randomly selected. This corpus was perturbed by adding additional sentences, and then pruning sentences from the augmented corpus. With small probability, a sentence was chosen randomly to add or prune. Otherwise, a sentence was chosen by checking the effect of adding or pruning each possible sentence and greedily adding or pruning the sentence that resulted in the corpus with the largest representativeness. Twenty perturbations of ten sentences each were performed; results were not sensitive to small variations in these parameters.

For both the random and optimized conditions, we created corpora with constrained complexity. Corpora were generated with complexity ranging from 0% to 100% complex sentences, at 5% intervals. A complex sentence was any sentence containing a relative clause. Additionally, random and optimized corpora were generated with no complexity constraint. Each corpus contained 100 sentences.

As shown in Figure 2, this procedure succeeds in finding subsets of sentences that are significantly more representa-

tive than randomly generated corpora of the same complexity. However, the limitation on complexity greatly affects representativeness. While limiting complexity significantly impacts the representativeness of only one rule, that which allows the introduction of the relative clause, this impact is severe enough to outweigh the representativeness of the other rules. Thus, an optimized sample of severely limited complexity is much less representative than a random sample in which complexity is not constrained. When the limit is not as severe, though, optimized corpora with somewhat limited complexity and random corpora with greater complexity have equal representativeness, due to the fact that the severity of the complexity constraint has a non-linear effect on representativeness (Figure 2). For corpora of unconstrained complexity, the results mirror the results for corpora with constrained complexity equal to the true base rate of complex sentences for the grammar (75%). The average representativeness of randomly selected corpora was 65.7 ± 4.9 , with $76.3\% \pm 4.9$ complex trees, while the average representativeness of corpora selected for representativeness was $87.7 \pm 8 \times 10^{-5}$, with $80.1\% \pm 10.3$ complex trees.

Representativeness with Unknown Structure

The previous simulation assumed that our corpus consisted of the structure of the sentences, from which we could directly compute the representativeness of a given corpus. However, one might alternatively assume that a language learner has only the sentences as data and must consider all possible structures. We examine this possibility by using the same corpora of sentences as in the previous simulation, but assuming the structure of each sentence is unknown.

As mentioned in the previous section, when the structure of sentences is unknown we need to resort to Monte Carlo approximation to compute representativeness. We used importance sampling (Neal, 1993); our proposal distribution was a Dirichlet distribution with parameters equal to the true distribution in the grammar multiplied by ten. Results are averages of 30 iterations of 10,000 samples each; in the case of random corpora, sampling was done for each of ten corpora with the same constraints on complexity. Given that variance for the optimized corpora was much smaller, sampling was done for only one optimized corpus of each level of complexity. We consider the same four levels of complexity as Elman (1993) and Rohde and Plaut (1999): 0%, 25%, 50%, or 75% of the total corpus size. Additionally, we consider corpora of unconstrained complexity.

Figure 3 shows that the general trends from the previous simulation hold, with a few variations. The separation between the optimized corpora and the random corpora is smaller than when the structure is known. This is partially due to the way the corpora were created. Presumably, if it was feasible to optimize over corpora with unknown structure, further separation might be attained. However, these results do suggest that optimizing the input sentences would not greatly help a learner who must consider all possible structures of sentences. Consistent with the previous simulations, repre-

²Grammar creation was facilitated by the Simple Language Generator (Rohde, 2003)

Figure 3: Representativeness of corpora with unknown structure. Limiting the complexity of a corpus limits its representativeness, with the most extreme limitation having the greatest effect.

representativeness increases non-linearly with complexity. Again, the least complex corpora are not as representative as those that match the base rate of complexity in the grammar.

Using an Overly General Grammar

One might consider the above assumptions too strong: What if the exact structure of the grammar is not known? In this variation, we instead assume the learner has an overly general grammar that includes rules not present in the true grammar (see Figure 1). For example, rather than having only the option of expanding a transitive verb phrase to a verb followed by a noun phrase, the learner’s grammar also has the possibility of expanding such a phrase to a noun phrase followed by a verb phrase. This simulates learning a grammar with unknown structure while maintaining a tractable hypothesis space (in this case, not knowing the word order in the language, but knowing the relevant syntactic classes). The extra rules give the learner a larger hypothesis space to consider, and our previous hypothesis space is the subset of the new space in which the probability of each of our newly added expansions was zero. By using an overly general grammar, we introduce much more ambiguity as to the structure of any given sentence. Thus, one might expect different results than in the previous simulation, where the number of possible derivations for any given sentence was relatively small.

The procedure for calculating representativeness in the case of an overly general grammar was very similar to the previous case. We again are considering representativeness for sentences with unknown structure, and thus used importance sampling to calculate the integral. The proposal distribution for sampling was modified so that expansions with the added rules (not present in the true grammar) would be considered. We again used a Dirichlet distribution, but the parameters were equal to ten times the true parameters plus one. Thus, rules that had zero probability in the true grammar had a parameter of one in the Dirichlet prior.

As shown in Figure 4, even with a grammar with extra rules, the results are very similar to the previous simulation. Optimizing the corpora has the strongest effect when the complexity is somewhat limited, but for the greatest representativeness, it is still best to use a corpus with greater complexity. This result suggests that even if a learner does not know the true grammar, it is still better to provide a cor-

Figure 4: Representativeness of corpora with unknown structure using a grammar with extra rules.

pus of full complexity rather than a “starting small” corpus. However, several concerns remain. The way in which we generalized the grammar was limited to switching the orders of verb phrases and noun phrases. This adds significant ambiguity to the grammar, but is not equivalent to considering any arbitrary grammar. For example, one could imagine a grammar that had over-general rules for producing relative clauses. In that case, it is still unclear whether representativeness in a corpus of severely limited complexity could equal the representativeness of a more complex corpus. To fully explore the problem, we would need a tractable way to consider all (infinite) possible grammars that could produce the data.

Representativeness with N-Grams

The above simulations assume the learner learns a PCFG, but existing neural network models formulate language learning as learning to predict the next word based on previous words. This corresponds to a model where the learner learns distributions over n-grams rather than rules, and thus we can apply the same mathematical tools to analyze the representativeness of corpora according to an n-gram model.

To calculate representativeness, we can use exact counts as in the first simulation. An n-gram is a sequence of two (bigram) or three (trigram) words, and we assume a language model that estimates the probability of the next word given the previous one or two words. Our target distribution is now the correct proportions for each n-gram, which we estimate by computing the n-grams on the large corpus from which the other corpora were drawn.

Despite the fact that the model of the language has changed significantly, similar results hold in this case as in the other cases. Figure 5 shows the representativeness of the same corpora used in the other simulations with respect to n-grams: the random corpora of full complexity are still more representative than optimized corpora with limited complexity.

Summary

In our analysis, we have shown that starting small limits the degree of representativeness of the corpora and that the effect on representativeness is greatest when the limitations are particularly severe. These results hold regardless of the variations we considered. While our task is not exactly the same as in Elman (1993) or Rohde and Plaut (1999), it has bearing on this debate. From a computational level perspective, the only

Figure 5: Representativeness of corpora using an n-gram model.

concern for such learning is whether the corpora are representative, and we have shown that starting small (at least in the extreme form) is not compatible with maximizing representativeness. However, if for mechanistic reasons one needs to start small, the above results suggest that starting “smaller” can result in similar representativeness in an optimized corpus to that of a random corpus of full complexity.

Discussion

We have shown how the concept of Bayesian representativeness can be applied to language in order to characterize an optimal sample and presented a case study of how representativeness changes with constraints on the sample. Mathematically, the Bayesian representativeness of language structures matches our intuitive sense of representativeness: a sample of language is most representative if the actual number of occurrences of each structure matches the expected number. While we cannot give a closed form expression for the representativeness of a corpus where the sentences structures are not given, simulations show that the trends concerning representativeness given constraints on complexity hold for these corpora as well. Finally, it is suggestive that given a grammar with overly general rules, we still find a disadvantage for corpora of limited complexity.

Our results suggest that if there is a beneficial effect of starting small, it is not located at the computational level: the statistical evidence a corpus provides in favor of the target language falls off as its complexity deviates from the complexity of the language. However, our results do show how it might be possible to start small in response to mechanistic information-processing constraints and still not impede learning, as it is possible to construct limited-complexity corpora that provide as much evidence as a random sample from the language. While suggestive, we note that these conclusions are tempered by the models we considered, and in particular the space of alternative hypotheses we allow the learner.

Overall, our analysis provides insight into what optimal linguistic input should look like in several interesting cases. A variety of next steps are possible. First, a more detailed exploration of the nature of an optimal sample given unknown rules would illuminate whether the preliminary results we have found hold given a larger space of possible grammars. Additionally, comparing our theoretical results to actual corpora of language acquisition would indicate whether child-directed speech is more representative than randomly selected adult-directed speech. This would suggest a pedagogical role

for child-directed speech. This work provides a foundation for addressing these more advanced questions.

Abstract

Positive priming effect has been found with a short interval between the prime and the target, while negative priming effect (i.e., a congruent prime causes longer RTs) has been found with a long time between the prime and the target. Negative priming effect has been shown mainly using masked priming but some recent studies have shown it without masks (i.e., in unmasked or conscious conditions). We employed our previous model of masked priming for the unmasked condition here, only by removing mask presentation. The model successfully simulated the negative priming effect in unmasked condition found in previous experimental studies.

Keywords: Negative congruency effect; Negative compatibility effect; modeling; attention; consciousness.

Introduction

Studies on priming have long shown reliable positive effects of the congruent prime on target processing. An early study, in the age of using tachistoscopes, was one conducted by Marcel (1983) on word and color naming. The effect of masked priming showed that masked stimuli are indeed processed to the level of response. Later studies on unmasked and masked conditions showed similar results both for masked priming (e.g., Neumann & Klotz, 1994; Dehaene et al., 1998; Eimer & Schlaghecken, 2002) and masked and unmasked priming differences (e.g., Cheesman & Merikle, 1986; Dehaene, Artiges, et al., 2003; Schlaghecken & Eimer, 2002).

In masked priming tasks, a brief masked stimulus (the prime) can affect the processing of the stimulus that follows (the target). A prime, a mask, and a target are presented sequentially and the task is to make a decision on the target. The result is usually a Positive Congruency Effect (PCE), also known as the positive compatibility effect. In PCE, the prime speeds up the performance on the target if they are congruent and slows down the performance if they are incongruent (e.g., Neumann & Klotz, 1994; Dehaene et al., 1998; Eimer & Schlaghecken, 2002; Jaśkowski & Ślósarek, 2007). Conversely, a negative priming effect has been found, called the Negative Congruency Effect (NCE). This effect is also known as the negative compatibility effect, where paradoxically the prime increases the performance on the target if they are incongruent and decreases the performance if they are

congruent (e.g., Schlaghecken & Eimer, 2000, 2002, 2006; Eimer, 1999; Eimer & Schlaghecken, 1998; 2001, 2002; Lleras & Enns, 2004, 2006; Verleger et al., 2004; Jaśkowski & Ślósarek, 2006). The PCE has been shown with a short mask-target Stimulus Onset Asynchrony (SOA), while the NCE has been shown with a longer mask-target SOA (see below).

The PCE has been found usually with verbal and shape stimuli and a short mask (e.g., 71 ms, as in Dehaene et al., 1998) and no or a small interval between stimuli. In contrast, the NCE has been shown mainly with arrow stimuli and a longer mask (e.g., 100 ms). Recently, it has been replicated with other stimuli, for example shapes (Jaśkowski & Ślósarek, 2006) and faces (Bennett, Lleras, Orient, & Enns, 2007). This effect has been found by using a long mask (about 100 ms) and a long mask-target SOA (>80 ms) or a long (> 30 ms) prime-mask Inter Stimulus Interval (ISI) or mask-target ISI (e.g., Eimer & Schlaghecken, 1998, 2002; Jaśkowski & Ślósarek, 2007). These manipulations all increase the prime-target SOA.

In Eimer and Schlaghecken's (2002) aforementioned experiments on the role of prime duration and mask density, participants who were better at detecting the prime showed a later change from positive to negative, and conversely those who were not good in reporting the prime showed an earlier change from positive to negative, showing that there is a close relationship between prime reportability and the direction of priming. Schlaghecken and Eimer (2000) and Eimer and Schlaghecken (2002, see also 2003) found that when there is no mask or the mask is peripheral (i.e., it does not make the prime unreportable), the result is PCE, unlike the situation with masked priming. Using their motor self-inhibition hypothesis, they argued that the inhibition is initiated (as an automatic or evolved process) when visual input disappears, otherwise is blocked by visual input. Therefore, they claimed that an NCE, being a result of this self-inhibition, occurs only in the masked condition because prime input is stopped by the mask. They added that with the reportable prime, motor self-inhibition is prevented by the prime, so a PCE occurs. However, recently Lleras and Enns (2006), by comparing different studies, showed that prime visibility has no linear relationship with NCE, meaning that NCE is not necessarily caused by prime invisibility (see below).

To investigate whether there is any differences between masked and unmasked priming, Cheesman and Merikle (1986) employed Marcel's colour priming task with modifications. They changed the ratio of congruent to incongruent trials, so that in one condition this ratio was 25:75 and in the other one it was 75:25. In the unmasked condition, they found that when the number of congruent trials was high (i.e., the 75:25 condition), the congruency effect was higher than when this number was low (i.e., the 25:75 condition). In other words, when an incongruent trial was frequently preceded by a congruent trial, the congruency effect increased, and conversely, when an incongruent trial was frequently preceded by an incongruent trial, the congruency effect decreased. This difference was not found in the masked condition. They argued that participants can use a strategy based on context only in the unmasked condition.

Jaśkowski (2007) combined Eimer and Schlegel's paradigm and Merikle and colleagues' (Cheesman & Merikle, 1984, 1986; Merikle & Joordens, 1997) to study the difference between the masked and unmasked conditions. In a congruent to incongruent ratio of 20:80, a PCE was found in the unmasked condition with both medium (100 ms) and long (800 ms) prime-target ISI. While in the congruent to incongruent ratio of 80:20, a PCE was found in medium (100 ms) ISI but an NCE was found, interestingly enough, in long ISI condition. In another experiment, while Jaśkowski found an NCE in the masked condition with a prime-target ISI of 100 ms, he found only a non-significant NCE with a long ISI. Therefore, surprisingly, with the long ISI the NCE for the unmasked condition was larger than it was for the masked condition, ruling out the necessity of the mask and invisibility of the prime in NCE. A similar result had already been found with a Stroop task (Merikle & Joordens, 1997).

In our previous work we have modeled masked priming using a neurocomputational cognitive model (Sohrabi and West, 2009a, b; see also Sohrabi, 2008). We employed that model of masked priming for the unmasked condition here. We only removed the mask presentation to simulate the unmasked condition in human experimental studies (here, Jaśkowski, 2007).

The Model

The model is based on previous neurocomputational modeling and neurophysiological studies (e.g., Usher & Davelaar, 2002; Gilzenrat et al., 2002, see also Aston-Jones & Cohen, 2005). It has been demonstrated that these types of reduced models can resemble the neural computation of a large group of neurons (e.g., Wong & Wang, 2006).

The model has been described previously (Sohrabi and West, 2009a, b; see also Sohrabi, 2008 and Sohrabi and West, 2010). It is a multi-layer dynamic neural model (shown in Figure 1) that consists of a feed-forward component for perceptuo-motor processing from the Input Layer (IL) to the Representation Layer (RL) and Motor Layer (ML, not shown). An assumption is that the cognitive

processing, including the response, is modulated by attention. The Alert Attention layer (AA) simulates attentional modulation that is supposed to be a model of Locus Coeruleus (LC) that potentiates cortical areas through norepinephrine (Aston-Jones & Cohen, 2005). The executive attention is only modelled through its effects on AA, using a Task Layer (i.e., TL) for conflict monitoring. The effect of TL on AA simulates direct cortical projections to LC (Aston-Jones & Cohen, 2005). The TL and ML are affected by both prime and target. The ML's architecture is identical to TL's, with the exception that it sends no outputs to AA, is slower, and noisier (see Table 1).

Each condition in a simulation consists of 20,000 trials (200 independent blocks of 100 trials each, with congruent and incongruent trials counterbalanced randomly within each block). A single trial takes 1100 cycles. Each block starts with 500 cycles without changes in IL to let the units in other layers reach a steady state of activation. Similarly the Inter-Trial Interval (ITI) for each trial is 500 cycles, which allows the activation of units to return to baseline following the responses. The prime is presented by clamping one of the two units in the IL to 1, intended to be left or right in the case of arrows. The mask units in IL are set to 1 at the time of mask presentation and are otherwise set to 0. Therefore, the recognition of the stimuli is implemented with a localized representation, for example, the left unit is turned on when the stimulus is an arrow pointing left; otherwise the right unit is turned on. Accordingly, as will be described below, in a congruent trial the two corresponding units (e.g., the left unit of the prime and target in IL) is set to 1 or 0 at the time of stimulus presentation, while in an incongruent trial, one of the two relevant units of the prime or target is set to 1 and the other to 0.

The units in each layer make connections, via excitatory weights, to their corresponding units in other layers. The activations of these units (except IL) are calculated by a sigmoid (logistic) function of the incoming information, and a small amount of random noise. The RL sends excitatory activities to ML and TL continuously but activates AA only if a unit of the prime or target reaches a designated threshold of .62. Similarly, when one of the two units in the ML reaches the same designated threshold it triggers a manual response (i.e., initiating a hand movement). When AA is activated and its activation reaches a threshold, it starts modulating information processing in RL, TL, and ML by making the activation function of their units steeper (see Figure 2, as described below).

As shown in Figure 1, the IL encodes the prime, the mask, and the target, and projects to RL through excitatory connections. For the sake of simplicity, prime and target units, as well as an identical mask unit for each (not activated in this simulation) were implemented in two separate paths. All units in TL have a self-excitation connection, intended to simulate mutual excitation among a group of neurons. Connections between mutual units (for prime and target and to the mask) from IL to TL have small

cross-talks (see Table 1), indicating feature overlaps or similarities among stimuli. The units also have lateral inhibition with neighboring units within the same layer. The mask units are activated after the prime and before the target for a specific time. They have lateral inhibition with prime and target. To simulate unmasked condition here the mask units are not activated (i.e., are not clamped) but units' baseline activities were preserved for the sake of model stability without changing the parameters.

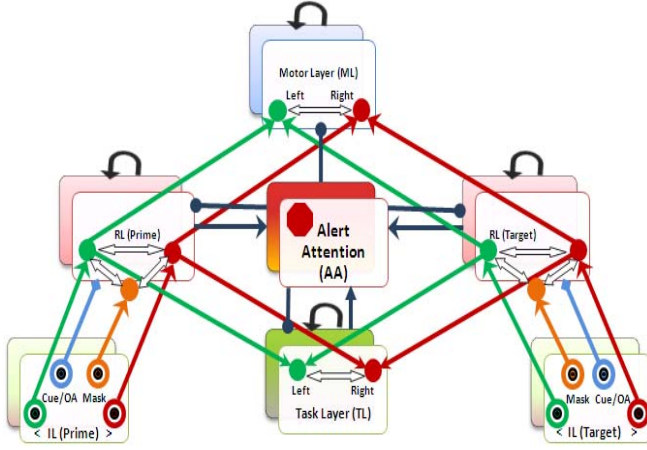

Figure 1. Architecture of the model showing hypothetical networks and connections. *Unit types:* ● IL ● TL and ML (not shown here) ● AA. *Attention types:* -◆ Cue/Orient Attention (OA) (not employed here) -► Executive (conflict driven) -• Alert. *Activation types:* ↻ Self-excitation and recurrent excitation ↔ Lateral inhibition → Feed-forward activation.

Figure 2. Effect of gain modulation on nonlinear activation function (adapted from Servan-Shreiber et al., 1990, see also Astone-Jones & Cohen, 2005).

The units in all layers (except IL and AA) receive additive Gaussian noise (zero mean and variance σ), intended as general, irrelevant incoming activities. The activations in the model are represented using units with real valued activity levels. The units excite and inhibit each other through weighted connections. Activation propagates through the network when the IL is clamped with input patterns, leading to a final response. As will be described below, the states of units in RL, ML, and TL are adopted in a method similar to a noisy, leaky, integrator algorithm (Usher & Davelaar, 2002; Gilzenrat et al., 2002). These types of models are noisy versions of previous connectionist models.

In each trial or epoch, one of the prime units in the IL is turned on and the network is left active for 43 cycles, then it is turned off for 168 cycles (short prime-target SOA), 234 cycles (long prime-target SOA), or 294 cycles (very long prime-target SOA), followed by turning on the target input in IL for 200 cycles. This is similar to a trial in human data (Dehaene et al., 1998; Eimer & Schlegelheken, 2002; Jaśkowski & Ślósarek, 2006; Jaśkowski, 2007).

The prime and target units in the IL are used to represent the stimulus features (here, direction). However, as mentioned before, the recognition of the stimuli is not implemented in detail, but is encoded as a binary code. For example, in the case of arrows here, 1 is used for the left unit if it points left, and 0 is used for the opposite (reciprocal) unit. In the congruent condition, the RL units of the prime and target at the same side (left or right randomly) are turned on (1) or off (0) in each trial at the time of stimulus presentation. By contrast, in the incongruent condition, the two units at the opposite sides are turned on and the other two are left off, with random selection of the two possible cases.

The RL is governed by a modified version of previous models (Usher & Davelaar, 2002; Gilzenrat et al., 2002), which is calculated with discrete integrational time steps using the dynamic equation:

$$X_i(t+1) = \lambda_x X_i(t) + (1-\lambda_x) f [WX_i X_i(t) + WX_i I_i(t) - WX_i X_j(t) - \theta X_i + \xi X_i] \quad (1)$$

Likewise, ML and TL are modelled in a similar way with their inputs coming from RL:

$$Y_i(t+1) = \lambda_y Y_i(t) + (1-\lambda_y) f [WY_i Y_i(t) + WY_i X_i(t) - WY_i Y_j(t) - \theta Y_i + \xi Y_i] \quad (2)$$

In equations (1) and (2), X and Y denote the activity of units through time t . W is the weight of the connections between units, I is the input, and the subscripts i and j are indexes of the units. The three weight parameters in the brackets correspond to recurrent self-excitation, feed-forward excitation, and lateral inhibition, respectively. However, for the sake of simplicity in equation 1, the lateral

excitation from mask units to the prime and target, WX_iX_j , and the cross-talk in prime and target to reciprocal units and mask units, WX_iI_j , are not present. The term θ is the bias, the term ξ is noise, and f is a sigmoid function (see equation 3). The term λ represents neural decay which is related to the discrete integrational time steps in the underlying equation (Usher & Davelaar, 2002).

The AA modulates other layers by changing their activation from sigmoid toward binary responses. The activation function, f , transfers the net input, X , of a unit, and modulatory gain, g , to its activity state, implementing the firing rate of a neuron or the mean firing rate of a group of neurons:

$$f(X_i) = 1 / (1 + \exp(-X_i g)) \quad (3)$$

Figure 3. An unmasked congruent trial (where no conflict occurs) of 1100 cycles, including 500 cycles inter-trial interval) with 234 cycles prime-target SOA that crosses the threshold after 876 cycles (including 500 cycles inter-trial interval). From the top, ML, TL, and AA (but RL-prime, RL-target, and IL are not shown).

A conflict-monitoring measurement was employed to take the activations of the units in the TL layer to adjust phasic and tonic response modes of AA. The activation of the TL units was used to measure the Hopfield energy function between units (Hopfield, 1982), as used previously (Botvinick et al., 2001). Conflict can be defined as the joint

effect of both prime and target in TL. Hopfield energy can be calculated as

$$E = -.5 X^t W X \\ = -.5 [X_1 \ X_2] \begin{bmatrix} 0 & -1 \\ -1 & 0 \end{bmatrix} \begin{bmatrix} X_1 \\ X_2 \end{bmatrix} \quad (4)$$

where E denotes energy, X denotes the activity of a unit, W is the weight of the connection between units, and the subscripts 1 and 2 are indexes of the two units.

As noted above, TL combines prime and target activations and measures conflict between its two units. When one TL unit is active and the other is inactive, conflict is low. However, when both units are active concurrently, the conflict is high. Activations in TL units are converted to 1 if they are equal to or greater than .5, and to 0 otherwise (i.e., using a threshold function). Also, $E > .5$ is considered as a conflict, otherwise as no conflict. When the activation of a prime or target unit in TL reaches the designated threshold, .62, the AA is activated with a phasic or tonic mode, depending on the absence or presence of conflict in TL. The change in AA response mode usually occurs by the presentation of a target that is incongruent with the prime. Here the AA is modeled using a reduced or abstracted version of LC neurons in a Willson-Cowan type of system (e.g., Wilson & Cowan, 1972) adopted recently (Usher & Davelaar, 2002) (there are similar models and detailed implementations of this type of attention (Gilzenrat et al., 2002):

$$\begin{aligned} X(t+1) &= \lambda_x X(t) \\ &\quad + (1 - \lambda_x) f [c (a_x X(t) - b Y(t) + I_x(t) - \theta_x)], \\ Y(t+1) &= \lambda_y Y(t) \\ &\quad + (1 - \lambda_y) f [c (a_y X(t) - \theta_y)], \\ G(t+1) &= \lambda_g G(t) \\ &\quad + (1 - \lambda_g) X(t) \end{aligned} \quad (5)$$

where f is again a sigmoid function (as in equation 3), X is the fast variable representing AA activity and Y is a slow auxiliary variable, together simulating excitatory/inhibitory neuron groups in the LC (Usher & Davelaar, 2002). The X and Y variables have decay parameters λ_x and λ_y , excitatory/inhibitory coefficients, a_x and a_y , as well as thresholds θ_x and θ_y , respectively. The G variable is the output of the AA, which is based on X . The g (used in equation 3) is computed from G : $g = G * K$. The AA modulates other layers when g crosses a threshold, 1. Its activity modes can be phasic or tonic depending on the conflict state, *low* or *high*, respectively.

In all conditions the TL can change the AA mode according to the conflict between prime and target (i.e., using within-trial conflict). The phasic and tonic modes of AA responses are implemented using high or low c value (3 or 1) (see equation 5). The c value is 3 at the beginning of each trial (for the prime), but it is set to 1 (for the target) if conflict occurs. The number of computer simulation cycles from the target onset until one of the ML units reached a designated threshold, .62, was considered as RT. A constant, as other sensory and motor processes, could be added to this RT, to increase the match between simulation and human data.

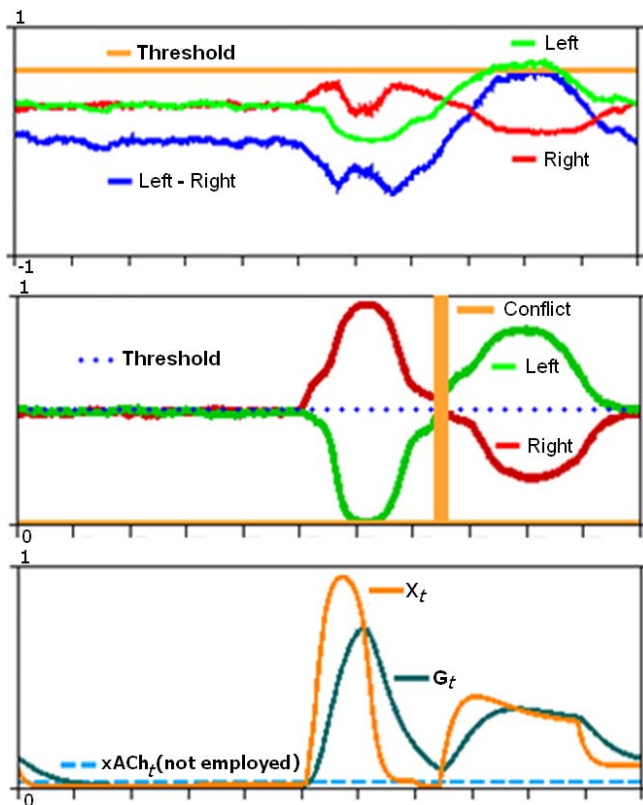

Figure 4. An unmasked incongruent trial (where no conflict occurs) of 1000 cycles, including 500 cycles inter-trial interval) with 234 cycles prime-target SOA that crosses the threshold after 876 cycles (including 500 cycles inter-trial interval). From the top, ML, TL, and AA (but RL-prime, RL-target, and IL are not shown).

Simulation Results

To create the short and long prime-target SOA conditions, a relatively short SOA (168 cycles) and two relatively long SOAs (234 and 294 cycles) were used. As shown in Figure 5, a strong PCE was found at prime-target SOA 168 cycles and a strong NCE was found at SOA 234 and 294 cycles. In the unmasked condition, in the current simulation, NCE remains high with further increases in SOA but it decreases slowly.

The simulation results in Figure 5 show a change from PCE to NCE and a drop in RTs, similar to the human data. However, the SOA in the long condition in Jaśkowski (2007) is much longer than the long conditions in the current simulation, due to a limited time course in the model, as the parameters were set for a short trial.

The activities in three layers (ML, TL, and AA) are shown for a given congruent and incongruent trial in Figures 3 and 4, respectively. There is smaller activation left in AA for the target, but it can be recovered as an effect of conflict in the incongruent condition as the phasic mode becomes tonic.

Figure 5. Unmasked priming using 168, 234, and 294 cycles prime-target SOAs, indicated by 1, 2, and 3, respectively, compared to 116.7 and 816.7 SOAs in Jaśkowski (2007), indicated by 1 and 2, respectively.

Discussion

A model that we have used for simulating masked positive and negative priming previously could simulate unmasked priming effect as well. Because there was no interruption by the mask, in the relevant unmasked prime condition, a PCE was found for short prime-target SOA. In this case, the PCE was large, consistent with the unmasked condition in Jaśkowski (2007). We assumed that a relevant or predicting prime as in Jaśkowski (2007) evokes a phasic activation in the so called alert attention to the prime but can lead to a refractory period of attentional response to the target.

An unmasked prime caused large PCE and NCE at short and long prime-target SOA, respectively. A few studies have previously shown an NCE in the unmasked condition. Here it is assumed that this effect was found in those studies because they used a medium (Koechlin et al., 1999) and long (Jaśkowski, 2007) prime-target SOA, and especially the tasks required action on (which requires attention too), or attention to, the prime, respectively. In the former, especially because of controlling physical repetition priming (and an action on the prime was required as on the target), and in the second, especially because of prime relevance (participants were told that prime highly predicts the target), the NCE was large. It could be caused by the strong refractory period created by attention to the unmasked prime. To simulate this phenomenon, in this simulation the prime was unmasked and AA mode for the prime was put in the high phasic mode ($c=3$), as with simulations of masked conditions.

At longer prime-target SOA, the relevant unmasked prime caused an NCE even larger than an equivalent masked condition (see Sohrabi and West, 2009a, b; see also Sohrabi, 2008; Sohrabi and West, 2010), consistent with Jaśkowski & Ślósarek, (2006) and Jaśkowski (2007). Interestingly, the conflict period caused by an unmasked incongruent prime (in all unmasked

conditions) was longer than that of masked incongruent prime consistent with Dehaene et al. (2003) that have shown more brain activations in unmasked incongruent compared to congruent condition.

Table 1. *Parameters in the model, fixed for all conditions, unless otherwise mentioned.*

WX_iI_i (IL to RL) [P & T] & WY_iX_i (RL to ML) [P & T]	3 & 1.5
WX_iI_i (IL to RL) [M] & WY_iX_i (RL to TL) [P & T]	1.5 & 1
WX_iX_j (RL) [P & T], WX_iX_j (RL) [M], WY_iY_j (TL), & WY_iY_j (ML)	1.5, 1.25, 1, & .9
WX_iX_j (RL) & WY_iY_j (ML & TL)	1 & 1
WX_iX_j (RL) [M to P & T] & WX_iI_j (IL to RL)	.75±.1 & .33
K (AA)	4.52
α & β (RL, TL, & ML) [M, P, T]	1 & 1
θ_x , θ_y (AA), θ_x (RL), θ_y (TL), & θ_y (ML)	1.25, 1.5, .5, .85, & 2
b, c , a_x & a_y (AA)	4, 1-3, 2, & 3
λ_x , λ_g , & λ_y (AA)	.92, .98, & .996
λ (TL), λ (ML), & λ (RL)	.75, .925, & .95
σ (CL), σ (RL) [P & T], σ (ML), & σ (RL) [M]	.025, .2, .25, & 1.25

IL=Input Layer; RL=Representation Layer; TL= Task Layer; ML=Motor Layer; AA=Alert Attention; P=Prime; T=Target; M=Mask.

Abstract

There is growing evidence that even the most abstract capacities of human cognition are not entirely amodal and disembodied. The present study presents two empirical studies which aim to demonstrate that relational reasoning is grounded in our sensory-motor experience. Experiment 1 shows that the affordances of tool-like objects have an effect on comparing functional relations. Experiment 2 makes sure that this finding can not be explained by an automatic activation of motor systems. The results are interpreted as evidence that at least certain functional relations are perceived by simulating interactions with the environment. It is also asserted that the process of comparing such relations is constrained by the properties of the human body such as hand-dominance.

Keywords: relations, situated cognition, embodiment, action, simulation, analogy

Introduction

Imagine you are asked to compare the relation between an axe and a wooden log with the relation between a meat chopper and a piece of meat. One way to solve this problem is to find out what relation holds in the first pair of objects, turn it into propositional form (e.g. ‘is used to cut(axe, wood)’), do the same for the second pair of objects and then compare the two symbolic structures. This is what many models of relational reasoning do (Gentner, 1983; Falkenhainer, Forbus, & Gentner, 1989). Some models can also establish a correspondence between distinct relational symbols by measuring their semantic similarity (Holyoak & Thagard, 1989; Kokinov, 1994; Hummel & Holyoak, 1997, 2003). However all these models do not address the problem of where the relational meaning comes from (how the propositions are encoded) and they all assume that the process of comparing relations is amodal and disembodied in nature.

On the other hand, there is plenty of evidence that human cognition is inherently modal and constrained by the characteristics of the human body (Glenberg, 1997; Barsalou, 1999; 2008; Lakoff, 1999; Fisher & Zwaan, 2008). For example, it has been shown that the perception of a graspable object immediately activates a potential motor interaction with this object, even when it is task-irrelevant (Tucker & Ellis, 1998, 2004; Beauchamp, Lee, Haxby & Martin, 2002; Beauchamp & Martin, 2007; Buccino, Sato, Cattaneo, Rodà & Riggio, 2009). Proponents of the

embodiment theory claim that this phenomenon is not a mere side effect of spreading activation, but that motor programs are part of the representation of objects. These motor programs are used to simulate potential interactions with an object and determine its function.

Similarly, the perception of a functional relation between two objects should require a mental simulation of the relevant interactions with the objects. For example, in order to comprehend the functional relation between an axe and a piece of wood, you would simulate grasping the axe and chopping the wood with it. And in order to compare two instances of functional relations you have to be able to compare the motor dynamics resulting from simulating the actions involved in each of the relations. Such an approach is justified by the study of Klatzky, Pellegrino, McClosky & Lederman (1993), which found that there is remarkable consistency in people's knowledge about the movements underlying functional interactions with objects. There is also evidence that sometimes people consciously try to detect the perceptual motor similarities of different situations in order to evaluate how analogous they are (Clement, 2009).

Figure 1: An example of the stimuli used by V&K. Participants had to compare the relation between the objects in the left part with the relation in the right part of the screen. The affordances of the objects were manipulated by making them easier to be grasped with the left or with the right hand. In this example, both affordances are right.

Recently, Vankov & Kokinov (2009) (henceforth V&K) proposed a model of grounding relational meaning in simulated interactions with the environment. According to the model, the motor dynamics resulting from these interactions is used not only to comprehend relations, but also to solve the role-filler binding problem (Hummel, 1999). The model makes two major predictions. First, it

predicts relation-specific motor effects when relations are perceived, even if the task does not involve any motor activity. The second prediction is that relations are compared most efficiently when it is possible to simulate the underlying interactions simultaneously or in close temporal proximity.

V&K reported an experiment which managed to provide support for both hypotheses. Participants were asked to compare the functional relations in two pairs of objects (Figure 1) by giving a verbal response – pronouncing ‘yes’ or ‘no’. An effect of the affordances of the objects was found. Right-handed participants’ response times were faster when the objects in the relation on the left were displayed in such a way, that it was easier to manipulate them with the left hand. The effect of the affordance of the object on the right was reversed in direction and much smaller in size. The very fact that an affordance effect was found is in support of the hypothesis that perceiving relations involves simulating actions. The bigger size of the effect of the affordance which was closer to the subjects’ non-dominant hand implied that subjects tried to simultaneously simulate the actions involved in the two relations. A control study ruled out the possibility that this result was due to the mere perception of objects with varying affordances. However it is still possible the effect was due to presenting the two relations at once. Another valid point is that the overall reaction time could have been affected mostly by the affordance of the relation displayed near the subjects’ non-dominant hand because it was harder to be simulated. Also the design of the experiment did not allow to control the sequence in which the subjects look at the two relations. Therefore it is possible that the effect of the relation which had been attended last was different (bigger or lesser) from the other one. A new experiment was designed and conducted in order to overcome these problems.

Experiment 1

The experiment used the same stimuli as V&K, but the relations were displayed one by one in the center of the screen in order to control the order in which they were perceived and isolate the effect of the presentation location.

The elimination of the factor of the presentation location served to set apart the effect of the affordances of the stimuli from any spatial compatibility effects. It is well known that people respond faster to stimuli which location is compatible to the response action (Simon & Rudell, 1967). Although the response action in V&K was verbal, it is possible that subjects’ reaction times had been affected by the congruence of the presentation location and the affordances of the stimuli. For example, an interaction between objects with a left affordance could be easier to be simulated with the right hand if they are displayed in the right part of the screen.

The new design also allowed testing the effect of a stimulus – the relation which was presented first – which had to be retrieved from memory at the time of the

comparison. If any affordance effect was found for the first relation, it would seriously question any disembodied view on relational comparison which assumes that relations are first encoded as symbols and then compared.

However, according to embodied view on relational reasoning, there must be an effect of both affordances because the sensory-motor dynamics of both relations is needed at the time of comparison. Moreover, the embodied view predicts that relations will be compared more efficiently when the underlying interactions with environment could be simulated in close temporal proximity. Therefore it is predicted that subjects will be faster when the affordances differ and they can employ both their hands in the simulations.

Method

Participants 36 right-handed participants (20 females) took part in the experiment for course credit or as volunteers. Their average age was 24.06 years (age range from 18 to 53, $SD = 5.91$).

Figure 2a: A left and a right affordance of a pair of objects which make a functional relation.

Figure 2b: Examples of the stimuli used in ‘same’ and ‘different’ trials.

Stimuli The stimulus set was the same one that was used in V&K. It consisted of 144 photos of various household objects. Each stimulus consisted of two pairs of objects. The objects in each pair participated in a certain functional relation, such as ‘hammer’ – ‘nail’, ‘key’ – ‘lock’, ‘fork’ – ‘spaghetti’, etc. In all pairs, it was possible to manipulate the affordance so that the interaction between the objects could be performed easier either with the left or the right hand

(Figure 2a). The relations in the two pairs were the same in half of the stimuli ('same' trials) and different in the others ('different' trials). A pre-test study was used to organize the objects pairs in such a way that there was maximal agreement among people whether the relations were same or different (Figure 2b). All images were resized to 400x400 pixels. In all pairs there was one tool-like, graspable object (axe, hammer, ironer, fork, etc) and it was always located at the bottom position.

Design The experiment had a 2x2 within subject design. The two independent variables were:

First affordance – left or right, depending on the affordance of the first pair of objects.

Second affordance – left or right, depending on the affordance of the second pair of objects.

The dependent variable was the reaction time of participants' verbal responses ('yes'/'no').

Figure 3: Experimental procedure. Reaction time was measured from the onset of the second relation until a verbal response was given.

Procedure Each stimulus was presented once to each subject. Affordance conditions and the order of presentation of the relations (first or second) were counterbalanced across subjects and it was made sure that the same combination of the affordance factors would not repeat more than 3 times in a row. Same/different trials were pseudo-randomized, so that a given correct response would not repeat more than 3 times. The trial sequence was fixed for all subjects, i.e. they saw the stimuli in the same order.

Participants were tested in a sound-proof booth. The stimuli were presented on 19" computer monitor with a

resolution of 1280x1024 pixels. Before the actual experiment all participants went through a microphone training session in order to make sure that they would articulate their responses clearly enough. The experimental session started with 8 practice trials, none of which appeared in the experimental part. Each trial began with a centrally location fixation cross (750ms), followed by the onset of the first pair of objects. The objects were displayed one below the other in the centre of the screen. Subjects were instructed to perceive the relation between the objects without making any response. The first pair of objects was presented for 3500 ms and when it disappeared the screen stayed blank for 1000 ms. After that a second pair of objects was presented at the same position as the first one. The stimuli stayed on the screen for 5000ms or until a response was generated. Participants were instructed to respond by saying 'yes' if the relation between the objects in the second pair was the same as in the first pair and say 'no' otherwise. The subject's response time (RT) was measured since the onset of the second pair of objects till the moment a verbal response was detected. Stimulus presentation and response recordings were controlled by E-prime software (Schneider, Eschman, & Zuccolotto, 2002). The inter-trial interval was 2500 ms. The experiment took about 10 minutes. The total number of test trials for each subject was 36, including 18 'same' and 18 'different' trials.

Results

Trials in which subjects failed to respond or the response was incorrect were excluded from the analysis. An incorrect response was counted when a subject said 'yes' in a 'different' trial or 'no' in a 'same' trial. RT lying more than ± 2.0 standard deviations from the mean 'same' and 'different' RT times were also removed. Thus a total of 82.10% of the originally collected RT data were included in the analysis.

Same and different trials were analysed separately. A 2x2 repeated measures ANOVA was performed on subject RT means in 'same' trials (Figure 4) and revealed a significant main effect of the affordance of the first relation ($F(1, 35) = 7.12, p < .05, \eta^2 = .17$). There was no effect of the affordance of the second relation ($F(1, 35) = 2.02, p = .16, \eta^2 = .06$). The interaction between the two affordance factors was not significant ($F(1, 35) = .20, p = .66, \eta^2 = .01$).

An analysis of mean item response times also found a main effect of the first affordance of 'same' items ($F(1, 17) = 9.05, p < .01, \eta^2 = .35$). The effect of the second affordance ($F(1, 17) = 2.69, p = .12, \eta^2 = .14$) and the interaction ($F(1, 17) = 2.15, p = .16, \eta^2 = .11$) were not significant.

Analyses of 'different' trials and items revealed similar patterns of results, but none of the effects reached significance.

Figure 4: Experiment 1 results for same trials. Subjects' responses were significantly faster when the affordance of the first relation was left although all subjects were right-handed. The tendency for the affordance of the second relation was reversed. Error bars represent standard errors.

Discussion

The results replicated the findings of V&K (2009) as long as an effect of left/right affordances on comparing functional relations was found. Also, the shortest reaction times were in the condition when one of the affordances was left and the other one was right. Another similarity was that the effect size of the first affordance effect was bigger than the effect size of the second affordance.

The major result of Experiment 1 was that the subjects, all of which were right-handed, were faster to respond when the first affordance was left. This result can not be explained by presentation location as all stimuli were presented in the center of the screen. At first glance, there is no reasonable explanation why participants would be faster when one of the stimuli is easier to process by their non-dominant hand. However the results start to seem logical if we assume that subjects tried to run the two simulations of functional interactions simultaneously in order to compare the resulting motor dynamics. It is reasonable to assume that subjects always engaged their dominant right hand in simulating the functional interactions of the visually available second relation, even when the affordance of the objects was congruent to their left hand. Thus, when they had to compare the two relations by running two simulations at once they could use only their non-dominant hand for recalling and simulating the first relation.

The pattern of results of Experiment 1 is inconsistent with any classical encode-and-compare account. If relations are first turned into propositions and then compared, then there would not be any effect of the first affordance. The first relation would have already been encoded by the time the second relation is presented and the response is given. If the effect is due just to the activation of the visual image of the first relation then the direction of affordance effect should be the same for both relations. Yet, we conducted a control study to make sure that main results of Experiment 1 are specific to the relation comparison task.

Experiment 2

Several researchers have shown that mere looking at manipulable objects activates regions of the brain related to action (Beauchamp et al., 2002; Beauchamp & Martin, 2007; Buccino et al., 2009). The goal of this experiment was to make sure that the main findings of Experiment 1 are not due to such kind of automatic motor activation. In particular we wanted to check whether if two objects with varying affordances are presented sequentially and the task is to compare them for some reason, the reaction times will be shorter when the affordance of first object is congruent with the non-dominant hand of the subjects.

Method

Participants 24 right-handed participants (17 females) took part in the experiment for course credit or as volunteers. Their average age was 22.79 years (age range from 17 to 32, $SD = 3.13$).

Stimuli The target stimuli set consisted of the manipulable tool-like objects which used in the 'same' trials of Experiment 1. Each target stimulus consisted of two such objects (Figure 5). Objects were paired in the same way as they were in the previous experiment. There were 18 target trials. An equal number of fillers were compiled using 18 photos of man-made objects, none of which was used in the target trials, and 18 photos of natural objects (fruits, plants, rocks, etc).

Figure 5a: An example of a target stimulus used in Experiment 2. Both objects are artifacts, so the subjects should respond by saying 'Yes'.

Figure 5b: An example of a filler. The correct response is 'No' as one of the objects is of natural origin. Either of the objects could be a natural one.

Design The design was identical to Experiment 1. The affordances of the objects were described by two independent variables – 'first affordance' and 'second affordance'.

Procedure The setting of the experiment was similar to Experiment 1 except for the task. Each trial began by a fixation cross (750 ms), followed by the presentation of the

first object (2000ms). After that, the screen stayed blank for 1000 ms and the second object was presented. Subjects were instructed to say 'yes' if none of the objects was of natural origin and say 'no' otherwise. Response time was recorded since the onset of the second object. All objects were displayed in the center of the screen. The order of presentation of the objects and the affordance conditions were counter-balanced across subjects.

Results

Fillers and trials with invalid or incorrect responses were excluded from the analysis. Response times lying more than ± 2.0 standard deviations from the mean RT time were removed. Thus a total of 92.40% of the originally collected non-filler RT data were included in further analysis.

A 2x2 repeated measures ANOVA was performed on subject means. It revealed main effects of the first ($F(1, 23) = 5.18, p < .05, \eta^2 = .18$) and the second object affordance ($F(1, 23) = 5.36, p < .05, \eta^2 = .19$). The interaction was not significant ($F(1, 23) = 0.22, p = .64, \eta^2 = .01$). Response times were faster when the affordances of both objects were right (Figure 6).

Figure 6: Results for trials with objects which were part of 'same' items in Experiment 1. Subjects were significantly faster when both objects were presented in such a way, that they were easier to be grasped with the right hand. Error bars represent standard errors.

Discussion

Experiment 2 showed that the main findings of Experiment 1 can not be explained by the automatic activation of motor programs by object affordances. Response times were shorter when the affordances of *both* objects were congruent to the subjects' dominant hand. Also, there was no difference between the sizes of the effects of the first and the second affordance. These results are different from what was found in the previous experiment and they show that the results of Experiment 1 are specific to the relation comparison process.

General Discussion

The presented experiments provide further evidence in support of the hypothesis that the meaning of functional relations is grounded in the sensory-motor dynamics

resulting from simulated interactions with the environment. The pattern of results is also consistent with the idea that comparing functional relations involves running two or more such simulations simultaneously or in close temporal proximity. The outcome of Experiment 2 rules out the possibility that the results were due to the object affordances per se.

The experiments were designed not to rely on the stimulus-response compatibility paradigm, unlike most other behavior studies of affordances (for instance Tucker & Ellis 1997, 2004; Spivey, Richardson & Cheung, 2001). In this way it was made sure that the results could not be attributed to accidental spreading of activation from conceptual to motor areas of the brain (Mahon & Caramazza, 2009). If the activation of motor areas was just a side effect it would not have had any effect on verbal responses as the motor areas dedicated to hand manipulations and language production are unlikely to be systematically connected. Informal debriefing after the experiments showed that subjects were completely unaware that the task had anything to do with their hands and simulations of actions.

The outcomes of the experiments are clearly in support of an embodied view on cognition. However one may attempt to interpret the results of Experiment 1 without adopting the specific idea of embodying relational representations and relational reasoning by referring to the theory of event coding (Hommel, Müsseler, Aschersleben & Prinz, 2001). According to this theory, elements of perception and action are encoded in a common medium. When the stimulus features related to perception and action are active for a long time period they become bound into an event file. Once bound, these features are less available for planning of other actions. Hence it is possible that a right affordance of the first pair of objects would bind the features representing the right hand of the subject to the stimulus features of the first relation. When the second relation is presented, the right hand of the subject would be less available for simulating the use of the presented objects and the response would be delayed. A result of this kind has been reported by Spivey, Richardson & Cheung (2001). Such an explanation reduces the role of simulated action to the process of object recognition.

However, the theory of event coding contradicts the results of the control study, unless it is assumed that the presentations times were too short for the event filing to happen. Such an assumption is highly unlikely to be true, as in the control study the first object was presented for a fixed period of 2000ms, followed by a 1000 ms inter-stimulus interval before the second object was displayed. This period is much longer than the time which was required for suppression of future actions in the studies of Spivey, Richardson & Cheung (2001) and Stoet & Hommel (1999). Also, there is no evidence so far that such a phenomenon could occur outside the stimulus-response compatibility paradigm and have an effect on verbal reaction time. Hence,

the event filing explanation can not adequately account for the results presented in this paper.

The results of the present study are broadly consistent with the 'body-specificity hypothesis' (Casasanto, 2009), according to which 'people who interact with their physical environments in systematically different ways should form correspondingly different mental representations'. We demonstrated that an asymmetry of our bodies, such as hand dominance, constrains performance in a task which is traditionally thought to be highly symbolic and abstract in nature. It remains however an open question to what extent abstract concepts and reasoning abilities are dependent on our bodies and whether such constraints are the only source of meaning.

Abstract

Theories of causal reasoning and learning often implicitly assume that the structural implications of causal models and empirical evidence are consistent. However, for probabilistic causal relations this may not be the case. We propose a causal consistency hypothesis claiming that people tend to create consistency between the two types of knowledge. Mismatches between structural implications and empirical evidence may lead to distortions of empirical evidence. In the present research we used trial-by-trial learning tasks to study how people attempt to create consistency between structural assumptions and learning data. In Experiment 1 we show biasing of empirical evidence with causal chains even after repeated testing of direct and indirect relations. Experiment 2 investigates whether different causal models lead to different judgments, despite identical data patterns. Overall, the findings support the idea that people try to reconcile assumptions about causal structure with probabilistic data, but also suggest that this may depend on the type of causal structure under consideration.

Keywords: causal reasoning; induction; Markov condition; top-down effects; heuristics and biases

Causal Reasoning and Empirical Evidence in Covariation Assessment

Probability judgments about indirect causal relationships may be based on direct observations of covariations between events (empirical evidence) or they may be derived from top-down assumptions about the underlying causal structure (structural knowledge). The crucial advantage of causal model knowledge is that we can make inferences about relations which we have not directly observed. For example, we may first learn about a causal relation $A \rightarrow B$, and later about a causal relation $B \rightarrow C$. By combining the single links into a causal chain $A \rightarrow B \rightarrow C$ we can make inferences regarding the initial event A and the final event C . For example, deterministic causal relations warrant transitive inferences, that is, the occurrence of A allows us to infer that C is present, too (like in logical ‘Modus Barbara’). However, most causal relationships tend to be probabilistic: a virus does not always cause a disease; a gene does not always cause a phenotypic trait. Crucially, in the case of probabilistic relations, transitivity relations do not necessarily hold (see Ahn & Dennis, 2000; von Sydow, Meder, & Hagmayer, 2009). However, causal models may nevertheless be used for assessing indirect relations from knowledge of direct relations, in a way that is inconsistent with direct empirical evidence.

Figure 1: A causal chain, a common cause (CC) and a common effect (CE) model.

The representation of causal relationships in qualitative causal models (Gopnik et al., 2004; Rehder, 2003; Sloman, 2005; Waldmann, Hagmayer, & Blaisdell, 2006; Waldmann & Holyoak, 1992) and in causal Bayes nets (Pearl, 2000; Spirtes, Glymour, & Scheines, 1993) suggests that people only represent direct causal relations and infer other relations from these causal models based on abstract assumptions about the structures. At the center of the Bayes net formalism is the *causal Markov condition*, which states that a variable in a causal network is conditionally independent of all other variables apart from its effects, given its direct causes. If the Markov condition holds, a causal chain (Fig. 1a) with positive direct relations, $A \rightarrow B$ and $B \rightarrow C$, entails a positive contingency between variables A and C . More specifically, the conditional probability of A given C , $P(C|A)$, is given by:

$$P(C|A) = P(B|A) \cdot P(C|B) + P(\neg B|A) \cdot P(C|\neg B) \quad (1)$$

Similarly, other indirect conditional probabilities can be derived from applying the Markov condition to the causal model. If we have a common cause model (CC, cf. Fig. 1b) $A \leftarrow B \rightarrow C$, the Bayes net formalism implies a positive relation between A and C . On the other hand, if the variables are linked in a common effect structure $A \rightarrow B \leftarrow C$ (CE, cf. Fig. 1c), no positive relation between A and C is entailed.

From a computational point of view, the Markov assumption is used as prerequisite for inducing causal structures from conditional dependency and independency relations, and as a basis for probabilistic inferences across complex causal networks (Spirtes et al., 1993; Pearl, 2000). On the other hand, the status of the Markov condition as a necessary and universal feature of causal representations has been criticized (Cartwright, 2001). However, the status of the Markov condition in human causal reasoning is still under dispute (e.g., Rehder & Burnett, 2005; Mayrhofer, Goodman, Tenenbaum, & Waldmann, 2008).

A Causal Consistency Hypothesis

A number of studies in causal learning have shown that people tend to use initial assumptions about causal models and do not tend to necessarily verify whether the assumptions underlying the model hold in the data. For example, Waldmann and Hagmayer (2001) showed that people make use of instructions regarding causal structures when assessing causal strengths, even when the data contradicted the initially suggested causal model. Waldmann, Meder, von Sydow and Hagmayer (2010) connected this research with categorization and demonstrated similar effects of category transfer with variable categorization schemes.

Similar phenomena may arise when participants are requested to make inferences about indirect relations within causal models. Previous research on inferences about indirect relations in causal chains has shown that people have a tendency to assume the Markov condition when making inferences from an initial event A to the final event C . Ahn and Dennis (2000) and Baetu and Baker (2009) have presented participants with data about direct relations between binary events. Learners' inferences about the indirect relations were consistent with the use of the Markov condition. However, they only investigated inferences in the absence of any evidence regarding the indirect relation.

Von Sydow, Meder and Hagmayer (2009) provided direct evidence about the indirect relation when learning causal chains. They showed that participants reasoned transitively (apparently assuming the Markov condition) even if the learning data provided evidence against transitivity. The present research continues in the wake of this work. Participants are again provided with data about the indirect relation. In addition, the influence of the amount of learning input, task features, and different causal structures are examined. We here particularly focus on the interplay between the implications of causal structures when the Markov condition is assumed and the observed data sample. Consider the data shown in Table 1. In these data, it holds that $P(B|A) = 0.75$ and $P(C|B) = 0.75$. Nevertheless, according to the data there is no contingency between A and C , since $P(C|A) = P(C|\neg A) = 0.5$. However, if we used these data to parameterize a causal chain $A \rightarrow B \rightarrow C$, and assumed the Markov condition, this causal model would imply that there is a positive contingency between the initial event A and the final effect C (i.e., $P(C|A) > P(C|\neg A)$, cf. Equation 1). Thus, depending on whether we assess the indirect relation between A and C directly from the data, or induce a causal model from the data and use the model to make inferences regarding indirect relations, we may arrive at very different conclusions. However, whether there is a potential tension between structural knowledge and data depends on the exact structure of the causal model. For example, a common effect model $A \rightarrow B \leftarrow C$ (Fig. 1c) does not entail a statistical dependency between A and C , as in this model the two events constitute independent causes of their common effect B .

Our causal consistency hypothesis suggests that when there is a mismatch between the causal model's structural implications and the observed data, people will create con-

Table 1: Sample of intransitive data from Experiment 1.

sistency by aligning the observed evidence with the causal model's implications. As a consequence, for an actually intransitive causal chain one should observe an overestimation of the statistical relations between the indirectly linked events A and C . For example, if learners assume the Markov condition when inducing a causal chain they should infer $P(C|A) > P(C|\neg A)$. This should also hold for common cause structures (but see von Sydow et al., 2009). By contrast, a common effect model implies no statistical dependency between A and C , as they represent independent causes of their common effect B . Thus, for this model there should be no conflict between the structural knowledge and the observed empirical probabilities.

Another potentially important factor which may affect how people deal with conflicts between structural implications and empirical evidence are the number and the focus of the test questions. In a previous study (von Sydow et al., 2009), participants were confronted with a causal chain and intransitive data, which did not show a positive statistical relation among the initial cause A and the final effect C , although the direct causal relations were positive. In these studies participants were first queried about the direct causal links before being asked about the indirect causal relation among A and C . Although participants had all relevant data available, they misjudged the relation between A and C to be positive. However, when participants are queried more often about the indirect relation, they may assess the relation directly, thereby arriving at estimates that correspond more closely to empirical probabilities.

Goals of Experiments and Hypotheses

The goal of the first experiment was to investigate how task features affect the integration of structural knowledge and empirical evidence. Participants were either asked frequently or only once about the indirect causal relation. We suspected that frequent queries would direct participants' attention to the empirical evidence regarding the indirect causal relation. Unlike in our previous studies (von Sydow et al., 2009) we presented subjects with trial-by-trial data instead of grouped data. Moreover, we used simpler dichotomous learning items, as opposed to variable category exemplars. Our goal was to find out whether these changes would make the empirical conditional probabilities more salient, thereby leading to judgments corresponding closer to the learning data. The main goal of Experiment 2 was to study other causal structures as well. While keeping the trial-by-trial

contingencies identical, we aimed to investigate whether the different possible causal structures modify the distortion of the empirical evidence. Participants were instructed about a causal chain, a common cause or a common effect model (Fig. 1). Their task was to investigate conditional probabilities between the direct and indirect causal relations. As outlined above, applying the Markov condition to these causal models leads only to a mismatch between data and model-based inferences in the chain model and in the common-cause model, but not in the common-effect model.

Experiment 1

Experiment 1 studied conditional probability judgments after successive trial-by-trial learning of two generative causal relations, $A \rightarrow B$ and $B \rightarrow C$, which were instructed to be part of a causal chain. Assuming the causal Markov condition, these relations imply a positive contingency between A and C . However, the learning data showed no statistical dependency between A and C , that is, $P(C|A) = P(C|\neg A) = 0.5$. We explored how the structure of the learning course, such as repeated queries about $P(C|A)$ might affect learners' estimates.

Methods

Design Experiment 1 had three conditions, each of which comprised eight learning phases and up to 12 test phases. Figure 2 depicts the succession of the phases. In all conditions, in the final test phase (P20) we requested estimates of the conditional probability $P(C|A)$ (Fig. 2). The state of all three events A , B , and C was presented simultaneously during learning, although the instructions focused participants on the direct relations of the causal chain, $A \rightarrow B$ and $B \rightarrow C$. Moreover, the directly linked pairs were circled to highlight their causal relation. After each learning phase, participants were requested to give probability estimates of the respective direct causal relation ($A \rightarrow B$ or $B \rightarrow C$). Because of the focus on direct relations we expected a substantial influence of structural knowledge.

In Condition 2 (C2), participants were also focused on the direct causal relations, but the conditional probability estimates of the indirect relation ($P(C|A)$) were additionally requested several times during learning (Fig. 2). This procedural change was intended to draw participants' attention to the indirect relation as well. We expected that repeated testing of the A - C relation would strengthen the influence of the empirical data.

Condition 3 (C3) served as control condition to ensure that participants used the scales correctly and were able to detect the zero contingency between A and C . In this condition participants only received the subset of information about the relation between A and C (cf. Fig. 2, Table 2).

Participants Sixty students from the University of Göttingen took part in the experiment for course credit or were paid 5€. They were randomly assigned to the conditions.

Procedure and Material Participants were instructed to take the role of a developmental biologist investigating newts that undergo a metamorphosis. The metamorphosis

proceeded in three stages. In each stage a particular type of carotene (Alpha, Beta, and Gamma; henceforth denoted as A , B , and C) could occur or not occur. These carotenes may or may not affect the presence of other carotenes in a later stage.

Figure 2: Design of Experiment 1

In the first condition (C1) participants were asked to assess one of the two causal relations after each learning phase (cf. Fig. 2), alternating between the first relation ($A \rightarrow B$) and the second ($B \rightarrow C$). Although in all learning phases all three events were shown, participants were only asked about the indirect relation between A and C after all eight learning phases. Condition 2 was similar, but here participants were asked to assess the indirect relation between A and C after every other learning phase (see Fig. 2). In the control condition (C3) participants only observed the relation between A and C . After every second learning phase learners had to assess $P(C|A)$.

In the two experimental conditions (C1 and C2) information about the state (present vs. absent) of all three types of carotene was presented in a trial-by-trial learning procedure. Table 2 shows the learning input. In each of the eight learning phases, 24 newts were presented in randomized order. In total, 192 newts were shown. The empirical

Table 2: Learning data in Experiments 1 and 2.

Pattern			Phase	Total
A	B	C	6	48
A	B	$\neg C$	3	24
A	$\neg B$	$\neg C$	3	24
A	$\neg B$	C	0	0
$\neg A$	B	$\neg C$	0	0
$\neg A$	B	C	3	24
$\neg A$	$\neg B$	C	3	24
$\neg A$	$\neg B$	$\neg C$	6	48
All			24	192

conditional probabilities were: $P(B|A) = P(C|B) = 0.75$, $P(B|\neg A) = P(C|\neg B) = 0.25$, $P(C|A) = P(C|\neg A) = 0.5$. Thus, in the data there was a zero contingency between C and A . The probabilities entailed by the chain model assuming the Markov condition were $P(C|A) = 0.625$ and $P(C|\neg A) = 0.375$, that is, a positive contingency.

Based on the outlined design (cf. Fig. 2) three types of test phases were used, in which we assessed participants estimates of the relations between A and B , B and C , and A and C . For each judgment we used a rating scale ranging from -100 to +100. For instance, when accessing $P(C|A)$, participants were asked whether newts that had developed Alpha carotene (A) in the first stage rather tended to develop

Gamma carotene (C) or to develop no Gamma carotene ($\neg C$) in the subsequent stage. The scale ranged from -100 ('newts with Alpha carotene never develop Gamma carotene') to +100 ('newts with Alpha carotene always develop Gamma carotene') in steps of 10. The middle point of the scale, 0, was labeled 'Alpha and Gamma carotene occurred together only by chance' (i.e., with $P(C|A) = 0.5$).

Results

Figure 3 shows the means of participants' ratings concerning the probability of B given A , of C given B , and of C given A over the course of learning (the different measurement points are denoted as t1 to t4).

Panels 1 and 2 reveal that participants detected the positive causal relation between the directly linked events quickly and rated the probabilities $P(B|A)$ and $P(C|B)$ roughly correctly ($P(B|A) = P(C|B) = .75$ or +50 on the used scale). Panel 3 shows learners' estimates of the indirect relation $P(C|A)$. The results suggest that in both experimental conditions (C1 and C2) the estimates were affected by structural knowledge. While in the control condition (C3) learners' estimates were around zero (corresponding to a probability of $P(C|A) = 0.5$), a very different pattern of judgments was obtained in the two experimental conditions. In both condition C1 and C2 participants gave judgments above zero; and the obtained estimates also differed from the control condition (C3). The results of C1 complement previous findings by showing that abstract causal knowledge guides learning and reasoning even when people are provided with almost 200 trials on the state of all three variables with a shown objective zero contingency. Nonetheless, the average estimate of $P(C|A)$ was actually about as high as if it were exclusively based on inference assuming the Markov condition (cf. Equation 1, $P(C|A) = .625$, or +25 on the used scale). The second condition (C2) illustrates the interplay between abstract causal knowledge and empirical evidence over the course of learning. From the first (t1) to the last measurement (t4) participants' estimates of the indirect relation A - C declined, showing the influence of the learning data. Nevertheless, even in the last test phase (t4) the judgments were above zero and higher than in the control condition. An analysis of variance of the final judgments with the three conditions as between subjects factor yielded significant results, $F(2, 56) = 6.95$, $p < .05$, $MSE = 594.0$. Additionally, we computed pair-wise comparisons, with a significant contrast between C1 and C2 ($M_{C1} = 24.5$, $M_{C2} = 8.5$) ($F(1, 56) = 17.21$, $p < .0001$), as well as between C2 and C3 ($M_{C3} = -7.5$; $F(1, 56) = 4.40$, $p < .05$) and between C1 and C2 ($F(1, 56) = 4.31$, $p < .05$).

In sum, Experiment 1 supports the idea that subjects' judgments for indirect causal relations were derived from causal model representations obeying the Markov condition, even when the available evidence indicated that this condition did not hold. C1 shows that even after a long period of learning of zero contingencies, a positive contingency between the initial and final event was inferred. The difference between C1 and C2 shows that the impact of evidence also

depends on the attentional focus during learning: when the attention is directed more clearly to the indirect relation, the distortion of the learning by top-down inferences is reduced. But even after almost 200 trials the bias did not disappear completely.

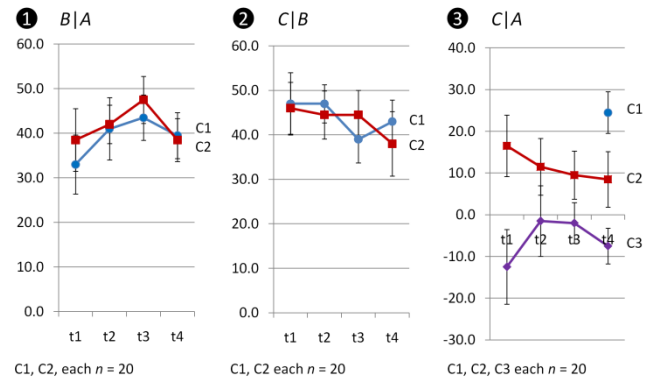

Figure 3: Mean judgments (\pm SE) in Experiment 1. t1 to t4 denote measurements at different points in time over the course of learning.

Experiment 2 – Causal Models

In Experiment 2 we investigated further causal structures. In addition to a causal chain we also used a common cause and a common effect model (Fig. 1). The learning data presented to participants were identical in all conditions and corresponded to Experiment 1 (Table 2). Although in the experiment participants were confronted with identical data about the three events the mapping of the events to their causal roles differed. In the chain condition A caused B and B caused C , in the common cause condition B was the common cause of A and C , and in the common effect condition A and C were independent causes of their common effect B (Fig. 1). If participants' mental causal models obeyed the Markov condition, increased values of $P(C|A)$ should be obtained in the chain and the common cause condition, but not in the common effect condition. Due to the lack of a mismatch between model and data in the CE model, participants should provide ratings corresponding to the empirical conditional probability of $P(C|A) = 0.5$.

Methods

Participants 150 students from the University of Göttingen participated for course credit or 5€. They were randomly assigned to one of the three causal model conditions.

Procedure and Material The procedure was almost identical to Condition 2 of Experiment 1 (Fig. 2), apart from the manipulations of the initial causal model assumptions. A different cover story was used, concerning the development of the metabolism of ravens. As causes and as effects we used three substances, which could be present or absent in different developmental stages of the ravens: Xantan, Yojan, and Zetosan (henceforth denoted as A , B , C). Participants in all condition were informed that they would have to answer questions about the potential direct causal relations (be-

tween A and B , and between B and C) as well as about the indirect relation between A and C after the learning phases. The causal links be present or absent.

The task investigated whether people assumed the Markov condition to hold when integrating single links into a larger causal structure. Although the instruction may well be interpreted to put a higher prior probability on the respective causal structures, the instructions were completely silent on whether one should assume the Markov condition. Hence, this provides a test for whether participants implicitly asserted the Markov condition and distorted the empirical probabilities accordingly.

Like in Condition 2 of Experiment 1 there were eight successive learning phases showing all three events A , B , and C . Again participants were focused on the respective direct causal relationship by the instructions and a circling of the directly related events. The data patterns were randomized within each learning phase; the learning data was identical in all conditions (Table 2).

In the test phases participants were again asked to assess conditional probabilities on a scale between +100 and -100 (cf. Experiment 1). When investigating the direct relations between A and B and B and C we assessed conditional probabilities in the causal direction (chain: $P(A|B)$, CC: $P(B|A)$). But note that in our learning data both conditional probabilities were identical ($P(B|A) = P(A|B)$). The wording of the question for $P(C|A)$ was identical, irrespective of condition.

Figure 3: Design of Experiment 2.

Results

Figure 4 shows participants' mean estimates in the three conditions (Panel 1 – 3) across the four test phases (t1 – t4). Estimates of $P(B|A)$ and $P(C|B)$ were all positive, although they underestimated the correct value. With regard to the crucial estimate, $P(C|A)$, an inspection of the data reveals that the results of the chain condition replicate the results of Exp. 1, but that the expected effect for the CC model was not obtained. Consistent with our predictions, participants' estimates in the CE condition were close to zero. We conducted an ANOVA with the test phases (t1 to t4) as within-subject factor and causal structure (Chain, CC, CE) as between-subject factor. This resulted in a significant main effect of causal structure, $F(2, 147) = 4.34, p < .05, MSE = 2312$. No other effects proved significant. The pair-wise contrasts between the chain and the CE condition and between the chain and the CC condition yielded significant differences, $F(1, 147) = 5.31, p < .05$ and $F(1, 147) = 7.52, p < .01$. However, the contrast between the CC and CE condition was not significant: $F(1, 147) = 0.19, p = .66$. A test of the mean estimates of $P(C|A)$ against zero showed that only the chain condition consistently and significantly differed from zero, with no reduction over time. (Chain: t1,

$t(50) = 2.49, p < .05$; t2, $t(50) = 2.04, p < .05$; t3, $t(50) = 2.98, p < .01$; t4, $t(50) = 3.27, p < .01$; CC: t1, $t(50) = -0.90, p = .37$; t2, $t(50) = -0.66, p = .51$; t3, $t(50) = .43, p = .66$; t4, $t(50) = -0.41, p = .68$; CE: t1, $t(50) = -0.19, p = .84$; t2, $t(50) = .99, p = .32$; t3, $t(50) = -0.49, p = .62$; t4, $t(50) = .15, p = .88$).

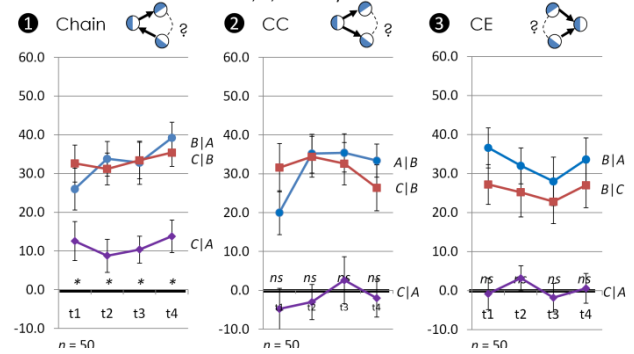

Figure 4: Means (\pm SE) of conditional probability estimates on a scale from -100 to +100 for the three causal structures (chain, common cause (CC), and common effect (CE)) across the four test phases (t1 to t4).

In sum, Experiment 2 replicated the biasing effect of structural knowledge with causal chains. As predicted by Bayes nets, no such effect was found for the common effect model for which top-down assumptions and empirical evidence were consistent with each other. Interestingly, no effect was obtained for the common cause model.

We can only speculate why we did not find an effect in the CC condition. Maybe the Markov condition is more intuitive in causal chains, in which the intermediate event can be easily represented as separating the initial from the final event. In contrast, screening-off relations may be harder to envision in common cause structures in which the intermediate event simultaneously causes several effects (see Cartwright, 2001). Actually, von Sydow et al. (2009) suggested that CC structures may often be interpreted to violate the Markov assumption, at least if one is concerned with the predication of attributes of a category (without representing alternative causes of the attributes). Attributes of categories are often represented as CC structures (Rehder, 2003). It has been argued that people may represent different kinds of noisy logical interaction patterns of such attributes (including XOR) (von Sydow, 2009). If such judgments correspond to a causal logic of CC structures, they would violate the assumption of conditional independence and unconditional positive correlation between effects (the Markov condition). However, further research is needed to connect models of noisy logical predication with theories of causal induction.

Another possibility may be that attentional factors caused the low ratings in the CC and CE condition, since we switched the direction of the question formats for the local causal links (e.g., $P(A|B)$ in the chain and $P(B|A)$ in the CC condition). Although, a predictive question format seemed to be most natural to elicit the causal representations that we

aimed to manipulate, this remains a factor that should be controlled for in future research.

General Discussion

The results of Experiment 1 corroborate our prediction that in a causal chain $A \rightarrow B \rightarrow C$ conditional probability judgments about the indirectly linked events A and C will be distorted by structural assumptions of the underlying causal model. We investigated the influence of causal inferences based on the Markov condition when learning such relations. Going beyond previous studies (Baetu & Baker, 2009; Ahn & Dennis, 2000), we provided data on the indirect relation, which showed a zero contingency. Hence, transitivity did not hold in the data (cf. von Sydow et al., 2009). In Experiment 1 we investigated this issue in a trial-by-trial learning scenario, assessing the role of repeated questions. The conditional probability estimates of $P(C|A)$ matched the values that would have been predicted if people estimated this probability based on their knowledge about the direct relations and structural assumptions about causal models (i.e., the Markov condition). This biasing effect was remarkably stable even if people obtained contradicting empirical evidence in several learning phases and were repeatedly queried about the indirect relation, which was intended to draw participants' attention to the indirect relation. With repeated queries the influence of causal reasoning became smaller, but did not disappear even after almost 200 trials.

Experiment 2 confirmed that chains and common effect structures ($A \rightarrow B \leftarrow C$) led to different judgments of $P(C|A)$ despite identical learning input. As predicted by causal Bayes nets, a biasing effect only occurred in the chain condition in which the data violated the structural constraints underlying chains. Consistent with this idea, no influence of structural knowledge was obtained for the common effect model. Interestingly, in the common cause structure ($A \leftarrow B \rightarrow C$) we did not find an influence of the causal model on participants' judgments. The reasons for this failure are unclear at present. One hypothesis may be that people find the Markov condition less plausible for these models (see also von Sydow et al., 2009). Alternatively, attentional effects during learning may have had an effect.

Taken together, the results provide further evidence for our claim that people try to create consistency between structural top-down knowledge and empirical evidence when making probabilistic causal inferences (von Sydow et al., 2009; cf. also Waldmann et al., 2010).

Abstract

We reveal spontaneous group formation and differentiation in an online dynamic coordination experiment. We observe increased group stratification and attribute it to increases in pairwise cooperative behavior, rather than uncooperative behavior. Our network analyses document the fine scale structure of coordination failure in the face of many established determinants of coordination success. We explore previous work in coordination failure to frame our own findings. Factors that have been previously shown to improve coordination in discrete-time, forced-decision experimental games do not prevent decisive coordination failure in our real-time, asynchronous group decision-making environment.

Keywords: coordination; coordination failure; n-player games; continuous-time games; stag hunt; functional networks; group structure

Introduction

Sixty years of literature have established cooperation as only a special-case outcome in experiments of economic behavior. Where there is a conflict between individual and group interest, the net benefit of all members may suffer in favor of individual gains. Even in coordination games, where individual payoffs are directly related to the group's outcome as a whole, the maximum levels of coordination and personal benefit have been notoriously difficult to attain in the laboratory (Devetag & Ortmann, 2007), either because of uncertainty inherent in the task or strategic uncertainty with regard to the actions of other participants. However, the majority of these coordination situations involve slow, round-based decisions. By contrast, humans and animals often make decisions within the time scales that characterize processing and decision time. In these environments, decision opportunities may be presented with little notice, and part of the decision process is deciding when to decide. Despite the increased cognitive demands, the ability of animal groups to coordinate successfully in these environments is well established in both experimental and observational experiments (Conradt & Roper, 2005; Petit, Gautrais, & Leca, 2009; Couzin, 2009). Recent research on group behavior has worked to understand how these faster-paced decision environments affect coordination.

We build on this work, applying dynamic network methods to estimate the changes in network structure between participants in an n-person stag hunt coordination game. Though we find support for many structural factors that have been proposed (all else being equal) to promote efficient outcomes,

participants fail to coordinate on payoff-dominant equilibria, and coordination continues to decay over the course of the experiment. We take advantage of the rich data available from these fine timescale experiments and introduce functional network measures to estimate the emergent structure of participant interactions.

Literature

Experiments in real-time group decision-making document both coordination failure and success. Dyer et al. report a collective navigation experiment in which human groups walked in the induced direction, despite constrained communication, and conflicting individual information (Dyer et al., 2008). Kearns, Suri, and Montfort examined coordination in a network experiment based on a map-coloring problem to investigate the effects of group topology and information differences on cooperation (Kearns et al., 2006). Roberts and Goldstone also looked at the effect of different information treatments in a collective number-guessing game and found that participants spontaneously adopt specific roles without communication (Roberts & Goldstone, 2009). Furthermore, the extent to which group members differentiated themselves predicted how well they solved the coordination problem. Related results have been found in minority and market entry games (Bottazzi & Devetag, 2007; Duffy & Hopkins, 2005). In another network game, continuous-time decision-making is proposed to improve coordination (Berninghaus, Ehrhart, & Ott, 2006). In all of these domains, participants were generally successful at resolving conflicts and finding solutions that brought a net collective benefit.

With continued ties to the study of coarse time-scale political and macroeconomic decision making (as in Schelling, 1980), experimental economists are traditionally interested in synchronous, normal form games wherein all players choose a strategy without knowledge of any other players' choices. However, there is still rich research in games that elicit decisions at finer time scales, as discussed by Berninghaus, Ehrhart, and Keser (1999). This literature has more often found coordination failure than success. Participants in the three games of E. Friedman, Shor, Shenker, & Sopher (2004) frequently failed to converge on any equilibrium, much less those that dominate with respect to payoff or certainty. However, Bottazzi and Devetag find emergent structure that leads to higher coordinative outcomes (2007) and Cheung and

Friedman observe successful coordination in a more complex continuous-time experiment modeling financial speculative attacks (2009).

From a game-theoretic standpoint, the game in this experiment shares several features with so-called stag hunt games, which have been extensively studied in the lab. In the allegorical stag hunt, two neighbors decide whether to hunt hare separately, or to work together to hunt (the more rewarding) stag. Even though both individuals benefit by coordinating for the larger quarry, they may decide that the costs of coordination, and their uncertainty as to the actions of their neighbor, are too great. In its synchronous form, game theory does not predict which outcome is more likely without refinements like risk and payoff dominance (Harsanyi & Selten, 1988). However, in the asynchronous, extended form, in which one neighbor is forced to make a choice that the other can observe beforehand, theory predicts that the rational player will select the high payoff equilibrium (Kuhn, 2009). Similarly, continuous-time games in the laboratory have led to more effective coordinative behavior than comparable synchronous games (D. Friedman & Oprea, 2009).

While real life uncertainty and decision cost dilemmas modeled by the stag hunt are at least as common for groups as for pairs of people, generalized n-player stag hunts have only been investigated in simulation (Pacheco, Santos, Souza, & Skyrms, 2009). However, as pointed out by Resnick (2007), the important coordination experiments of Van Huyck et al. (1990) are relevant. The precedents in both of these investigations seem to predict that adding players to the stag hunt makes coordination failure more likely in our experiment.

We introduce a coordination game building on previous evidence of emergent social conventions in repeated coordination games (Bottazzi & Devetag, 2007; Rankin, Huyck, & Battalio, 2000; Roberts & Goldstone, 2009; Uzzi & Spiro, 2005). Taken together, the above theoretical and experimental results make contrasting predictions about how participants should perform in the asynchronous environment provided by the real-time nature of our group experiment.

Experiment

Paradigm

Groups of two to six participants played an n-player stag hunt game on networked computers. Each player was shown information about the payoff and location of the other uniquely identified participants (Figure 1). Participants were instructed to “harvest” points from any of twelve game tiles. Participants were awarded a tile’s points after waiting for a specified amount of time. To introduce the incentives of the stag hunt, tile payoffs increased with each tile’s *coordination number*. The coordination number specified the quorum of participants necessary to harvest the points on a tile. When a tile reached its quorum, a visible timer on the tile would start counting down to zero. During this time, any participant on the tile could leave it and other participants could join. If a timer reached zero, each participant on the tile received the

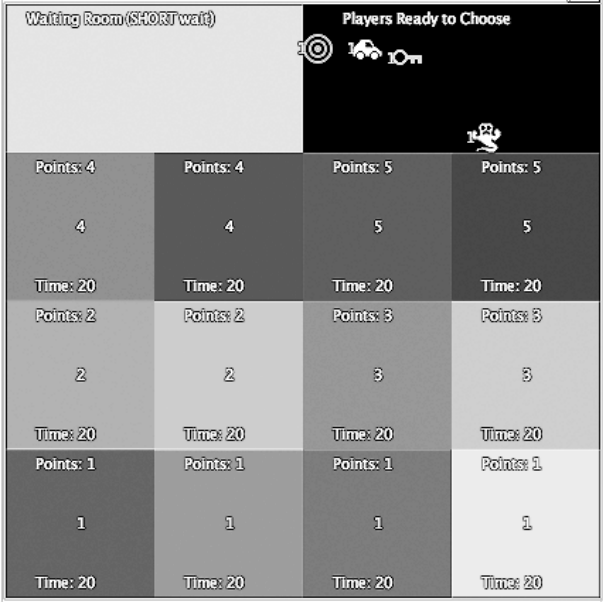

Figure 1: Screenshot of game board. Icons are controlled by participants, each of whom may select any tile. The coordination number in the center of each tile reflects how many participants must wait for the listed Time to each receive the specified number of Points. The number to the left of each player reflects his or her accumulated number of points.

tile’s payoff, even if participant presence on a tile was above quorum. If the tile fell below quorum during countdown, the timer was reset and no points were distributed.

The coordination number ranged from one to five, even in cases where there were more than or fewer than five participants in a session. To allow for the possibility of independent action, tiles at each possible coordination level (of five) were distributed redundantly among all possible tiles (twelve). This allowed participants to harvest points alone on tiles with a coordination number equal to one, or to harvest tiles collectively with other participants on tiles with higher coordination numbers. We may have introduced theoretical difficulties by providing multiple tile choices at a given coordination level, but participants showed an ability to coordinate at higher levels, perhaps due to focal point effects or the cheap decision costs of the environment.

In this game, the most efficient strategy was to repeatedly choose one tile with the coordination number equal to the group size. The strategy least vulnerable to strategic uncertainty was to always choose a tile with coordination number equal to one.

Participants started in a “staging area” on the game board from which they selected a tile to harvest from. After distributing its points, a harvested tile was reset and its participants were held for two seconds before being returned to the staging area. Participants were never forced to make any choice, and the ability of any participant to make a choice did not depend on “turns” or any system of rounds that structured when participants made decisions relative to each other.

We thus distinguish between the real-time, asynchronous and non-forced aspects of decision-making in this environment. This less constrained structure allowed us to explore the effects of changes in pay level, risk, and experience on spontaneous group coordination and structure in an environment that evokes real world, short time-scale decision-making.

Manipulations

After a practice round, participants played eight five-minute rounds of the game (permitting up to 75 consecutive harvesting events). We manipulated *pay level* and *harvest time* over rounds in a $2 \times 2 \times 2$ block factorial design ([low versus high payoff] \times [long versus short harvest time] \times [first versus second block]). The first four rounds (block one) consisted of the 2×2 set of low and high payoffs and short and long harvest times, randomly permuted, and were followed by a second random permutation of the same four conditions. The blocks controlled for order effects and enabled investigation of the effects of experience with the group.

The two levels of pay level were *low* (tile payoff is the same as the tile coordination number) and *high* (tile payoff is the square of tile coordination number). Scaling payoffs with coordination number created an incentive for participants to risk coordinating with other participants for a higher payoff. The two levels of harvest time, the number of seconds necessary to harvest any tile, were *fast* and *slow* (two and ten seconds, respectively). This factor manipulated the amount of time that a tile had to remain at or above quorum to deliver payoffs, and thus how vulnerable participants were to strategic uncertainty—uncertainty as to the beliefs and future actions of their peers.¹

Participants were introductory psychology undergraduates receiving course credit. Participants did not receive monetary compensation, but observational reports indicate that participants found earning points intrinsically motivating. Participants often spontaneously cheered when they received a large payoff. There were forty-three participants over twelve experiments. Our experiments ultimately had five levels of *group size*, with four groups of 2 participants, two groups of 3, two groups of 4, three groups of 5, and one group of 6. Though it was not controlled, our analysis will treat group size as an independent, between-participant variable. Each experiment lasted one hour.

Measures

The structure of the experiment allowed us to develop and compare a number of measures of coordination. The game was implemented such that the state of each player was recorded approximately twice every second. This enabled investigation of each individual's decisions as a time series, and of participants' decisions together as a multivariate time series.

¹Strategic uncertainty is strictly uncertainty as to the beliefs and actions of other participants (Huyck et al., 1990), but this experiment provides full information as to the actions of peers in the experiment.

For each participant, in each condition, we recorded *payoff*, *wait tile*, and *success tile*. Payoff represents how many points a participant earned in a condition. Wait tile represents the mean tile that a participant spent time on. Success tile represents the mean tile that a participant successfully harvested a payoff from. In terms of these measures, highly successful coordination would be reflected by maximum payoffs and wait and success tile values equal to group size, all identical across participants. Conversely, zero-coordination behavior would be reflected in minimal payoffs and wait and success tiles equal to one.

We also used the multivariate nature of the time data to calculate measures of functional proximity between participants in a group. These measures reflect the extent to which any pair of participants coordinated on a tile. We then assembled these dyad weights into fully connected networks representing the pattern of behavioral couplings in the group. Since these networks are fully connected, edge weights replace edge presence in representing heterogeneity within a group. With these graphs of internal group structure, we used a variety of network statistics as additional measures of coordination. These “functional networks” have been used in computational neuroscience to infer how regions of the brain are related, and to determine the extent to which dynamic functional relations correspond to physical anatomical connections (Bullmore & Sporns, 2009; Hagmann et al., 2008). Given the rich data available in the experiment, and the wealth of theoretical issues common to neuroscience and group behavior (Couzin, 2009), the extension of these tools to the study of social behavior was natural. Because functional networks have only recently been applied to the study of group behavior (Nagy, Akos, Biro, & Vicsek, 2010), we implemented three separate measures of proximity: choice distance, mutual information (Cover & Thomas, 2006) and transfer entropy (Schreiber, 2000). Because the three measures gave analogous, consistent results, this investigation will treat only the choice distance, the simplest of the measures.

The *choice distance* between a pair of participants is the number of seconds that they were on different tiles. In the resulting graph, two participants that always made the same choice are *close*, with a choice distance of zero. If their choices were always different, they are *far*, with a distance equal to the number of seconds that they could have been on the same tile. The matrix representing this graph is symmetric, and its diagonal, representing the number of times a participant is on his or her own tile, is always zero.

For every condition, we calculated the mean and variance of each individual's proximity to every other participant in their group. The mean proximity is related to the closeness centrality metric in graph theory and social network theory (Wasserman & Faust, 1994), but it preserves measure units. A change in a participant's mean proximity across some experimental condition entails that the participant coordinated more or less closely, on average, with all other participants in

their experiment. The image of a loaf of raisin bread provides a simple visualization of a net change in average choice distance. If yeast caused the loaf to rise, each raisin will be farther from every other. By analogy, an increase in mean choice distance is a net expansion of the graph. A net increase in the variance of this distance, which we interpret as stratification, corresponds to a case where the raisins in the bread all start equidistant from each other, and differently attract and repel each other over time. Together with wait tile and success tile, these graph statistics provide a powerful toolkit for investigating the internal structure of groups in our coordination game.

Table 1: Payoffs

Payoff	Observed		Min:Max ²		Efficiency	
Harv. time	slow	fast	slow	fast	slow	fast
Low pay	21.5	62.7	25:99.4	75:298	-5%	-3%
High pay	68.1	181	25:430	75:289	9%	9%

Results

Group structure

Groups stratified with time, as seen in an increase by block in the variance of participants' choice distances from each other ($F(1,38) = 10.51, p < 0.05$). However, despite the reliable decrease in other measures of coordination (below), it does not seem that mean choice distance changed by block. The mean choice distance of participants from each other (the number of seconds that they spent on different tiles) was about 33 seconds in blocks one and two. The significant increase in standard deviation about this mean was from 7.5 seconds in the first block to 8.8 seconds in block two.

A change in the variance in a given participant's choice distances suggests an increase in graph heterogeneity: either a selective decrease in the minimum distances, a selective increase in the largest distances, or a combination of the two. An increase in the maximum distance would be consistent with choice refusal, a phenomenon observed in iterated prisoner's dilemma experiments by which participants choose not to reenter a game with a peer who has defected against them in previous iterations (Stanley, Ashlock, & Testfatsion, 2004). Additionally, an increase in trust between only some peers in the group, and a corresponding net decrease in the minimum distance, could also account for the increase in variance with time. We found only insignificant evidence that the maximum choice distance increases with block ($F(1,38) = 2.34, p = 0.134$ with sample mean maximum distances of 79.8 and 83.1 for blocks one and two) and slightly stronger evidence that the minimum choice distance decreased with time ($F(1,38) = 3.88, p = 0.056$, with sample mean minimum distances of 54.6 and 50.2 by block). This experiment thus provides only minimal support for choice refusal and somewhat stronger support for trust building.

Coordination

In addition to these changes in group structure with time, we also documented decisive coordination failure. We define minimum efficiency as strictly individual, zero-coordination behavior (all players select tiles with coordination number one), and maximum efficiency as group-wide fully cooperative behavior.² Normalizing over these extremes, participants performed at negative, or very low efficiencies. For low pay level, observed efficiency was below that of purely individual behavior, presumably due to an excessive time cost of coordination, since waiting on a tile below quorum can yield no payoff. Similarly at the high pay level, the square scaling of payoffs by coordination number brought efficiency up only 9% above minimum (Table 1). Wait tile was on average 47% of maximum for each group size, and success tile was significantly lower at 35% ($t(656) = 6.49, p < .001$) (Table 2). This difference shows that participants consistently took risks on high coordination tiles that were not rewarded with success, even in the face of increasing coordination failure.

This failure of groups to coordinate at higher equilibria increased over the course of the experiment. Wait tile, success tile, and payoff all decreased slightly with block (all $p < 0.001, F(1,38) = 26.2, F(1,38) = 40.3$, and $F(1,42) = 14.4$). results on Table 3).

Only one exception appeared: one of the four 2-person groups had high coordination in the first block and reached near perfect levels of coordination in the second block. Although some groups did not produce significant decreases in coordination with time, this group was the only one to increase coordination, ultimately to the payoff-dominant equilibrium by the end of the experiment. On average, at group size two, wait and success tile stayed the same over block, and payoff did not increase significantly. This serve as limited evidence for the relative stability of two-player stag hunts in continuous time.

Supporting results

Another observed block effect was a significant reduction in participants' information entropy ($F(1,38) = 4.57, p < 0.01$), from 2.67 to 2.46 bits, suggesting that participants had more predictable behavior in the second block. This supports previous observations in a group minority game in which participants tended towards pure strategies over time (Bottazzi & Devetag, 2007), the key difference being that in the minority game experiment participants successfully coordinated towards benefits exceeding those predicted by the mixed-strategy equilibrium for that environment.

Both larger pay levels and shorter harvest times were strongly associated with higher wait tiles and higher success tiles (all $p < 0.001$, Table 3). Thus participants coordinated more when they were receiving higher payoffs, sup-

²Coordination number of all harvest tiles equals group size. Maxima in table calculated over four groups of 2, two groups of 3, two groups of 4, three groups of 5, and one group of 6. For the group of six, full cooperation implies that all six participants are on a tile of coordination five, the highest that we implemented.

porting the results of Brandts and Cooper (2006) in a minimum effort game. Participants' average choice distance correlated with wait tile ($\beta = -13.5, p < 0.05$) and success tile ($\beta = -20.0, p < 0.05$).

Table 2: Observed Wait and Success Tile by Group Size

Group size	2	3	4	5	6	ave	max ³
Wait tile	1.5	1.7	2.6	2.9	3.1	2.5	3.98
% of max	.53	.37	.54	.49	.42	.47	1.00
Succ. tile	1.4	1.5	2.3	2.3	2.6	2.1	3.98
% of max	.40	.27	.45	.33	.31	.35	1.00

Discussion

Group structure

Investigation of participant time series revealed a detailed perspective into the evolution of group structure during the coordination task. Previous investigations into group behavior over time have focused on the differentiation of individuals into less complex roles (Bottazzi & Devetag, 2007; Roberts & Goldstone, 2009). This investigation extends these results by composing specific relationships into a group-level representation of interaction patterns. Groups tended to stratify in time as participants came to preferentially coordinate with and, to a lesser extent avoid, specific peers. In their model of Broadway musical production teams, Guimera et al. (2005) modeled the preference of past team members to work together in the future, but they included no complimentary aversion mechanism corresponding to choice refusal. Our results support this modeling decision.

Coordination failure

To our surprise, participants failed to coordinate on the most efficient outcomes and the extent of their coordination decreased over time. In their review of laboratory coordination failure, Devetag and Ortmann propose a number of efficiency-enhancing design principles for coordination success (Devetag & Ortmann, 2007). Within the controlled factors of this experiment, we directly support two of the proposals in their review. We observed that an increase in pay level corresponded to increases in wait tile and payoff, supporting the efficiency-enhancing effect of "lowering the attractiveness of the secure action relative to the risky action required for the efficient equilibrium." Our manipulation of harvest time corresponded to both "lowering the costs of experimentation" and creating "less stringent coordination requirements," all of which are *ceteris paribus* efficiency-enhancing. In addition to this direct support, our design had a majority of the other features observed to be efficiency-enhancing: participants received zero deviation costs, they had repeated encounters in

a fixed-group match, and participants had full information as to their peers' states and action choices. Also, although there was no explicit communication, participants' ability to make and change their decisions at low cost may have permitted signaling—some behavioral equivalent of "cheap talk" as Bottazzi and Devetag propose to explain their observations in a group minority game (2007)—thus providing another efficiency-enhancing factor.

In addition to implementing a majority of Devetag and Ortmann's efficiency-enhancing conditions, we also implemented a number of efficiency-enhancing conditions that they did not report. Our groups operated in a continuous time environment in which they made decisions asynchronously, and in which part of their decision was when, or whether, to make a decision. Continuous time environments have been observed to improve coordination in an experimental prisoner's dilemma (D. Friedman & Oprea, 2009) and a number of other studies (Berninghaus et al., 1999; Cheung & Friedman, 2009; E. Friedman et al., 2004). Asynchronous, extended form decision making is hypothesized to improve coordination in stag hunts (Kuhn, 2009). In the face of all of this previous qualitative evidence for high coordination outcomes, our participants still produced net coordination failure and increasing coordination failure with time, in all groups except one of the smallest.

Devetag and Ortmann make no claim for a simple additive relationship between their thirteen design principles, and they repeatedly stress that each factor is only efficiency-enhancing if all else is equal. Therefore, we think it is most reasonable to look to our experiment's major differences to explain the increasing failure of participants to coordinate on payoff-dominant equilibria. Despite the rich evidence supporting continuous time and asynchronous environments as efficiency-enhancing, we suspect that either of these factors or the third, non-forced decision making, may have overwhelmed the other efficiency-enhancing factors built into the experiment.

Conclusion

In an internet-enabled, computer-run coordination experiment, we show spontaneous group formation and differentiation. We also use functional network methods from computational neuroscience to document the fine scale structure of coordination failure in the face of many established determinants of coordination success. Within the experiment's controlled factors, we support previous claims with regard to the efficiency effects of payoff changes and uncertainty, but in the greater context of a coordination failure that increases over time.

Learning from Failures for Cognitive Flexibility

Abstract

Cognitive flexibility is an important goal in the computational modeling of higher cognition. An agent operating in the world that changes over time should adapt to the changes and update its knowledge according to them. In this paper, we report our progress on implementing a constraint-based mechanism for learning from failures in a cognitive architecture, ICARUS. We review relevant features of the architecture, and describe the learning mechanism in detail. We also discuss the challenges encountered during the implementation and describe how we solved them. We then provide some experimental observations and conclude after a discussion on related and future work.

Keywords: cognitive architecture, constraints, constraint violations, learning from failures, skill acquisition

Introduction

In computational models of higher cognition, it is important to simulate the broad human functionality that we call *adaptability* or *flexibility*. Cognitive flexibility is, of course, a multi-dimensional construct, but in this paper, we focus specifically on the ability of humans to act effectively when a familiar task environment is changing, thus rendering previously learned skills ineffective or obsolete.

Traditionally, researchers discussed two types of error correction mechanisms for this problem. *Weakening* (Anderson, 1983, pp. 249–254) assumes that certain knowledge structures like rules, skills, schemas, or chunks have strengths associated with them, and it decreases the strength of the particular structure that generates a negative outcome. However, actions themselves are not typically correct or incorrect, or appropriate or inappropriate. Instead, they are appropriate, correct or, useful in some situations but not in others. The goal of learning from failure is thus to distinguish between the class of situations in which a particular type of action will cause errors and the class of situations in which it does not. Weakening does not accomplish this, because lower strength makes an action less likely to be selected in all situations.

Another mechanism proposed for error correction is *discrimination* (Langley, 1987). The key idea behind this contribution is to compare a situation with a positive outcome and another with a negative outcome to identify discriminating features. If an action generates both positive and negative outcomes across multiple situations, the system identifies any features that were true in one situation but not in the other, and uses them to constrain the applicability of the action. But the computational discrimination mechanism also has several problems including: the lack of criterion for how many instances of either type are needed before a valid inference as to the discriminating features can be drawn; the possible

existence of a very large number of potential discriminating features, leading to complex applicability conditions or large numbers of new rules or both; and the inability to identify potential discriminating features with a causal impact from those of accidental correlation.

In response, Ohlsson (1996) developed a *constraint-based specialization* mechanism for learning from negative outcomes. The production system implementation of the mechanism overcomes most of the weaknesses of previous methods. It assumes that the agent has access to some declarative knowledge in the form of *constraints*, which consist of an ordered pair with a relevance criterion and a satisfaction criterion. The system matches the relevance criteria of all constraints against the current state of the world on each cycle of its operation. For constraints with matching relevance conditions, the system also matches the satisfaction conditions. Satisfied constraints require no response, but violated constraints signal a failed expectation due to various reasons including a change in the world or erroneous knowledge. This constitutes a learning opportunity, and the system revises the current skill in such a way as to avoid violating the same constraint in the future. The computational problem involved here is to specify exactly how to revise the relevant skill when an error occurs, and the constraint-based specialization provides a solution to this problem.

Unlike weakening, the constraint-based approach identifies the specific class of situations in which an action is likely (or unlikely) to cause errors. It also differs from the discrimination method, and the mechanism does not carry out an uncertain, inductive inference. Instead, it computes a rationally motivated revision to the current skill. However, these advantages were limited by a simplistic credit/blame attribution algorithm and the lack of serious architectural supports like other learning mechanisms that can operate in parallel. In this paper, we adapt the constraint-based specialization mechanism to a cognitive architecture, ICARUS, and address these limitations. The architecture features hierarchical knowledge structures, and it has a variety of well-developed capabilities including learning from positive outcomes (Langley & Choi, 2006). We first review the relevant features of the ICARUS architecture, and describe the constraint-based specialization mechanism in some detail. Then we identify the challenges we encountered during the implementation in ICARUS, with a particular attention to the credit assignment problem. Finally, we report some experimental observations with the system, and discuss related and future work.

The ICARUS Architecture

Cognitive architectures aim for a general framework for cognition. They include a set of hypotheses covering representation, inference, execution, learning and other aspects of cognition. Soar (Laird et al., 1986) and ACT-R (Anderson, 1993) are some of the well-known cognitive architectures, and the ICARUS architecture exhibits some similarities to them but has some important differences as well (Langley & Choi, 2006). In this section, we review the fundamental aspects of the architecture before continuing our discussion to the specifics of learning from failures in this framework.

Representation and Memories

ICARUS distinguishes conceptual and procedural knowledge. Concepts describe the environment, and enable the system to infer beliefs about the current state of the world. Skills, on the other hand, consist of procedures that are known to achieve certain goals. The architecture also distinguishes long-term, abstract knowledge and short-term, instantiated structures. Long-term concepts and skills are general descriptions of situations and procedures, and the system instantiates them before applying them to a particular situation. Instantiated concepts and skills are short-term structures, in that they are applicable only at a specific moment. ICARUS has four separate memories to support these distinctions.

The architecture encodes concepts with definitions that are similar to Horn clauses. They consist of a head and a body that includes perceptual matching conditions or references to other concepts. Table 1 shows some sample concepts. The first concept has a head, `(same-color ?block1 ?block2)`, and specifies perceptual matching conditions among the variables involved in its `:percepts` and `:tests` fields. It is a *primitive* concept, which does not have any reference to other concepts. The second concept also has a head and some perceptual matching conditions, but it has references to other concepts in the `:relations` field, and therefore, it is a *non-primitive* concept.

<code>(not</code>
<code>(same-color ?block1 ?block2)))</code>

On the other hand, ICARUS' skills resemble STRIPS operators. The head of each skill is the predicate it is known to achieve, and therefore, all skills are indexed by their respective goals. Each skill has a body that consists of perceptual matching conditions, some preconditions, and either direct actions to the world or references to its subgoals. Like in con-

cepts, skills with no references to any subgoals are *primitive*, while the ones with them are *non-primitive*. The hierarchical organization provides multiple layers of abstraction in the specification of complex procedures.

In Table 2, the first skill indexed by its goal `(stacked ?block ?to)` has some perceptual matching conditions and a precondition, `(stackable ?block ?to)`. It includes several direct actions in the world (marked with asterisks), and therefore, it is a primitive skill. The second skill, however, is a non-primitive one, with references to subgoals, `(stackable ?block1 ?block2)` and `(stacked ?block1 ?block2)`. The subgoals are ordered, and they invoke other skills that achieve them. For instance, the second subgoal will invoke skills like the first example in the table. In this manner, ICARUS's skills are hierarchically organized.

Inference and Execution

The ICARUS architecture operates in cycles. On each cycle, the system instantiates its long-term concepts based on the current situation. The bottom-up inference of concepts creates beliefs in the form of instantiated conceptual predicates. The inference process starts with the perceptual information about objects in the world. The system attempts to match its concept definitions to the perceptual information and, when there is a match, it instantiates the head of the definitions to compute its current beliefs.

Once the architecture computes all its beliefs, it starts the skill retrieval and execution process. ICARUS' goals guide this process, and the system retrieves relevant long-term skills based on the current beliefs. When it finds an executable path through its skill hierarchy, from its goal at the top to actions at the bottom, ICARUS executes the actions specified at the leaf node of the path. This execution, in turn, changes the environment, and the system starts another cycle by inferring the updated beliefs from new data received from the environment.

Problem Solving and Learning

During the execution for its goals, the architecture sometimes encounters a situation where it can not find any executable skill path. When this happens, ICARUS invokes its means-ends problem solver, chaining backward from its goal. It at-

tempts to use two types of *chains*, a skill chain that uses a goal-achieving skill with unsatisfied preconditions and a concept chain that decomposes the goal into subgoals through concept definitions. Once the system finds a subgoal with an executable skill during this process, it immediately executes the skill and continue to the next cycle until it achieves all the top-level goals.

When the architecture finds a solution and achieves a goal (which includes both the top-level goals and any of their subgoals), it learns new skills from the successful problem solving trace. The learned skills differs in their forms based on the type of the problem solving chain. Further discussions on the problem solving and learning capabilities would require more space than we can afford here, but Langley and Choi (2006) covers all the details. In the subsequent sections, we explain the details of the constraint-based specialization mechanism and its implementation in ICARUS.

Learning from Failures

As described in the previous section, ICARUS has hierarchically organized skill knowledge and it can learn from positive outcomes through problem solving. However, the architecture can not adapt to environmental changes when some of its existing skills become incorrect or obsolete. Extending ICARUS with the constraint-based specialization mechanism provides this capability.

Representation of Constraints

The extended architecture stores each constraint as a pair of relevance and satisfaction conditions, following Ohlsson and Rees (1991). Both relevance and satisfaction conditions are conjunctions of predicates, and the ICARUS architecture keeps a list of such pairs in a separate constraint memory.

Table 3 shows some sample constraints we use in the Blocks World domain. For convenience, we store each pair with a name like *color*, *top-block*, or *width*. The first constraint, *color*, says that two blocks should have the same color when they are stacked, which, in effect, enforces all towers to have a single color. Similarly, the other two constraints mean that a block that is designated as a *top-block* should always be clear, and that a block on top of another block should be smaller than the one below, respectively.

Table 3: Some sample constraints for the Blocks World.

(color	:relevance	((on ?a ?b))
	:satisfaction	((same-color ?a ?b)))
(top-block	:relevance	((top-block ?b))
	:satisfaction	((clear ?b)))
(width	:relevance	((on ?a ?b))
	:satisfaction	((smaller-than ?a ?b)))

Detection of Constraint Violations

On each cycle, the system checks if the current belief state satisfies all the constraints. It first attempts to match the relevance conditions of its constraints against the current state,

and, if a match is found, verifies that the satisfaction conditions also hold. When it finds an unsatisfied constraint, it attempts to revise the skill that caused this violation.

We distinguish two different types of constraint violations. In the first type, a constraint just becomes relevant after an action but not satisfied at the same time. For instance, when an agent stacks a red block, *A*, on top of a blue block, *B*, it achieves (on *A B*), so the corresponding instance of the color constraint in Table 3 matches and the constraint becomes relevant by the stacking action. But the satisfaction condition, (same-color *A B*), is not met in this case, because one of the blocks is red and the other is blue. We refer to violations like this as *type A* violations.

Another type of violations, which we call *type B* violations, involves a constraint that has been relevant and satisfied, but becomes unsatisfied as a result of an action while it still stays relevant. An example of this type occurs when an agent stacks a block *C* on top of a block *TB* that is designated as a top block. In this case, the top-block constraint stays relevant before and after the stacking action, since the predicate, (top-block *TB*) continues to hold. But the satisfaction condition, (clear *TB*) becomes false as a consequence of the action, and the constraint is violated.

Skill Revisions

Once the system detects constraint violations of either type, it randomly chooses one of them and attempts to make revisions to the skill it just used. The revision process shares its basic steps with those used in previous research (Ohlsson, 1996; Ohlsson & Rees, 1991). The goal of this process is to constrain the application of the skill to situations in which it will not violate the constraint.

For a type A violation, where a constraint becomes relevant but violated, one of the revisions forces the constraint to stay irrelevant, and the other ensures that it is both relevant and satisfied. On the other hand, a type B violation, in which a constraint stays relevant but becomes violated, invokes one revision that makes sure the constraint is irrelevant, and another that restricts the use of the skill to cases where the satisfaction is not affected.

The system revises skills by adding preconditions, and Table 4 shows how the system computes the new preconditions for the two types of violations. C_r and C_s represent the relevance and satisfaction conditions. O_a and O_d are the add and delete lists of the executed primitive skill. The rationale for these computations has been developed in detail in prior publications (Ohlsson, 1996; Ohlsson & Rees, 1991).

As an example, let us revisit the Blocks World cases. In the first case, we have a red block, *A*, and a blue block, *B*. The system executes an instance of the first skill shown in Table 2, (stacked *A B*), which adds the predicate to the state. This implies that the relevance condition of the color constraint, (on *A B*) also becomes true, but the satisfaction condition (same-color *A B*) does not. When detecting this type A violation, the system computes additional preconditions and attempts to make two revisions. The first calculation, $\neg(C_r -$

Table 4: New preconditions created in response to constraint violations.

Type \ Revision	1	2
A	$\neg(C_r - O_a)$	$(C_r - O_a) \cup (C_s - O_a)$
B	$\neg C_r$	$C_r \cup \neg(C_s \cap O_d)$

O_a), leads to $(\text{on } A \ B) - (\text{stacked } A \ B)$, which results in a null precondition. Therefore, the system ignores the first revision and tries the second one. This time, the additional precondition comes from $(C_r - O_a) \cup (C_s - O_a)$, which leads to $(\text{same-color } A \ B)$. The system adds this precondition to the skill that caused the violation, and restricts the execution of the stacking action to the case where two blocks have the same color.

In the second case, we have two blocks, C , and TB . When the system stacks the block C on top of the block TB using the skill $(\text{stacked } C \ TB)$, the top-block constraint becomes unsatisfied ($(\text{clear } TB)$ not true in the state) while it stays relevant continuously ($(\text{top-block } TB)$ true in the state). Upon detecting this type B violation, the system computes two sets of additional preconditions using the formulas, $\neg C_r$ and $C_r \cup \neg(C_s \cap O_d)$. These lead to $(\text{not } (\text{top-block } TB))$ and $((\text{top-block } TB) (\text{not } (\text{clear } TB)))$, respectively, which are added to two separate revisions of the skill. The first revision prevents the use of the stacking action onto a block designated as a top-block. The second revision is a case of over-specialization, which makes it impossible to fire. Nevertheless, the two revisions achieve the proper restriction of the skill for the top-block constraint.

Challenges in Implementation

Although this implementation in the context of ICARUS shares the basic steps with previous systems using constraint-based specialization, various important differences between the ICARUS architecture and production system architectures require some significant changes in the revision process. In this section, we discuss the challenges and our solutions to them.

Hierarchical Organization

First of all, ICARUS' hierarchical organization of skill knowledge poses the most significant change, in relation to the assignment of blame. Production systems have flat structures, and it is mostly the case that the last executed rule caused a violation. But in ICARUS, execution involves a skill path, which may include more than one skill instance. Skill instances near the top of the path are more abstract, and those close to the bottom are more specific. Depending on the level of abstraction at which the violated constraint exists, the skill that needs to be revised can be anywhere on this path, and no simple attribution rule will be sufficient. So, the question is how ICARUS can identify the right skill to revise generally.

An analysis of multiple examples indicates that the architecture should find the highest level in the skill path in which all the variables involved in the additional preconditions for the revision are bound. All the additional preconditions are fully instantiated at this level and, therefore, it is the highest level in which the preconditions become meaningful. This makes it the right level at which to make the corresponding revisions. The results of running ICARUS indicate that this solution is correct. This solution is easily computable and general across domains. The possibility that it applies to other types of hierarchical systems might deserve attention.

Add and Delete Lists

Another problem occurs during the computation of the additional preconditions for skill revisions. Unlike production systems that have explicit and complete add and delete lists associated with actions, the ICARUS architecture has skills associated with goals. Goals typically do not include any side effects we do not care about, and they do not specify any predicates that should disappear after a successful execution. For this reason, the add and delete lists are not explicit in the architecture, and we must compute them from other sources.

Meanwhile, the use of add lists during the revision process is limited to the calculation of logical differences, and we can use goals as if they represent complete add lists. This will make the revised skill more restrictive rather than less so, thus making it safe. However, we should compute the delete list explicitly because of the way it is used during the revision process. We chose to calculate the list by comparing two successive belief states, although this may include some predicates removed by sources external to the agent. Again, however, this makes the revisions more restrictive, rather than more general, keeping the agent safe, because the delete list is negated during the computation of preconditions.

Disjunctive Definitions

ICARUS' support for multiple, disjunctive definitions of concepts adds another layer of complexity. When computing additional preconditions for skill revisions, the system should decompose any non-primitive concepts. Disjunctive concepts create multiple expansions, possibly resulting in more than one set of additional preconditions. The architecture accepts all such expansions and create multiple revisions.

The consequences of this approach are significant. When the system experiences a constraint violation, the situation might involve a particular disjunction of a concept. Nevertheless, the architecture learns multiple revisions from this case, covering all possible disjunctions of the concept. This approach is based on the understanding that there is a good reason why the disjunctive concepts have the same head, and that the system benefits from learning about all such cases. In future tasks, the system might confront a situation in which another one of the disjunctions applies, and, due to its prior learning, the system will already know how to avoid making an error in this situation even though it has never encountered it before.

Experimental Observations

To verify that the system works as intended, we performed experiments in two domains. We give only the basic concept and skill sets to the system at the beginning, along with the information on constraints. This means that the system knows how to operate in the world, but not at the level of expertise that enables it to satisfy the constraints at all times. It is as if humans sometimes know what should happen and what should not, but do not necessarily know how to impose these rules and often make mistakes. As the system learns from its failures, it revises the basic skills to avoid constraint violations in the future.

Blocks World

We modified the familiar Blocks World from the typical setup to include blocks of different colors and sizes. This modified domain supports various constraints like the color and size of the blocks in a tower or the maximum height of each tower. Table 3 shown earlier includes three of the constraints we have in this domain. The *color* constraint says whenever a block is stacked on top of another the two blocks should have the same color. This, in effect, forces any tower to have only the blocks of one color. The *top-block* constraint means any block designated as a top block (according to the system's conceptual knowledge) should always be clear, having no other blocks on top. The last constraint, *width* enforces that a block is smaller than the block underneath it.

Figure 1: Number of simulated subjects that violated a constraint at each trial.

We ran simulation experiments with several different goals, and Figure 1 shows the result from one of them. In this experiment, we had ten simulated subjects, and each subject performed ten trials of the given task. We recorded the number of subjects that violated any constraints during each trial. The graph clearly shows that the revision process gradually reduces the number of the simulated subjects with constraint violations.

Route Generation

Another domain we used to test the system is a simplified version of route generation between places. Here, in addition to testing the specialization mechanism in ICARUS, we also want to verify that the mechanism can operate in parallel to other learning schemes like learning from success. The agent starts at a certain location, and has the goal of getting to a target location elsewhere. Using the information on connections between neighboring locations, the system performs problem solving to find a route to its target. As a result, it finds one of the several possible routes that involve different waypoints, and ICARUS learns specific route knowledge from this positive experience.

But some of the routes might become unavailable for travel due to various reasons like a broken bridge. At subsequent runs, the agent encounters situations where it can not use routes it learned before. While attempting to get to the target using a learned route, ICARUS recognizes that it gets stuck at a location with no outlet, violating a constraint not to be at a dead end. This failure triggers the system to learn a revised skill, which prevents it from moving to a location without any outlet. On the next trial, armed with this new skill, the system attempts to find another route to get to its target, and learns a skill for an alternate route for later use.

Let us see this behavior in a sample run. We give the system a goal to get to a target location, *B*, starting from the initial location, *A*. The two locations are connected by two alternate routes using waypoints *W1* and *W2*, respectively. The system starts out with two concepts and a skill as shown in Table 5. It also has the connection information between the locations, *A*, *B*, *W1*, and *W2* as some static beliefs. The only constraint it knows of is,

(at ?location) \rightarrow (not-dead-end ?location)

which simply says that it should not be at a dead end at any time. During the first trial, the system finds a path, *A* - *W1* - *B* through problem solving, and learns a specific skill for this route. Before we continue to the next trial, we intentionally remove the connection between *W1* and *B*, making the path obsolete. On the next trial, the system attempts to reuse the path, but it finds that it violates the constraint while it is at location *W1*. This violation triggers a revision process, resulting in another new skill. Once the system learns this new skill, it attempts to find an alternate route through yet another problem solving process, resulting in the path, *A* - *W2* - *B*. After ICARUS stores this route as a specific skill, it executes the skill when it encounters the same task at a later time.

Related and Future Work

The current work on the constraint-based specialization has important similarities to some work in the explanation-based learning (EBL) literature (see Ellman, 1989; Wusteman, 1992 for reviews). EBL methods assume a significant amount of domain theories presumed to be perfect. However, in most of the domains, this is not true, and they require some ways

Table 5: Two concepts and a skill given to ICARUS for the route generation domain, and the two skills the system learned. The first skill is learned from problem solving (marked as P-S), and the other is learned from constraint-based specialization (marked as C-S). The additional precondition in this skill is shown in bold face.

Given:	<pre> (at ?location) :percepts ((self ?self location ?location))) (not-dead-end ?location) :percepts ((location ?location)) :relations ((connected ?location ?to1) (connected ?location ?to2)) :tests ((not (equal ?to1 ?to2))) (at ?location) :percepts ((location ?from)) :start ((at ?from) (connected ?from ?location)) :actions ((*move-to ?location))) </pre>
Learned from P-S 1:	<pre> (at B) :subgoals ((at W1) (at B)) </pre>
Learned from C-S:	<pre> (at ?location) :percepts ((location ?from)) :start ((at ?from) (connected ?from ?location) (not-dead-end ?location)) :actions ((*move-to ?location))) </pre>
Learned from P-S 2:	<pre> (at B) :subgoals ((at W2) (at B)) </pre>

to augment or correct the domain theories. There, researchers worked on the similar problems of blame assignment and theory revision, although the exact formulations were different. Unlike most of these work, our approach uses explicit descriptions of constraints, which the system uses to detect failures and revise existing theories accordingly.

With the successful implementation of the constraint-based specialization mechanism in ICARUS, we are able to study the important problem of interactions between two learning mechanisms. People learn in a variety of ways (Ohlsson, 2008) and human-level flexibility is the outcome of the interactions among multiple learning mechanisms. Currently, we have only a limited understanding of how learning mechanisms interact to produce flexible behavior. We intend to add additional mechanisms to ICARUS, including learning from examples or from analogies, and explore the conditions under which multiple mechanisms produce more flexible behavior than individual mechanisms.

Another key problem is how to interleave thinking (search in a mental, symbolic problem space) and action (search in an external, physical environment). The two types of processes differ in a variety of ways, most importantly in that a return to a previous state can be achieved by fiat in the internal search space, but has to be accomplished through physical action in the external environment. We intend to experiment with multiple schemes for controlling the interleaving in multiple task domains.

Conclusions

An intelligent agent cannot be limited to learning from positive experience. When task environments change, the extrapolation of prior experience to cover future situations inevitably leads to errors, mistakes and unacceptable outcomes. To exhibit human-level flexibility, an artificial agent needs learning mechanisms that specify how to change in the face of such negative outcomes. The constraint-based specialization mechanism provided this capability in a production system framework before, and we implemented it with the hierarchical skill representation in the ICARUS architecture successfully, after resolving multiple conceptual problems. We performed some test runs in the Blocks World and a navigation domain, and found the mechanism successfully removes failures after revisions. We also verified that the mechanism works well in parallel to another learning mechanism, allowing further study of human level flexibility in this direction.

Abstract

Recently, researchers have suggested that when we see an object we automatically represent how that object affords action (Tucker & Ellis, 2001). However, the precise nature of this representation remains unclear: is it a specific motor plan or a more abstract response code? Furthermore, do action representations actually influence *what* we perceive? In Experiment 1, participants responded to an image of an object and then made a laterality judgment about an image of a hand. Hand identification was fastest when the hand corresponded to both the orientation and grasp type of the object, suggesting that affordances are represented as specific action plans. In Experiment 2, participants saw an image of a hand before interpreting an ambiguous object drawing. Responses were biased towards the interpretation that was congruent with the grasp type of the hand prime. Together, these results suggest that action representations play a critical role in object perception.

Keywords: object perception; motor affordances

Background

Traditional approaches to visual perception have assumed that the primary goal of the visual system is to construct a detailed internal picture of the external world based on a noisy retinal image (e.g. Marr, 1980). Recently, however, there has been a growing appreciation for the possibility that visual perception may be equally concerned with how we move around and act in our environment (Milner & Goodale, 1995). The idea that vision and action are intimately linked can be traced to the ecological psychology of James Gibson (1979), who argued that organisms see the world in terms of how it affords *action*. While Gibson eschewed the notion of mental representation, contemporary scholars have suggested that visual perception may be at least partially characterized by a mental representation of the *affordances* in the environment (Tucker & Ellis, 1998). For example, seeing the coffee mug on the desk before me might involve mentally representing how I could reach out and grasp it in order to drink from it. However, the precise nature of these affordance representations and how they relate to object perception remains unclear.

Several researchers have suggested that affordances are represented as action plans in the motor systems of the brain (e.g. Tucker & Ellis, 1998; Chao & Martin, 2000). Tucker and Ellis conducted a series of studies to test whether people automatically generate a motor representation in response to the visual presentation of an object, even when there is no intention to act on the object (e.g. Tucker & Ellis, 1998,

2001). In one experiment, participants had to make a left or right-handed button press to indicate whether an image of an object on the screen was upright or inverted. The objects were chosen to have clear right or left-handed affordance (e.g. a frying pan with a handle oriented to the left affords a left-handed grasp). Participants responded faster and made fewer errors when their responding hand was congruent with the (task-irrelevant) affordance of the object on the screen. Similar stimulus/response compatibility (SRC) effects have been obtained for other types of *micro-affordances*, such as *grasp type* (Tucker & Ellis, 2001) and *wrist orientation* (Tucker & Ellis, 1998).

Others have argued that the motor representations activated when we observe an object form an integral part of our perception of the object (e.g. Helbig, Graf, & Kiefer, 2006). For example, Helbig et al. (2006) presented participants with images of two objects in quick succession. Participants were more accurate in naming the second object when similar actions were required to make use of two objects (e.g. pliers and a nutcracker). These findings raise important questions regarding, (1) the level at and specificity with which affordance information is represented, and (2) the potential causal role this information plays in the process of object perception.

For instance, several researchers have argued that the SRC effects obtained by Tucker and Ellis actually reflect abstract response coding rather than specific motor plans (e.g. Anderson, Yamagishi, & Karavia, 2002). Indeed, even Tucker and Ellis (2001) suggested that these effects could not be explained by appealing exclusively to the neural systems responsible for the on-line control of actions because they were obtained using both images of objects as well as real-world objects that were out of reach of participants. Rather, affordance representations might be more abstract, specifying, for example, the general class of hand shape required to interact with an object rather than precise motor parameters. Further, while the results of Helbig et al. (2006) are consistent with motor affordance representations contributing to object perception, the data could also be explained by the fact that objects that are used in similar ways are typically similar to one another in other ways as well (e.g. semantically).

In this paper we describe two experiments designed to address these issues. First, we wanted to know whether motor affordances might be represented as specific action plans for interacting with an object rather than as abstract response codes. To this end, in Experiment 1 we made use of a dependent measure that is known to draw on very

specific manual action representations, namely the hand identification task (Parsons, 1987). Previous work has shown that the time it takes to identify whether an image is of a left or right hand is directly proportional to the time it would take, and how difficult it would be, to rotate your own hand into that position (Parsons, 1987). In our study, participants first made a response towards an image of an object that afforded a particular grasp type and wrist orientation. They then saw an image of a hand and had to indicate whether it was a right or left hand. If seeing an object leads to the activation of a specific manual action representation, participants should be faster to respond to an image of a hand that matches that object on grasp type and wrist orientation.

Second, we investigated the possibility that action representations actually contribute to the perceptual representation of objects. In Experiment 2, participants were first primed with an image of a hand depicting a specific grasp type. They then saw a drawing of an ambiguous object and had to indicate what they thought it was. The object could be interpreted as affording a power grasp (e.g. a football) or a precision grasp (e.g. a coffee bean). Responses were biased towards the interpretation that was congruent with the primed hand. We also included a control condition designed to rule out task demand and memory-based explanations of our findings. Together, these results suggest that action representations play a critical role in object perception.

Experiment 1

What motor information becomes activated when we look at an object? Previous research suggests that abstract response codes representing individual micro-affordances such as *grasp type* or *wrist orientation* become activated during object perception (Tucker & Ellis, 2001). Experiment 1 makes use of a novel application of the hand identification task in order to test the specificity of motor representations activated during object perception. Participants first made judgments on an image of an object that afforded a particular grasp type (power, precision, or no grasp affordance) at a particular wrist orientation (upright or inverted). Then they made laterality judgments on an image of a hand that was configured in a particular grasp type (power or precision) at a particular orientation (upright or inverted). To the extent that viewing objects activates specific manual motor plans selective for both grasp type and wrist orientation, laterality judgments should be fastest when *both* of the micro-affordances manipulated align between the images of the object and hand.

The degree to which various micro-affordances are activated during object perception might also depend on current goals (Bekkering & Neggers, 2002). Experiment 1 was designed to test whether viewing objects activates motor plans more strongly when participants make grasp-related compared with grasp-unrelated judgments about the objects. Similar reaction time profiles between these conditions would suggest that motor affordances are

activated automatically during object perception, regardless of current task goals. Conversely, differences in reaction time profiles between the grasp-related and grasp-unrelated conditions would suggest that the current task goals do affect the kind of motor representation activated.

Methods

Participants Sixty-eight right-handed individuals from the Stanford community were recruited to participate in this study in exchange for payment or class credit.

Stimuli Object Images: Objects used in Experiment 1 varied on two dimensions: required *grasp type* (power, precision, or none) and required *wrist orientation* (upright or inverted). The dimensions were fully crossed within-subjects to produce 6 different object types. Two power grasp objects (flashlight and glass), two precision grasp objects (pushpin and tweezers), and four objects with no grasp affordance (desk, bookcase, grandfather clock, and sofa) populated the object categories. Hence, participants saw 16 unique images, each of which was repeated 32 times for a total of 512 object presentations.

The object stimuli were designed to afford right-handed responses because we recruited exclusively right-handed participants. The upright version of each object faced upward and to the left so as to afford an upright right-handed grasp on the part of the observer. The upright version of each object was rotated 90 degrees counter-clockwise in order to create the inverted version, which faced down and to the left. Pilot testing confirmed that right-handed individuals most often reached for real-world objects in both the upright and inverted orientations with their right hands.

Hand Images: The hand images varied on three dimensions: *grasp type* (power or precision), *wrist orientation* (upright or inverted), and *laterality* (left or right). The dimensions were fully crossed within-subjects to produce 8 different hand types. Four images of hands producing a power grasp and four images of hands producing a precision grasp were used to populate each of the hand categories. Hence, participants saw 32 unique hand images, each of which was repeated 16 times for a total of 512 hand presentations. The upright and inverted right and left hand images were generated using the same process described above for the upright and inverted object images.

	Object Grasp Affordance			Hand Grasp	
	power	precision	none	power	precision
upright					
inverted					

Figure 1: Sample stimuli from Experiment 1

Procedure Each trial in Experiment 1 had two parts. Participants first responded to a picture of an object and then to a picture of a hand. Participants were randomly assigned to one of two conditions: an *Orthogonal Judgment Condition* and a *Non-orthogonal judgment condition*. In the Non-orthogonal Condition, participants made a grasp-related judgment in response to each object (“Can you pick it up with one hand?”). In the Orthogonal Condition, participants made a grasp-unrelated judgment in response to each object (“Is it smaller than a shoebox?”). In both conditions, participants pressed the “j” key with their right index finger to enter a “yes” response, and the “f” key with their left index finger to enter a “no” response. Participants were told to respond as quickly and accurately as possible. Each object in Experiment 1 was preceded by a 500 ms fixation period. The image remained on the screen until the participant responded or the 10-second deadline expired, at which point the trial advanced to the hand portion.

Each hand image was preceded by a 500ms fixation period. Participants pressed the “j” key with their right index finger for pictures of right hands, and pressed “f” with their left index finger for pictures of left hands. The experiment advanced when the participant entered a response or at the end of the 10-second deadline. A black screen appeared for 750 ms to mark the end of each trial. The 16 unique object images were fully crossed with the 32 unique hand images to generate 512 unique experiment trials, each of which participants saw only once.

Results

The data from eight participants were removed because they did not contribute to all cells in the analysis or they had extremely high error rates or reaction times.

Trials analyzed: Only trials in which participants made correct responses to both the object and hand images were analyzed, resulting in the exclusion of 13.4% of trials. Any response times faster than 200 ms. or slower than 5000 ms. were omitted from all analyses, resulting in the removal of 1.4% of remaining trials across conditions. Finally, the stimuli used in Experiment 1 were designed to elicit right-hand affordances from right-handed individuals. As a result, only images of right hands were analyzed.

Coding: In ‘Orientation Match’ trials the orientation of the object was identical to that of the subsequent hand (collapsing across upright and inverted images). In ‘Orientation Mismatch’ trials the orientation of the object differed by 90 degrees in angular rotation from that of the subsequent hand.

RT Analyses: Figure 2 illustrates the mean pairwise RT differences (Orientation Match – Orientation Mismatch) across all levels of Object Affordance (power, precision, none) and Hand Stimulus (power, precision). Negative difference scores suggest a match advantage with respect to orientation. Positive difference score suggest a mismatch advantage with respect to orientation. The difference scores were submitted to a 3 (Object Affordance: power, precision, none) x 2 (Hand Stimulus: power, precision)

repeated measures ANOVA. The analysis produced no main effects of object affordance ($F(2,57)=1.53$, ns) or hand stimulus ($F(1,58)=0.436$, ns), but a reliable quadratic interaction between the two variables ($F(1,58)=13.14$, $p<0.001$).

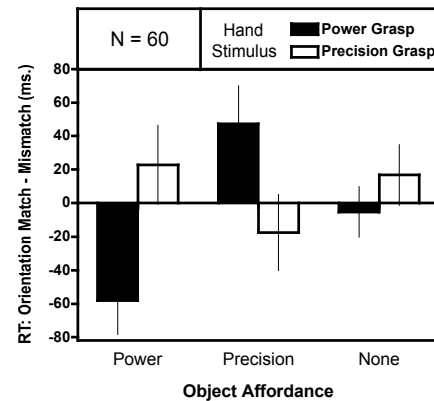

Figure 2: Differences in reaction time (Orientation Match – Mismatch) to the hand stimulus in Experiment 1. Error bars reflect the SE of the mean for each cell.

Participants showed a reliable match advantage to images of hands in a power grasp after having seen an object affording a power grasp ($M=-58$ ms, $SD=158$) compared to having seen an object with no manual action affordance ($M=-5$ ms, $SD=116$) ($t(59)=-2.31$, $p<0.05$). Conversely, participants showed a reliable mismatch advantage to images of hands in a power grasp after having seen an object affording a precision grasp ($M=47$ ms, $SD=177$) compared to having seen an object with no manual action affordance ($M=-5$ ms, $SD=116$) ($t(59)=2.05$, $p<0.05$). Images of hands in a precision grasp showed analogous trends, but none of the relevant comparisons reached significance (all $p>0.2$). This may be due to the fact that these hands were harder to correctly identify and thus they produced more errors and more variance in RT compared to grasp hands. The effect of orientation for hands in a precision grasp did, however, differ from the effect of orientation for hands in a power grasp both when the preceding object required a power grasp ($M=22.80$, $SD=23.51$) ($t(59)=-2.58$, $p<.05$) and when the preceding object required a precision grasp ($M=-17.54$, $SD=22.63$) ($t(59)=2.05$, $p<.05$).

The data appear to follow a Mexican hat distribution (Muller et al., 2005), such that reaction times *increase* when the object affordance only somewhat overlaps with the hand stimulus and *decrease* when the two overlap entirely (relative to trials where the preceding object had no grasp affordance). To further test for such a distribution, trials were binned into five similarity-based categories (Figure 3). For each of the bins, the object affordance on a given trial relative to the subsequent hand stimulus was either: (1) same orientation and grasp type, (2) same grasp type only, (3) same orientation only, (4) different orientation and grasp type, or (5) had no grasp affordance. A repeated measures

ANOVA yielded reliable quadratic ($F(1,58)=8.04, p<0.01$) and cubic ($F(1,58)=6.05, p<0.02$) effects of similarity.

Figure 3: RT to hand stimuli in Experiment 1, binned by how similar the hand was to the set of manual affordances in the previous object

Finally, there was no main effect of the between-subjects condition (Task Goals: grasp-related, grasp-unrelated) ($F(1,58)=1.50, p>0.20$), nor did condition interact with the quadratic Object Affordance by Hand Stimulus interaction ($F(1,58)=2.81, p>0.10$) or the effect of similarity ($F(1,58)=1.76, p>0.15$). As a result, all analyses described above were run on the combined data from the two conditions.

Discussion

In this experiment we asked whether people generate a specific motor plan for interacting with an object when they see that object. RTs for the hand laterality judgment were fastest when the hand corresponded in both grasp type and wrist orientation to the previous object. This suggests that when we look at an object we represent the specific motor parameters necessary for interacting with that object. In other words, when we see a drinking glass we actually simulate reaching out and grasping it.

Interestingly, RTs for the laterality judgment were slowest when the object and hand corresponded in just one micro-affordance dimension (i.e. either grasp type *or* wrist orientation). Researchers have argued that similar reaction time profiles in classic vision and attention tasks suggest an underlying surround inhibition mechanism (Muller et al., 2005; Roeber, Wong, & Freeman, 2008), where activating a particular representation suppresses highly similar but not distantly similar representations. Importantly, motor cortex is believed to have the kind of connectivity that would support surround inhibition (Lukashin & Georgopoulos, 1993; Sohn & Hallett, 2004). Thus it is plausible that viewing an object in the present study activates a highly specific action representation, which in turn spreads inhibition to highly similar but not distantly similar action representations. These patterns of activation and inhibition would result in slower RTs to trials in which the images of the object and hand differ on one but not all dimensions, which is precisely what was found in Experiment 1.

Such connectivity further predicts a full Mexican hat-like distribution of response times such that the representations in similarity space just beyond the inhibited surround should see facilitation that tapers off as distance increases (Muller et al., 2005). That is, responses to hands preceded by objects that afford the wrong grasp in all dimensions should be faster than those preceded by objects that afford no grasp at all. The cubic effect of similarity found in Experiment 1 is driven by that very difference, suggesting a Mexican hat response time profile (Muller et al., 2005). Studies better designed to test for such a pattern are currently underway. As it stands, the pattern observed in Experiment 1 is consistent with the kind of connectivity believed to exist in motor cortex. Furthermore, the hand identification task used in this study was selected precisely because it is believed to be supported by specific motor regions. As a result, the present findings are consistent with the hypothesis that object perception activates highly specific action representations in the motor system and does so in a manner similar to the act of grasping itself.

Finally, varying participants' task goals when viewing the object had no significant effect on these results. Whether participants made a grasp-related ("Can you pick it up?") or grasp-unrelated ("Is it smaller than a shoebox?") judgment towards the object, the same affordance information appears to have been represented. This supports the original findings of Tucker and Ellis (1998), who argued that affordance information is represented irrespective of the intentions of the observer. However, other researchers have found effects of intentions on affordance representation (e.g. Bekkering & Neggers, 2002), and the effects in the present study tended to be more robust in the task-related than the task-unrelated condition, which suggests that more research is called for on this issue.

Experiment 1 supports the idea that motor affordances are represented as specific action plans in the motor system regardless of task goals. However, it is unclear how this action representation relates to our ability to actually perceive the object. We turn to this issue in Experiment 2.

Experiment 2

Does action representation contribute to object perception? One possibility is that the visual and motor aspects of object perception are fairly independent: extracting the visual features of an object occurs in one processing stream while extracting the affordance information relevant for action occurs in a different processing stream (Milner & Goodale, 1995). Alternatively, visual and motor processes may be more interdependent, and currently activated action representations might play a causal role in visual object processing. Experiment 2 was designed to test the latter possibility by priming participants with a specific manual action to see if it would affect their interpretation of an ambiguous object drawing. We also ran a control condition where we presented the ambiguous object image first in order to control for task demand or memory-based explanations for the data.

Methods

Participants 245 individuals from Amazon's Mechanical Turk website participated in exchange for payment.

Stimuli & Procedure The stimuli for this experiment included four photographs of hands taken from Experiment 1 and an ambiguous object line drawing created by the authors. The four hand photographs showed either left or right hands in either a power or precision grasp. Pilot testing suggested that the ambiguous object drawing could be interpreted as an object that afforded a power grasp (e.g. *football*) or as an object that afforded a precision grasp (e.g. *coffee bean*).

In the *experimental condition*, one of the four hand images was randomly selected for each participant and displayed on the screen for three seconds. After this, the ambiguous object drawing was displayed for three seconds. Then, participants were asked to name the object in the line drawing that they had just seen and to identify whether the hand they had seen was a left or right hand. The only difference in the procedure for the *control condition* was that participants were shown the ambiguous object image first and hand image second. Thus participants were not primed with an action representation prior to viewing the ambiguous object, but they saw the same two images prior to making their object interpretation response.

Figure 4: On the left, images of the left hand stimuli used in the experiment displaying precision and power grasps. On the right, the ambiguous object drawing.

Results

The data from 19 participants were removed because they failed to respond to the test questions appropriately ($N=8$) or because they took the survey more than once ($N=11$). We then coded the object interpretation responses for the remaining participants in terms of what sort of grasp would be afforded by the perceived object. We used the following coding scheme: Power (e.g. *football* or *coconut*), Precision (e.g. *coffee bean* or *nut*), and None (e.g. *lips* or any response that listed more than one interpretation).

Experimental Condition: For our analyses we collapsed across left and right hand prime stimuli and excluded object interpretation responses coded as *none*. A 2 (hand prime stimulus: power grasp vs. precision grasp) X 2 (perceived object affordance: power vs. precision) chi-square test of independence showed a significant relationship between hand prime stimulus and perceived object affordance, $\chi^2=7.04$, $p<0.01$. Participants primed with an image of a power grasp hand were more likely to interpret the ambiguous

image as an object affording a power grasp while participants primed with a precision grasp hand were more likely to interpret the ambiguous image as an object affording a precision grasp.

Figure 5: Experiment 2, *Experimental Condition*: Proportion of ambiguous object interpretations coded for perceived object affordance. Error bars are the SE of the proportion.

Control Condition: A 2 (hand stimulus: power grasp vs. precision grasp) X 2 (perceived object affordance: power vs. precision) chi-square test of independence showed no relationship between hand stimulus and perceived object affordance, $\chi^2=0.74$, $p>0.38$.

Interaction Analysis: A 2 (interpretation: congruent vs. incongruent) X 2 (condition: experimental vs. control) interaction analysis showed that hand stimuli only affected ambiguous object interpretations in the experimental condition, $\chi^2=4.05$, $p<0.05$.

Discussion

In this experiment we asked whether currently active motor representations would influence what participants saw when they looked at an ambiguous object. We found that when participants were primed with a hand displaying a power grasp they were more likely to interpret an ambiguous image as an object that afforded a power grasp (e.g. *football*). Conversely, when they were primed with a hand displaying a precision grasp, they were more likely to interpret the image as an object that afforded a precision grasp (e.g. *coffee bean*). This finding suggests that action representations can play a causal role in the process of object perception.

That said, there are a number of possible alternative explanations for these data. First, because of the simple design of this experiment, participants may have simply figured out what we wanted from them and tried to give it to us. The results of the control condition suggest that this is unlikely, however. In that condition, participants also saw both the ambiguous object and the hand stimulus prior to giving their object interpretation response, the only difference being they saw the ambiguous object first. If the results from the experimental condition were due to demand characteristics, we would expect to find the same pattern of results here. However, in the control condition there were

no such effects. This also helps rule out the possibility that the results of the experimental condition were due to associations in memory rather than the online effects of action representation on perception.

Finally, because we used purely visual stimuli in this experiment, it is possible that our results reflect visual priming rather than motor priming. While prior research has demonstrated that visually processing images of hands typically involves activating motor representations of one's own hand (Parsons, 1987), it is difficult to rule out visual priming as an explanatory mechanism at the present time. Research currently underway in our lab is moving away from visual prime images and towards actual motor movements as priming stimuli. Moreover, we are developing additional controls that include reversible images that do not afford grasping in order to rule out alternative mechanisms such as altered scanpaths or attentional patterns.

General Discussion

In this paper we explored the role that action representation plays in visual object processing. In Experiment 1 we took a bottom-up approach, asking whether we generate a specific motor plan or a more abstract response code when we observe an object with a particular set of manual affordances. Participants made a judgment about an image of an object that afforded a particular grasp type and wrist orientation. They then made a laterality judgment about an image of a hand displaying a particular grasp type and wrist orientation. RTs for the laterality judgment were fastest when the hand corresponded in both grasp type and wrist orientation with the previous object. This suggests that when we look at an object we represent the specific motor parameters necessary for interacting with that object within the motor systems of the brain.

Intriguingly, RTs for the laterality judgment were slowest when the object and hand corresponded in just one micro-affordance dimension (i.e. either grasp type *or* wrist orientation). This "Mexican hat" response time function has been found by other researchers studying motor representation in the brain (Loach, Frischen, Bruce, & Tsotsos, 2008; Lukashin & Georgopoulos, 1993; Sohn & Hallett, 2004), providing further support for the idea that affordances are represented as specific action plans in the motor system.

In Experiment 2 we took a top-down approach, asking whether activating a particular manual action representation would influence the perception of an ambiguous object image. The results suggest that action representations can play a causal role in the process of object perception.

All together, the results of these experiments suggest that action representation plays a crucial role in visual object processing. As we look around the world we are not merely constructing an internal picture of what's out there, we are also preparing to act and behave on what's before us. Furthermore, our current action state affects how we process the *what* that is out there.

Abstract

Explaining moral intuitions is one of the hot topics of recent cognitive sciences. In the present article we focus on a factor that attracted surprisingly little attention so far, namely the temporal order in which moral scenarios are presented. We argue that previous research points to a systematic pattern of order effects that has been overlooked until now: Only judgments of actions that are normally regarded as morally acceptable are affected by the order of presentation. Additionally, this is only the case for dilemmas immediately preceded by a scenario where the proposed action was judged as morally unacceptable. We conducted an experiment that confirmed this pattern and allowed us to analyze the individual level responses it was generated by. We argue that investigating order effects is necessary for approaching a complete descriptive moral theory.

Keywords: moral intuitions; trolley dilemmas; order effects

Introduction

In the past decades, trolley dilemmas have been used extensively for testing philosophical and psychological theories of moral judgments. In the standard description of the trolley dilemma introduced by Philippa Foot (1967), an out-of-control train threatens to kill five people standing on its track. The only way to prevent this is to pull a switch that redirects the train onto a different track where it will kill only one person. In a modification of this scenario (Thomson, 1976), the only possibility to prevent the five people from being killed is to push a heavy person from a footbridge onto the track. This would stop the train but kill the heavy person. Numerous studies (e.g., Hauser, Cushman, Young, Jin, & Mikhail, 2007) have shown that given the same number of people being killed vs. saved, participants approve of acting in the first but not in the second scenario. Several competing descriptive theories explicate psychological principles supposed to underlie this pattern of moral intuitions (e.g. Greene et al., 2001; Hauser, 2006). However, surprisingly little is known about potential effects of the order in which several consecutive scenarios are presented. It is plausible to assume that consecutive scenarios will not be judged independently of each other: A principle or mechanism that is activated when a particular scenario is represented or evaluated might later be applied to a series of subsequent scenarios. However, only few studies

have dealt with this issue so far (Petrinovich & O'Neill, 1996; Lanteri, Chelini, & Rizzello, 2008). Their results suggest that under certain circumstances moral judgments can indeed be transferred from one situation to another.

If such order effects could be replicated systematically, this would have important implications for psychological theories aiming to explain patterns of moral reasoning at a descriptive level. Furthermore, relevant practical implications would arise both for methodological considerations inside the research laboratory (in terms of controlling for order effects when designing experiments) and for everyday judgments outside the lab.

The present work has three main goals. First, we will provide the first comprehensive review of previous empirical research on order effects in moral judgments, and we will demonstrate that a systematic pattern of results has been overlooked so far. Second, we will empirically test the existence, extent and direction of order effects in reasoning about moral dilemmas. Finally, we will discuss the theoretical and practical implications of our findings, focusing on psychological theories of moral reasoning.

Order Effects in Previous Research

Speaking of order effects in moral judgment, there are at least two possible interpretations that could be labelled “within-scenario order effect” and “between-scenarios order effect”, respectively. The first type of effect results if the order in which information concerning one particular situation is presented affects judgment. If, for example, the task is to judge the permissibility of an action, and the results solely differ as a function of the particular sequence in which positive and negative consequences are presented, a “within-scenario order effect” occurs. Second, a judgment regarding an action in a particular scenario might be influenced by a judgment that had previously been made about a different scenario. To illustrate, consider two conditions in which a given scenario C is preceded by one of two different scenarios (A vs. B). Differences in judgments of the action scenario C between the two conditions would – all other things being equal – instantiate a “between-scenarios order effect”. The present research will focus on this second category of order effects.

One of the few studies addressing “between-scenarios order effects” in moral reasoning was conducted by Petrinovich and O’Neill (1996). Their aim was to analyze whether the presentation order of a set of moral dilemmas would affect participants’ level of agreement or disagreement with the action proposed in each case. In one condition (standard order), the dilemmas were arranged according to decreasing predicted agreement with the potential action, whereas in the second condition (reversed order) the presentation order was reversed. While Petrinovich and O’Neill (1996) did not report any order effects in an experiment comparing three dilemmas that differed with regards to content (Study 2, Forms 1 and 1R), a reanalysis of their data revealed an order effect for the dilemma with the highest predicted agreeability. In particular, the average agreement rating in this scenario was significantly higher if the scenario had been presented first than if it had been preceded by the other two dilemmas ($t_{57}=2.11$; $p<.05$, two-tailed). In contrast, the other two dilemmas received almost equally low ratings in both order conditions. A reanalysis of a similar experiment using a different set of dilemmas (Study 2, Forms 3 and 3R) also revealed that the average rating for one of the positively rated dilemmas varied between the two order conditions. The average rating was lower if the scenario had been directly preceded by a dilemma that received lower (as opposed to higher) ratings ($t_{68}=2.88$; $p<.01$, two-tailed).

Another experiment reported by Petrinovich and O’Neill (1996; Study 2, Forms 2 and 2R) compared three different versions of the trolley dilemma. As in the previously reported experiments, a reanalysis revealed order effects for the two scenarios with the highest predicted agreeability ($t_{57}=2.93$; $p<.01$, two-tailed, and $t_{57}=2.58$; $p<.05$, two-tailed, respectively). However, the third scenario that involved pushing a person from a footbridge in order to stop the train (cf. Table 1) was not affected by the order of presentation.

Similarly, Lanteri, Chelini, and Rizzello (2008) reported order effects for the standard trolley dilemma, but not for the footbridge scenario. In addition, similar order effects were found incidentally in some studies. For example, Nichols and Mallon (2006) found that acting in a case equivalent to standard trolley was marginally more likely to be judged as breaking a rule if the scenario was preceded by a footbridge-equivalent case than if presented in the first position. No analogous effects of a preceding standard trolley-equivalent case on judgments in the footbridge-like case were reported. Recently, Lombrozo (2009) incidentally found results analogous to those obtained by Lanteri et al. (2008). Finally, Alistair Norcross (2008) described an interesting order effect outside of an experimental setting that is nevertheless relevant for the present research. He points out that when he asked his students to evaluate the standard switch-trolley dilemma in the first position, the majority judged that diverting the trolley is permissible. However when this dilemma was preceded by a scenario in which saving the lives of five patients requires to kill a healthy person in order to transplant his organs, the

proportion of students judging that diverting the trolley is permissible was considerably lowered.

A Systematic Pattern

We claim that a closer look at the findings reported reveals a systematic pattern: First, all dilemmas that are affected by an order effect were rated positively (in the sense that the proposed action is on average rated as morally right/acceptable). Dilemmas that received a negative rating seem to be unaffected. Second, the dilemmas that were rated positively are only affected if they are directly preceded by a dilemma that was rated negatively. In this case, the ratings were lower or, in those cases in which the response format is dichotomous, the proportion of people that judge the action to be acceptable decreased.

Previous attempts to account for between-scenario order effects failed to fully capture the pattern we are suggesting here. For instance, Petrinovich and O’Neill (1996) argue that the initial strength of the response (agreement vs. disagreement) influences subsequent responses. If this were true, dilemmas that are normally rated negatively should also be affected by the order of presentation. However, this does not seem to be the case, since these dilemmas seem to be rated equally negative in all cases. Lanteri et al. (2008) take this asymmetry into account when explaining their results. However, they focus on properties of specific scenario contents instead of formulating a general pattern.

It is important to note that so far there is no evidence for a major change of people’s judgments at a qualitative level. In Petrinovich and O’Neill’s study (1996), the ratings for the proposed action do not seem to change enough to be regarded as acceptable in one order condition but as unacceptable in the other. In Lanteri et al. (2008), the percentage of people judging the proposed action as acceptable is indeed lowered, but it still remains above 50%.

Taking into account all the previous points, the main goal of our work will be to empirically test the existence of the pattern described above. If an order effect is present we will aim to determine its strength and, in particular, whether it can be strong enough to lead people to disagree with a proposed action that they would normally (i.e., when evaluated independently) agree with. We will use several variations of the trolley dilemma due to the existence of a large body of previous research establishing how the modification of different factors in these dilemmas affects how they are judged.

Experiment

Subjects

Fifty participants (35 women) were recruited using the lab in the psychology department at the University of Göttingen. They were randomly distributed to the different experimental conditions. The average age was 23 ($SD=2.83$).

Materials

We presented participants a series of five moral dilemma scenarios (the standard switch trolley and four modifications; see Table 1). Each scenario included a brief description of a situation and an action that could potentially be carried out in each case, accompanied by a diagram depicting the situation schematically. The initial description of the situational set-up was identical for all scenarios: An out-of-control trolley rapidly approaches three railroad workers who will die if Karl, the only bystander in the scenario, does not intervene.

Table 1: Summaries of the actions proposed in the five dilemmas

Scenario	Proposed action
Push	Push the large person from the bridge in order to stop the train
Trap	Push a button that will open a trap door in order to let the person on top of the bridge fall onto the track and stop the train
Redirect	Redirect a train containing one person that is on a safe parallel track onto the main track in order to stop the train
Run Over	Redirect an empty train that is on a safe parallel track onto the main track in order to stop the train thereby running over a person that is on the connecting track
Standard	Press a switch that will redirect the out-of-control train onto a parallel track where it will run over one person

This introduction was followed by a description of a specific action that Karl could conduct in order to save the three workers. This action was different for each of the five scenarios, but in all cases it resulted in the death of one innocent person (see Table 1). Instructions were included to ensure that participants assumed that the proposed action was the only available option in each case that, if carried out, would always lead to the described outcome. The number of potential victims (3 vs. 1) was kept constant across scenarios.

In order to establish a baseline of agreement with the action proposed in each of the five different scenarios we conducted a pilot study using a different sample consisting of 100 University of Göttingen students. Participants were

individually approached on campus and asked to indicate for one of the scenarios ($n=20$) whether Karl should act in the proposed way or not on a scale from 1 to 6, where 1 was “not at all” and 6 was “absolutely”. Table 2 shows the average ratings for the different scenarios.

Table 2: Mean ratings (standard deviations) of agreement and percentage of subjects disagreeing with the proposed action in the five scenarios when evaluated independently.

Measure	Scenario (each $n=20$)				
	Push	Trap	Redirect	Run Over	Standard
Mean Rating	1.95	3.4	4.15	4.4	4.45
(SD)	(1.76)	(1.76)	(1.42)	(1.14)	(1.15)
% Disagreement	80	40	30	10	15

Note. % Disagreement is the percentage of subjects who gave a rating <3.5 on a scale ranging from 1 to 6.

Based on these results we ordered the five scenarios according to level of agreement with the proposed action (i.e., $\text{Push} < \text{Trap} < \text{Redirect} < \text{Run Over} < \text{Standard}$). From here onwards we will refer to this ordering as the *level of agreeability* of the scenario, as defined by the extent to which participants agree with the action when the dilemmas are judged independently.

Procedure

The experiments were run individually on computers. Initially, the instructions were presented on the screen, followed by the five different scenarios. After each scenario, participants were requested to rate, on a scale from 1 to 6, whether Karl should act in the proposed way or not, where 1 was “not at all” and 6 was “absolutely”. Half of the participants saw the sequence of dilemmas in increasing order of agreeability (Least Agreeable First [LAF] condition, beginning with Push), whereas the other half saw the sequence of dilemmas in the reverse order (Most Agreeable First [MAF] condition, beginning with Standard). The computerized format of the task guaranteed that each dilemma was judged before the following one was presented. Furthermore, there was no possibility for participants to withhold their judgment until the end of the sequence or to switch back in order to change a previously given rating.

Results

To test whether the pattern of ratings of the dilemmas differed in the two orders of presentation, a 2×5 mixed analysis of variance (ANOVA) was conducted, where the first factor was the order of presentation (LAF vs. MAF, between-subjects) and the second factor was the scenario judged (within-subjects). The results are shown in Table 3 and Figure 1. They revealed a main effect for order of presentation. Specifically, average ratings were significantly lower in LAF compared to MAF ($F_{[1,48]}=8.03$; $p<0.01$). Furthermore, we found a main effect for scenario

($F_{4,192}=23.44$; $p<0.001$), confirming our expectation of different average agreeability ratings for the scenarios. Crucially, the interaction between order of presentation and scenario was significant ($F_{4,192}=8.2$; $p<0.001$), suggesting the presence of a strong asymmetric order effect, in line with our predictions.

Figure 1: Mean ratings of agreement with the proposed action in the five scenarios when evaluated sequentially, as a function of the order of presentation. Error bars indicate SEM. The bold line at $y=3.5$ indicates the division between average agreement and disagreement. MAF = Most Agreeable First; LAF = Least Agreeable First.

Table 3: Mean ratings (standard deviations) of agreement and percentage of subjects disagreeing with the proposed action in the five scenarios evaluated sequentially, as a function of the order of presentation.

Order Condition	Scenario				
	Push	Trap	Redirect	Run Over	Standard
Mean ratings (SD)					
MAF (n=25)	2.16 (1.21)	3.24 (1.69)	3.84 (1.52)	3.84 (1.57)	4.08 (1.53)
LAF (n=25)	2.16 (1.31)	2.12 (1.33)	2.52 (1.42)	2.52 (1.36)	2.68 (1.41)
% Disagreement					
MAF (n=25)	76	52	40	32	32
LAF (n=25)	80	80	72	72	68

Note. % Disagreement is the percentage of subjects who gave a rating <3.5 on a scale ranging from 1 to 6. MAF = Most Agreeable First. LAF = Least Agreeable First.

In order to test our prediction more specifically, we conducted planned comparisons involving Standard and Push as examples of scenarios typically eliciting high and low agreeability ratings, respectively. The average rating for Standard varied considerably depending on the position in which it appeared. When it had been evaluated first, the

average rating was 4.08, while the average was only 2.68 when it appeared at the end of the sequence. This difference was significant ($F_{1,48}=11.39$, $p<0.01$). In contrast, the average rating for the Push scenario was the same in both orders (2.16). Moreover, after computing the within-subjects differences between the ratings for the Standard and the Push scenarios, it can be shown that the average difference is significantly larger in MAF than in LAF ($F_{1,48}=14.69$; $p<0.001$), a result that further supports our prediction of an asymmetrical order effect.

It is worth noting that the difference between the ratings for the Standard scenario in the two order conditions is relevant not only in quantitative but also in qualitative terms: Treating ratings below 3.5 as disagreement and above 3.5 as agreement with the action proposed in a particular scenario, the majority of participants' ratings in LAF would fall into the first category (18 out of 25; 72%) whereas the majority of participants' ratings in MAF would fall into the second (18 out of 25; 72%). This difference is significant ($\chi^2_1=9.68$; $p<0.01$). The same is true for Run Over ($\chi^2_1=8.01$; $p<0.01$), Redirect ($\chi^2_1=5.20$; $p<0.05$), and Trap ($\chi^2_1=4.37$; $p<0.05$), but not for Push ($\chi^2_1=0.12$; $p=0.73$).

Discussion

In sum, the data were largely in line with the pattern we discovered in previous studies: The judgments of actions that received a positive rating when inquired independently (Standard, Run Over, Redirect) differed significantly in the two order conditions. In contrast, ratings for the action in Push, which was rated negatively when judged independently, did not differ in the two conditions. Furthermore, in the MAF condition, the pattern of the average ratings was very similar to the one obtained when the scenarios were judged independently. In contrast, the average ratings in the LAF condition differed widely from those independent ratings.

It should be noted, however, that the results obtained for one of the scenarios cannot be directly derived from the aforementioned pattern. In particular, Trap was also affected by the order of presentation (both in quantitative and in qualitative terms), even though the proposed action in this scenario was rated slightly negative when judged independently. This finding motivated us to have a closer look at the results at the level of individual participants. In particular, we explored the data treating the ratings as a set of binary choices made by each participant (i.e., treating ratings <3.5 as indication of disagreement and ratings >3.5 as indication of agreement with the proposed action) and observed the tendency that a disagreement with an action was "transferred" to the judgment of the action in the next scenario. That is, an action receiving a positive rating when judged independently received lower ratings when presented as part of a sequence if the preceding scenario was rated negatively by the same participant. In contrast, positive ratings did not affect the ratings of the next action (i.e. changing them into positive ones) if this action was rated negatively in independent ratings. For instance, in the LAF

condition, only three out of 20 participants who disagreed with the proposed action in the initial Push-scenario changed their rating towards agreement during the whole sequence, resulting in 17 votes against the proposed action in the final Standard scenario. In contrast, when participants started with Standard, eleven out of the 17 participants who voted in favor of the proposed action changed their ratings towards disagreement on the way to Push, resulting in only six positive ratings for the proposed action in this final scenario of the sequence. Reformulating the pattern this way allows order effects to occur not only for actions rated positively when judged independently but also for actions rated negatively on average provided that the number of participants who would disagree with the proposed action in a particular scenario is sufficiently higher than the number of participants who would disagree with the action in the subsequent scenario. Within a sequence of scenarios this excess of “disagreements” can be transferred to the next scenario and cause an order effect. On the flipside, an order effect might also occur when the action to be judged in a particular dilemma is preceded by a dilemma where the proposed action is judged positively. Again, it just has to be the case that the number of disagreements in the preceding scenario would be sufficiently higher than in the following scenario if both scenarios were rated independently.

A similar distribution of nominal data could well underlie the results obtained by Petrinovich & O'Neill (1996). Unfortunately, we cannot conclusively confirm this claim because only aggregated results are reported.

It is not possible to determine from our data why the reported asymmetry occurs. However, a possible explanation is the existence of a difference in the urge to justify prohibitions and permissions. When we, e.g., prohibit a child to play with knives we automatically think of – or already have in mind – a justification for this prohibition. Prohibitions seem to call for a justification. In contrast, we do not think about a justification regarding most things we permit. We do not feel an urge to explain or justify to someone why, e.g., he or she is allowed to walk around. Normally, we only justify or explain permissions when a prohibition is the default case. For instance, we might explain to a child that in the case of an emergency an ambulance is permitted to drive over red lights although it is usually prohibited. Applying this line of reasoning to the asymmetric pattern found in our data it might be the case that because participants prohibited the proposed action in Push they were – consciously or unconsciously – thinking about a justification for their prohibition. If they reach a rough justification like “You must not kill an innocent person”, they might keep this principle in mind and apply it to the remaining scenarios. Since an innocent person has to be killed in all scenarios in order to rescue three persons, participants might judge all proposed actions as prohibited. In contrast, when they start with a scenario where they judge the proposed action as permissible it might be the case that no effort is invested in justifying this judgment and,

therefore, no such justification is applied to the remaining scenarios.

Implications for Descriptive Moral Theories

An important goal of descriptive moral theories is to provide an explanation of an average person's moral judgments that is as comprehensive as possible. A potential source of variance in moral judgments which has received comparably much attention is the structural set-up of the situations in question (e.g., whether the victim serves as means or side-effect in saving the three workers; see Cushman, Young, & Hauser, 2006). However, the effects generated by the manipulation of these factors are usually fairly small, i.e. they account only for a very limited amount of the total variance in moral judgments and thus leave a good portion of between-subject differences unexplained. Thus, considering only factors concerning the objective situational set-up is by no means sufficient to generate a comprehensive descriptive moral theory. Rather, it seems to be necessary to take into account additional psychological mechanisms that influence how a given situational set-up is apprehended, represented, and evaluated. In our experiment, for example, previously judged scenarios seemed to serve as a reference which influenced the judgment of subsequent scenarios. This reference is exogenous to the subsequent scenarios, but indispensable to predicting and explaining the reactions regarding them. Note that, under a certain order condition (LAF), the effects of objective situational parameters that can usually be found have almost entirely vanished. The strength of this effect demonstrates the large predictive potential of such exogenous factors and underpins the importance of spending more efforts on investigating them in the future.

According to our results, differential experiences prior to a moral judgment can have a profound influence on this judgment. Such effects can be expected to be especially large under conditions that strongly suggest the adequacy of transferring a certain judgment from one scenario to the next. This is the case if one person is required to give several subsequent judgments on various cases similar in structure or content in a within-subjects design. As our results suggest, extreme caution is required if responses generated under such conditions are to be attributed to properties of the scenarios themselves.

Finally, we believe that between-scenario order effects might also play a role under conditions outside the laboratory. The viewpoints taken by people discussing moral issues in everyday life might be highly affected by the issues that have been discussed immediately before. This influence might not only be quantitative, but even qualitative. Possible areas of application might be the design of public opinion polls or surveys that consecutively gauge responses to several (moral) issues. Previous research in other contexts showing that such instruments can be highly sensitive to effects of question positioning (e.g., Benton & Daly, 1991;) in combination with our results from the moral domain support this claim. On the other hand, we

acknowledge that the similarity between the dilemmas used in our study might particularly encourage the transfer of judgments between scenarios. It might be that in cases where the issues in question present a larger variability in structure or content, order effects would diminish, and ratings would be more similar to those made independently.

Summary and conclusions

In this article, we have argued that order effects can have a profound influence on judgments of actions in moral dilemma situations. Amongst order effects, we subsume cases in which a given action is judged differently when rated independently, as compared to when it has been preceded by one or several other scenarios. We began by reviewing the (scarce) literature on order effects in moral psychological research. We then reported the results of an experiment conducted in order to find out whether the pattern of results extracted from the literature reviewed could be replicated. For four out of our five scenarios this was the case: Three scenarios that received positive ratings when evaluated independently received negative ratings when directly preceded by a scenario that had been judged negatively. The ratings for Push were also in line with this pattern, since the proposed action in this case was rated negatively when judged independently and was not affected by the order of presentation.

However, one scenario where the proposed action received slightly negative ratings when judged independently (Trap) was also affected by the order of presentation. This finding motivated us to have a closer look at the results by performing an analysis treating the individual ratings as binary choices. Following this analysis, we reformulated the pattern as follows: In those cases in which a participant disagrees with the action proposed, this judgment is likely to be “transferred” to the judgment of the action in the next scenario, even if this action is rated positively when judged independently. However, positive ratings are not able to change the ratings of the next action into positive ones if people normally disagree with the action proposed in this case.

We went on by speculating what could explain the asymmetry between negative and positive ratings in terms of the potential to be transferred to the next case. One candidate feature discussed was the greater urge to justify prohibitions (negative ratings) compared to permissions (positive ratings). Of course, more research is needed in order to evaluate explanatory mechanisms underlying the observed asymmetry.

In the last section of the paper, we discussed the implications of our findings for descriptive theories of morality. We argued that descriptive moral researchers should be extremely cautious when interpreting results of experiments using within-subjects designs. Furthermore, we contended that they should devote more attention to general psychological mechanisms contributing to moral judgment in addition to focusing on features of particular scenarios.

Overall, the present study should draw the attention of descriptive theories of moral judgment to previously overlooked important sources of variance such as order effects. Due to the crucial implications of these findings, much more empirical and theoretical research needs to be done in the future in order to address determinants, mechanisms, and boundary conditions of the issues discussed here.

Abstract

How do we reason with imprecise spatial descriptions? Do reasoners typically prefer one conclusion (over another) consistent with the imprecise descriptions? Based on empirical findings we are able to give a positive answer for the second question for spatial reasoning with cardinal direction relations. Analyzing further the pattern of the preferred conclusion reflects the idea of informativeness of the description. In consequence, we briefly explain heuristics and present a Bayesian model representing subjective belief of the reasoner.

Keywords: Probabilistic Reasoning; Preferential Reasoning; Qualitative Reasoning

Introduction

Reasoning with spatial information requires sometimes to reason with incomplete information. Take for example,

Berlin is north-east of Paris.

Paris is north-west of Rome.

You can (based on this information alone, e.g. no background knowledge, no map) easily infer that Berlin must be north of Rome. But you cannot infer (based on this information alone) if Berlin is eastern or western of Rome. But if you have to reason without having assumptions about geographic positions – do we prefer certain relations? The question on how humans solve such deduction problems is at the core of qualitative reasoning. In other words, how do we infer new knowledge (a *conclusion*) from given knowledge, and moreover, what are the differences to formal approaches in artificial intelligence?

Formally, there are two main approaches in AI on how such reasoning problems can be solved: By the application of (transitivity) rules or by the construction and inspection of models. Principally, both approaches are equivalent (Russell & Norvig, 2003), i.e. it is not possible to derive more information with each of these methods. This equivalence, however, makes it harder to distinguish which method(s) is applied by humans while solving such problems. Nonetheless, a number of empirical studies investigate this research question by psychological means. The most prominent and best supported theory with respect to the number of effects that can be accounted for is the theory of mental models (MMT) (Johnson-Laird & Byrne, 1991) (to name only a few: the indeterminacy effect (Johnson-Laird & Byrne, 1991), the form of premises and the figural effect (Knauff, Rauh, Schlieder, & Strube, 1998), the wording of conclusions (Van der Henst & Schaeken, 2007), etc.). According to the MMT, linguistic processes are relevant to transfer information from the premises

into a spatial array and back again, but the reasoning process itself relies on model manipulation only. A *mental model* is an internal representation of objects and relations in spatial working memory, which matches the state of affairs given in the premises. The semantic theory of mental models is based on the mathematical definition of deduction, i.e. a propositional statement ϕ is a consequence of a set of premises \mathcal{P} , written $\mathcal{P} \models \phi$, if in each model \mathcal{A} of \mathcal{P} , the conclusion ϕ is true.

Figure 1: The nine base relations of the cardinal direction calculus in the projection based representation. Other representations are cone-based representations (Ligozat, 1998)

An interesting finding is the so-called preference effect, i.e. in multiple model cases (nearly always) one preferred model is constructed from participants and used as a reference for the deduction process (Rauh, Hagen, Schlieder, Strube, & Knauff, 2000). Further findings showed that during the validation phase alternative models are constructed by small modifications to the initially constructed model. This was the reason why the mental model theory for spatial reasoning was extended within the framework of preferred mental models (Rauh et al., 2000).

A new research line (Oaksford & Chater, 2007) focuses on Bayesian explanations for preferred solutions, e.g. for syllogistic reason. The authors use here the notion of informativeness to explain why a certain quantifier is used. The question is still open, if the Bayesian approach is sufficient to model spatial reasoning.

This paper is structured as follows: First, we will present an empirical investigation analyzing the question about pref-

ferences in cardinal direction. Our empirical findings are then analyzed w.r.t. the main theories in the field (Theory of Mental Models, Theory of Mental Logic) with heuristics and we present a Bayesian model representing subjective belief of the reasoner. Finally, we discuss the different findings.

Preferences in Cardinal Direction

The language of cardinal direction consists of points in the euclidean plane \mathbb{R}^2 . Based on the point algebra it is possible to distinguish 9 base relations $a, b \in \mathbb{R}^2$:

CD	EQ	N	NE	E	SE	S	SW	W	NW
PA	(=,=)	(=,>)	(>,>)	(>,>)	(>,>)	(=,<)	(>,<)	(<,<)	(<,<)

In other words $a N b := a_x = b_x \wedge a_y > b_y$, b is a northly. An *assignment* of a set of CD constraints C over the vocabulary $\mathcal{B} = \{N, NE, E, SE, S, SW, W, NW, EQ\}$ is a function $\alpha : V(C) \rightarrow \mathbb{R}^2$, mapping each variable x , occuring in C to coordinates in the real plane.

Over the euclidean plane these *jointly exhaustive* and *pairwise disjoint*-base relations (cp. Fig. 1) with the composition table (cp. Figure 2) form a relation algebra. In the first experiment discussed here we used relations from the set $\mathcal{B}' := \mathcal{B} \setminus \{EQ\}$ to construct a type of relational reasoning task that is referred to as three-term-series-problems (3ts-problems) in cognitive research (e.g. (Hunter, 1957)). In these tasks always two statements are used as premises and the task of the participants is to generate a statement that is consistent with the premises – the conclusion. E.g.,

A is northeast of B.

B is west of C.

Which relation holds between A and C?

The 3ts-problems can be formally described by the composition of two base relations and the question for a satisfiable relation. The set of all possible relations with premises $a R_1 b$, $b R_2 c$ are denoted by the composition $R_1 \circ R_2$. Normally, it is presented as a composition table (cf. Figure 2).

For the above example $NE \circ W$ contains the following three relations: NE, N, NW. Since CD consists of nine base relations, there are without EQ 64 possible compositions of two base relations. In other words, exactly 64 different three-term-series problems exist. If we omit all one-relation cases (cells with one entry in Figure 2), it results in 40 multiple relation cases out of the 64 possible compositions. The participants of our studies were confronted with all 64 problems and had to infer a conclusion.

Empirical Data

The first central question we are interested in is: How do people reason about cardinal directions? Do they construct preferred mental models, and if so, what are the principles? An answer to this question might give hints of how preferences differ between large-scale spaces and small-scale spaces. For the latter scale of space, preferences have already been identified (Ragni, Fangmeier, Webber, & Knauff, 2007).

Participants. 24 students of the University of Freiburg took part in this web experiment (14m/10f, $M = 23.5/22.1$, $SD = 2.3/2.1$). They were paid for their participation.

Figure 2: The preferred relations in reasoning with cardinal direction. In each cell, the first number gives the number of correct relations and the relations. In the second row we have the preferred relation, then in the indeterminate case the relative frequency of this relation, i.e. how often it was chosen by the participants and then the error rates.

Materials. The experiment used the whole set of Cardinal Direction relations presented in Fig. 1. In the main part of the experiment all participants had to solve the same set of 64 3ts-problems. Here is an example-problem:

A is northwest of B.

B is southeast of C.

Which relation holds between A and C?

In half of the trials we asked for the relation between A and C and in half of the trials between C and A.

Procedure and Design. The experiment was conducted as a web experiment (partially conducted at our site for control) using webexp2. Tasks were presented in a randomized order. The premises were presented sequentially, i.e. the first premise disappeared when the second premise appeared. In other words, the participants were forced to hold the premise information in the working memory. All premises were presented in a self-paced procedure. Finally, the participants had to give a relation as an answer.

Overall, 87% of the problems were correctly solved. The results regarding the preference effects can be found in Figure 2.

As shown in Figure 2 out of the given 64 problems exactly 24 are determinate problems and 40 are indeterminate problems. Most of the indeterminate problems exactly 90% (only 4 relations were not significantly preferred: $N \circ S$, $W \circ SE$, $W \circ E$, $SW \circ E$) were solved with a clear preference for one relation. However, it is remarkable that several relations could have been chosen as a possible conclusion, but, in fact, the participants chose just one of them and their preferences also often corresponded.

Discussion. There are differences between preferred relations in small-scale spaces and in large-scale spaces. Contrary to the small-scale spaces (Ragni, Fangmeier, et al., 2007) where the first-free fit strategy has been identified in relational reasoning in large-scale spaces participants used a first-fit strategy. In other words they inserted the third object C in-between A and B (cp. the relations $S \circ N$ and $E \circ W$ where in the first case S and in the second W has been reported). The inverse composition $N \circ S$ and $W \circ E$ are not statistically significant.

By a formal analysis it was possible to explain the preferred mental model in indeterminate cases by the following distinction

- Principle 1 (*In-between Insertion Principle*): If the two relations of the composition are inverse (e.g. S and N , W and E) then the third object C is inserted in-between A and B , (e.g. A is S of C and B is north of C , and so on).
- Principle 2 (*Cut Principle*): Choose always the relation in the geometrical cut of the two relations, i.e. if $NE \circ NW$ is composed and the relations NW , N , NE are possible than the relation N is chosen.

The participants preferred the cut between relations, e.g. in the composition of $NE \circ NW$ and $NW \circ NE$ they preferred the relation N . The same pattern holds as well for $SW \circ NW$ and so on. This gives an indication that without additional information they use (independently of projection based or cone based representation of Cardinal Direction) similar distances.

Theories of Deduction

In this section we ground the intuitively used theories formally (and mathematically) and analyze them with respect to their reasoning power.

A *relational structure* is a tuple $(D, (R_i)_{i \in I})$ consisting of a domain D (sometimes called discourse universe) and a set of (usually binary) relations R_i (Russell & Norvig, 2003). For example, geographic knowledge like *New York is north-east of Washington* can be expressed by cardinal direction relations N, NE, E, SE, \dots over the domain of cities. More complex expressions can be formed by using connectives like conjunctions (*New York is north-east of Washington and New York is in the U.S.*) and disjunctions (\dots or \dots). By allowing negations, we have a propositional relational language \mathcal{L} over cardinal direction relations. Such relational structures can be used to describe *knowledge representation*. But how can new information be derived?

Theory of mental logic

The theory of mental logic (Rips, 1994) assumes that we use (transitivity) rules to draw conclusions, whereas the classical model theory argues that we use models for this inference process. The classical mental model theory (Byrne & Johnson-Laird, 1989) claims that in multiple model cases (i.e. more than one model is consistent with the premises) other models are inspected.

1. $West(x, y) \ \& \ North(z, x) \rightarrow West(z, y)$
2. $West(x, y) \ \& \ North(z, y) \rightarrow West(x, z)$
3. $West(x, y) \ \& \ West(y, z) \rightarrow West(x, z)$
4. $West(x, y) \leftrightarrow East(y, x)$
5. $(West(y, x) \ \& \ West(z, x)) \rightarrow (West(y, z) \text{ or } West(z, y))$
6. $(West(y, z) \text{ or } West(z, y)) \ \& \ North(w, z) \rightarrow (West(y, w) \text{ or } West(w, y))$

Figure 3: Set of (incomplete) inference rules specified for spatial reasoning adapted from Van der Henst (2002).

The central idea of this approach can be characterized as follows: “Reasoning consists in the application of mental inference rules to the premises and conclusion of an argument. The sequence of applied rules forms a mental proof or derivation of the conclusion from the premises, where these implicit proofs are analogous to the explicit proofs of elementary logic” (Rips, 1994, p. 40). Hagert (1984) defined a first set of spatial inference rules (cf. Fig. 2). This set of rules has been extended by two additional rules (cf. the rules 5 and 6 in Fig. 2) to deal with indeterminacy by Van der Henst (2002). The rules in Fig. 2 are successively applied to the premises of a problem description.

There is, however, no recent theory in explaining the construction of the preferred relations (Figure 2).

Theory of mental models

The mental model theory assumes that the human reasoning process consists of three distinct phases: The *model generation phase*, in which a first model is constructed out of the premises, an *inspection phase*, in which the model is inspected to check if a putative conclusion is consistent with the current model. In the *validation phase*, finally, alternative models are generated from the premises that refute this putative conclusion. The indeterminacy effect is mainly responsible for human difficulty in reasoning (Johnson-Laird, 2001).

Recent findings indicate a phenomenon encountered in multiple-model cases, namely that humans generally tend to construct a *preferred mental model* (PMM). This model is easier to construct, less complex, and easier to maintain in working memory compared to all other possible models (Knauff et al., 1998). The principle of economicity is the determining factor in explaining human preferences (Manktelow, 1999). This principle also explains that a model is constructed incrementally from its premises. Such a model construction process saves working memory capacities because each bit of information is immediately processed and integrated into the model (Johnson-Laird & Byrne, 1991). In the model variation phase, this PMM is varied to find alternative interpretations of the premises (Rauh et al., 2000). From a formal point of view, however, this theory has not been formalized yet and is therefore not fully specified in terms of necessary operations to process such simple problems as were described above.

A model \mathcal{A} is called *consistent* with a set of premises Φ over a relational language \mathcal{L} (mathematically $\mathcal{A} \models \Phi$) if all

expressions of Φ are true in \mathcal{A} . Then a conclusion Ψ can be derived from the premise set Φ (mathematically $\Phi \models \Psi$, whereby \models is called the *consequence relation*) if

$$\begin{aligned}\Phi \models \Psi &\Leftrightarrow \text{All models of } \Phi \text{ are models of } \Psi. \\ &\Leftrightarrow \text{There is no model } \mathcal{A} \text{ with} \\ &\quad \mathcal{A} \models \Phi \text{ and } \mathcal{A} \models \neg\Psi.\end{aligned}$$

A model \mathcal{A} with the property $\mathcal{A} \models \Phi$ and $\mathcal{A} \models \neg\Psi$ is called *counter-example*. It follows if there is a counter-example to Φ and Ψ then $\Phi \models \Psi$ cannot hold.

This classical (mathematical) consequence relation, however, does not explain how initial mental models are constructed and varied (Rauh et al., 2000). Since there is a huge empirical evidence supporting the preferred mental model theory for different calculi (Rauh et al., 2000; Ragni, Fangmeier, et al., 2007; Ragni, Tseden, & Knauff, 2007) it seems worth to ground this theory mathematically.

A Probabilistic Approach

As already stated, a new approach are probabilistic models (Oaksford & Chater, 2007) to explain preferred relations. Those are based on the consideration to use probabilities instead of truth values as the representation of semantics. This is a valid consideration as a probability might be interpreted in a *subjective* manner describing a subjective degree of belief rather than a relative frequency of an event. Following this subjective interpretation probability theory can be utilized for belief updating and inference. The probabilistic approach to inference is based on:

$$P(\text{“If } p \text{ then } q\text{”}) = P(q|p). \quad (1)$$

Thus, the probability of a conditional proposition is identified with the conditional probability of the proposition. The a-posteriori belief in the fact q in face of certainty about the fact p is given by the a-priori conditional probability: $P_1(q) = P_0(q|p)$, if $P_1(p) = 1$. This is called “conditionalization”. It constitutes the basis of probabilistic inference.

The probabilistic representation of conditionals as given in equation 1 enables the application of Bayes’ theorem:

$$P(q|p) = \frac{P(p|q) P(q)}{P(p)} \quad (2)$$

This has two advantages: First, whereas $P(q|p)$ is a rather abstract value, the probabilities of its right hand side can often be derived from the agent’s experience. Second, it implies basic patterns of performance while reasoning with conditional propositions which appear as “errors and biases” from a logicistic standpoint.

Bayesian Rationality arises from a rational analysis of the problem, the environment, and the constraints of an agent while conducting deductive tasks. As such, it is not a theory of the actually psychological processes in use, but a description of general regularities. It is further independent of cognition *about* probabilities. It shows that cognition often obeys the laws of probabilistic theory.

The following models¹ are to reproduce the frequency distribution of the 3ts-task on cardinal directions this way.

Spatial Bayesian Models The spatial reasoning task of the previous section uses the set of cardinal relations $\mathcal{B}' = \{N, E, S, W, NE, SE, SW, NW\}$. The statement of an item in the 3ts-task is given by a pair of relations $R_1, R_2 \in \mathcal{B}'$ with aR_1b and bR_2c for three locations a, b, c . The subject’s guess for the relation between a and c is another relation $R_3 \in \mathcal{B}'$. The relative frequency of R_3 for an item R_1, R_2 will be referred to as $f_{R_1, R_2}(R_3)$.

The objective of a Bayesian model for the 3ts-task is to implement a probability distribution of R_3 parametrized by the task item R_1, R_2 , i.e. $P_{R_1, R_2}(R_3)$. This probability distribution is assumed to be a prediction of the experiment’s relative frequencies f_{R_1, R_2} . Thus, model M ’s preferred relation given the task’s relations R_1 and R_2 is

$$M(R_1, R_2) := \arg \max_{R_3 \in \mathcal{B}'} P_{R_1, R_2}(R_3).$$

The per-item probability distribution of R_3 can be identified with the probability of R_3 conditioned by the item’s relations. Therefore, it further allows the application of Bayes’ theorem (equation 2):

$$P_{R_1, R_2}(R_3) := P(R_3|R_1, R_2) = \frac{P(R_1, R_2|R_3) P(R_3)}{P(R_1, R_2)} \quad (3)$$

Consequently, it is sufficient for a Bayesian model of the 3ts-task to specify merely the reversed conditional probability $P(R_1, R_2|R_3)$ as well as the marginal probabilities $P(R_3)$ and $P(R_1, R_2)$.

The following sections will describe such implementations. The quality of each model M will be compared to the empirical data by three factors: a) the mean correlation C^M between P_{R_1, R_2} and the empirical data f_{R_1, R_2} , b) the sum E^M of the squared differences between P_{R_1, R_2} and f_{R_1, R_2} and c) the number N^M of correctly predicted preferred relations.

The Unit Layout (Model M_1) The computation of $P^{M_1}(R_1, R_2|R_3)$ is based on a heuristic for detours when moving by R_3 in the so called *unit layout*. R_1 and R_2 describe the detour. The farther the detour the smaller is the conditional probability of R_1, R_2 .

The unit layout is a rectangular subset of \mathbb{Z}^2 and separately defined for each direction R_3 . The brackets $[\cdot]^{R_3}$ map the locations a and c each to a field in \mathbb{Z}^2 such that $[a]^{R_3} R_3 [c]^{R_3}$. Each pair of relations R_1, R_2 with $R_3 \subset R_1 \circ R_2$ is likewise mapped to a field in \mathbb{Z}^2 by $[\cdot]^{R_3}$ such that

$$[a]^{R_3} R_1 [R_1 R_2]^{R_3} \text{ and } [R_1 R_2]^{R_3} R_2 [c]^{R_3}.$$

The fields $[a]^{R_3}$ and $[c]^{R_3}$ must be chosen in such a way that each $[R_1 R_2]^{R_3}$ is definite. That way, the unit layout is definite in \mathbb{Z}^2 up to translations. Figure 4 shows the unit layout for $R_3 = NW$.

¹The source code is available at <http://tiny.cc/hmi3f>.

SE-NW	S-NW	SW-NW	SW-N	SW-NE
E-NW	a	W-NW	W-N	W-NE
NE-NW	N-NW	NW-NW	NW-N	NW-NE
NE-W	N-W	NW-W	c	NW-E
NE-SE	N-SE	NW-SE	NW-S	NW-SE

Figure 4: The *unit layout* for $R_3 = NW$. Field a is to the north-west of c . All other field are uniquely labeled with relations R_1 - R_2 . It holds for each of them that field a is R_1 -wards of it and it is R_2 -wards of c .

For $R_3 \subset R_1 \circ R_2$, the unit layout entails the costs of a “de-tour” moving from field $[a]^{R_3}$ via $[R_1 R_2]^{R_3}$ to $[c]^{R_3}$ utilizing a metric d on \mathbb{Z}^2 .

$$c_{R_1, R_2}^{R_3} := \frac{d([a]^{R_3}, [R_1 R_2]^{R_3}) + d([R_1 R_2]^{R_3}, [c]^{R_3})}{d([a]^{R_3}, [c]^{R_3})}$$

The costs $c_{R_1, R_2}^{R_3}$ for $R_3 \not\subset R_1 \circ R_2$ are defined by the model parameter *distimposs*. This cost measure entails the wanted conditional probability:

$$P^{M_1}(R_1, R_2 | R_3) := \frac{c_{R_1, R_2}^{R_3} - 1}{\sum_{R'_1, R'_2 \in \mathcal{B}'} c_{R'_1, R'_2}^{R_3} - 1}.$$

This points out the influence of the model parameter *distimposs*: For infinity, the model performs accurate and it simulates errors for positive numbers.

This is how model M_1 computes the conditional probability of the right-hand side of equation 3. The marginal probability of $P^{M_1}(R_3)$ is a unit distribution which can be furnished with a probability gain for the main cardinal directions by *cardinalgain* and an additional gain towards the west by *westgain*. The probability of $P^{M_1}(R_1, R_2)$ is assumed to be a unit distribution.

Parameter Variations Varying the metric d between Euclidian, Manhattan, and maximum had no noteworthy effect on the quality estimation factors (C^M , E^M , N^M). So we chose the euclidian metric, as it matches the intuitive concept of distance best. The model parameter *distimposs* was varied systematically between 20 and 200, the parameters *cardinalgain* and *westgain* were varied between 0.1 and 0.9.

We found a maximal convergence against the empirical data with model parameters *distimposs* = 150, *cardinalgain* = 0.2, and *westgain* = 0.2.

It has a mean correlation $C^{M_1} = 0.91$, a summed error of $E^{M_1} = 2.82$ and predicts the preferred relation correctly in $N^{M_1} = 59$ cases. This instance of model M_1 has a mean correlation of 0.96 in 60 items of the task. Nevertheless, the mean correlation for the task items with opposing intermediate directions is as little as 0.17. This suggest the appearance of another strategy in these cases.

Figure 5: Relative frequencies of R_3 for task items with $R_1 = NE$ from the experiment (circles: \circ) as well as M_1 's (pluses: $+$), and M_2 's (crosses: \times) probabilities.

A Secondary Strategy (Model M_2) Model M_2 is an extension of the model presented in the preceding section. It adds a probability gain g_{R_1, R_2} to the value of $P_{R_1, R_2}^{M_1}$. This gain implements priming effects on the relations R_1 and R_2 . The amounts of priming towards R_1 and R_2 are controlled by the model parameters *firstprim* and *secondprim*, respectively. Values of 0 each void the priming effect.

The extent of this probability gain is in turn controlled per task item by the certainty z_{R_1, R_2} of M_1

$$z_{R_1, R_2} := \max_{R_3 \in \mathcal{B}'} P_{R_1, R_2}^{M_1}(R_3).$$

The (yet to be normalized) probability distribution of M_2 is defined as

$$P_{R_1, R_2}^{M_2}(R_3) := z_{R_1, R_2} \cdot P_{R_1, R_2}^{M_1}(R_3) + (1 - z_{R_1, R_2}) \cdot g_{R_1, R_2}(R_3).$$

It weakens M_1 's probability distribution $P_{R_1, R_2}^{M_1}$ and strengthens the priming effect g_{R_1, R_2} as a function of decreasing certainty.

Parameter Variations In a systematic search through the parameters of model M_1 as well as *firstprim* and *secondprim* we found an instance of M_2 with mean correlation of $C^{M_2} = 0.94$, summed error $E^{M_2} = 2.67$ and $N^{M_2} = 62$ correctly predicted items. Along with it, this instance has a mean correlation of 0.73 for the task items with opposed intermediate directions. The parameters were *distimposs* = 180, *cardinalgain* = 0.1, *westgain* = 0.2, *firstprim* = 0.3 and *secondprim* = 0.2.

Figure 5 shows results both from model M_1 and M_2 for $R_1 = NE$. M_2 's improvement is apparent for $R_2 = SW$.

Interpretation

The following lines give a clue of how the found model parameters can be read as a hints on the underlying cognitive processes.

Utilizing Experience The first model, M_1 , shows that the spatial reasoning task can be modelled by a Bayesian approach. The computation of $P(R_3 | R_1, R_2)$ is based on an “intuition of the benefit” to move towards R_1 first and then towards R_2 to attain towards R_3 overall. This intuition might

reflect complying knowledge of the subject arising from basic experience navigating through the world.

It was possible to further increase the convergence of the model towards the empirical data by means of higher marginal probabilities of the cardinal directions, and additionally the west. This might reflect frequency effects for the cardinal directions as well as an effect of the reading direction for the western direction.

Shifting Strategies Whereas model M_1 behaved poorly for tasks with opposed intermediate directions, model M_2 's correlation on those could be improved by simulating priming effects on the relations given by the current task item. Those tasks excel in a high uncertainty about the answer. This suggests the subjects shift their strategy to be driven by priming effects under uncertainty.

General Discussion

If incomplete information is available only (i.e. several relations are possible), humans tend to take a relation more into account than others. This finding complements a series of findings for preferred spatial reasoning with intervals (Rauh et al., 2000), with the spatial relations right and left (Jahn, Knauff, & Johnson-Laird, 2007), and with topological relations (Ragni, Tseden, & Knauff, 2007).

Our starting point was the question if it is possible to model preference effects for cardinal directions in both theories (the Mental Model Theory and the Bayesian rationality) based on heuristics. Only by a formalization it is possible to compare human reasoning to approaches in AI. A formal handling of the preferred mental model theory by a consequence relation allows to make precise predictions about which kind of conclusion(s) are drawn (from a given set of premises) and which are neglected. These heuristics can be described by two principles: the in-between insertion principle and the cut principle. Both together can explain the preferences in the composition table (Figure 2) and support the theory of cognitive economicity (Manktelow, 1999).

The primer raised question, if the Bayesian approach is expressible enough to model preference effects in spatial reasoning (with cardinal directions) can be positively answered. Moreover, it reproduces the full frequency distribution quite well: The first model is based on a heuristic for detours which explains the preferences (Figure 2). It has a mean correlation of 0.91 and predicts the preferred relation correctly in 59 from 64 cases. The second model which adds a priming effect leads to an increase from 0.17 to 0.73 in the correlation in the four cases of opposed intermediate directions.

A possible limitation of the Bayesian model is connected to the certainty of the conclusion. While each statement is given with absolute certainty (Berlin is north-east of Paris) a conclusion has only a degree of certainty. Taken together, the results clearly indicate that the preference effect can be explained by heuristics in both mental models and bayesian approach. Further research necessarily requires an investigation for a general heuristic explaining preference relations for

the diverse spatial calculi.

One point, however, is certain: the role of heuristics has been vastly underestimated in explaining the preferences in spatial reasoning.

Expanding Retrieval Promotes Long Term Retention by Preventing Rapid Rates of Forgetting

Aimee A. Callender (aac0005@auburn.edu)

Department of Psychology, 226 Thach Hall
Auburn, AL 36849 USA

Abstract

Expanding retrieval, increasing the delay between retrieval attempts of recently studied material, should lead to better memory than equally spaced retrieval, however, recent results have been mixed. Ninety-six participants studied word pairs with the following expansion schedules: 1-2-3; 1-5-9; 3-5-8; 5-8-13. An evenly spaced (5-5-5) condition was also used. A final test was given after a 10 minute or 48 hour retention interval. Performance after the 48 hour retention interval was best in the 5-8-13 condition. The higher level of performance in this condition was due to no forgetting between the final learning trial and the immediate final test.

Keywords: Memory; Retrieval; Expanding Retrieval;

Introduction

Spacing out study trials and retrieval attempts is a simple and effective way to improve memory for verbal material (see Cepeda, Pashler, Vul, Wixted & Rohrer, 2006 for a review). Repeated testing has also produced robust memory effects in the laboratory (Roediger & Karpicke, 2006) and classroom studies of repeated testing. One aspect of repeated testing that has produced mixed results is the effects of timing of the repeated tests or retrieval practice on long term retention. Two basic ways that repeated testing can be implemented are to evenly space out the retrieval attempts or to gradually increase the interval between each retrieval attempt, called expanding retrieval. Intuitively, expanding retrieval is thought to improve long term retention, yet the literature is mixed. This experiment investigated two different aspects of the retrieval schedule, the number of intervening items between the study period and the first retrieval attempt and the number of intervening items in the remainder of the schedule, to further delineate the conditions under which expanding retrieval may or may not improve long term retention.

Expanding Retrieval

Expanding retrieval is a method in which an initial study period is followed by retrieval attempts that are spaced out with increasingly longer intervals between each attempt. For example, a typical expansion sequence used in the literature is a 1-5-9 sequence (see Cull, Shaughnessy, & Zechmeister, 1996; Karpicke & Roediger, 2007), meaning that after the initial study period, there is one intervening item between study and retrieval, then five intervening items between the first and second retrieval attempts, and

finally, nine intervening items between the second and third retrieval attempts.

Intuitively, and anecdotally, expanding retrieval is thought to produce better long term retention than evenly spaced retrieval. Theoretically, one would expect expanding retrieval to improve long term memory based on the principle of desirable difficulty (Bjork, 1994). According to Bjork (1994), conditions that introduce difficulty into the learning process increase the likelihood of retrieving the information on a long term retention test. Expanding retrieval is built on the idea of introducing difficulty into the learning process. The initial conceptualization of expanding retrieval posited that the first retrieval attempt should occur soon after the learning trial to ensure successful retrieval. Difficulty is introduced on subsequent retrieval attempts by increasing the number of intervening items between each attempt. Gradually increasing the delay between each retrieval attempt makes each subsequent attempt more difficult than the previous attempt. Surprisingly, recent research investigating the benefits of expanding retrieval has produced mixed results. Some studies have found that expanding retrieval does improve memory when compared to an evenly spaced control condition (Cull et al., 1996) whereas others found that expanding retrieval is no better than evenly spaced retrieval (Logan & Balota, 2008).

Karpicke and Roediger (2007) explored possible reasons for the mixed results and found that the benefits of expanding retrieval depend on two factors: the time of the final test (immediate or delayed) and the number of items between the study trial and the first retrieval attempt. With respect to the time of the final test, expanding retrieval produced better performance than evenly spaced retrieval on a test that occurred 10 minutes after learning. When the final test occurred after a 48 hour retention interval, the effects reversed, and equally spaced retrieval produced superior performance compared to the expanding retrieval conditions. The results of the second factor that was investigated, the delay between the study period and the first retrieval attempt, indicated that expanding retrieval improved retention the most when the first retrieval attempt was delayed regardless of the rest of the sequence (whether it was evenly spaced or expanding).

Although Karpicke and Roediger (2007) addressed and reduced the confusion surrounding expanding retrieval, the extant research on expanding retrieval is restricted by two limitations. One limitation (see Karpicke and Roediger, 2007, Exp. 3) was that the expanding sequences that were used to investigate the number of intervening items between

study and the first retrieval attempt were not true expanding sequences. In order to investigate the interval between the study trial and the first retrieval attempt and to control for the number of intervening items, the sequences were constructed by simply adding an initial retrieval attempt onto the standard 5-5-5- and 1-5-9 sequences. The evenly spaced sequence became a 5-5-5-5 sequence and the expanding sequence became a 5-1-5-9 sequence. The expanding sequence was no longer a true expanding sequence as it contracted before expanding. This experiment addressed this issue by comparing the 5-5-5 sequence against an expanding sequence that started with a first retrieval attempt after 5 intervening items (5-8-13).

The other limitation is that few other studies investigating expanding retrieval have distinguished between the effectiveness of different expansion sequences (but see Logan & Balota, 2008), and most studies have used a 1-5-9 expanding sequence (Cull et al, 1996; Karpicke & Roediger, 2007; Morris, Fritz, Jackson, Nichol, & Roberts, 2005). Other schedules have been used, for example Landauer and Bjork (1978) used 1-4-10 and 0-1-3-8 schedules, and in an experiment with preschool age children, Fritz, Morris, Nolan and Singleton (2007) used a 1 minute-1day-2 day expansion sequence. However, the different schedules have not been compared against one another. Other than Karpicke and Roediger's (2007) investigation of the initial retrieval attempt and Logan and Balota's (2008) study of various schedules of spacing, the remainder of the expansion schedule has not been a variable of interest. Thus, the present experiment investigated different expansion sequences to determine if the benefits of expanding retrieval depend on the particular sequence that is used.

According to Bjork's theory of Desirable Difficulty it is critical to create a task that is challenging and difficult for the individual, but is not so difficult such that the individual cannot complete the task. The difficulty of the expansion sequence can be manipulated by increasing the number of intervening items between the study trial and the first retrieval attempt or by increasing the average number of intervening items across the entire expansion schedule. This experiment manipulated both types of difficulty, but focused on the number of intervening items between the study trial and the first retrieval attempt.

The Current Experiment

The current experiment investigated 5 different sequences: an evenly spaced control (5-5-5) and four expansion sequences (1-2-3; 1-5-9; 3-5-8; 5-8-13). The 1-5-9 sequence was chosen because it has been used in the majority of previous research. Although the expansion sequences may appear to be chosen at random, the three novel sequences used in this study (1-2-3; 3-5-8; 5-8-13) were chosen because they come from the same number sequence that occurs in nature, the Fibonacci sequence. The Fibonacci sequence is a naturally expanding sequence in which each number is determined by adding together the

two previous numbers in the sequence. By using portions of the Fibonacci sequence for each of the novel sequences used in this experiment, each expanding sequence expands in the same way.

The expansion sequences used in this study were chosen from the Fibonacci sequence by considering two factors. First, the critical issue in this experiment was to investigate the number of intervening items between the study trial and the first retrieval attempt. Thus, sequences were selected by choosing different starting points in the Fibonacci sequence to correspond to the initial retrieval attempts that have been used in previous literature (1 or 5). This resulted in the 1-2-3 and 5-8-13 sequences. The other factor that was considered was the average number of intervening items across the entire sequence. The average number of intervening items in the 5-5-5 and 1-5-9 sequences that are typically used in the literature is 5. Thus, the 3-5-8 condition was selected.

The comparison of most interest was to investigate the difference in performance between the 5-5-5 condition and the expanding condition that also had five intervening items between the study trial and the first retrieval attempt, 5-8-13. This comparison was vital because Karpicke and Roediger's (2007) investigation of this variable found that delaying the first retrieval attempt improved performance regardless of the rest of the expansion sequence. However, the expansion sequences were different from the expansion sequences used in this experiment as their sequences started over from 1 after the first retrieval attempt (5-1-5-9) whereas the expansion sequence in the present experiment continued to expand from that first retrieval attempt (5-8-13).

Method

Participants

Ninety-six undergraduate students at Auburn University participated in the study in exchange for extra credit for a psychology course. Participant were between the ages of 17 and 25, 74% were female, 26% were male, 88% were white, 9% were African American, and 3% identified themselves as another race/ethnicity.

Design and Materials

The experiment used a 2 (retention interval) x 7 (testing schedule) mixed design. The final retention interval (10 minutes or 48 hours) was manipulated between subjects and the various testing schedules were manipulated within subjects. The testing schedules included an evenly spaced control (5-5-5), 3 expanding schedules based on the Fibonacci sequence (1-2-3; 3-5-9; 5-8-13), a standard expanding schedule (1-5-9), and two single test conditions in which participants took a single test immediately (Single0) or after 2 intervening items (Single2).

The experiment was based on Karpicke and Roediger (2007), using word pairs in which the first word was an unfamiliar (low frequency) word such as *Tumbrel*, and the

second word was a one word synonym or definition, *Cart*. During the study phase, the word pairs were presented together, *Tumbrel-Cart*, and during the testing phases the first word was presented and participants were required to type in the appropriate word pair. Fifty-six word pairs were constructed. Forty of the word pairs were critical word pairs. For each of the 7 testing conditions, there were 5 word pairs to study. The remaining 5 items served as unstudied control items. Eight counterbalancing conditions were constructed to allow for each set of 5 word pairs to be rotated through each of the testing and unstudied conditions. This resulted in 40 critical word pairs (5 for each of the 7 conditions, counterbalanced so remaining 5 were unstudied or control items). Additionally, 16 filler items were included for a total of 56 word pairs. Two filler items were used as buffers at the beginning of the task, and 3 filler items were used as buffers at the end of the task. The remaining fillers were interspersed throughout the list to allow for the appropriate spacing of all of the study and test trials. This resulted in a total of 142 trials in the experiment.

Procedure

Data collection occurred in groups of up to 15 participants in a computer lab. Participants were instructed that they would study word pairs that included one familiar word and one unfamiliar word. They were instructed to study the word pairs and type in the appropriate response during the test trials. Each of the trials (study or test) was 8 s. with a 500 ms. intertrial interval. Participants had to spend the entire 8 s. viewing the study screen, but during the test trials they were allowed to press Enter to move on to the next trial once they entered their response. If no response had been entered within 8 s., the computer program automatically advanced to the next trial. This task (142 trials) generally took between 15 and 20 minutes for participants to complete.

The final retention test tested participants on the 40 critical word pairs. Thirty-two of the participants took the final test after 10 minutes, and 32 took the test after a 48 hour delay. Participants were instructed that they were going to be tested on the words that they had learned previously, and to type in the appropriate word pair. Each trial was 14 s. (participants could press Enter to advance to the next trial once they entered a response) and the interstimulus interval was 500 ms. If no response had been entered in, the computer program automatically advanced after 14 seconds. This task generally took about 10 minutes to complete.

Results

Three separate analyses were conducted. The first analysis investigated performance on the learning trials, that is, each retrieval attempt during the expanding or evenly spaced sequence. A second analysis was conducted on final cued-recall performance. The third analysis investigated forgetting between the last learning trial and the final cued-recall test.

Learning Trials

A 5(spacing condition) x 3 (learning trial) within subjects ANOVA was conducted (the single trial conditions were not included in this analysis). The effect of learning trial was significant, $F(2, 464) = 5.82, p = .003, \text{partial } \eta^2 = .02$, which was qualified by a significant interaction of learning trial and spacing condition $F(8, 930) = 4.52, p < .001, \text{partial } \eta^2 = .04$. Table 1 shows that performance in the two conditions in which there was only one intervening item between the study trial and the initial retrieval attempt (1-2-3 and 1-5-9) was much higher on the learning trials than the other three spacing conditions (3-5-8; 5-8-13; 5-5-5), indicating that the trials that had more intervening items before the first retrieval attempt were more difficult to learn (See Table 1).

Table 1: Performance on learning trials by spacing condition.

Spacing	Trial 1	Trial 2	Trial 3
1-2-3	.68 (.02)	.56 (.02)	.58 (.02)
1-5-9	.66 (.03)	.52 (.03)	.56 (.06)
3-5-8	.43 (.03)	.48 (.07)	.42 (.03)
5-8-13	.46 (.03)	.44 (.03)	.43 (.04)
5-5-5	.43 (.03)	.44 (.03)	.45 (.03)

Note. Standard errors are in parentheses.

Final Cued Recall

A 2 (delay) x 7 (spacing condition: 1-2-3; 1-5-9; 3-5-8; 5-8-13; 5-5-5; Single0; Single2) repeated measures ANOVA was conducted on the final recall performance. Both the within-subjects effect of spacing and the effect of delay were significant; $F(6, 89) = 25.45, p < .001, \text{partial } \eta^2 = .64$, and $F(1, 94) = 26.14, p < .001, \text{partial } \eta^2 = .22$, respectively. The spacing by delay interaction was marginally significant, $F(6, 89) = 2.15, p = .06, \text{partial } \eta^2 = .07$. As Table 2 shows, performance in the 5-8-13 condition was the highest in both the immediate condition (although not significantly) and was significantly higher than the other spacing conditions (except for the 1-5-9 condition) after the 48 hour delay. The 5-5-5 spacing condition was not significantly better than the other spacing conditions on either the immediate or delayed test.

Table 2: Final recall as a function of spacing condition and delay.

Spacing	10 min.	48 hours
1-2-3	.37 (.03)	.17 (.03)
1-5-9	.37 (.04)	.18 (.04)
3-5-8	.34 (.04)	.15 (.04)
5-8-13	.42 (.04)	.25 (.04)
5-5-5	.38 (.04)	.15 (.04)
Single 0	.14 (.02)	.02 (.02)
Single 2	.23 (.03)	.07 (.03)

Note. Standard errors are in parentheses.

Forgetting

A 2 (retention interval) X 5 (spacing condition: 1-2-3; 1-5-9; 3-5-8; 5-8-13; 5-5-5) repeated measures ANOVA was conducted on the amount of forgetting that occurred between the final learning trial and the final test. There was significantly more forgetting in the delayed condition than the immediate condition, $F(1, 94) = 55.69, p < .001$, $\eta^2 = .37$. Forgetting also depended on the spacing condition, $F(4, 91) = 19.28, p < .001$, $\eta^2 = .46$, but there was no interaction. Table 3 shows the amount of forgetting in each condition. Comparing the 5-8-13 condition to the 5-5-5 condition, there was less forgetting on the immediate test (although not significantly less), and significantly less forgetting on the delayed final test, $p = .001$.

Table 3: Forgetting as a function of spacing and delay.

Spacing	10 min.	48 hours
1-2-3	.18 (.03)	.45 (.03)
1-5-9	.13 (.09)	.44 (.09)
3-5-8	.08 (.03)	.27 (.03)
5-8-13	.02 (.03)	.18 (.03)
5-5-5	.07 (.03)	.30 (.03)

Note. Standard errors are in parentheses.

Discussion

Expanding retrieval can lead to better long term retention than evenly spaced retrieval when a slight modification is made to the original conceptualization of the method. Long term retention is best when the learning trials are constructed by combining a delayed initial retrieval attempt with an expanding sequence for the remainder of the learning trials. In accordance with Karpicke and Roediger (2007), increasing the number of intervening items between the study trial and the first retrieval attempt is critical to improve learning and memory of the information. Additionally, as the current experiment shows, it is also critical for the sequence to expand for optimal long-term retention.

Several findings from this experiment provide insight into the conditions under which expanding retrieval will produce better long term retention than evenly spaced retrieval. The first relevant finding is, as stated above, the first retrieval attempt after the study period must be sufficiently difficult. Both of the spacing conditions that only had a single item between study and retrieval produced high performance on the initial retrieval attempt, but those conditions also saw a large decline in performance across the learning trials. The 1-2-3 and 1-5-9 conditions, for example, both had a 10 percentage point drop in performance between the first and third retrieval attempts. The conditions that were more difficult and had at least three items between studying and the first retrieval attempt had no forgetting across the learning trials. Thus, increasing the difficulty of the first retrieval attempt produced steady performance throughout

the learning trials. Maintaining a steady rate of performance throughout learning may be important in preventing rapid forgetting from occurring.

The next important finding was concerned with forgetting in each of the conditions. Forgetting, as Tables 1 and 3 show, was quite rapid in the 1-2-3 and 1-5-9 conditions both during learning (as performance decreased across learning trials) and during the final test retention intervals. Although there was no forgetting across learning trials for the sequences that began with a larger number of intervening items, performance on the third and final learning trial was still higher in the 1-2-3 and 1-5-9 conditions than the 3-5-8, 5-8-13 or 5-5-5 conditions. However, on the final test given 10 minutes later, the 5-8-13 condition produced numerically better performance than the other conditions, including the evenly spaced (5-5-5) condition. This result was due to almost no forgetting in the 5-8-13 condition. This trend continued, and the 5-8-13 condition produced significantly better performance than evenly spaced retrieval on the final test administered after a 48 hour retention interval. In this retention interval condition, the 5-8-13 sequence produced half the amount of forgetting as the 5-5-5 condition.

The 5-5-5- and 5-8-13 conditions were considered the critical comparison in this study and addressed the question of whether expanding retrieval can produce superior performance on a long term retention test compared to evenly spaced retrieval. On the learning trials, these two conditions produced similar levels of performance. After a 10 minute retention interval the 5-8-13 condition produced slightly better results, and after 48 hours, the 5-8-13 condition produced significantly better memory for the word pairs than the 5-5-5 condition.

Thus far, the question of whether expanding retrieval can produce superior performance compared to evenly spaced retrieval on immediate and long term retention tests has been mixed at best. In fact, equally spaced retrieval has generally produced better performance than expanding retrieval on tests taken at least 24 hours later. Karpicke and Roediger (2007) even noted that, "we know of no existing study using a continuous paired associate learning task...that has shown that expanding retrieval produces greater long-term retention (after delays greater than 24 hr) than equally spaced practice." The present experiment is one that does show that expanding retrieval produces greater long-term retention after 48 hours. Based on the current results, it is not entirely surprising that the previous research has been so mixed. Considering that a key factor in this experiment was the difficulty of the initial retrieval attempt, the 1-5-9 condition that has been used most widely is not a sequence that would be expected to improve long term retention. This also explains why the 5-5-5 condition, which begins with a difficult initial retrieval attempt, has produced such good performance in previous experiments.

The unique 5-8-13 expansion sequence, which combined a difficult first retrieval attempt with expanding retrieval, not only resulted in virtually no forgetting during both the

learning trials and on a test administered after a 10 minute retention interval. This particular sequence prevented the rapid forgetting that normally occurs immediately after learning takes place. Further, and of most importance to the question at hand, is that the combination of a difficult initial retrieval attempt and an expanding sequence resulted in half the amount of forgetting on the long-term retention test when compared to the evenly spaced control.

In summary, increasing the difficulty of the initial retrieval attempt protects against rapid forgetting that can occur within minutes of the study trial. This is evidenced by the small amount of forgetting during learning and on the 10 minute retention interval test in both the 5-5-5 and the 5-8-13 conditions. However, expanding retrieval from a difficult initial retrieval attempt produces better performance on a final test 48 hours. Combining a difficult initial retrieval attempt with even more difficult subsequent attempts reduces the forgetting that normally occurs immediately after learning (described by Ebbinghaus, 1885/1913; Rubin, Hinton & Wenzel, 1999) and up to 48 hours later.

Abstract

Structure-Behavior-Function (SBF) models of complex systems use functions as abstractions to organize knowledge of structural components and causal processes in a system. We describe an interactive learning environment called ACT (Aquarium Construction Toolkit) for constructing simple SBF models of classroom aquaria, and report on a case study on the use of SBF thinking and the ACT tool in middle school science classes. We present initial data indicating that SBF thinking supported in part by the ACT tool leads to enhanced understanding of functions and behaviors of aquaria.

Keywords: Science education, Middle school science, Complex systems, Ecological systems, Functional models, Interactive learning.

Motivation and Goals

Understanding of complex systems enables important tasks such as monitoring, measurement, sensemaking, troubleshooting, explanation, prediction, diagnosis, redesign and design. Thus, understanding complex systems has been recognized as a key idea in science education in national science standards (National Research Council, 1996) as well as local standards (e.g., New Jersey Department of Education, 2006).

However, understanding complex systems is cognitively hard not only because of the large number of components and variables in a given system, but also because complex systems are dynamical and contain feedback loops (Forrester 1968) and exhibit hierarchical structure but are only nearly decomposable (Simon 1996); causal processes at one abstraction level in a complex system emerge out of interactions among components and processes at lower levels; and while some components of a complex system may be visible, many components, relations and processes typically are invisible. Thus, understanding complex systems challenges cognitive resources such as attention, memory and perception. The juxtaposition of understanding complex systems as an educational standard and the cognitive difficulty of understanding complex systems in turn poses a practical challenge for cognitive and learning sciences.

Theories of understanding complex systems in terms of functional models use functions as abstractions for organizing knowledge of structural components and causal processes (e.g., Chandrasekaran 1994a, 1994b; Kitamura et al. 2004; Rasmussen 1986). In Structure-Behavior-Function (SBF) models, for example, Structure refers to components of a complex system as well as connections among the components; Behaviors pertain to causal processes in the complex system; and Functions are abstractions of structural components and causal behaviors (Goel et al, 1996; Prabhakar & Goel, 1998; Goel, Rugaber & Vattam 2009). Representations of structural components and causal processes specify the functions they accomplish; representations of functions in turn act as indices into the components and processes that combine to accomplish them.

The SBF theory of understanding complex systems has led to lesson plans and interactive tools for learning about complex systems in science education. Our ongoing ACT project, for example, is an interactive learning environment that enables middle school children to construct and simulate SBF models of classroom aquaria (Vattam et al. 2010). An initial study indicates that teacher-led SBF thinking about aquaria, supported in part by use of ACT by small teams of students, led to significant improvement in understanding the basic structure, behaviors and functions of aquaria. However, we also found that in practice, middle school teachers and students did not use ACT the way we had planned. Instead of using ACT to construct and simulate full SBF models of aquaria, middle school students in our studies used the tool mainly to construct SBF graphical models of aquaria (Jordan et al. 2009).

In this paper, we report on a new study that utilizes a new version of the ACT interactive tool. The new version of ACT (ACT3) directly builds on our observations of SBF thinking practices in middle school science classrooms in the initial studies as well as feedback from the middle school teachers and students on the use of the previous version of ACT (ACT2). Preliminary results from new studies of SBF thinking about aquaria, stimulated, scaffolded and supported in part by the new ACT tool, appear to replicate the findings from the earlier studies with the new and more engaging tool.

The SBF Theory of Understanding of Complex Systems

Narayanan (2007) characterizes complex systems as follows: complex systems exhibit hierarchical structures composed of subsystems and components; subsystems and components exhibit natural behaviors or engineered functions; the subsystem/component behaviors causally influence other subsystems/components; the propagation of these causal influences creates chains of events in the operation of the overall system and gives rise to its overall behavior and function; and these chains of events extend in temporal and spatial dimensions. The origin of both Narayanan's characterization and our SBF models lies in Chandrasekaran's (1994a) Functional Representation (FR) scheme. Chandrasekaran (1994b) traces the development of FR; Goel, Rubager, Vattam (2009) describe the evolution of SBF from FR. Briefly, (1) the structure portion of an SBF model of a complex system specifies the "what" of the system, namely, the components of the system as well as the connections among them. (2) Behaviors specify the "how" of the complex system, namely, the causal processes occurring in the system. A behavior typically comprises of multiple states and transitions among them. The transitions are annotated by causal explanations for them. (3) Functions specify understanding of the "why" of the system. A function is a teleological interpretation of the components and processes in the system. (4) A component of a complex system can itself comprise a system and thus have its own SBF model. (5) The behavior of a system specifies the composition of the functional abstractions of its subsystems into the system functions.

Other researchers have described similar functional models of complex systems, e.g., Rasmussen (1986) and Kitamura et al. (2004). Although the various functional models differ in many features, they typically share some key characteristics, viz., explicit representation of function, use of functional representations to organize knowledge of causal behaviors and structural components, a hierarchical system-subsystem organization of knowledge, a view of causal behavior as an intermediate abstraction between structure and function, and domain-independent vocabularies for representing structure, behaviors and functions of complex systems. Erden et al. (2008) provide a recent survey of functional models of complex systems and their use in design.

Note that in the SBF theory of understanding complex systems, functions are mental abstractions, and thus are not intrinsic to the complex system. In case of designed systems, a functional abstraction corresponds to an intended output or observable behavior of a system, subsystem, or component. However, since functions are abstractions, we have also used the SBF theory to model natural systems including biological systems such as the human heart and ecological systems such as aquaria. Like designed systems, natural systems exhibit the types of causal processes and multiple levels of abstraction that characterize complex systems. We use function as a lens through which to view complex biological

systems as well. For example, we may model a pond as being able to regulate the chemicals inside its water to maintain a livable environment for fish and plants. We may also specify the invisible causal process that achieves this self-regulation of the pond. In addition, we may state how this causal process combines functional abstractions of other processes and subsystems into the self-regulation function of the pond. In this functional representation of the pond, functional abstractions provide explanations for the relevance of specific subsystems in the context of a causal process.

Since SBF models explicitly represent functions, they differ fundamentally from causal models of complex systems (e.g., Chi 2005). The interactive tool called Betty's Brain (Biswas et al. 2005) is a good representative of the use of causal models in interactive learning because it too works in the same general domain (ecology) and targets the same general audience (middle school students). The innovation in the system lies in transforming the role of students into teachers of problem-solving software agents (Betty). This role transformation is motivational and engaging to middle school students. The models that students help Betty build, however, are causal graphs, with no mention of function and only implicit specification of structure. Although SBF models also represent behaviors in the form of causal graphs, the behavioral representations are grounded in the structure and indexed by their functional abstractions.

ACT: Interactive Construction of SBF Models

Empirical studies in the SBF framework show that while aquaria experts and hobbyists typically understand aquaria in terms of their structure, behavior and function, novices such as middle school students and pre-service teachers familiar with aquaria focus on the visible structure, show minimal understanding of function, and show little evidence of understanding the invisible causal behaviors (e.g., Hmelo-Silver, Marathe & Liu 2007). Thus, we developed a suite of interactive tools called RepTools that included SBF-inspired function-centered hypermedia (Liu & Hmelo-Silver 2009) as well as NetLogo simulations of aquaria generated by experts (Hmelo-Silver et al. 2007). Using the SBF coding scheme to analyze students' work on pre- and post- tests and the metrics for measuring SBF understanding of complex systems developed earlier (Hmelo, Holton & Kolodner 2000), we showed that the use of RepTools leads to deeper SBF understanding of complex systems in middle school science classrooms.

Although RepTools provided a useful learning environment, it did not provide a knowledge construction facility that allowed students to explicitly articulate their SBF understanding of complex systems. However, we know that scientists *construct* models of complex systems they seek to understand (Clement 2008; Nersessian 2008). From a constructivist perspective, much of learning entails active, social construction of knowledge (Palincsar 1998), and research on interactive learning increasingly emphasizes collaborative construction of external representations (Kozma 2000; Lajoie et al. 2001; Suthers 2006).

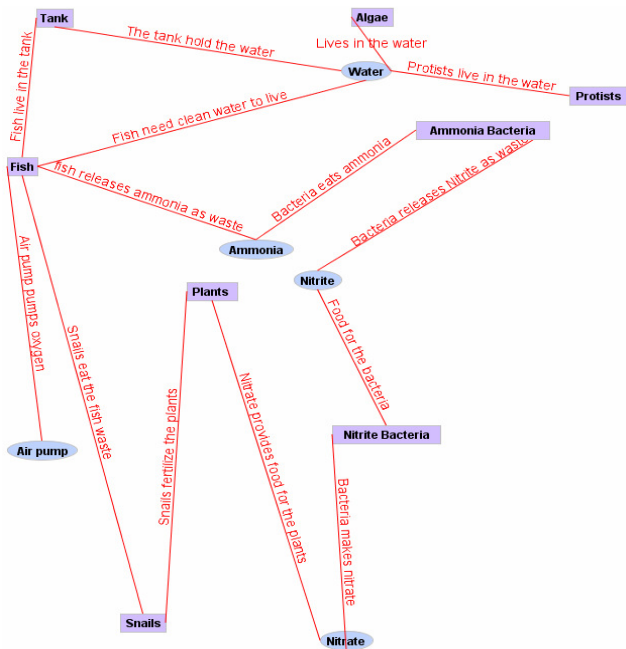

Figure 1: Model Graph of the nitrification process designed by a 7th grade student using ACT3.

Thus, we developed an interactive learning environment called ACT that provided a tool (called SBFAuthor) for constructing SBF models of classroom aquaria in middle school science (Vattam et al. 2010). In order to adapt the SBF modeling language to serve as an effective modeling tool for learners, we augmented it with a visual syntax to obtain vSBF: a visual SBF modeling language. Creating an SBF model of a particular complex system in vSBF now becomes an exercise in drawing an annotated, flowchart-like diagram of the system using the modeling primitives provided by the language. ACT also integrated SBFAuthor with the Netlogo simulation platform (Wilensky 1999; Wilensky & Resnick 1999). In addition, ACT provided access to extant RepTools. The goal was to encourage middle school students to understand complex systems in terms of functional abstractions and casual behaviors. The intended method was teacher-led SBF thinking supported by the use of ACT for construction, simulation and revision of SBF models of classroom aquaria.

In an initial study conducted in 2008, we introduced the original ACT tool (ACT2) into three middle school classrooms consisting of one hundred and fifty seven students (Jordan et al. 2009). One example of SBF thinking used by the three middle school teachers in the initial study pertained to the nitrification process. The nitrification process is the process by which an aquarium cleans itself of waste that is poisonous to fish. Fish release ammonia in their waste, a highly poisonous chemical; nitrosomonas consume this

ammonia and output nitrite, while nitrobacters eat this nitrite and release nitrate. Nitrate, though still poisonous to fish in large quantities, is much less dangerous than ammonia. In this example, the structural components in the system are the fish and bacteria. These components serve certain functions; for example, one function of the nitrosomonas is to clean the water of harmful ammonia and provide food for nitrobacters. Of course, this function is merely our teleological interpretation of this action of nitrosomonas, since (insofar as we know) the bacteria do not intentionally set out to serve a purpose to the fish. The behavior by which these nitrosomonas accomplish cleaning is through a natural ingestion/output behavior. In this example, it is also possible to see how SBF models may examine systems at multiple levels of abstraction. One could state that the aquarium as a whole serves the function of cleaning itself, and the behavior by which it accomplishes this is the nitrification process. One can also imagine how a similar analysis could be applied to how bacteria eats one chemical and outputs another.

Our initial study indicated that teacher-led SBF thinking, supported in part by use of the ACT tool, led to statistically significant improvement in understanding of classroom aquaria as a complex system (Vattam et al. 2010). The finding appeared robust in that it was independent of the teaching styles of the three middle school teachers in the initial study. We also found the middle school students in our initial study did not use the ACT tool as we had intended. Instead of using ACT to construct and simulate SBF models of the nitrification process described above, middle school students in our studies used the tool mainly to construct simple SBF graphical models of the process (Jordan et al 2009). This may have been in part because the 1-week and 2-week science units in which the ACT tool was used were too short for students to become familiar enough with SBF thinking as well as the ACT tool to construct and simulate SBF models of the nitrification process. It may also partially be due to difficulty in understanding the notions of states and transitions between states. Detailed feedback from some middle school teachers suggested the need for SBF tables that list the structural components, causal behaviors, and their functional abstractions.

The New ACT: Simplification of SBF Models

Given our observations of the practice of SBF thinking and learning in the initial study, as well as the feedback from middle school teachers and students in the study, we redesigned the ACT interactive environment. The new ACT environment (ACT3) supports two tools: SBFAuthor and RepTools. Further, SBFAuthor enables the construction of simple, partial, single-level SBF models through a Model Graph tool and Model Table tool that work in conjunction with each other. These can be seen in Figures 1 and 2.

Model Graph		Model Table	Notes
Component (What)		Component Function (Why)

Figure 2: The Model Table derived from the previously shown Model Graph.

Figure 3: Dialog for adding details to the structure in the model graph.
Note the specification of the function of the component.

Model Graph: The Model Graph enables users to create the structural portion of an SBF model in terms of its structures (components and substances) and their associated connections; Figure 1 depicts a Model Graph actually constructed by a student in the classroom. The structure model is presented as a graph. For each component or substance in the structure, a corresponding node is created. Nodes are linked together by behaviors, which are represented by lines drawn between nodes. Functions of the structures and behaviors are added using a dialog window (see Figure 3), as well as the Model Table (see Figure 2). In this way, students can define and connect structures, behaviors and functions in an externalized view, which helps guide them toward a more expert-like understanding. Most importantly, this allows students to explicitly define the functions of the system in order to better understand how larger processes emerge from underlying functions.

Model Table: The Model Table is an organizational tool intended to allow students to engage in their natural thought process when first encountering a complex system. An example can be seen in Figure 2. The Model Table features three columns: one for Structure, one for Behavior, and one for Function. Structures are linked to Behaviors in a one-to-many association, while Behaviors are linked to Functions in a one-to-one association. The Model Table is more than a preliminary brainstorming tool, however. Adding structures to the Model Table will automatically result in their creation on the Model Graph. Behaviors and Functions appear in the Model Graph after their addition to the Model Table, through the Structure's pop-up dialog menu. The control works both ways: new Structures, Behaviors and Functions added on the Model Graph automatically appear on the Model Table.

RepTools: ACT also links to the extant RepTools. RepTools was designed to accompany a physical aquarium installed in each classroom. It provides digital tools that feature function-centered hypermedia from which students can read about the structures, behaviors, and functions occurring within an

aquarium system (Liu & Hmelo-Silver 2009). It also includes a micro and macro-level NetLogo-based simulations (Wilensky 1999) developed by experts. The macro-level simulation enables students to test ideas about fish spawning and water quality, and the micro-level simulates the nitrification process that occurs within an aquarium as part of its biological filtration (Hmelo-Silver et al. 2007). In combination, these digital tools allow students to not only test ideas about the aquarium system but also gain insight into the explanations behind the processes and outcomes that occur at multiple levels within the aquarium.

Methods

Setting

Overall, two hundred and seventy three (273) students participated in this 2009 study from four middle schools classrooms in central New Jersey - three from seventh grade and one from the eighth grade. Their science teachers integrated this unit as a part of their regular science instruction. Prior to beginning the study, none of the students were taught to use SBF as a representational tool for complex systems. All four teachers attended an evening workshop where they were introduced to these digital tools prior to implementation in the classroom. The curriculum unit lasted from one to two weeks.

Besides the eighth grade classroom, none of the other classes had a physical model of the aquatic ecosystem (aquarium) as a part of their classroom environment. In order to prepare for the unit, the researchers set up aquariums in the remaining three seventh grade classrooms. Students used the digital tools (ACT, SBFAuthor, RepTools) on laptops while working in small groups, which varied from 2 to 6 students per computer, to generate models for analysis in this study.

Classroom Instruction

The four science teachers appropriated the curriculum and implemented it based on their individual scientific knowledge and learning styles of their students. While all the teachers used the SBF as a representational tool to organize their thinking about complex systems, there were variations within actual implementations of the curriculum.

SBF Introduction: Two teachers decided to begin the instruction with a discussion on the aquarium and focus on SBF as an initial activity using the ACT Model Table. The other teachers adopted the reverse strategy. Their introduction to the unit began with description of the SBF while illustrating it from students' immediate environment (for e.g. the classroom as a complex system). This top down effect was intended for the students to think about the SBF from a micro to macro level.

Modeling Aquatic Ecosystem: While some teachers emphasized the importance of the models as a means to represent ideas in summative fashion, other teachers chose to use the modeling task throughout implementation as a means to continually formulate and refine ideas. Additionally, some

teachers chose to have students model the entire system, while other teachers had students generate a model based on a portion of the system that corresponded quite closely to one of the NetLogo simulations.

Figure 1 illustrates a model graph created in ACT by a 7th grade student as part of an SBF model construction activity in one of the middle school classrooms. This figure shows the one of the systems frequently modeled in the classrooms: the nitrification process, described previously. Structures are shown as nodes (purple for biotic structures, blue for abiotic structures), while behaviors link together structures that directly and relevantly influence one another. Although not depicted in the figure, inside the structure boxes are statements about a component's function as indicated in the dialog box of Figure 3; these functions can also be seen in the Model Table in Figure 2. In this way again, students are encouraged to recognize and explicitly state the functions of the system, reinforcing a functional understanding.

Results

To assess the effectiveness of the SBF-driven curriculum and technology, identical tests were administered before and after engagement in the aquarium unit. These tests asked about the structures, behaviors and functions of the aquaria, and were also given problems to solve regarding aquarium processes. To examine learning with respect to SBF, we coded the pre- and post- tests using an SBF coding scheme (Hmelo, Holton & Kolodner 2000). Structural components, such as fish, plants, filter, was coded as structure. A reference to the mechanisms of how the components worked was coded as behavior. For example, a behavior of the plants could be absorb some of the carbon dioxide in the fish tank and produce oxygen through photosynthesis. Reference to the outcome of a behavior was coded as function. For example, a function of the filter could be to clean and circulate water. All tests were coded blind to condition by one rater.

Table 1: Pre- Posttest Results

	Structure	Behavior	Function
Pretest Mean (SD)	8.08 (2.624)	3.80 (2.107)	4.78 (2.924)
Posttest Mean (SD)	9.33 (2.347)	6.20 (2.766)	8.12 (3.241)
<i>t</i> (273)	5.60*	11.65*	12.55*
Effect size	0.24	0.44	0.47

*All $p < .05$

In this preliminary study, the objective was to ensure that the SBF curriculum described here is successfully increasing understanding of functions and behaviors. Since students already are generally familiar with the structure of aquaria, increases in understanding of structure are considered a baseline for comparison of how the curriculum enhances understanding of functions and behaviors. Table 1 shows initial results from the pre- and post- tests collapsed across the four middle school classrooms consisting of 273 students. The first number in the first two rows refers to the Mean and

the second number in parentheses to the Standard Deviation. As indicated by the effect sizes, gains in structural understanding were modest, while we saw the greatest effect size for increase in behavioral (or causal) and functional understanding for all groups. These tests suggest that the SBF-driven curriculum and the ACT technology effectively increase understanding in terms of the deeper concepts of functions and behaviors. Thus, these results replicate the findings from our initial study. A sibling paper (Honwad et al. 2010) that too appears in these proceedings focuses on the use of RepTools in the ACT learning environment and reports on more recent data collected in 2010.

Conclusions & Open Issues

Functional models use functions as abstractions to organize knowledge of complex systems. We are pursuing a research program that investigates the use of Structure-Behavior-Function modeling for helping middle school children understand complex systems such as classroom aquaria (Hmelo-Silver et al. 2008; Jordan et al. 2009, Vattam et al. 2010). In this paper we described a new version of an interactive tool called ACT that enables middle school children to author simple SBF models of complex processes such as the nitrification process that results in self-cleansing in aquaria. We also described teacher-led SBF thinking in multiple classrooms supported in part by use of the ACT tool by small teams of middle school children. Preliminary results from the SBF-driven science curriculum in this study indicate significant improvement in understanding of the basic structure, behaviors and functions of aquaria. These results appear to confirm initial results from earlier studies.

Of course, there remain many open issues, including the following three. Firstly, now that we have experimentally affirmed that the SBF curriculum and ACT technology is effective in learning about functions and behaviors of aquaria, there is a need to conduct controlled experiments. In particular, there is a need for finer analysis of the effectiveness of SBF thinking and the ACT tool based experiments featuring many conditions, such as curriculum without software and software without curriculum. Secondly, there is a need to determine whether the improved understanding of the functions and behaviors of aquaria is enabling improved reasoning about tasks such as establishment and maintenance of aquaria. Thirdly, there is growing evidence that middle school teachers on their own are appropriating SBF meta-models and transferring them to other complex systems such as the human digestive system (Hmelo-Silver et al. 2010). There is a need to determine if middle school children too are appropriating and transferring SBF meta-models to other complex systems.

Abstract

Cognitive alertness decreases at night due to circadian rhythms with adverse effects on performance across domains and tasks, including real-world tasks like driving and flying. Additionally, the strategy used on a task may have a substantial effect on performance. However, little is known about whether and how circadian rhythms and strategy interact to affect performance. The current study investigates participants' performance on an orientation task performed over a period of two weeks. Participants were assigned to simulated day or night shift conditions, and were trained to use one of two strategies for the orientation task. The results indicated that shift condition had little impact on a more declarative strategy for the task, but had a significant impact on a more spatial strategy. The results illustrate how different aspects of cognitive functioning may be affected differently by circadian rhythms, and point to some important implications for training and task performance in real-world contexts.

Keywords: spatial; sleep; circadian rhythm; fatigue; learning; shift work

Introduction

Critical, safety-sensitive activities, such as driving and air traffic control, are performed at all times of the day and night. Yet, it is not well understood how nighttime operations affect task performance in contexts such as these. Most research on night and shift work has focused on how shift differences affect sleep and frequency of accidents (e.g., Åkerstedt, 1988). Little work has focused on how shift work and task differences affect different cognitive processes alone or in interaction.

Variations in alertness due to circadian rhythms and sleep loss have been shown to affect various components of cognitive functioning (Jackson & Van Dongen, in press). For example, vigilant attention (Lim & Dinges, 2008), perceptual learning (Mednick, Nakayama & Stickgold,

2003), and motor learning (Walker, Brakefield, Morgan, Hobson & Stickgold, 2003) are all affected by fluctuations in alertness associated with time awake and circadian rhythms.

For shift work, circadian rhythms are particularly important. Circadian rhythms are driven by a biological clock in the suprachiasmatic nuclei of the hypothalamus, which imposes cyclical changes in alertness throughout the day, leading to increased pressure for sleep at night. This leads to nocturnal degradations in cognitive performance (Van Dongen & Dinges, 2005), as demonstrated in a variety of tasks and domains (e.g. Caldwell, 2003; Dinges, 1995).

The present research investigates how strategies recruiting different cognitive-perceptual processes may be differentially affected by fluctuations in alertness resulting from circadian rhythms in laboratory-simulated shift work. This is accomplished within the context of a spatial direction task, where distinct alternative cognitive strategies have been identified (Gunzelmann, Anderson & Douglass, 2004). In this task, participants are presented with two views of a set of objects (Figure 1). One of the views (the left side in Figure 1) is an overhead, ego-oriented perspective, based on a viewpoint at the bottom of the screen. Within the ego-oriented view, one of the objects (small circles) in each trial is filled in to identify it as a target. The other view (the right side in Figure 1) shows a map-like perspective with the viewpoint indicated by the arrow, which may be misaligned relative to the ego-oriented view on the left. The task requires participants to identify the location of the target in the map-like perspective.

In the study described here, participants were taught to use one of two strategies for the spatial direction task: one based on counting and the other on mental rotation, as in Gunzelmann et al. (2004). The strategies are described in more detail below. The key feature is that the strategies emphasize different cognitive functions, declarative and

spatial, and lead to reliably different performance in participants trained to use them.

The alternative strategies for the spatial direction task offer an opportunity to explore how different cognitive capabilities may vary in their susceptibility to fluctuations in alertness. Such variations can be important in naturalistic contexts, where a variety of strategies may be available. To address this issue in the context of a common situation, we compare performance on the spatial direction task between individuals placed on a simulated night shift schedule for two weeks versus individuals sleeping according to a simulated day shift schedule.

Method

This experiment was conducted as part of a larger study to understand how circadian rhythms and sleep disruption affect performance in a variety of domains.

Participants

Twenty-six individuals, 14 female and 12 male, ranging in age from 22 to 39 years old (mean = 27), from the general community of Spokane, Washington participated in the experiment. The participants were screened to be healthy and without sleep disorders, with no evidence of brain damage or learning disabilities, and free of drugs of abuse. Participants gave written informed consent, and were paid for their participation.

Stimuli

Participants completed the task shown in Figure 1. There are 8 possible target locations and 8 possible misalignments (45 degree intervals). However, performance is roughly equivalent for right-left mirrored stimuli (see Gunzelmann et al., 2004). For instance, response times for targets located in the lower-left and lower-right positions are similar for a given misalignment. Likewise, response times are similar for misalignments that differ only in the rotation direction, such as assumed perspectives at positions 4 versus 6 on the map. Because of this correspondence, participants were presented with only one of these trials in each session. There were therefore 25 trials per session — 5 target locations (bottom, near, middle, far, and top) crossed with 5 misalignments (0, 45, 90, 135, and 180 degrees) — which were presented in random order.

Participants responded using the numeric keypad portion of a computer keyboard, which was spatially mapped to the possible response locations on the map view. So, if the correct response was the bottom position on the map (as it is in the sample trial shown in Figure 1), participants responded by pressing the “2” on the numeric keypad.

Procedure

Participants were in the laboratory for fourteen consecutive days. The first day was a baseline day with 10 hours in bed for sleep (22:00–08:00). Subsequently, some of the participants ($n = 12$) changed to a simulated night shift. Night shift participants were given five hours in bed (15:00–20:00) on the second baseline day, before starting five

consecutive work days with 10 hours in bed during the daytime (10:00–20:00) on each day. On the seventh and eighth day, night shift participants had a simulated weekend during which they had 5 hours in bed (10:00–15:00), 7 hours awake, 10 hours in bed during the night (22:00–08:00), 7 hours awake, and then 5 hours in bed (15:00–20:00) before resuming their night shift schedule for the next 5 days. This schedule represented a stereotypical schedule for individuals working a night shift, who frequently shift back to a nighttime sleep schedule during weekends. After the last night shift day, night shift participants received 5 hours in bed (10:00–15:00), 7 hours awake, and then, on the final day of the study,

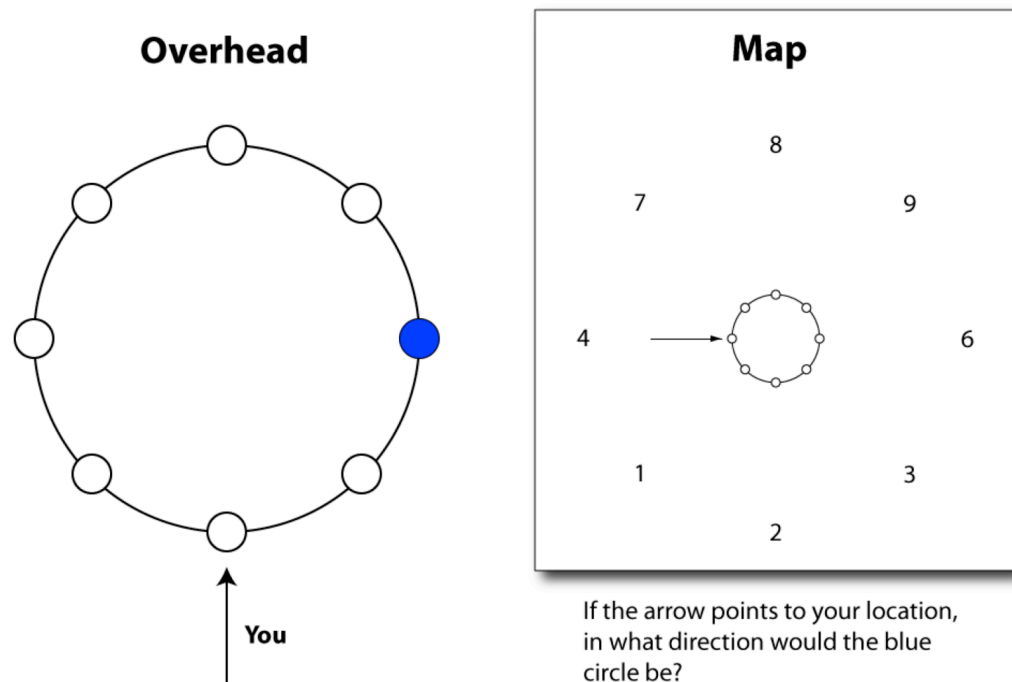

Figure 1: An example trial. The target on the overhead ego-oriented view (left side), indicated by the filled circle, is at middle distance to the right of center. The perspective on the map view (right side), indicated by the arrow, is misaligned by 90° clockwise. The correct response in this example trial is “2.”

were given 10 hours in bed (22:00–08:00) for recovery.

Participants on the day shift ($n = 14$) maintained the same sleep schedule throughout the study, with 10 hours in bed (22:00–08:00) each night. Note that participants on the day shift and night shift schedules were given the same amount of time in bed over the course of the experiment, although it was distributed differently.

Participants completed fifty-one test sessions of the spatial direction task over the fourteen consecutive days, with 2 to 4 sessions per day. On the first baseline day, participants completed three sessions; on the second baseline day, they completed two sessions. On each of the remaining days of the study, participants completed four sessions up until the last day when they completed two sessions.

Before the first session, participants were presented with instructions for the task, including training for either the rotation ($n = 13$) or counting ($n = 13$) strategy for which they completed four practice sessions. Training on the rotation strategy encouraged the participants to mentally rotate the relative positions of the viewpoint and the target on the overhead view (left side) to align them with the viewpoint indicated on the map view (right side). Specifically, they were taught to imagine an angle that connects the viewpoint (indicated by the “You” arrow) to the target on the overhead view, with the vertex at the center of the field (a 90 degree angle in Figure 1). They were then told to mentally shift to the map view, and to rotate the angle so that the arrow in the overhead view was aligned with the arrow in the map view (a rotation of 90 degrees clockwise in the trial shown in Figure 1). At this point, the answer could be determined by finding the target end of the angle.

Training on the counting strategy taught the participants to count the number of objects from the arrow at the bottom of the ego-oriented view to the target position (the count is 2 in Figure 1) and note the direction in which the target was located (counterclockwise in Figure 1). They were then told to count the same number of steps around the map view in the appropriate direction from the location indicated by the smaller arrow.

Results

The analyses focused on how the study condition (night shift versus day shift) interacted with the trained task strategy to affect performance. Previous research using this task has shown that some people use special-case strategies when the target is at the top (“across from where I am”) or bottom (“where I am”) of the ego-oriented view (Gunzelmann et al., 2004). In order to ensure that the analysis truly reflected differences in the use of the counting and rotation strategies, these special cases were removed from the analysis. Additionally, we only included data in the analysis for sessions when the sleep schedules were different for the two groups (i.e., when the night shift group was up at night), that is, days 3 to 7 and days 9 to 13.

Linear mixed-effect models were used for the analysis, using the R environment (R Development Core Team, 2009) with the nlme package (Pinheiro, Bates, DebRoy, Sarkar & the R Core Team, 2009). The skewed distribution of the response time data was corrected using an inverse square root. An alpha level of .05 was used for all statistical tests.

The analysis concentrated on the effects of the *strategy* that the participant was taught (rotation or count), the *work shift* of the participant (day or night), the *day* of participation, the location of the *target* (near, mid, and far), and *misalignment* between camera and target view (0°, 45°, 90°, 135°, and 180°). These were all included in the nlme analysis as multi-level factors, except for day, which was continuous. Participant was used as a repeated-measure grouping factor, and intercept, target and misalignment were included as random factors.

Table 1 shows the mean response times by strategy and shift. Neither the strategy, $F(1, 22) = 0.05$, $p = .83$, nor the shift, $F(1, 22) = 0.47$, $p = .50$, displayed a simple main effect on response time. As seen in Figure 2, participants performed better in later days, $F(1, 15458) = 2,300$, $p < .001$, reflecting a learning curve. As seen in Figure 3, targets located further away required more time, $F(2, 15458) = 81$, $p < .001$, and larger misalignments also required more time, $F(4, 15458) = 150$, $p < .001$. Additionally, misalignment had a larger effect when targets were further away, $F(8, 15458) = 26$, $p < .001$.

Performance improved more as time progressed for participants using the rotation strategy than for participants using the count strategy, $F(1, 15458) = 11$, $p < .001$. Performance of participants on the day shift improved faster than that of participants on the night shift, $F(1, 15458) = 21$, $p < .001$. Figure 2 shows the interaction of strategy, shift, and day, which was significant, $F(1, 15458) = 15$, $p = .008$. Up until day six, participants using the rotation strategy were performing worse, no matter which shift they worked, than those using the counting strategy. Later, participants using the rotation strategy on the night shift eventually reached the performance level of those using the count strategy, and participants using the rotation strategy on the day shift outperformed the other groups.

Observed error rates were low ($M = 4\%$, $SD = 3\%$). The error rates tended to correlate with the response time ($r^2 = 0.58$), suggesting that the between-group differences did not stem from a speed-accuracy trade-off.

An analysis of the baseline data alone was conducted to explore the possible influence of differences among the groups at the start on the observed effects. Importantly, neither the strategy, $F(1, 22) < 0.01$, $p = .99$, the shift, $F(1,$

Table 1: Mean (SD) response times (ms) by strategy and shift.

		Shift	
		Day	Night
Strategy	Counting	2016 (802)	2113 (945)
	Rotation	2015 (1033)	2210 (1041)

Figure 2. Reaction time as a function of strategy trained, work shift, and day in study. Data from days 1 and 2 (baseline) prior to work shift and day 14 (last day) after work shift are shown for reference, but were not included in the primary analysis. The sleep schedule was interrupted by a simulated weekend on day eight (dotted line), which was not included in the analysis or shown here. Error bars indicate ± 1 standard error.

Figure 3. Response time as a function of misalignment and target location. Error bars are too small to be visible.

22) = 0.12, $p = .73$, nor their interaction, $F(1, 22) = 0.04$, $p = .85$, were significant, indicating that the groups were roughly equivalent in their performance at the start.

Discussion

All of the participants gained extensive expertise in the task by performing the task multiple times per day over a two-week period. Still, the strategy the participants trained on

and the work shift to which they were assigned had a significant impact on performance.

During the first two days of the experiment (i.e., baseline days), performance was not significantly different across work shift conditions, which supports the conclusion that differences seen in the subsequent weeks were real and not a result of selection bias. Differences seen in the baseline condition with respect to strategy are consistent with previous research using this task (Gunzelmann et al., 2004). As seen in Figure 2, participants trained to use the counting strategy initially performed slightly better (but not significantly better) than participants trained to use the rotation strategy, and, as shown in Figure 3, misalignment angle and target location interacted, both of which are in line with those previous results.

Participants on the night shift tended to perform worse than those on the day shift. Previous research has shown that performance on a variety of tasks tends to be worse at night (e.g., Van Dongen & Dinges, 2005) and a number of commercial and industrial disasters have been attributed to degraded cognitive functioning associated with such shift work (Caldwell, 2003; Dinges, 1995). Further, within each shift condition, participants using the rotation strategy tended to perform worse than those using the counting strategy. As with the baseline data, this was expected, as it is consistent with previous research (Gunzelmann et al.,

2004). However, the results also suggest that, although initially more difficult, the rotation strategy may be a more efficient approach to the task by the end of the experiment (at least in the day shift condition).

Asymptotic performance appears to have been reached earlier when the counting strategy was used. Further, asymptotic performance appears to have been the same for day and night shift when the counting strategy was used. When the rotation strategy was used, the rate of performance improvement was reduced. However, on the night shift, performance using the rotation strategy was eventually equivalent to performance using the counting strategy. Moreover, on the day shift, performance with the rotation strategy continued to improve through the end of the protocol, and was eventually better than the performance in all other conditions. These results suggest that (a) learning occurs faster for the counting strategy than for the rotation strategy, (b) the task is learned equally well when the counting strategy is used whether performed during the day or night, (c) the task is not learned as well at night when the rotation strategy is used, and (d) the rotation strategy may ultimately display the greatest amount of learning, when performed during the day.

So what could cause this interaction of strategy and shift? One possibility is the familiarity of the knowledge and transformations needed for the two strategies. The counting strategy relies heavily on well-known facts: the order of integers. That familiarity may have limited the impact of lower alertness and allowed participants on the night shift to arrive at a level of performance comparable to those on the day shift by the second half of the experiment.

In contrast, the rotation strategy may rely on knowledge that is less well practiced, thus requiring more cognitive or perceptual learning. Mental rotation is often associated with the visual perceptual system (e.g., Kosslyn, Thompson, & Ganis, 2006). While mental rotation is a well-practiced process, it may be stimulus or task specific. For instance, research has shown that the rate of rotation varies with stimulus complexity (Bethell-Fox & Shepard, 1988). While the stimuli in this task are relatively simple, the angle to be rotated by the participants is defined only by the end points, which may have added to the difficulty in maintaining an accurate visualization. Results of this imaginal visualization may be more difficult to learn or recall with a lower level of alertness, thus resulting in slower performance for participants on the night shift.

With practice, specific angles and rotations may be consolidated and stored in declarative memory. Within a session, the same combination of target and misalignment angle was never repeated. However, trials were repeated across sessions. This may have allowed participants to learn the results of mental rotations over days.

In addition, the rotation strategy may allow for more optimization of the procedural knowledge than does the counting strategy. Perhaps because mental rotations require more effort than counting, there was more pressure for additional optimization in the rotation strategy. Initially, the

task takes longer to execute using the rotation strategy. This extra time may work as additional pressure to optimize (either explicitly or implicitly) the procedural knowledge brought to bear on the task. Further, variations in alertness may affect the pressure to optimize or the results of the optimization.

If the rotation strategy involves more learning throughout the task, either through declarative or procedural knowledge processes, then this may explain why participants using that strategy on the night shift performed more poorly. It is possible that one effect of decreased alertness is to decrease the effectiveness of learning. Specifically, fluctuations in alertness may affect the encoding, consolidation, or retrieval of declarative knowledge gained through effortful processes, like mental rotations, or interfere with the optimization of procedural knowledge (Jackson & Van Dongen, *in press*).

Importantly, performance on the last day of the experiment, when all participants performed the task during the day, does not support the argument that memory retrieval was the cause of slowed performance at night. Performance continued to improve only for participants using the rotation strategy on the day shift, but remained fairly consistent with the previous three days for all other participants. If retrieval processes, rather than learning or encoding, were causally involved, we would expect performance for night shift participants using the rotation strategy to improve noticeably on the last day. Additional research is required to determine if declarative knowledge, procedural knowledge, or both are affected by decreased alertness when performing orientation tasks at night.

Conclusion

Performance differences based on strategy and sleep patterns have both real-world and theoretical importance. The results have implications for task training and performance in real-world contexts, and also illustrate how different cognitive processes may be affected differently by circadian rhythms.

This study shows that training must be evaluated in context. The time of day in which the task will be performed and the time allowed for training need to be considered, among other things. If the choice of strategy were based upon the best day shift performance alone, the preferred strategy in this task may be rotation. However, shift alone is only part of the story. The rotation strategy resulted in performance improvements over the counting strategy only near the end of the two-week experiment. If the training period were short or if consistent performance across shifts were an important criterion, a strategy that uses familiar knowledge, as the count strategy does, may be more beneficial.

Choosing the correct strategy for the task environment can help reduce the effects of night shift decrements in alertness. Even small differences in performance can have drastic effects on some tasks. Orientation tasks are commonly performed in parallel with many time-critical tasks, such as driving or flying. Distractions from the

primary tasks of even a couple hundreds of milliseconds can have unwanted consequences, especially when magnified in more complex tasks and environments. This is true in many situations, in addition to orientation tasks, where delays and errors can have severe consequences.

This research also reveals ways in which different components of cognitive functioning, utilized by different strategies, are differentially affected by circadian rhythms. The performance of individuals using the counting strategy did not vary significantly between those on a day shift schedule and those on a night shift schedule. This robustness was likely the result of using familiar knowledge in the strategy, leading to similar learning trends regardless of shift assignment.

In contrast, there was a significant impact of shift on performance for those using the rotation strategy, suggesting that the cognitive processes involved may be less robust to degradations in alertness at night. This vulnerability may be due to a greater reliance on the learning of visual perceptual information (i.e., angles and rotations), which appeared to be hindered by lower alertness.

In conclusion, the findings presented here speak to both the need for considering the strategy set used in a task and the potential for decrements in learning caused by decreased alertness. In other words, when evaluating the effects of cognitive moderators, such as alertness, it is critical to consider the strategy people use to complete tasks.

A Distributional Account of Covariance Effects and Talker Adaptation in Infant and Adult Phonetic Category Recognition

Bevan K. Jones (Bevan.Jones@Brown.edu)

Department of Cognitive and Linguistic Sciences
Brown University

Abstract

Both infants and adults are sensitive to the non-linguistic features of speech, and this sensitivity impacts speech sound categorization, but with somewhat different effects. While both infants and adults sometimes confuse the non-linguistic for the linguistic and are susceptible to categorization problems when the two covary, adults, on the other hand, are often able to exploit non-linguistic features to improve perceptual categorization. We present a Bayesian account of both adult and infant behavior, arguing that differing levels in linguistic maturity correspond to different models of linguistic structure. The infant's task is one of structure learning, adults, on the other hand, are estimating parameters for an already established structure.

Keywords: Speech perception; distributional learning; language acquisition; Bayesian models.

Introduction

Talker variability is a fundamental challenge in speech perception. The same phonetic category as uttered by two different talkers may seem quite different. At the same time, distinct categories produced by two different talkers may be acoustically quite similar (Dorman, Studdert-Kennedy, & Raphael, 1977; Magnuson & Nusbaum, 2007). Unsurprisingly, this variability poses a problem for infants as they acquire their language. In particular, studies have shown that infants are prone to confounding talker-specific characteristics with phonetic categories when the talker covaries with the category during learning (Houston & Jusczyk, 2000; Creel, Aslin, & Tanenhaus, 2008). For instance, when taught to recognize two different categories, one produced exclusively by a female speaker and the other by a male speaker, infants were unable later to identify those phones when spoken by the opposite sex. This suggests that learning not only involves acquiring information about the features of the exemplars of the category, but, more fundamentally, about which features relate to the categorization task at all.

Adults are not immune to talker variability either and can also be misled by talker differences (Kraljic, Brennan, & Samuel, 2008; McQueen, Norris, & Cutler, 2006), but the same studies also demonstrate that adults are able to adapt to the differences. In fact, speaker identity may even be exploited to improve recognition performance at times, as suggested by experiments with episodic memory. Goldinger (1996) showed that words spoken by one speaker can be more easily recognized when uttered by the same speaker even after significant time has elapsed. This suggests that not only do listeners note linguistically weighted cues but also indexical cues that might be used for talker identification.

While both infants and adults are faced with similar input and utilize statistical learning mechanisms, the nature of the problem they each face is quite different. Both face a categorization problem. Infants are still struggling to decide which dimensions in the high dimensional perceptual space are most relevant to the categorization task. Voice onset time, for instance, serves largely to distinguish the words “dime” and “time” since “d” is followed by a much shorter voicing delay than “t”. Other features such as fundamental frequency may serve an indexical function (aiding in distinguishing whether the talker is male or female, for instance) but are much less clearly related to the linguistic content in a language like English. Infants are engaged in a kind of feature selection, narrowing down the infinite set of possible features to just those that are most useful. Adults, on the other hand, have already determined which features are linguistic and which are not. However, far from simply discarding the non-linguistic information, adults may employ indexical features to track the talker, allowing them to adapt to the peculiarities of the individual's speech patterns.

We present a Bayesian account for both the infant and adult behavioral results. In the infant's case, the problem can be framed in terms of a model selection problem, a search through some space of models that relate the latent phonetic category to the observed features, both linguistic and non-linguistic. In the adult's case, talker adaptation is more of a problem of parameter estimation given an already learned model relating phonetic category, talker, and the observed linguistic and indexical features.

The models we present fall within the distributional learning paradigm. It is well known that speech sounds of all types tend to fall according to a Gaussian distribution (Peterson & Barney, 1951; Lisker & Abramson, 1964; Espy-Wilson, 1992). Furthermore, Maye, Werker, and Gerken (2002) show that bimodal distributions tend to prompt infants to identify two sounds where unimodal distributions lead to identification of a single category, suggesting that learners may rely to some extent on an assumption of something like a Gaussian distribution. Thus, learning can be characterized as a kind of parametric statistical search over unimodal or, in our case, Gaussian distributions.

We present an array of models to account for the different behaviors, arguing that not one, but several different models of the dependencies between features are required. Linguistic development is characterized under our assumption of multiple models as the selection of one model over another based

on accumulated evidence. In the early days, when infants have little evidence of which model is likely to generalize, infants make decisions based on recent experience. Hence, covarying talker with phonetic category during training results in the infant’s selecting a model that does not generalize to a more natural situation where talker and phonetic category do not covary. Similarly, we argue that adult talkers also shift between models depending on the available information. In the adult’s case experience is not so acute an issue, but some features are not always present in the input, or are obscured by noise, and thus they must use an alternative model that does not depend on those features.

We argue for a fluid shifting between models over a single monolithic model. Shifts between qualitatively different models, as opposed to a gradual adjustment of a single model, accounts for how distinct situations result in different processes. Yet each model operates on the same basic principles of distributional learning, where even the shift between models may be accounted for within a Bayesian framework.

Model Definitions

Figure 1 presents the four different structural relationships we consider, slight variations but with important implications. At heart, they are all instances of a Gaussian mixture model which attempts to explain the linguistic feature x_i of the i^{th} sound by a distribution indexed by the sound’s phonetic category c_i . The more complex models (\mathcal{M}_3 and \mathcal{M}_4) elaborate on the theme by introducing talker specific distributions over x_i , and introduce an additional latent variable t_i for each sound to represent talker identity. All the models assume exactly two phonetic categories, and the talker specific models in turn assume exactly two talkers, a restriction that is easily relaxed but does not interfere with our purpose: explaining the human behavior in certain psycholinguistic experiments.

In the case of models \mathcal{M}_1 and \mathcal{M}_3 each speech sound also bears an indexical feature y . The two models treat y quite differently, however. \mathcal{M}_1 assumes all features are linguistic, and therefore represents a direct dependency between c_i and y_i , paralleling the dependency between c_i and x_i . \mathcal{M}_3 , however, distinguishes between linguistic and indexical features, and introduces a direct dependency between the indexical feature and the talker instead of the phonetic category. This change captures the notion that indexical features primarily serve to identify the talker, and only secondarily aid in recognition. This feature could be anything: fundamental frequency, or even an odd way of smacking ones lips at the end of each utterance. Since we are primarily interested in modeling phonetic category learning and not so much talker recognition, we treat this feature as a simple Bernoulli variable with a predefined parameter. That is, while the model learns the parameters for the distributions over x , y is determined by a pre-specified Bernoulli parameter.

These models attempt to explain the phenomena observed in certain psycholinguistic experiments. Houston and Jusczyk (2000) demonstrated that 7.5 month olds were able

to recognize words in a segmentation task when they were produced by a speaker of the same sex during test time as during training, but were unable to generalize across sexes. Singh (2008) demonstrates a similar sensitivity to other covariant non-linguistic features. Model \mathcal{M}_1 captures the behavior of infants in these situations, where all features are treated as linguistic. Since the model assumes all features are directly relevant to the categorization task, it will have a tendency to over fit when presented with data where talker and phonetic category accidentally covary (or are contrived to do so by an experimenter). Model \mathcal{M}_2 , on the other hand, treats the indexical feature as independent, only modeling the dependency between x and c , and is more likely to generalize across speakers.

Models \mathcal{M}_3 and \mathcal{M}_4 introduce the ability to adapt to individual talkers by providing separate talker-specific distributions for the linguistic feature x . However, the individual talker-specific distributions for a particular phonetic category are related to each other by a distribution for the category common to all talkers. Thus, we introduce a hierarchical Gaussian distribution over linguistic features, capturing the notion that, although each talker may have his own peculiar way of producing a sound, sounds of the same category all tend to be similar across speakers. The hierarchical distribution allows for speech recognition even when faced with a completely unfamiliar talker, since the λ and γ parameters define a prior over talker specific categories, providing a mechanism of generalization from familiar talkers to novel talkers.

Goldinger (1996) showed that adults are better able to understand speech when presented by the same talker. Similarly, Kraljic et al. (2008) noted that adults adapt to speaker-specific idiosyncrasies. In particular, they showed that when presented with speech where the alveolar fricative “s” as in the word “see” was shifted to a more palatal place of articulation resembling “sh” as in “she”, subjects were able to adapt and correctly identify the shifted “s” sounds — so long as they were provided with cues as to which variant of “s” was likely to occur. These situations are modeled by \mathcal{M}_3 and \mathcal{M}_4 . \mathcal{M}_3 uses the additional cue y to help identify the talker, and hence, the correct distribution for the category over linguistic cue x . This way the indexical feature has an indirect impact on recognition even if there is no direct dependency between c and y . \mathcal{M}_4 attempts to adapt to the talker without the aid of the indexical cue. The model assumes such features exist, but are not observed and therefore cannot assist in identifying the talker. The prediction for \mathcal{M}_4 is that, like the subjects in the study by Kraljic et al. (2008), the model will perform more poorly and will incorrectly allow talker-specific variation to influence recognition of other talkers.

Inference

The models were implemented using WinBUGS (Spiegelhalter, Thomas, Best, & Lunn, 2003), which uses an automatic Gibbs sampling MCMC approach to estimate parameters and allows rapid prototyping and testing

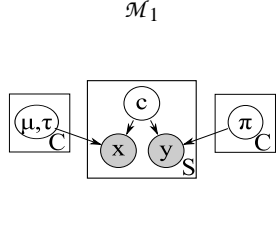

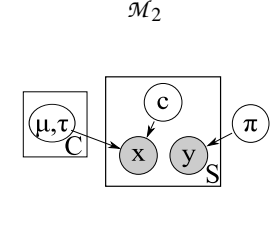

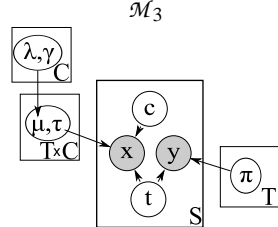

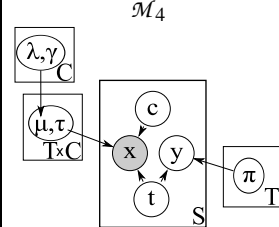

\mathcal{M}_1	\mathcal{M}_2	\mathcal{M}_3	\mathcal{M}_4

$\mu_c \sim \mathcal{N}(30, 5 \cdot 10^{-4})$ $\tau_c \sim \text{Gamma}(0.2, 0.2)$ $x c, \mu, \tau \sim \mathcal{N}(\mu_c, \tau_c)$ $y c, \pi \sim \text{Bern}(\pi_c)$	$\mu_c \sim \mathcal{N}(30, 5 \cdot 10^{-4})$ $\tau_c \sim \text{Gamma}(0.2, 0.2)$ $x c, \mu, \tau \sim \mathcal{N}(\mu_c, \tau_c)$ $y \pi \sim \text{Bern}(\pi)$	$\lambda \sim \mathcal{N}(30, 5 \cdot 10^{-4})$ $\gamma \sim \text{Gamma}(0.2, 0.2)$ $\mu_{c,t} \lambda_c, \gamma_c \sim \mathcal{N}(\lambda_c, \gamma_c)$ $\tau_{c,t} \sim \text{Gamma}(0.2, 0.2)$ $x c, t, \mu, \tau \sim \mathcal{N}(\mu_{c,t}, \tau_{c,t})$ $y t, \pi \sim \text{Bern}(\pi_t)$	$\lambda \sim \mathcal{N}(30, 5 \cdot 10^{-4})$ $\gamma \sim \text{Gamma}(0.2, 0.2)$ $\mu_{c,t} \lambda_c, \gamma_c \sim \mathcal{N}(\lambda_c, \gamma_c)$ $\tau_{c,t} \sim \text{Gamma}(0.2, 0.2)$ $x c, t, \mu, \tau \sim \mathcal{N}(\mu_{c,t}, \tau_{c,t})$ $y t, \pi \sim \text{Bern}(\pi_t)$

Figure 1: Four Possible Speech Perception Models: \mathcal{M}_1 treats all features as linguistic, \mathcal{M}_2 distinguishes the true and false linguistic features, \mathcal{M}_3 models individual talkers and treats some features as indexical, and \mathcal{M}_4 models talkers where the indexical features are absent or obscured. The variables are defined as follows: c is the speech sound category, t is the talker, x is a linguistic feature, y is an indexical feature, and the other variables are distributional parameters, defining talker and category specific distributions. C is the set of categories, T is the set of talkers, and S is the set of all speech sound tokens.

of Bayesian models.

We use an explicit initialization strategy, running the models in a generative mode with no observed variables and drawing category parameters for x at random from a $\mathcal{N}(50, 0.0025)$ for the mean and a $\text{Gamma}(2, 2)$ distribution for the precision. Using an initialization strategy such as this could speed convergence, since it tends to start the model out in a higher probability space. It also has the effect of reducing problems with numerical underflow error in WinBUGS. We were careful to pick the parameters randomly in such a way as to avoid biasing search in favor of any particular model or clustering, since we are primarily interested in the model properties, not the effects of initialization on convergence.

We find that even the more complex models converge in well under the 30,000 iterations we use. We average over the next 1000 iterations after convergence to measure the various parameters and statistics we report in subsequent sections. We take care in observing performance over these last 1000 iterations for any trends or abrupt changes. These mixture models have multiple symmetric optimal solutions, where “t” may be associated with cluster 1 and “d” with 2, or vice versa. If left to run long enough, the MCMC search strategy tends to switch between these different symmetric configurations every few thousand iterations. Averaging over instances of multiple such symmetric cases results in increased error in measurement. For instance, attempting to estimate the mean x value for phones in a cluster that toggles between “t” and “d” gets an average that is dissimilar to both configurations, and not only results in a measurement that is far from the gold standard but does not even accurately reflect the station-

ary distribution of the sampler.

Simulations

Data

We run the model on three synthetic data sets, illustrating the contrast between English word initial “t” and “d”. The primary difference between the two is in the voice onset time (VOT). We generate 100 sounds. Table 1 shows the model parameters used to generate each of the three data sets. For data set one we generate sounds as though there is only one speaker. For data set two we use two talkers, covarying the category with the talker so that instances of the first phone are produced by talker one and all instances of the second phone are produced by talker two. Finally, for data set three we split the 100 sounds evenly between the two talkers and the two categories, where talker and category are independent.

Simulation 1: The Developmental Situation

To simulate a situation similar to the psycholinguistic experiments of Houston and Jusczyk (2000), we present the models with two different data sets: data set one, where there is only one talker, and data set two, where there are two talkers, each producing just one of the two phones. In the behavioral experiment, it was observed that infants trained with word stimuli in a female voice were only able to reliably recognize words at test time when they were again presented in a female voice, and could not generalize to a male voice. Thus, the infants seem to confuse some non-linguistic feature of the sound, perhaps fundamental frequency, with the linguistic identity of the sounds. In this simulation, we shall

Table 1: Three Synthetic Data Sets

Talker	Parameter	Data Set		
		One	Two	Three
One	π_1	0.5	0.8	0.8
	π_2	0.5	0.8	0.8
	μ_1	15	15	0
	μ_2	35	-	35
	τ_1	15^{-2}	15^{-2}	15^{-2}
	τ_2	5^{-2}	-	5^{-2}
Two	π_1	-	0.2	0.2
	π_2	-	0.2	0.2
	μ_1	-	-	15
	μ_2	-	35	65
	τ_1	-	-	15^{-2}
	τ_2	-	5^{-2}	5^{-2}
Talkers Covary		-	Yes	No

say that our indexical feature y corresponds to a thresholded fundamental frequency: sounds with a high fundamental frequency are more likely to be produced by the female talker, and lower fundamental frequency sounds by the male talker.

To simulate the developmental character of an infant’s nascent linguistic capabilities, we perform a kind of structure discovery using Bayesian model selection between \mathcal{M}_1 and \mathcal{M}_2 , where the infant is attempting to determine if the indexical feature y is relevant to the linguistic category (\mathcal{M}_1) or not (\mathcal{M}_2). We do this by introducing an additional latent variable corresponding to the model and define a uniform prior over the model. Then, we compute the probability of the model given the data, integrating out all other variables. To compare the two models, we simply compare the probabilities assigned to each model given the data. Typically, in such cases if the ratio $P(\mathcal{M}_1|D)/P(\mathcal{M}_2|D)$, called the Bayes factor, is greater than one, we say that model one is preferred, and otherwise model two is preferred.

In this case, whether we use data set one or two, virtually all the probability mass (approximately 100%) is placed on exactly one of the two models. \mathcal{M}_1 is overwhelmingly preferred when using data set two, the case where talker and phonetic category covary. On the other hand, data set one, the data set where both phonetic categories are produced by the same talker, results in an overwhelming preference for \mathcal{M}_2 .

Table 2 presents accuracy results for the two models on the two data sets. Note that in general for these sorts of clustering algorithms there is an identifiability problem. That is, we cannot immediately say whether a particular category value $c = 1$ corresponds to the “t” or “d” sound. However, this poses less of a problem for this simple case with only two categories. For our purposes, it seems sufficient to assign the category that achieves highest accuracy.

We observe that while the model that mistakes the indexical for a linguistic feature (\mathcal{M}_1) performs very well for the artificially contrived covarying data, it performs worse on the

Table 2: Categorization Accuracy

Model	Data Set		
	One	Two	Three
\mathcal{M}_1	0.77	0.89	0.52
\mathcal{M}_2	0.81	0.81	0.76

Figure 2: The conditional distribution over x given c for the true data set as compared to the two models \mathcal{M}_1 and \mathcal{M}_2 . The clusters for the two talkers have been merged for ease of comparison. We also compare model 1’s clusters against the distribution over x given the talker t .

data set that has only a single talker, and very nearly at chance for the data set with two different talkers that don’t covary with the category. Figure 2 depicts the clusterings found by the two models on data set three (the data set with two talkers that don’t covary with the phone). While \mathcal{M}_2 seems to do as well as can be hoped considering its inability to adapt to individual talkers, \mathcal{M}_1 very nearly fails to differentiate at all between “t” and “d”. \mathcal{M}_1 attempts to cluster according to the indexical, collapsing the two categories together for each talker and clustering by talker instead of by category.

Thus, the model selection approach predicts the psycholinguistic results very well. Training on sounds in one talker’s voice, as in the covarying data set, results in the incorrect model being learned, which then fails to generalize to the same sound produced in the other talker’s voice.

Simulation 2: Talker Adaptation

Adult talkers actually have the ability to adapt to individual talkers, learning to exploit talker specific variations

(Goldinger, 1996). To simulate this ability, we compare the performance of models \mathcal{M}_3 and \mathcal{M}_4 . Model \mathcal{M}_3 corresponds to a case where the subject has learned that the indexical feature y can be used to identify the talker. On the other hand, \mathcal{M}_4 corresponds to the case where, although the subject is aware that the sounds may be produced by a different talker, the voice is disguised so that no cue is available for the identification of the talker. The contrast between these two models is similar to that demonstrated by Kraljic et al. (2008), where subjects were presented with ambiguous sounds that, in one condition, were accompanied by an additional cue indicating the ambiguity was result of talker dialect, and, in a second condition, were presented without this cue. This dialectical indicator, based on a phonological context, corresponds to our indexical feature y . Thus, condition one corresponds to \mathcal{M}_3 and condition two to \mathcal{M}_4 . In the behavioral study, it was observed that subjects were much more prone to confusing the two different phonetic categories when the sounds were presented without the additional cue. Thus, we expect \mathcal{M}_3 to do much better.

Table 3 contains the categorization accuracy results for \mathcal{M}_3 and \mathcal{M}_4 . Note that these models can theoretically identify the talker as well as the phonetic category, and we report accuracy for both. \mathcal{M}_3 does slightly better at clustering the phonetic categories, which is likely due to its much better ability to identify the talker. Note that without the indexical feature, \mathcal{M}_4 is at chance with regard to talker identification.

Table 3: Categorization Accuracy for Data Set Three

Model	Category	Talker
\mathcal{M}_3	0.86	0.78
\mathcal{M}_4	0.81	0.50

Figure 3 shows the clusters inferred by the two talker adapting models. The inferred Gaussian distributions for the two talkers are much more distinct for \mathcal{M}_3 than they are for \mathcal{M}_4 and more closely resemble the true distribution.

The inferred clusters, presented in Figure 3, are particularly interesting when compared against the findings of Kraljic et al. (2008), who observed that when the dialectical cue was absent, subjects adjusted their perceptual judgments for all talkers, not just the talker that produced the ambiguous variant. Model 3 makes use of the additional feature y for keeping the two talkers distinct, and therefore is less likely to let experience with the ambiguous talker influence its judgment for the other talker. Similarly, model 4 captures the situation where no additional cues are available. In this case, even if separate clusters are maintained for each talker, the two are functionally identical, falling somewhere in between the two true clusters. The mean is the mean of the two talker specific variants of the category, and, in the case of the “d” sound, the variance is much larger. Thus, the ambiguous talker influences recognition of the other talker when no additional cues are available, but not nearly as much when additional cues are

Figure 3: The conditional distribution over x given c for the true data set as compared to the two models \mathcal{M}_3 and \mathcal{M}_4 .

discernible.

As in the case of the developmental simulation, we see that the alternate performance of two models predicts the empirical results much better than would any one of the two.

Discussion and Conclusion

We have presented a computational model demonstrating a distributional account of certain covariance effects in infant and adult speech perception observed in the psycholinguistic literature. In particular, we found that by modeling the development of infant speech perception as a type of Bayesian model selection, we can account nicely for documented effects of covarying talker and phonetic category on infant confusions between categories (Houston & Jusczyk, 2000). We also found that by modeling talker identity, the same talker-specific features that confused the infant models could be exploited to improve performance, similar to demonstrations of talker adaptation in adult subjects (Kraljic et al., 2008). Also consistent with Kraljic et al. (2008), we found that when the talker adapting models were deprived of observed indexical information, talker specific speech habits influenced the category representations for all talkers not just the talker that produced the offending speech sounds.

While it would be difficult to account for all the phenomena with a single model of the statistical dependencies in the data, multiple models predict the empirical results fairly closely. This raises the question of how human subjects move between models, begging a model of the model selection process itself. Developmental shifts are readily handled in the Bayesian framework as a model selection problem, just the

approach we took for explaining the infant behavior. Though it is beyond the scope of this paper, a similar selection process may account for a shift between the infant and adult stages, perhaps with several additional intermediate structures. We argue that modeling the developmental process as a shift between models rather than a gradual adjustment of a single model better matches the fact that there are distinct developmental stages. One set of models may correspond to a particular stage, where the underlying behavioral causes are made explicit by the dependency structure of the model.

Although the simulations we presented dealt primarily with covariance between talker and phonetic category, we expect that models based on similar principles could explain equally well other kinds of covariance phenomena, such as with speech affect and category (Singh, 2008). Note that the models we presented to explain infant phenomena had no explicit model of talker identity. Thus, the choice between the two models in the developmental case only constituted a feature selection task, where features that clearly covaried with the phonetic category were greatly preferred by the selection criterion. Thus, these simple models, in fact, generalize directly.

Similarly, while the talker adapting models do contain an explicit representation of talker identity, there is nothing that requires that the t variable refer to a talker. Similar variables could represent modes of talking, such as infant directed speech, or happy speech, or to dialectical variations or any number of other categorizable speech types. That is, the talker adapting models present a general adaptation strategy that could be employed with little or no modification.

We argue for the generality of the principles underlying our computational account while stressing that the full speech recognition problem, or even just that of phonetic category recognition, is a difficult one, and we have not attempted to model it in its entirety. In fact, we made several explicit simplifications. First, we assumed there are only two categories and two talkers. Second, we assumed that there are roughly equal numbers of tokens of each category, and that each talker produces about half of the sounds. Also, since we were primarily interested in how phonetic categories are learned, we assumed a simple Bernoulli distribution for the indexical feature, when, in fact, in many cases this feature too may very well be continuous. Furthermore, it was sufficient for our purposes to model a recognition problem along only one or two dimensions of the perceptual space.

These simplifications eased the implementation work but did not interfere with our ability to simulate the behavioral situations in which we were interested. They should not limit the generalizability of the results, and could be relaxed in a fairly straightforward manner if we wished to increase the realism. For instance, the first restriction could be relaxed by allowing the model to infer how many categories there are from the data using an infinite mixture model. We could also use a beta prior to infer relative talker and phonetic category frequency. A similar prior could be used to infer the distribution over the indexical features. Finally, multivariate

Gaussians could be used for multiple correlated linguistic features (Vallabha, McClelland, Pons, Werker, & Amano, 2007). These are obvious extensions to consider for future work.

Abstract

We report on an experiment where the decision behavior of annotators issuing linguistic metadata is observed with an eye-tracking device. As experimental conditions we consider the role of textual context and linguistic complexity classes. Still preliminary in nature, our data suggests that semantic complexity is much harder to deal with than syntactic one, and that full-scale textual context is negligible for annotation, with the exception of semantic high-complexity cases. We claim that such observational data might lay the foundation for empirically grounded annotation cost models and the design of cognitively adequate annotation user interfaces.

Keywords: Natural Language Metadata Annotation; Annotation Behavior; Eye-Tracking; Syntactic Complexity; Semantic Complexity; Cognitive Cost Modeling

Introduction

Supervised approaches to machine learning (ML) are currently very popular in the natural language processing (NLP) community. While linguistic regularities are no longer hand-crafted by human experts in this paradigm, human intervention is still required to produce sufficient amounts of reliably annotated training material from which ML classifiers may learn or, considered as empirically valid ground truth, against which NLP systems can be evaluated.

The assignment of linguistic metadata (e.g., related to parts of speech, syntactic parses, or semantic interpretations) to plain natural language corpus data, a process called *annotation*, is a complex cognitive task. It requires a sound competence of the natural language in the corpus, as well as a decent level of domain and even text genre expertise.

Meanwhile lots of annotated corpora have been built which contain these precious human judgments (e.g., PennTreeBank (Marcus, Santorini, & Marcinkiewicz, 1993), PennPropBank (Palmer, Gildea, & Kingsbury, 2005) or OntoNotes (Pradhan et al., 2007)). Almost all of these annotated corpora were assembled by collecting the documents to be annotated on a random sampling basis (once the original document set had been restricted thematically or chronologically).

Only recently, more sophisticated approaches to select the annotation material are being investigated in the NLP community. One of the most promising approaches is known as *Active Learning* (AL) (Cohn, Ghahramani, & Jordan, 1996 ; Tomanek, Wermter, & Hahn, 2007) where an intentional selection bias is enforced and only those linguistic samples are selected from the entire document collection which are considered to be most informative to learn an effective classification model. When different approaches to AL are compared

with each other, or with standard random sampling, in terms of annotation efficiency the AL community, up until now, assumed *uniform* annotation costs for each linguistic unit, e.g., words (Ringger et al., 2008 ; Settles, Craven, & Friedland, 2008 ; Arora, Nyberg, & Rosé, 2009). This claim, however, has been shown to be invalid in several studies (Hachey, Alex, & Becker, 2005 ; Settles et al., 2008 ; Tomanek & Hahn, 2010). If uniformity does not hold and, hence, the number of annotated units does not indicate the true annotation efforts required for a specific sample, empirically more adequate cost models have to be developed. Accordingly, we here consider different classes of syntactic and semantic complexity that might affect the cognitive load during the annotation process, with the overall goal to find empirically more adequate variables for cost modeling.

The complexity of linguistic utterances can be judged either by structural or by behavioral criteria. Structural complexity emerges, e.g., from the static topology of phrase structure trees and procedural graph traversals exploiting the topology of parse trees (see Szmezcányi (2004) or Cheung et Kemper (1992) for a survey of metrics of this type). However, structural complexity criteria do not translate directly into empirically justified cost measures.

The behavioral approach accounts for this problem as it renders observational data of the annotators' eye movements. The technical vehicle to gather such data are eye-trackers which have already been used in psycholinguistics (Rayner, 1998). Eye-trackers were able to reveal, e.g., how subjects deal with ambiguities (Frazier & Rayner, 1987 ; Rayner, Cook, Juhas, & Frazier, 2006 ; Traxler & Frazier, 2008) or with sentences requiring re-analysis, so-called garden path sentences (Altmann, Garnham, & Dennis, 2007 ; Sturt, 2007).

The rationale behind the use of eye-tracking devices for the observation of the annotation behavior is that the length of gaze durations and the behavioral patterns underlying gaze movements are considered to be indicative for the hardness of the linguistic analysis and the expenditures for the search of clarifying linguistic evidence (e.g., anchor words) to solve hard decision tasks such as phrasal attachments or word sense disambiguation. Gaze duration and search time are then taken as empirical correlates of processing complexity and, hence, unveil the *real* costs. We therefore consider eye-tracking as a promising means to get a better understanding of the nature of linguistic annotation processes with the ultimate goal of identifying predictive factors for annotation cost models.

Figure 1: Text snippets taken from MUC7 documents annotated by *LOCation*, *PERson*, and *ORGanization* entity types.

Experimental Design

The focus of our study is on semantic annotation, the annotation of named entity mentions in particular. In this task, a human annotator has to decide for each word in a sentence whether it belongs to one of the entity types of interest or not. For the first time ever to the best of our knowledge, we applied eye-tracking to study the cognitive processes underlying the annotation of linguistic metadata.

We used the English part of the MUC7 corpus (Linguistic Data Consortium, 2001) for our study, which contains *New York Times* articles from the year 1996 reporting on plane crashes. These articles come already annotated with three types of named entities considered important in the newspaper domain, viz. “persons”, “locations”, and “organizations”. Figure 1 depicts typical text snippets from these articles along with the available annotations.

Annotation of these entity types in newspaper articles is admittedly fairly easy. We chose this rather simple setting because the participants in the experiment had no previous experience with document annotation and no serious linguistic education background. Moreover, the limited number of entity types reduced the amount of participants’ training prior to the actual experiment, and positively affected the design and handling of the experimental apparatus (see below).

We triggered the annotation processes by giving our participants specific *annotation examples*. An example consists of a text document having one single *annotation phrase* highlighted which then had to be semantically annotated for named entity mentions. The annotation task was defined such that the correct entity type had to be assigned to each word in the annotation phrase. If a word belongs to none of the three entity types a fourth class, “no entity”, had to be assigned.

The phrases highlighted for annotation were *complex noun phrases* (CNPs), each a sequence of words where a noun (or an equivalent nominal expression) constitutes the syntactic head and thus dominates dependent words such as determiners, adjectives, or other nouns or nominal expressions (including noun phrases and prepositional phrases). CNPs with even more elaborate internal syntactic structures, such as coordinations, appositions, or relative clauses, were isolated from their syntactic host structure and the intervening linguistic material containing these structures was deleted to simplify overly long sentences. We also discarded all CNPs that did not contain at least one *entity-critical* word, i.e., one which might be a named entity given its orthographic appearance (e.g., starting with an upper-case letter). It should be noted that such

orthographic signals are by no means a sufficient condition for the presence of a named entity mention within a CNP.

The choice of CNPs as stimulus phrases is motivated by the fact that named entities are usually fully encoded by this kind of linguistic structure. The chosen stimulus – an annotation example with one phrase highlighted for annotation – allows for an exact localization of the cognitive processes and annotation actions performed relative to that specific phrase.

Independent Variables

We defined two measures for the complexity of the annotation examples: The *syntactic* complexity was given by the number of nodes in the parse tree dominated by the annotation phrase (Szmrecsányi, 2004).¹ According to a threshold on the number of nodes in such a parse tree, we classified CNPs as having either high or low syntactic complexity.

The *semantic* complexity of an annotation example is based on the inverse document frequency $df(w_i)$ of each word w_i of the respective CNP according to a reference corpus.² We calculated the semantic complexity score as $\max_i \frac{1}{df(w_i)}$, where w_i is the i -th word of the annotation phrase. Again, we determined a threshold classifying CNPs as having either high or low semantic complexity. This automatically generated classification was then manually checked and, if necessary, revised by two annotation experts. For instance, if an annotation phrase contained a strong trigger (e.g., a social role or job title as with “spokeswoman” in “spokeswoman Arlene”; cf. Figure 1), it was classified as a low-semantic-complexity item even though it was assigned a high inverse document frequency due to the infrequent word “Arlene”.

Two experimental groups were formed to study different kinds of textual context. In the *document context* condition the whole newspaper article was shown as annotation example, while in the *sentence context* condition only the sentence containing the annotation phrase was presented. The participants³ were randomly assigned to one of these groups. We

¹Constituency parse trees were generated using the OpenNLP TreeBank parser (<http://opennlp.sourceforge.net/>).

²We chose the English part of the Reuters RCV2 corpus, a collection of over 400,000 news stories from 1996 and 1997, as the reference corpus for our experiments.

³20 subjects (12 female) with an average age of 24 years (mean = 24, standard deviation (SD) = 2.8) and normal or corrected-to-normal vision capabilities took part in the study. All participants were students with a computing-related study background, with good to very good English language skills (mean = 7.9, SD = 1.2, on a ten-point scale with 1 = “poor” and 10 = “excellent”, self-assessed), but without any prior experience in annotation practice and without previous exposure to academic linguistic education.

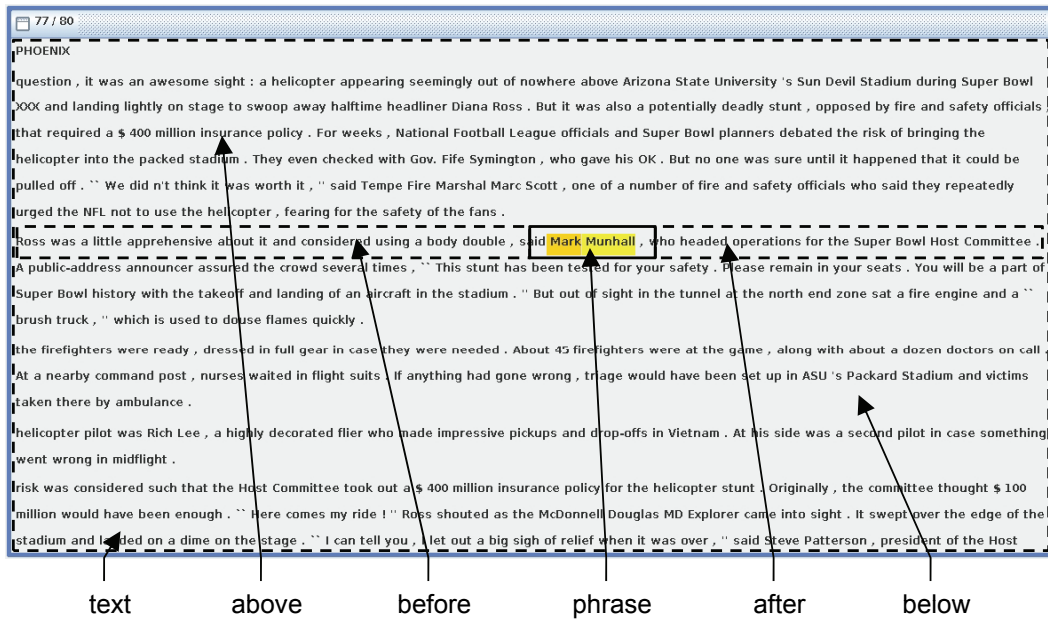

Figure 2: Subareas for the eyetracking analysis. Annotation example is of low semantic and low syntactic complexity.

decided for this between-subjects design to avoid any irritation of the participants caused by constantly changing contexts. Accordingly, the participants were assigned to one of the experimental groups and corresponding context condition already in the second training phase that took place shortly before the experiment started (see below).

Hypotheses and Dependent Variables

We tested the following two hypotheses:

Hypothesis H1: *Annotators perform differently in the two context conditions.*

H1 is based on the linguistically plausible assumption that annotators are expected to make heavy use of the surrounding context because such context could be helpful for the correct disambiguation or de-anaphorization of entity classes. Accordingly, lacking context, an annotator is expected to annotate worse than under the condition of full context. As an adverse effect, the availability of (too much) context might overload and so distract annotators, with a potentially negative effect on annotation performance.

Hypothesis H2: *Annotators' performance is different for varying levels of syntactic and semantic complexity.*

The assumption is that high syntactic or semantic complexity, in contrast to low complexity, for both complexity types significantly lowers the annotation performance.

In order to test these hypotheses we collected data for the following dependent variables: (a) the annotation accuracy – we identified erroneous entities by comparison with the original gold annotations in the MUC7 corpus, (b) the time needed per annotation example, and (c) the distribution and duration of the participants' eye gazes.

Stimulus Material

According to the above definition of complexity, we automatically preselected annotation examples characterized by either a low or a high degree of semantic and syntactic complexity. After manual fine-tuning of the example set assuring an even distribution of entity types and syntactic correctness of the automatically derived annotation phrases, we finally selected 80 annotation examples for the experiment. These were divided into four subsets of 20 examples each falling into one of the following complexity classes:

sem-syn	low semantic – low syntactic complexity
SEM-syn	high semantic – low syntactic complexity
sem-SYN	low semantic – high syntactic complexity
SEM-SYN	high semantic – high syntactic complexity

Experimental Apparatus and Procedure

The annotation examples were presented in a custom-built tool and its user interface was kept as simple as possible not to distract the eye movements of the participants. It merely contained one frame showing the text of the annotation example, with the annotation phrase highlighted (as with "Mark Munhall" in Figure 2). A blank screen was shown after each annotation example to reset the eyes and to allow for a break, if needed. The time the blank screen was shown was not counted as annotation time. The 80 annotation examples were presented to all participants in the same randomized order, with a balanced distribution of the complexity classes. A variation of the order was hardly possible for technical and analytical reasons but is not considered as a drawback due to extensive, pre-experimental training (see below). The limitation to 80 annotation examples reduced the chances of errors due to fatigue or lack of attention that can be observed in long-lasting annotation sessions.

subareas	above	left	phrase	right	below
percentage of participants looking at a subarea	35	32	100	34	16
average number of fixations in a subarea per participant	2.2	14.1			1.3

Table 1: Distribution of annotators’ attention among sub-areas per annotation example.

Five introductory examples (not considered in the final evaluation) were given to get the subjects used to the experimental environment. All annotation examples were chosen in a way that they completely fitted on the screen (text length was limited) to avoid the need for scrolling and thus eye distraction. The contextual position of the CNP was randomly distributed, excluding the first and last sentence.

The participants used a standard keyboard to assign the entity types for each word of the annotation example. All but 5 keys were removed from the keyboard to avoid extra eye movements for finger coordination (three keys for the positive entity classes, one for the “no entity” class, and one to confirm the annotation). Pre-tests had shown that the participants could easily issue the annotations without looking down at the keyboard.

We recorded each participant’s eye movements on a Tobii T60 eyetracking device which is invisibly embedded in a 17” TFT monitor and comparatively tolerant to head movements. The participants were seated in a comfortable position with their head in a distance of 60-70 cm from the monitor. Screen resolution was set to 1280 x 1024 px and the annotation examples were presented in the middle of the screen in a font size of 16 px and a line spacing of 5 px. The presentation area had no fixed height and varied depending on the context condition and length of the newspaper article. The text was always vertically centered on the screen.

All participants were familiarized with the annotation task and the guidelines in a pre-experimental workshop where about 60 minutes were spent on annotation exercises. During the next two days, the actual experiments were conducted, each one lasting between 15 and 30 minutes, including calibration of the eye-tracking device. Another 20-30 minutes of training time directly preceded each individual experiment. After the experiment, the participants were interviewed and asked to fill out a questionnaire. Overall, the experiment took about two hours for each participant for which they were financially compensated. The participants were also instructed to focus more on annotation accuracy than on annotation time as we wanted to avoid random guessing. Accordingly, as an extra incentive, we rewarded the three participants with the highest annotation accuracy with cinema vouchers. None of the participants reported serious difficulties with either the newspaper articles or the annotation tool and all subjects agreed that they understood the annotation task very well.

Results

We used a mixed-design analysis of variance (ANOVA) model to test the hypotheses, with the context condition as between-subjects factor and the two complexity classes as within-subject factors.

Testing Context Conditions

To test hypothesis H1 we compared the number of annotation errors on entity-critical words made by the annotators in the two contextual conditions (complete document vs. sentence). Surprisingly, on the total of 174 entity-critical words within the 80 annotation examples, we found exactly the same mean value of 30.8 errors per participant in both conditions. There were also no significant differences on the average time needed to annotate an example in both conditions (means of 9.2 and 8.6 seconds, respectively, with $F(1, 18) = 0.116$, $p = 0.74$).⁴ These results seem to suggest that it makes no difference (neither for annotation accuracy nor for time) whether or not annotators are shown textual context that contains the annotation phrase beyond the sentence.

To further investigate this finding we analyzed the eye-tracking data of the participants gathered for the document context condition. We divided the whole text area into several subareas as shown in Figure 2. We then determined the average proportion of participants that directed their gaze at least once at these subareas. We considered all fixations with a minimum duration of 100 ms, using a fixation radius (i.e., the smallest distance that separates fixations) of 30 px and excluded the first second as it was mainly used for orientation and identification of the annotation phrase.

Table 1 reveals that on average only 35% of the participants looked in the textual context above the annotation phrase embedding sentence, and even less perceived the context below (16%). The sentence parts before and after the annotation phrase were, on the average, visited by one third (32% and 34%, respectively) of the participants. The uneven distribution of the annotators’ attention becomes even more apparent in a comparison of the total number of fixations on the different text parts (see Table 1): 14 out of an average of 18 fixations per example were directed at the annotation phrase and the surrounding sentence, the text context above the annotation chunk received only 2.2 fixations on the average and the text context below only 1.3.

Thus, eye-tracking data indicates that the textual context is not as important as might have been expected for quick and accurate annotation. This result can be explained by the fact that participants of the document-context condition used the context whenever they thought it might help, whereas participants of the sentence-context condition spent more time thinking about a correct answer, overall with the same result.

⁴In general, we observed a high variance in the number of errors and time values between the subjects. While, e.g., the fastest participant handled an example in 3.6 seconds on the average, the slowest one needed 18.9 seconds; concerning the annotation errors on the 174 entity-critical words, these ranged between 21 and 46 errors.

experimental condition	complexity class	e.-c. words	time		errors		
			mean	SD	mean	SD	rate
document condition	sem-syn	36	4.0s	2.0	2.7	2.1	.075
	SEM-syn	25	9.2s	6.7	5.1	1.4	.204
	sem-SYN	51	9.6s	4.0	9.1	2.9	.178
	SEM-SYN	62	14.2s	9.5	13.9	4.5	.224
sentence condition	sem-syn	36	3.9s	1.3	1.1	1.4	.031
	SEM-syn	25	7.5s	2.8	6.2	1.9	.248
	sem-SYN	51	9.6s	2.8	9.0	3.9	.176
	SEM-SYN	62	13.5s	5.0	14.5	3.4	.234

Table 2: Average performance values for the 10 subjects of each experimental condition and 20 annotation examples of each complexity class: number of entity-critical (e.-c.) words, mean annotation time and standard deviations (SD), mean annotation errors, standard deviations, and error rates (number of errors divided by number of entity-critical words).

Testing Complexity Classes

To test hypothesis H2 we also compared the average annotation time and the number of errors on entity-critical words for the complexity subsets (see Table 2). The ANOVA results show highly significant differences for both annotation time and errors.⁵ A pairwise comparison of all subsets in both conditions with repeated *t*-test measurements showed non-significant results only between the SEM-syn and syn-SEM subsets.⁶ Thus, the empirical data generally supports hypothesis H2 in that the annotation performance seems to correlate with the complexity of the annotation phrase, on the average.

Context and Complexity

We also examined whether the need for inspecting the context increases with the complexity of the annotation phrase. So we analyzed the eye-tracking data in terms of the average number of fixations on the annotation phrase and on its embedding contexts for each complexity class (see Table 3). The values illustrate that while the number of fixations on the annotation phrase rises generally with both the semantic and the syntactic complexity, the number of fixations on the context rises only with semantic complexity. The number of fixations on the context is nearly the same for the two subsets with low semantic complexity (sem-syn and sem-SYN, with 1.0 and 1.5), while it is significantly higher for the two subsets with high semantic complexity (5.6 and 5.0), independent of the syntactic complexity.⁷ These results suggest that the need for context mainly depends on the semantic complexity of the annotation phrase, while it is less influenced by its syntactic complexity.

This finding is qualitatively supported by gaze plots we generated from the eye-tracking data. Figure 3 shows such

⁵ Annotation time results: $F(1, 18) = 25$, $p < 0.01$ for semantic complexity and $F(1, 18) = 76.5$, $p < 0.01$ for syntactic complexity; Annotation complexity results: $F(1, 18) = 48.7$, $p < 0.01$ for semantic complexity and $F(1, 18) = 184$, $p < 0.01$ for syntactic complexity.

⁶ $t(9) = 0.27$, $p = 0.79$ for the annotation errors in the document context condition, and $t(9) = 1.97$, $p = 0.08$ for the annotation time in the sentence context condition.

⁷ ANOVA result of $F(1, 19) = 19.7$, $p < 0.01$ and significant differences also in all pairwise comparisons.

complexity class	fixation on phrase		fixation on context	
	mean	SD	mean	SD
sem-syn	4.9	4.0	1.0	2.9
SEM-syn	8.1	5.4	5.6	5.6
sem-SYN	18.1	7.7	1.5	2.0
SEM-SYN	25.4	9.3	5.0	4.1

Table 3: Average number of fixations on the annotation phrase and context for the document condition and 20 annotation examples of each complexity class.

a plot for one participant which illustrates a scanning-for-coreference behavior we observed for many annotation phrases with high semantic complexity. Words were searched in the upper context, which according to their orthographic appearance might refer to a named entity, but which could not fully be resolved only relying on the information given by the annotation phrase itself and its embedding sentence. This is the case for “*Roselawn*” in the annotation phrase “*Roselawn accident*”. The context reveals that *Roselawn*, which also occurs in the first sentence, is a location. A similar procedure is also performed for acronyms and abbreviations which cannot be resolved from the immediate local context. As indicated by the gaze movements, it also became apparent that texts were rather scanned for hints instead of being deeply read.

Summary and Conclusions

We explored the use of eye-tracking technology to investigate the behavior of human annotators during the assignment of three types of named entities – persons, organizations and locations – based on the eye-mind assumption. We tested two main hypotheses: one relating to the amount of contextual information being used for annotation decisions, the other relating to different degrees of syntactic and semantic complexity of expressions that had to be annotated. We found experimental evidence that the textual context is searched for decision making on assigning semantic meta-data at a surprisingly low rate (with the exception of tackling high-complexity semantic cases and resolving co-references) and that annotation performance highly correlates with semantic complexity and to a lesser degree with syntactic complexity.

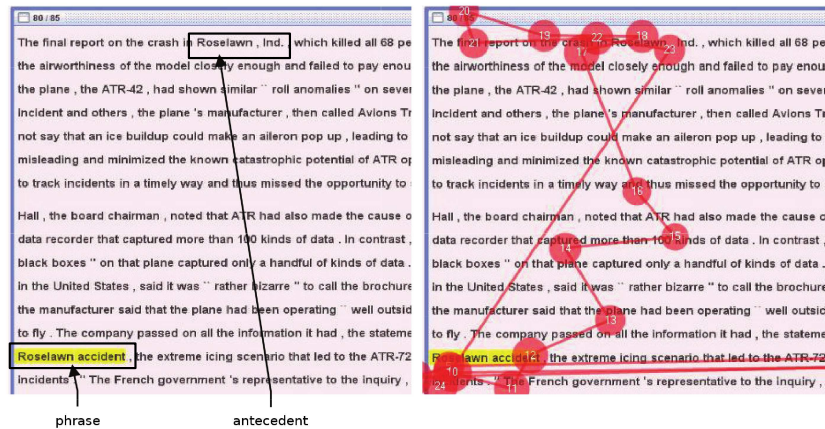

Figure 3: Annotation example with annotation phrase and the antecedent for “Roselawn” in the text (left), and gaze plot of one participant showing a scanning-for-coreference behavior (right).

The results of these experiments can be taken as a heuristic clue to focus on cognitively plausible features of learning empirically rooted cost models for annotation (see Tomanek, Lohmann, Ziegler, et Hahn (2010) for more details).

Subject-Object Asymmetries in Korean Sentence Comprehension

Abstract

The Entropy Reduction Hypothesis (Hale, 2006) derives the subject-object asymmetry in Korean relative clauses. This asymmetry has been observed by Kwon, Polinsky, and Kluender (2006), among others. Agreement between the Entropy Reduction predictions and the available empirical data suggests that the heightened comprehension difficulty attested in object-extracted relatives is due to distinctive incremental parser states associated with comparatively greater temporary ambiguity.

Keywords: sentence comprehension, relative clauses, Korean, probabilistic grammar, Entropy Reduction, syntax

Introduction

Relative clauses (RCs) have long been objects of fascination for cognitive scientists interested in language comprehension (Kaplan, 1974). In the well-known “subject-extracted” (SRC) and “object-extracted” (ORC) cases, a large literature exists. In languages such as English and French, a processing advantage for SRCs has been confirmed in a wide variety of measures including phoneme-monitoring (Frauenfelder, Segui, & Mehler, 1980), eye-fixations (Holmes & O’Regan, 1981), reading times (King & Just, 1991), PET (Stromswold, Caplan, Alpert, & Rauch, 1996) and fMRI (Just, Carpenter, Keller, Eddy, & Thulborn, 1996). It has been suggested that the SRC advantage may be a processing universal (Lin, 2008). If ORCs are harder than SRCs in all languages, then what is it about human sentence comprehension that makes this so? The Korean language is a key test for any universal processing theory because it is syntactically different from English and French. These differences include verb-final clauses and prenominal RCs.

In this paper, we offer an account of the SRC/ORC asymmetry in terms of the information-processing difficulty of incremental parsing in general. This proposal relates the hardness of parsing to syntactic facts about Korean. A language independent complexity metric known as Entropy Reduction (Wilson & Carroll, 1954; Hale, 2003, 2006) correctly derives the SRC advantage when applied with a Korean grammar. This demonstration supports the claim that human comprehension difficulty reflects the kind of information-processing work that Entropy Reduction quantifies.¹

¹A longer companion paper, Hale (under review), develops an automaton model of the sentence comprehension process. It presents a generalized left-corner parser that operates in accordance with the Entropy Reduction Hypothesis when its decisions about how to resolve nondeterminism are guided by experience.

Theories of the Subject-Object Asymmetry

As an empirical phenomenon, the SRC/ORC processing asymmetry is well-established. However, its implications for the architecture or mechanisms of human language comprehension remain controversial. Three broad classes of theory have been advanced. LINEAR DISTANCE theories, illustrated in Figure 1, point to a greater number of intervening elements between the relativized position and the headnoun to which it is meaningfully related. The boxed *e* notation stands for an “empty” element. Particular theories of LINEAR DISTANCE offer alternative ways of measuring the separation between this omitted position and the headnoun (Wanner & Maratsos, 1978; Gibson, 2000; Lewis & Vasishth, 2005). These theories all provide an adequate account of the English pattern, and in some cases relate this prediction to plausible mechanisms of human sentence comprehension. They are thwarted, however by data that confirm an SRC-over-ORC processing advantage in Korean (O’Grady, Lee, & Choo, 2003; Kwon et al., 2006; Lee, 2007). Figure 1(b) shows how theories of this type derive the wrong prediction for Korean.

The second broad class includes STRUCTURAL DISTANCE theories. The simplest theory of this kind maintains that ORCs are harder because the relativized element is more deeply embedded when it is an object. If ORCs are formed by a movement rule, then this movement would “cross” both a VP node and an S node to arrive at its surface position (O’Grady, 1997, 179). Hawkins (2004, 175) singles-out “a connected path that must be accessed for gap identification and processing.” Hawkins’ path is shown using dotted branches in Figure 2. This path is shorter for SRCs in both Korean and English. This general account is thus adequate but not very precise. It leaves open, for instance, the question of where exactly greater difficulty should start to accrue during incremental processing.

The third broad class contains the INFORMATION-THEORETICAL approaches. The Entropy Reduction Hypothesis (ERH) fits into this class. It holds that a person’s difficulty at a word reflects the amount by which that word helped him or her to ascertain which construction the speaker intends. The ERH uses the concept of entropy to quantify the average uncertainty about derivations consistent with an observed initial string. This entropy is high when there are many equiprobable continuations and low when there are just a few continuations or the probability distribution on them is sharply concentrated. This quantity stands in for the degree of confusion in the comprehender’s mind. When it is reduced in the transition from one word to the next, the comprehender

Figure 1: Predictions of LINEAR DISTANCE

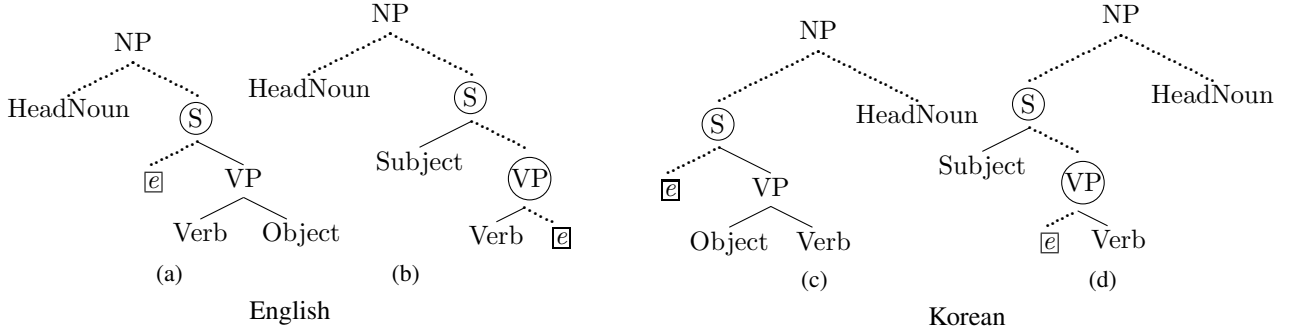

Figure 2: Predictions of STRUCTURAL DISTANCE. In ORCs, ((b),(d)) the pathway between \boxed{e} and HeadNoun crosses two circled nodes whereas in SRCs it crosses just one ((a),(c)). This asymmetry makes the right prediction in both languages.

has accomplished disambiguation work. The ERH interprets this theoretical work as a word-by-word metric of incremental comprehension difficulty.

Hale (2006) derives Entropy Reduction predictions for English relative clauses. Asymmetries between them suggest that relativized non-subjects are harder to comprehend because of greater temporary ambiguity at the embedded verb. While it is well-known that Korean exhibits considerable temporary ambiguity in the middle of sentences, precise levels have not been compared across constructions. Figure 3 illustrates this ambiguity with a prefix string that could signal at least four different clause-types. The ERH offers the possibility of accounting for the SRC/ORC asymmetry in terms of contrasting levels of such ambiguity.

Procedure

We calculate Entropy Reductions at every inter-word point in Korean SRC and ORC sentences using a procedure that mirrors Hale (2006). One of us (JY) prepared a Korean grammar that covers the sentences listed in the Appendix. This grammar is written in Stabler’s Minimalist Grammars (MG) formalism (Stabler, 1997). This transformational formalism adopts certain themes of Chomsky’s Minimalist Program (1995) and has been shown to be mildly context-sensitive in the sense of Joshi (1985) by Michaelis (2001). We consider subject-extraction and object-extraction in each of the four clause-types shown in Figure 3. Our analysis supposes that the headnoun moves in relativization. We use the MG *move* rule to implement this analysis. Figure 4 shows a structural description generated by this grammar. This grammar analyzes postnominal case markers as separate words and

verb suffixes as part of verbs. Here, a coindexed trace, $t(3)$ indicates movement of the headnoun *kica* ‘reporter’ from its base position in a specifier of little *v* to a position outside the RC. Weighting each construction type listed in the Appendix by its attestation count in a Korean Treebank (Han et al., 2006), we estimate a probabilistic context-free grammar (PCFG) of MG derivations. By chart parsing, we recover a new PCFG for each prefix of the sentences of interest. This chart-PCFG is an alternative presentation of the AND-OR graph encoded by the chart (Lang, 1991). It represents all possible analyses that are consistent with the given prefix. We calculate the entropy of the start symbol of this chart-PCFG to arrive at the conditional entropy of the prefix string. This value is a cognitive model of an incremental comprehender’s degree of confusion about which construction he or she is in. When it goes down, disambiguation work has occurred.

Results

Table 1 summarizes the ERH predictions: SRCs are easier to comprehend than ORCs. This prediction also follows in noun complement clauses. However, empty elements in subject position are not always easier. In simple matrix clauses and adjunct clauses, no difference is predicted.

Clause type	SBJ Extraction	OBJ Extraction
Matrix Clause	19.6	19.6
Adjunct Clause	34.66	34.66
Complement Clause	32.1	42.98
Relative Clause	27.13	35.65

Table 1: Average Entropy Reduction in bits-per-word

matrix clause ㉔ <i>uywon ul kongkyekhayssta</i> pro senator ACC attack-DECL '(someone) attacked the senator.'	complement clause ㉔ <i>uywon ul kongkyekhan sasil</i> pro senator ACC attack-ADN fact 'the fact that (someone) attacked the senator'
adjunct clause ㉔ <i>uywon ul kongkyekhayese</i> pro senator ACC attack-ADV 'because (someone) attacked the senator,'	relative clause ㉔ <i>uywon ul kongkyekhan kica</i> gap senator ACC attack-ADN reporter 'the reporter who attacked the senator'

Figure 3: The same initial morphemes signal at least four different clause types²

Figure 4: Structural description of SRC example (d) from the Appendix

Word-by-word Entropy Reduction graphs, shown in Figure 6, illustrate how predicted difficulty peaks coincide with the positions that disambiguate clause-type and the role of omitted elements. This is indicated with double-circles in Figure 5. The subject-object asymmetry in RCs is predicted to show up on the headnoun at the position marked N in Figure 6(d). This prediction matches the findings of Kwon et al. (2006), who observe a reading time asymmetry at this point.

Discussion

The Entropy Reduction account of the subject advantage in relative clauses and complement clauses is rooted in contrasting levels of uncertainty about syntactic structure. The crucial position, immediately after the adnominal form of the verb, is marked ③ in Figure 7. In the ORC case, the conditional entropy at this point is 32.28 bits, while in the SRC case, the corresponding value is only 23.76 bits. The conditional entropy values at ④ are exactly the same — 17.43 bits in both

cases. Thus, the ERH models the greater difficulty in the object cases with greater conditional entropy at point ③.

The disparity between these conditional entropies reflects contrasting numbers of alternative continuations. These continuations correspond to different roles the prefix string might play at the matrix level. Figure 8 shows that the ORC prefix **N NOM V-ADN** could be in fact the beginning of a reading on which the nominative-marked noun is a complete matrix-level subject on its own, where both the subject and the object of the embedded clause are omitted. These properties allows the ORC prefix to have the multiple parses shown in (1-3) below. The disparity derives, ultimately, from syntactic properties of Korean. As we have seen, it is an SOV language with prenominal RCs; crucially, arguments may be freely omitted when they are recoverable in-context. Such additional structures are not acceptable as a continuation of the SRC prefix **N ACC V-ADN**, which cannot be split by additional empty categories.

Related work

These results offer a new perspective on the work of Ishizuka, Nakatani, and Gibson (2006). Using Japanese RCs, which are structurally similar to Korean, these authors show that the penalty for ORC processing can be mitigated or even eliminated if certain readings are pragmatically suppressed by prior discourse. The ERH suggests that disambiguating those readings is exactly the source of the ORC penalty. It quantifies the difficulty of coping with all the available alternatives.

Our results also suggest a lack of subject-object asymmetry in adjunct clauses. We would like to emphasize that this does not entail a contradiction with the experimental results of Kwon et al. (2006). The design of this experiment leverages that fact that a matrix clause noun is a felicitous controller of *pro* when it appears in an embedded clause. Indeed, these authors suggest that “the identification of the gap in an adjunct clause does not involve any syntactic operations.” It is thus appropriate that our syntax-only approach predicts no distinction between missing subjects and objects in this clause type. The ERH might naturally be combined with a pragmatic component to yield a broader theory. We leave this extension to future work.

Conclusion

The ERH, in conjunction with an appropriate formal grammar, can account for the subject advantage in Korean RCs. Its predictions cannot be summarized by simply saying that missing objects are always harder; for instance both types of main clauses are predicted to be equally easy. However

they do include the prediction of a subject-object asymmetry in complement clauses with omitted arguments. The effect should appear on the word *sasil* ‘fact’. This prediction would not follow on a STRUCTURAL DISTANCE account, since no movement relation exists between the empty element *pro* and *sasil* in that construction. If a subject-object asymmetry were to be experimentally observed at that point, this would leave the ERH as the only theory able to explain the English as well as the Korean results. We hope that our work encourages empirical investigation of this case.

Acknowledgment

The authors would like to express their appreciation to Nayoung Kwon for her comments on the manuscript. Thanks are due as well to Na-Rae Han for information about the Korean Treebank. This research was supported by a Small Grant from the Cornell University Institute for the Social Sciences.

Appendix: Examples

The Minimalist Grammar used to derive the comprehension-difficulty predictions graphed in Figure 6 covers all of the examples listed below. The combinatorics of the promotion analysis imply the existence of other grammatical strings such as the examples (1)–(3) in discussion.

- a. matrix clause with a *pro*-subject

uywon ul kongkyekhayssta.
 senator ACC attack-DECL

‘Someone attacked the senator.’

- b. adjunct clause with a *pro*-subject

uywon ul kongkyekhayse kica ka
 senator ACC attack-ADV reporter NOM
 yumyenghaycyessta.
 become-famous-DECL

‘Because someone/he attacked the senator, the reporter became famous.’

- c. complement clause with a *pro*-subject

uywon ul kongkyekhan sasil i palkhyecyessta.
 senator ACC attack-ADN fact NOM is-revealed-DECL

‘The fact that someone attacked the senator was revealed.’

- d. subject relative clauses

uywon ul kongkyekhan kica ka
senator ACC attack-ADN reporter NOM
yummyenghaycyessta.
become-famous-DECL

'The reporter who attacked the senator became famous.'

e. matrix clause with a *pro*-object

kica ka kongkyekhayssta.
reporter NOM attack-DECL

'The reporter attacked someone.'

f. adjunct clause with a *pro*-object

kica ka kongkyekhayse uywon i
reporter NOM attack-ADV senator NOM
yummyenghaycyessta.
become-famous-DECL

'Because the reporter attacked someone/him, the senator became famous.'

g. complement clause with a *pro*-object

The Benefit of Imitating Particular Individuals

Yasuaki Sakamoto (ysakamot@stevens.edu)

Hongyuan Shi (hshi@stevens.edu)

Hoboken, NJ 07030 USA

Abstract

We examined the benefits of different search strategies by testing four computational models. In one model, agents in a group always innovated. The other three models incorporated some mechanisms of imitation. In the second model, each agent imitated the best solution of a random other. In the third model, each agent followed preferential attachment and imitated the best solution of the agent that was asked by many agents. In the fourth model, each agent developed a familiarity with an agent based on how often it asked a certain agent, and imitated this agent. In two simulation studies, following the most popular or the most familiar agent resulted in a good compromise between efficiency and diversity in finding good solutions. People's desire to follow particular individuals may be a key to their adaptive behavior, allowing them to disseminate ideas efficiently while encouraging the exploration of new ideas.

Keywords: Innovation and imitation; computational modeling; social learning; search.

Introduction

How do we search for information? Some individuals like to innovate. Others like to imitate. We all engage in both. Because we are social beings, we often rely on other's behavior to shape our own behavior. By observing and imitating others, people can entertain solutions that they would not have even considered otherwise (Bandura, 1965). The creation of innovative solutions (Kraatz, 1998), the evolution of language (Smith et al., 2003), and the development of culture (Dennett, 1995) all result from the process of iterated learning, in which people learn from the previous outputs of others.

In the current work, we examine the benefits of different types of search strategies through computer simulation. We know that whereas too much innovation results in poor dissemination of good solutions, too much imitation results in under exploration of good solutions (Gureckis & Goldstone, 2006). A group of people needs to both innovate and imitate to prosper. But when should we innovate and when should we imitate? Who should we observe if we decide to imitate?

When people are unsure about the best solution, they use other's information as an indicator of what is best (Cialdini & Goldstein, 2004; Deutsch, & Gerard, 1995; Festinger, 1954; Sherif, 1935). People also adopt other's information due to their desire to be liked and to not appear deviant (Asch, 1956; Deutsch, & Gerard, 1995). This imitation behavior is consistent with the principle of preferential

attachment (Barabási & Albert, 1999), in which people are attracted to already popular solutions. For example, people instantly get in line when they see a long line outside of a cupcake store, assuming that the store must be offering some really good cupcakes. If everyone imitates, however, it will be difficult for the group to find another cupcake store that also serves really good cupcakes. Thus, imitation leads to efficient problem solving when there is a single best solution. When there are multiple good solutions, however, imitation can lead the group to quickly converge to a single solution, under-exploring the others: some people need to explore other possibilities.

For studying innovation and imitation, we used a simple search game, inspired by a recent social learning tournament (<http://www.intercult.su.se/cultaptation/tournament.php>). In our game, five agents guessed an action value between 0 and 100, and received as feedback the number of points obtained from the guess. A function converted the guess to a payoff. The agents did not know the function and did not try to learn it. They simply stored the guessed action value that was associated with the highest payoff. The payoff distributions are displayed in Figures 1 and 2. In one case, the search space had a single peak at action 80 as shown in Figure 1. In another case, the search space had three peaks at action values 10, 50, and 80 as shown in Figure 2. Although the game may seem overly simple and artificial, it is analogous to many tasks we encounter every day (see Page, 2007).

The five agents, A_1, \dots, A_5 , selected to either innovate (randomly select a value between 0 and 100) or imitate (receive another agent's value with the highest payoff) in turn. Four groups are simulated:

1. **Innovate:** Agents only innovated.
2. **Ask Random:** Agents imitated a randomly selected agent. The preference weight of A_i asking A_j , p_{ij} , was equal for all j .
3. **Ask Majority Preference:** Agents imitated another agent who was imitated by many others. That is p_{ij} was determined by the number of times A_j was asked by other agents, m_j . This group followed the principle of preferential attachment, and conformed to the majority's behavior.
4. **Ask Individual Preference:** Agents imitated another agent based on how often they asked a certain agent:

$$p_{ij} = P_1 + \frac{P_2 - P_1}{1 + \exp[-C(f_{ij} - F)]}$$

where $P_1 = 0$, $P_2 = 10$, $C = 0.2$, and $F = 15$. The ask history, f_{ij} , tracked the number of times A_i imitated A_j . Agents maintained a counter for every other agent it had interaction with. They followed the footstep of a particular agent they became familiar with.

The imitating agent always received another agent's current best solution. That is, the asked agent always returned the action value associated with the highest payoff that it previously guessed. In the current simulation, when asked agents returned worse solution than the existing one (i.e., the imitating agent had a better solution than the one asked), the agent innovated on the next round. Likewise, when asking someone does not result in good solution, humans often explore the environment by themselves. After innovating once, the agent tried to imitate again. Without this innovation round, always imitating can quickly converge to an action value regardless of its payoff.

Figure 1: The distribution of payoff in Simulation 1 is shown. There is a single peak at action 80.

Figure 2: The distribution of payoff in Simulation 2 is shown. There are three peaks at action 10, 50, and 80.

Which group will result in all agents finding the value associated with the highest payoff most efficiently? Imitating others will help disseminate ideas. But which type of asking is best? Humans often conform to the group, similar to the Majority Preference model (e.g., Cialdini & Goldstein, 2004; Sakamoto et al., 2009). They also build familiarity for a particular other, and follow this individual (e.g., Sadlon, et al., 2009; Sakamoto et al., 2008). This following behavior allows us to make near-optimal decision in a limited amount of time in many different social

circumstances (Gigerenzer et al., 2000). At the same time, vocal group members often sway the opinion of individuals, and thus the opinions produced by a group may only reflect those of a small subset of the group. Then, imitating others may not be advantageous when there are multiple good solutions to find. In this case, the Innovate group may be successful because the group has no social influence that converges their solutions. Previous work has focused on how given social network structures influence the dissemination of ideas (e.g., Mason & Goldstone, 2008). In the current work, the agent's behavior determines the kinds of social networks built and thus how information is spread within the group.

Simulation Study 1

In Simulation Study 1, the four groups of agents searched for the action with the highest payoff in a space with a single best solution as shown in Figure 1. The agents did not know what the maximum payoff was. Each group had five agents that all followed the same behavioral rule as described previously: innovate, ask random, ask majority preference, or ask individual preference. Each group had 500 cycles to search, each cycle consisting of an agent taking its action. We used 500 cycles so that each group would perform well at the end and we could see the entire course of evolution. Each group was simulated 30 times.

Figures 3 to 6 show the results from the four groups. The left most graph of each figure shows the evolution of total payoff (sum of all agents' payoffs) over the course of 500 cycles, averaged over 30 simulations. During the first 200 cycles, the Innovate model and the Majority Preference model lag behind the Random model and the Individual Preference model. The Innovate model is especially far behind the other models early on. After 300 cycles, the Innovate model is performing the worst, the Random model performing the best, and the two preference models in between. After 400 cycles, the two preference models catch up with the Random model, while the Innovate model is still behind the other models. At 500 cycles, every model has nearly all agents discovering the action with the highest payoff.

The middle three histograms in each figure show the frequency of total payoff for the 30 simulations. At 50 and 100 cycles, the disadvantage of the Innovate model is apparent: no simulation resulted in total payoff of 80 or 100. At 500 cycles almost all 30 simulations for each group result in every agent knowing the best action.

The color map on the right side of each figure shows the evolution of each agent's payoff averaged over 30 simulations. The Innovate model is darker in general, indicating that it took longer to find good solutions than the other models. In addition, the Innovate model has darker horizontal band, indicating that some agents had hard time innovating a good solution. In contrast, the other three models incorporating imitation disseminated the best action efficiently. The Random model was especially quick at disseminating good solutions.

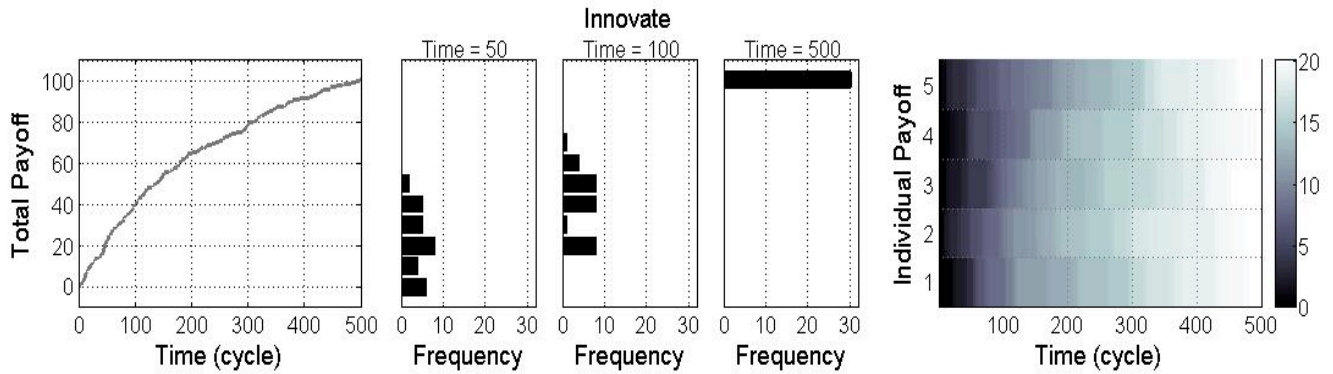

Figure 3: The results from the Innovate model in Simulation Study 1 are shown. The left most graph shows the evolution of total payoff (sum of all agents' payoffs) over the course of 500 trials, averaged across 30 simulations. The middle three histograms show the frequency of total payment for the 30 simulations at 50, 100, and 500 cycles. The color map on the right side shows the evolution of each agent's payoff averaged over 30 simulations.

Figure 4: The results from the Random model in Simulation Study 1 are shown. The left most graph shows the evolution of total payoff (sum of all agents' payoffs) over the course of 500 trials, averaged across 30 simulations. The middle three histograms show the frequency of total payment for the 30 simulations at 50, 100, and 500 cycles. The color map on the right side shows the evolution of each agent's payoff averaged over 30 simulations.

Figure 5: The results from the Majority Preference model in Simulation Study 1 are shown. The left most graph shows the evolution of total payoff (sum of all agents' payoffs) over the course of 500 trials, averaged across 30 simulations. The middle three histograms show the frequency of total payment for the 30 simulations at 50, 100, and 500 cycles. The color map on the right side shows the evolution of each agent's payoff averaged over 30 simulations.

Figure 6: The results from the Individual Preference model in Simulation Study 1 are shown. The left most graph shows the evolution of total payoff (sum of all agents' payoffs) over the course of 500 trials, averaged across 30 simulations. The middle three histograms show the frequency of total payment for the 30 simulations at 50, 100, and 500 cycles. The color map on the right side shows the evolution of each agent's payoff averaged over 30 simulations.

The results from Simulation Study 1 show that for a single peak search space, asking random others can be especially beneficial when the time to search is limited. Every group member innovating can slow the team performance down. If there is a reasonable amount of time, the Majority Preference model and the Individual Preference model work fine. The success of the Random model suggests that we should sometimes observe different, random others, instead of always following the same individuals.

Simulation Study 2

In Simulation Study 2, the search space had three best solutions as shown in Figure 2. In this case, imitating can limit the number of good solutions the group discovers by causing all agents to conform to a single good solution. In contrast, the group can collectively find different solutions if group members innovate.

The procedure for Simulation Study 2 was the same as that for Simulation Study 1. The same four models were evaluated using a diversity metric and a normalized search speed for finding good solutions. The diversity metric was defined as the percentage of the group finding two or more best actions in 30 simulations. The normalized search speed, \hat{v}_e , is a relative metric defined by the time required to achieve 70% of the optimal result for a group, T_e . If a constant S quantifies the solution space, behavior model k has an observed average exploration speed, v_e :

$$v_e(k) = \frac{S}{T_e(k)}$$

Then the normalized search speed for model k , $\hat{v}_e(k)$, is:

$$\hat{v}_e(k) = \frac{v_e(k)}{\min_j v_e(j)} = \frac{S/T_e(k)}{\min_j S/T_e(j)} = \frac{\max_j T_e(j)}{T_e(k)}$$

	Number of Solutions			Diversity Metric
	1	2	3	
Innovate	0%	30%	70%	100%
Ask: Random	96.7%	3.33%	0%	3.33%
Ask: Majority Preference	70%	30%	0%	30%
Ask: Individual Preference	73.3%	26.7%	0%	26.7%

Table 1: The results from Simulation Study 2 are shown. The diversity metric shows the percentage of finding two or more best solutions in 30 simulations. The Innovate model was able to find two best solutions 9 times (30%) and three best solutions 21 times (70%), resulting in 100% diversity score. In contrast, the Random model resulted in finding only one good solution in 29 of 30 simulations. The performances of the Majority and Individual Preference models were in between those of the Innovate and Random models.

Table 1 displays the simulation results for the payoff distribution with three peaks. As predicted, the Innovate model was able to find multiple best solutions, resulting in a high diversity score. In contrast, the Random model resulted in the discovery of only one good solution in almost all 30 simulations (96.7%). The Majority Preference model and the Individual Preference Model were in between the Innovate model and the Random model. Although the two

preference models could not find all three best solutions, they were able to find two best solutions in some cases, much more frequently than the Random model.

Figure 7: Each group’s normalized search speed is shown as a function of its diversity metric. The normalized speed axis shows how quickly the group achieves a high total payoff (higher speed means faster). The diversity metric shows the percentage of finding two or more best actions in 30 simulations. The Innovate model (Innov) results in a high diversity measure but is slow to have all agents finding a good solution, indicated by low normalized speed. The Random model (Ask: Rn) leads to a high normalized speed, but this group converges to a single solution too quickly and thus results in low diversity of good solutions. The Majority Preference model (Ask: MP) and the Individual Preference Model (Ask: IP) were in between the Innovate model and the Random model.

Figure 7 shows each group’s normalized search speed as a function of its diversity metric. The normalized speed axis shows how quickly the group achieves a high total payoff. This axis shows that we have essentially replicated Simulation Study 1 in terms of speed of finding a good solution as a group: Random, Individual Preference, Majority Preference, and Innovate, from fastest to slowest.

The diversity metric is the new measure relevant to the multiple best solutions in Simulation Study 2. All agents innovating results in a high diversity measure but, as Simulation Study 1 found, is slow to have all agents finding a good solution. The opposite of the Innovate model is the Random model. Asking random others leads to efficient dissemination of a solution and thus a high normalized speed, but makes the group converges to a single solution too quickly. Thus the Random model under explore the

search space. The Majority Preference model and the Individual Preference model are quite efficient in disseminating a solution relative to the Innovate model. At the same time the two preference models have the time to explore the space. This is because always asking a particular individual has a higher chance of resulting in incidental innovation in the next round than asking a random other. When the asked agent does not have a good solution, the asking agent will be dissatisfied and innovate on the next round. When imitating a particular other, the imitating agent will likely keep asking the same agent. If this asked agent does not have a good solution, the asking agent will have many opportunities to innovate. When imitating a random other, the imitating agent will ask different agents at different cycles. There is less chance that the imitating agent always asks another agent with a poor solution in the Random ask model than in the two preference models. Thus the random imitation does not result in innovation as often as the other types of imitation.

Discussion

In the current study, we examined the benefits of different search strategies through computer simulation. We tested four models. In the Innovate model, each of the five agents in the group innovated on each cycle. The other three models incorporated some mechanisms of imitation. In the Random model, each agent imitated the best solution of a random other on each cycle. In the Majority Preference model, each agent imitated the best solution of the agent that was asked by many agents. This group followed the principle of preferential attachment, and conformed to the majority’s behavior. In the Individual Preference model, each agent tracked how often it imitated the other agent, and imitated another agent based on how often it asked a certain agent. In this group, agents developed familiarity with a particular agent and followed this agent. We tested these four models in two kinds of search space: single best solution and three best solutions. In the current simulation, when imitating did not result in a better solution than the existing one, the agent innovated on the next time cycle and then resumed the imitation on the following time cycle.

The results from Simulation Study 1 showed that for a single peak search space, asking random others could be especially beneficial if the time to search was limited. In contrast, every group member innovating could take a long time for all the group members to find a good solution. The Majority Preference model and the Individual Preference model found good solutions in a reasonable amount of time.

In Simulation Study 2, the four models were tested under the three-peak environment. All agents innovating resulted in the group finding multiple good solutions, but, as Simulation Study 1 found, was slow to have all agents finding a good solution. In contrast, asking random others led to efficient dissemination of a solution, but the group converged to a single solution too quickly, and thus the Random model under explored the search space. Majority Preference model and the Individual Preference model had

the time to explore the space and were still quite efficient in disseminating a solution relative to the Innovate model.

Taken together, these results suggest that following a particular other, whether the most popular one or the most familiar one, results in a good compromise between speed and diversity in finding good solutions. It is interesting that these models that incorporate characteristics found in humans are most robust in the sense that they work well in different environments, although they may not be optimal in a single environment. Perhaps people's desire to follow particular others is a key to adaptive behavior, allowing people to disseminate ideas efficiently while still encouraging the innovation of new ideas.

Future work should explore more complex models, in which the group can have a mix of innovators and imitators. Individual differences can be useful when the group tends to converge too quickly. When group members converge quickly to an optimal solution, responding to a new situation becomes a problem (Resnick, 1994). For example, if all team members responded to an immediate threat in area X (which happens in the real world), it may take a while for everyone to respond to a new alert in area Y. Analogously, a group may fail to respond to a new and better solution when the group converges to a good solution too quickly. A simple way to avoid such failure to adapt to better solution is to include individuals with different abilities in a team (Sakamoto & Nickerson, 2007). By making some individuals innovate more often than others, we can encourage some learners to focus on disseminating solutions, and others to explore the space for new situations. These models incorporating individual difference can be robust to changing environments, such as when the payoff distribution shifts from time to time. Future work should include these variables, such as changing environment and individual difference, to make the simulation world closer to the world we live in. Future work should also compare these models against people.

In conclusion, the current simulation studies showed that people's natural tendency to follow particular others may have survived for a good reason: It leads to reasonable performances in a reasonable amount of time in different environments. If the dimension to optimize is well defined, one may tailor the search strategy. For example, if the time is not an issue, a group of agents that all innovate can find a diverse set of good solutions as a group. If there is a need to disseminate information widely and quickly, then asking random others will be the way to search the space. If one does not know what to optimize, following the particular others will result in a reasonable performance.

Arithmetic Notation...now in 3D!

Abstract

When people reason formally, they often make use of special notations—algebra and arithmetic are familiar examples. These notations are often treated as mere shorthand—a concise way of referring to meaningful mathematical concepts. Other authors have argued that people treat notations as pictures—literal diagrams of an imagined set of objects (Dörfler, 2003; Landy & Goldstone, 2009). If notations depict objects that exist in space, then it makes sense to wonder how they are arranged not just in the two visible dimensions, but in depth. In four experiments, we find a consistent pattern: properties that increase mathematical precedence also tend to make objects appear closer in space. This alignment of formal pressures and informal pressures suggests that perceived depth may play a role in supporting computational reasoning processes. Although our primary focus is documenting the existence of depth illusions in notations, we also evaluate several sources of information that might guide depth judgments: availability of an object for computational actions, formal syntactic structure, relative symbol salience and voluntary attention shifts. We consider relationships between these nonexclusive possible sources of information in guiding how people judge depth in mathematics.

Keywords: Mathematical cognition, embodied cognition, depth perception

Introduction

Special notations are ubiquitous markers of mathematical thinking. Often, these notations are treated as mere conventional patterns, which serve as the target of rule-learning systems such as generic production systems (e.g., (Koedinger, Alibali, & Nathan, 2008; Anderson, 2005; Koedinger & MacLaren, 2002). From this perspective, the exact format and layout of the expression doesn't much affect how reasoning happens—what makes learning difficult is the rules, not the layout. However, growing evidence suggests a different account. It seems formal operations—from reasoning to logic to simple mathematics—are not always computed through the action of an abstract reasoning system, but instead make use of perceptual-motor systems typically involved in real-world perception and action.

In the case of mathematics in particular, reasoning that on the surface appears to require formal operations can be simplified if reasoners treat notations as pictures of a physical scene (Dörfler, 2003; Landy & Goldstone, 2009). For instance, algebraic syntax has a hierarchical structure

partially described by the order of operations. In any equation, operations bind in the following order: parentheses, exponents, multiplications and divisions, additions and subtractions. This apparently arbitrary system appears to require explicit memorization, but in fact can be computed using basic perceptual-motor mechanisms such as grouping (Landy & Goldstone, 2007) and automatic attentional biases (Landy, Jones, & Goldstone, 2008). On this account, computing the answer to a math problem involves taking physical actions to transform abstract forms.

If notations really are fundamentally abstract, then their implied physical structure is entirely given by their surface form: there is no sense in which any of the symbols are 'close' or 'far away.' However, if people indeed often reason by treating symbols as pictures of objects in space, then these objects must be laid out in some three-dimensional arrangement. Thus, it is at least possible that different symbols would be seen as closer or further away than others. In the next section, we outline some reasons to expect such differences.

Reasons to Expect Illusions of Differential Depth

Actual equations and expressions are of course purely two-dimensional; thus actual depth experience should not directly inform perceived depth judgments with mathematical forms. Furthermore, accounts that treat notation as basically abstract predict no particular differences in apparent depth of different symbols. However, several factors might affect the perceived depth of symbols seen as objects that exist in space, which can be acted on in particular kinds of ways.

One clear prediction is that symbols that afford action appear proximal relative to those that do not. Several studies have found that depth perception can be affected by the action capabilities of the observer (Linkenauger, Witt, Stefanucci, Bakdash, & Proffitt, 2009; Witt, Linkenauger, Bakdash, & Proffitt, 2008; Witt & Proffitt, 2005; Witt, Proffitt, & Epstein, 2005). Therefore, if solving a mathematical equation requires actions on the part of the solver, high precedence terms—those most available for actions—should generally seem most proximal in arithmetic expressions. Put simply, years of experience acting first on multiplications in expressions like $3 + 4 \times 5 = 23$ will lead the multiplication to appear closer than the addition.

We hypothesized, more generally, that terms and operation signs that were most immediately available for

action would be seen as more proximal. In some cases, general syntactic factors do not align with action. That is, unlike in the stimuli in Figure 1, in some cases low-precedence operations afford more immediate action than high-precedence operations. This issue is taken up again in Experiment 3.

Another reason to expect systematic biases in perceived depth of arithmetic signs comes from the salience structure of those signs. As mentioned above, typical multiplication signs (the dot and the cross) are more salient and readily attended than addition signs. Salience and attention present conflicting pressures in the paradigm employed here. Voluntary attention has been shown to influence the perceived depth of ambiguous figures (Kawabata, 1986). In the case of arithmetic expressions, attention shifts systematically from high-precedence operations to low-precedence over the course of problem solution. Since participants made depth judgments after solving the problem, attention would most recently have been primarily allocated to additions, potentially causing addition signs to seem closer immediately after computation.

Salience also affects perception of figure and ground such that highly salient parts tend to be interpreted as parts of figures (Hoffman & Singh, 1997). Generally speaking, this may imply that salient objects will tend to be seen as proximal (though see Huang & Pashler 2009). The higher salience of multiplications should then also cause them to be perceived as proximal.

In three of the experiments reported below, participants were asked to solve simple mathematical problems, superimposed over two views of a baseball (see Figure 1). After solving the problem, they judged the relative distance of the two baseballs. If the relative availability of computational action affects perceived depth, the baseball associated with the high-precedence sign (the multiplication sign) should appear closer than the baseball under the low-precedence sign. The baseballs were used to ground the participants' judgments and make clear the nature of the task; our assumption is that judged distance of the baseball reflects primarily the relative perceived depth of the symbol superimposed on it.

$$2 \text{ } \text{baseball with } + \text{ } 5 \text{ } \text{baseball with } \times \text{ } 6$$

$$2 \text{ } \text{baseball with } \times \text{ } 5 \text{ } \text{baseball with } + \text{ } 6$$

Figure 1: Sample stimuli used in Experiment 1.

Figure 2: Results of Experiments. Errors represent 95% confidence intervals on proportions.

Experiment 1

Method

Participants Forty-eight students from the University of Richmond received partial course credit for participation. All participants had normal or corrected to normal vision.

Materials Participants viewed simple two-operation arithmetic expressions superimposed over images of a baseball (see Figure 1). The same image that appeared under the plus sign appeared under the multiplication sign, rotated 90°. Instructions informed participants that one baseball was close, and approaching, while the other baseball was farther away, and receding.

Procedure Participants were asked to solve the arithmetic problem. After doing so, they were asked to decide the relative distance of the two baseballs. Half of the participants were asked to circle the baseball that was closer; the other half to circle the baseball that was farther. Each participant responded to two expressions; one was in the format $a + b \times c$, the other $a \times b + c$. The order of presentation of the problems was counterbalanced across participants, as was which image orientation appeared on the left (thus image orientation and operation sign were independent). The task was performed as part of a distracter, between two phases of an unrelated experiment. Several other short problems appeared in between the two baseball judgments.

Results On each trial, the participant circled either the multiplication sign or the addition sign (see Figure 2). These choices were analyzed using two repeated measures logistic regressions: one included just an intercept, while the other also included judgment type (closer vs. farther) as a between-participants factor. Including judgment type

significantly improved the quality of the fit over the baseline model, ($\chi^2(1) = 10.2$, $p < .01$).

Discussion The primary purpose of Experiment 1 was to evaluate whether there was consistency in how depth would be judged in a simple arithmetic expression. The results demonstrated that there is. In a simple two operation problem, multiplications are seen as closer than additions. In simple arithmetic processes, the higher precedence operation is perceived as more proximal to the reasoner than is the lower precedence operation.

Though predicted by the idea that multiplication is more available than addition in this expression, these results could be produced by any combination of an effect of the higher salience of cross signs over plus signs, the syntactic order of operations, and the relative availability of multiplication in this expression. The prediction that voluntary attention toward the plus sign at the end of solving the problem would dominate proximity judgment was not borne out.

Experiment 2a

In this experiment, we tested whether the bias in perceived depth revealed in Experiment 1 was due to particular salience differences between the addition and multiplication sign rather than order of operations. In Experiment 2a, we used the same stimuli and design as in Experiment 1, except that we used parentheses to make the plus sign the first operation rather than the multiplication. If the result in Experiment 1 was due simply to perceptual differences between the multiplication and addition signs, then we should expect to replicate Experiment 1. However, if the result is due to order of operations, adding the parentheses should result in either a null effect or the opposite effect.

Method

Participants Forty-eight students from the University of Virginia received partial course credit for participation. All participants had normal or corrected to normal vision.

Materials Packets were created using the same stimuli as in Experiment 1, except the stimuli were modified so that the two numbers adjacent to the plus sign were enclosed by parentheses.

Procedure The procedure was the same as in Experiment 1 except that rather than serving as a distracter in an unrelated task, these judgments served as the primary experiment. In between the two trials, participants completed a distracter task which involved solving a maze.

Results and Discussion Participant choices were analyzed using a repeated measures logistic regression (see Figure 2).

Including judgment type did not improve the fit by a likelihood ratio test over the null model ($\chi^2(1) = .12$, $p \sim .68$).

Unlike Experiment 1, there was no sign of a consistent relationship between perceived relative depth and operation sign in simple expressions with parentheses. One plausible interpretation of the disparity is that the higher precedence of multiplication sign interacts with a pressure to see parenthesized terms as closer. There are (at least) two plausible reasons why this would occur: first, as hypothesized, terms that can be computed early may appear closer than they otherwise would. Second, visual factors intrinsic to parentheses may make them things inside parentheses appear differentially closer.

Consider Figure 3. In the top part, the circle on the left appears to be in front of (and consequently partially occluding) the illusory oval induced by the curved lines. This, in turn, causes it to appear closer than the circle on the right. In a similar manner, it may well be that the parentheses create a (relatively weak) illusory oval. If the symbols are interpreted by the visual system as being in front of that oval, then they may be perceived as being closer than the symbols not inside the parentheses.

Experiment 2b

One difference between Experiment 1 and 2a is that the populations differed, one being drawn from University of Richmond students and the other from the University of Virginia. Therefore, to eliminate the possibility that the null results in Experiment 2a were due to differences between the student populations, a second experiment was run at the University of Virginia to ensure that similar perceptual effects as in Experiment 1 could be

Figure 3: Visual factors could influence the relative perceived proximity of terms inside parentheses. Just as the circle on the left appears to be closer than the circle on the right, so apparent occlusion may cause the 5 on the left to be in closer than the 5 on the right.

Figure 4. Example Stimuli from Experiment 2b. found in this population. In addition, this experiment offers a more indirect judgment of relative proximity.

Method

Participants Twenty-two students from the University of Virginia received partial course credit for participation. All participants had normal or corrected to normal vision.

Stimuli and Apparatus Mathematical equations were superimposed onto an illustration of the vase-face illusion so that either the multiplication sign was on the vase and the plus on the face or vice versa (see Figure 4). Instructions printed above the picture directed participants to solve the equation and then indicate whether or not they saw a vase or faces. The equation was either on the right side of the illustration, as in Figure 4, or on the left.

Packets were created which consisted of two face-vase trials. A maze was inserted in between the vase-face trials, which acted as a distracter task. Half of the packets contained vase-face illusions in which equations were located on the right; the other half had the equations located on the left. Within each packet, one illusion had the multiplication sign on the vase, and the other had the multiplication sign on the face. Order was counter-balanced across packets.

Procedure Participants were given a packet and told to complete it in full. They were asked to follow the instructions written on each sheet, and not to look at the subsequent sheets until they had completed their task on the current sheet.

Results and Discussion Arbitrarily, each trial was coded as positive if the participant chose the faces as the foreground. A significantly better fit was found for a logistical regression including position of the multiplication sign as a factor, than for the null model ($\chi^2(1) = 5.1, p < 0.05$). Overall, when the multiplication sign was over the vases, participants chose the face interpretation less often ($M = .5, CI = 0.28-0.71$) than when the multiplication sign was over the faces ($M = .82, CI = 0.60-0.95$).

These results show that the effect in Experiment 1 can generalize across populations and across tasks. This finding is also a less direct manipulation of perceived depth and is less likely to be affected by demand characteristics. Whether the face or vase is seen in the foreground is

indicative of the depth relationship between the vase and the face. Therefore, participants determined which figure they saw instead of directly specifying the depth relationship between the mathematical operators. Interestingly, order of operations influenced the figure-ground and therefore, the depth relationship in an ambiguous figure illusion.

Prior results have shown that fixations (Gibson & Peterson, 1994) and exogenous cues (Vecera, Flevanis, & Filapek, 2004) guide figure-ground segmentation, as long as the cues appear inside figures (as was done here). Thus, these results could result from the greater salience of multiplication signs. However, once again, voluntary attention shifts are unlikely to account for these effects, as voluntary attention is most likely directed toward the addition at the end of computation (when participants were instructed to make their judgments).

The first two experiments indicated that syntactic precedence, available formal actions (computations), and perceived proximity tend to go together. Experiment 3 distinguishes between syntactic precedence and action structure by repeating the structure of Experiments 1 and 2A in the context of an algebraic rather than an arithmetic task. Because linear equations are solved starting from the lowest, rather than the highest precedence operations, in Experiment 3 the two theories make opposite predictions. If availability of formal actions guides perceived depth, then lower precedence items should be seen as proximal in Experiment 3; if syntactic precedence predicts or guides depth, then high precedence operations should appear proximal, as in Experiments 1 and 2B.

Experiment 3: Linear Equations

Method

Participants Twenty students from the University of Virginia received partial course credit for participation. All participants had normal or corrected to normal vision.

Materials Packets were created using a format identical to Experiment 2A. Similar stimuli were used, except the stimuli were modified from an arithmetic computation to the solution of a linear equation (see Figure 5). Participants were instructed to solve the equation before deciding which ball was closer (further).

Figure 5. Example Stimulus from Experiment 3.

Two other changes were made to the stimuli: first, the dot notation was used for multiplication in place of the cross. This sign is much more typical in algebraic contexts, and is less likely to be confused for a variable than the cross. Furthermore, crosses and dots have similar salience advantages in mathematical contexts (Landy et al., 2008). Second, the baseballs were moved from behind the operations to behind the operands. This was done because, in an equation solution context, the operands are more relevant units of action. That is, one solves the problem illustrated by cancelling the *b*, and then the *a*. Thus, the effect of perceived action was predicted to be strongest in this configuration.

Procedure The procedure was identical to Experiment 2A.

Results and Discussion Participant choices were analyzed using a repeated measures logistic regression (see Figure 2). Including judgment type significantly improved the fit over the baseline model ($\chi^2(1) = 6.0, p < 0.05$). Participants were more likely to judge the baseball under the multiplicative term as closer than the baseball under the additive term.

The results of Experiment 3 contradicted our original hypothesis that perceived depth would align with available actions, instead supporting the idea that syntactically central symbols appear to be closer than syntactically peripheral symbols in mathematical expressions.

The results of Experiment 3 are to some degree compatible with the interpretation that low-level visual features guide perceived proximity. In this case, perceived depth of the baseball images would be affected by the terms adjacent to the judged baseballs, rather than those directly behind it. In a pre-cuing task, Baylis and Driver (1995) reported that exogenous cues to attention did not affect figure-ground segregation (which tends to align with depth perception in most cases, though see Huang & Pashler, 2009), when the cue appeared outside the area in which the figure appeared (see also Vecera et al., 2004). Nonetheless, in this case, it is possible that the highly salient dot adjacent to the baseball increases its apparent proximity. It is also possible that the multiplicative terms and the multiplication sign are visually grouped and therefore that the salience of one part of the group (the multiplication sign) causes the entire group to appear closer.

General Discussion

Although mathematical notation is a formal language, and is inherently two dimensional, readers of these notations come to quite consistent judgments about the relative proximity of terms in formal expressions. Three experiments demonstrated that factors that determine formal precedence (operation sign and parentheses) also systematically influence perceived depth.

Variations in perceived depth aligned in our stimuli with formal precedence. The current results do not distinguish between the possibilities that syntactic precedence directly affects perceived depth, and that the low-level visual

features of typical mathematical notation determine apparent depth. Although future work should distinguish these two possibilities, we think it notable that mathematical notation is structured in such a way that there is a systematic relationship between low-level visual features affecting and mathematical syntax. This alignment raises the possibility that perceived three-dimensional structure may be used as a cue to mathematical ordering.

As long as episodes of formal reasoning are indeed typically organized by attention-based interactions with external environments (Landy et al., 2008; Patsenko & Altmann), the alignment of perceptual factors such as visual grouping, salience, and depth may be significant factors in making symbolic mathematical notation such a powerful and successful system for supporting reasoning.

Three limitations of the current work are worth noting: one is that it does not indicate the strength of the judgment. Although judgments were significant and consistent in Experiments 1, 2A, and 3, participants made forced choice binary judgments. Thus, while we can conclude that people generally perceive multiplications as closer than additions, the current experiments give no indication of the magnitude of the perceived difference.

Another limitation is that there is no indication in the current studies of whether this perceived difference in depth has any effect on mathematical judgments. Future work should explore whether explicit manipulations of apparent depth disrupt mathematical reasoning processes. Finally, there is a possibly important confound in Experiment 1. In these stimuli, the laces on the baseballs overlap, and are obscured by, the addition sign slightly more than the multiplication sign. This might provide a stronger depth cue, causing subjects to see the baseball under the addition sign as farther away. This confound could not explain the difference between Experiment 1 and 2a, nor could it explain the effect in Experiment 3. In Experiment 3, the baseballs appeared under the letters. These were counterbalanced across condition, and so could not have led to differences in judgment.

Recognizing these limitations, nevertheless the existence of consistent depth cues in mathematical notations bolsters interpretations that treat mathematical reasoning as (sometimes) a form of spatial reasoning over symbolic objects. Accounts that treat symbolic reasoning as abstract rule learning cannot make systematic predictions about depth, such as those seen here. Understanding how and when such factors matter for reasoning promises to further illuminate our understanding of general formal reasoning processes.

Computational Semantic Detection of Information Overlap in Text

Julia M. Taylor (jtaylor@riverglassinc.com)

RiverGlass Inc, 2001 South First St

Champaign, IL 61820 USA

Abstract

This paper is an attempt to investigate whether a computer is capable of finding similar information in structurally different texts, as people do it, without relying on lexical matching and without guessing the meaning of sentences based on word co-occurrence. Considered texts describe the same event, but each text may focus on different parts of the event. The considered texts are not paraphrases, but rather human-produced descriptions of a simple picture. The goal is not to find similar words in texts, which can be easily done, but to meaningfully connect the overlapping concepts and relationships used in the text descriptions. The meaning-based approach does not use any statistical/machine-learning techniques. The performance of a machine in finding similarity is compared to human performance not just in numbers but in the found information. The results show that the machine matches four out of the five human findings.

Keywords: text duplication and similarity, information overlap detection, meaning processing, ontological semantics.

Overview

This paper examines the use of the Ontological Semantic Technology (OST)—a modified version (Raskin et al 2010) of Ontological Semantics (Nirenburg & Raskin 2004)—for processing similar texts and compares it to human processing. Instead of selecting existing texts and assessing their similarity, users were given the same picture to describe. Clearly, the users will emphasize different objects or events on the picture, but at the same time, because they are all looking at the same picture, some of the provided information will overlap. The experiment is done to demonstrate the ability of the technology to understand the meaning of text, regardless of individual words that are used and of the length of the sentences.

The OST claim to fame is that it “understands” the meaning of text. The meaning of text includes paraphrases of sentences or paragraphs. A large number of paraphrases can be produced from a single sentence, an even larger number can be produced from a paragraph. Because of this large number of potential paraphrases, and because it is unclear which ones are good enough, instead of asking people to paraphrase a text, we ask them to describe a picture.

The untested assumption is that looking at the picture should activate the same schema(ta) as reading a paragraph. Thus, the main information received should be approximately the same whether looking at the picture or reading text. Instead of *reconstructing* original sentences after reading or listening to a text, the subjects were asked to *describe* what they see on the picture in their own words. The tasks of paraphrase and describing a picture are by no

means identical, even for short sentences when compared to very simple pictures. Several things should be noticed: 1. Length of the sentences in paraphrases has probably some correlation to the length of the original sentences. 2. The choice of words for the description task is not limited by the original sentence, whereas it is possible that, in the paraphrase, the subjects would try to come up with unnatural synonyms in their desire to paraphrase. 3. The order of sentences is free in the picture description, while it is possible that the sentences would be ordered according to the original text in the paraphrase.

While paraphrase detections have received some attention from the machine-learning community (Fernando & Stevenson 2008, Clough et al 2002, Qiu et al 2006, Zhang & Patrick 2005), to the best of our knowledge same picture descriptions have not been addressed. This is surprising because most real life event descriptions are more similar to picture descriptions than to paraphrasing tasks.

The task of paraphrase limits information that is available to the subjects to that in the task, while describing the picture provides more freedom of focus. For example, the sentence *a black ball is on top of a green cube*, can only be paraphrased in term of the provided information. Possible paraphrases are: *a green cube is under a black ball; a black sphere-shaped object is above a green cube; a ball is positioned on top of a cube, the ball is black and the cube is green*. Notice that there may be a considerable variation among paraphrases in terms on the words used, the order in which they are described, and the number of clauses used in the description. What they all have in common, however, is the properties and attributes that connect the described objects: all describe shape either explicitly as in *sphere-shaped object*, or by accessing the knowledge of a shape of a lexical item as in *ball* or *cube*; and all describe color. However, if picture is shown (Figure 1), other things may come into focus for different people, such as relative size of the objects.

Figure 1: A black ball on top of green cube

It would be interesting to see if such unmentioned-in-the-text characteristics would ever be brought up by the subjects in the paraphrase generation as unknown. It is, however, not the purpose of this experiment. The only significant assumption for this paper is that the greater variation of text should be encountered in the picture experiment, which in turn tests the machine’s capability of catching the overlap to

a much greater extent. On the other hand, it would be interesting to see if a coherent description of a situation could be constructed from a union of all descriptions, as it is likely that these descriptions, to some extent, complement each other.

It is this overlap information in descriptions reported by subjects, as well as the difference or the union, that is captured and analyzed by the machine, as compared to the overlap and difference in information in responses as perceived by human is the subject of the paper. The theoretical knowledge obtained in this kind of research is applicable to an increasingly urgent task of easing the information overload by removing duplicate and overlapping information¹.

Ontological Semantics Technology

OST is an upgraded, much improved and implemented (and, on occasion, perverted) version of (Nirenburg & Raskin 2004) that detects the meaning of text. Ontological Semantics is a theory, methodology and technology for representing natural language meaning, for automatic transposition of text into the formatted text-meaning representation (TMR), and for further manipulation of TMRs for inferencing and more advanced reasoning, both theoretically and in a growing variety of applications. The main knowledge resources in OST are the language-independent ontology and language-specific lexicons.

The OST is not a toy system that works on a handful of examples; instead, it works with unrestricted texts in real-life applications, as well as avoiding the scalability problems (see Raskin et al 2010).

Ontology

The ontology contains information about the world; it is a constructed, engineered model of reality, a theory of the world (Gruber 1993, 1995; Nirenburg & Raskin 2004:138-139). It is a structured system of concepts covering the processes, objects, and properties in all of their pertinent complex relations, to the grain size determined by an application or by considerations of computational complexity. The ontology contains PROPERTIES, EVENTS, and OBJECTS. The concepts are named purely for the convenience of a human: the label itself does not contribute to the information content. Every OBJECT and EVENT is defined with a number of properties, thus allowing the concept to differ not only in label, but also in machine-understandable information. The child concepts inherit properties from the parent concepts.

Formally, the OST ontology is a lattice of conceptual nodes (for a construction of ontology and verification see Hempelmann et al. 2010 and Taylor et al 2010 respectably), each of which is represented as:

concept-name

¹ The author believes that whether an overlap indicates an importance of information in text is a separate (to her, dubious) hypothesis, which will not be addressed in this paper.

```
(property (facet(property-filler+))+)+
property-filler
  concept-name | literal value
property
  attribute | relation
facet
  SEM | VALUE | DEFAULT | RELAXABLE-TO2
```

The current implementation of OST uses the following three axioms:

- subClassOf for concepts: IS-A (example: PHYSICAL-OBJECT IS-A OBJECT)
- subPropertyOf for properties: IS-A (example: COLOR IS-A PHYSICAL-OBJECT-ATTRIBUTE)
- inverse for properties: INVERSE (example: THEME INVERSE THEME-OF)

Concept interpretation (without facets, for the ease of reading) can be looked at using the following: given a set of objects \mathcal{D} , where \mathcal{D} is the disjoint union of \mathcal{D}_c (concepts) and \mathcal{D}_d (literals), and given its interpretation function I , for every atomic concept B , $I[B] \subseteq \mathcal{D}_c$; for every literal V , $I[V] \subseteq \mathcal{D}_d$; for every relation R , $I[R] \subseteq \mathcal{D}_c \times \mathcal{D}_c$; for every attribute A , $I[A] \subseteq \mathcal{D}_c \times \mathcal{D}_d$. Moreover, the following is true for concepts C and D :

$$\begin{aligned} I[ALL] &= \mathcal{D} \\ I[\epsilon] &= \emptyset \\ I[C \ D] &= I[C] \cup I[D] \\ I[\text{and } C \ D] &= I[C] \cap I[D] \\ I[(\text{Rel}(\mathcal{D}))] &= \{x \in \mathcal{D}_c \mid y \in I[D], \langle x, y \rangle \in I[\text{Rel}]\} \\ I[(\text{Rel}(\text{and } C \ D))] &= I[\text{Rel}(C)] \cap I[\text{Rel}(D)] \\ I[\text{Rel}(C \ D)] &= I[\text{Rel}(C)] \cup I[\text{Rel}(D)] \\ I[C(\text{Rel}(\mathcal{D}))] &= I[C] \cap I[\text{Rel}(D)] \\ I[(\text{Att}(V))] &= \{x \in \mathcal{D}_c \mid y \in I[V], \langle x, y \rangle \in I[\text{Att}]\} \end{aligned}$$

Clearly, concept C is a descendant of D if $I[C] \subseteq I[D]$; and $I[(C(\text{Rel}(\mathcal{D}))) \subseteq I[C]$. Whenever relation Rel is defined with a domain D and range R , if $I[C] \subseteq I[D]$ and $I[E] \subseteq I[R]$, then $C(\text{Rel}(E))$ is equivalent to $I[C] \cap I[D(\text{Rel}(\text{and } E \ R))]$.

For the examples in this paper, it is sufficient to mention that when facets are involved, the highest priority facet takes precedence over the lower priority one.

Lexicon

The lexicon is the starting point for machine interpretation of language in OST. Since Ontological Semantics is centered on meaning, we will largely concentrate on the semantic structure (sem-struc) part of the lexicon entries.

In general, the lexicon can be looked at as a collection of words (and phrasals), organized such that each word is

² The list shown has been enriched in the current implementation of OST, but since facets do not contribute much to this paper, the list is left as it was first introduced.

listed with all of its senses. Each sense of the word in a lexicon follows the following structure:

```
(WS-PosNo
(cat(Pos))
(synonyms "WS-PosNo"))
(anno(def "Str")(ex "Str")(comments "Str"))
(syn-struct((M)(root($var0))(cat(Con))(M))
(sem-struct(Sem))
)
```

where the following grammar defines what is allowed:

```
M → (Srole((root(Var))(cat(Cpos)))
→ (Srole((opt(+))(root(Var))(cat(Cpos)))
→ (M(M))
Pos → N | (noun)
→ V | (verb)
→ Adj | (adjective)
→ Adv | (adverb)
→ ...
Con → NP | (as defined by rules omitted)
→ VP | (here to save space)
→ Con Con |
→ Pos
SRole → subject | (syntactic roles,
→ directobject | only some are shown
→ pp-adjunct | to save space)
→ ...
No → [1-9] (any digit)
Str → [A-Z|a-z| |,|.] (any string)
Var → $varNo
→ Str
Sem → C | (any ontology concept)
→ ^Var(R(F(C))) | (R, F, C from ontology)
→ C(R(F(^Var))) (C, R, F from ontology)
```

When the machine processes text with the help of the resources, the ontological concepts are accessed through the (English) lexicon. For example, a lexical entry for the verb *run* will contain all the possible senses, of which #6 is shown below:

```
(run-v6
(cat(v))
(anno
(comments "...")
(def "meet unexpectedly")
(ex "I ran into my teacher at the movies last
night."))
(syn-struct
((subject((root($var1))(cat(np))))
(root($var0))(cat(v))
(prepare((root(into))(cat(prepare))))
(directobject((root($var2))(cat(np))))
)
(sem-struct
(meet-with
(agent(value(^$var1(should-be-
a(sem(human)))))))
```

```
(beneficiary(value(^$var2)))
(intentionality(value(<0.3))(relaxable-to(<0.5)))
)
)
)
```

The entry shows that this sense of *run* means ‘unexpected meeting event’ (from *sem-struct*), and it needs a preposition *into* (from *syn-struct*) to be activated. It also shows that in its normalized form the subject is usually the agent of the event, and the direct object is the beneficiary. Optional properties such as time, place, etc are usually not shown in the lexical items.

OST On Black balls and Green Cubes

OST uses the Semantic Text Analyzer (STAn) to interpret the meaning of sentences. The (machine generated) output of STAn is a text meaning representation (TMR) that shows the conceptual representation of the text, regardless of the language of the input. Let us go back to the sentence *a black ball is on top of a green cube*. The resulting TMR is:

```
Event: pred1
(theme(value (physical-object1
(shape(value(sphere)))
(color(value(black)))
(above(value(physical-object2
(shape(value(cube)))
(color(value (green)))
))))
)))
```

Possible paraphrases from the previous section is: *a green cube is under a black ball*:

```
pred1
(theme(value (physical-object1
(shape(value(cube)))
(color(value(green)))
(below(value(physical-object2
(shape(value(sphere)))
(color(value (black)))
))))
)))
```

Another interesting paraphrase is: *a ball is positioned on top of a cube, the ball is black and the cube is green*, which will result in the following:

```
put1
(theme(value (physical-object1
(shape(value(sphere)))
(above(value(physical-object2
(shape(value(cube)))
))))
)))
pred1
(theme(value (physical-object1
(shape(value(sphere)))
(color(value(black)))
```

```

)))
pred2
(theme(value (physical-object2
  (shape(value(cube)))
  (color(value(green)))
)))

```

Notice that besides the PUT event, corresponding to *is positioned*, and the inverse of the BELOW-ABOVE properties, the rest of the information is identical for any purposes, including reasoning. The third example is especially interesting, as the colors are assigned to the indexed objects, referenced by the previous sentence.

The intersection of the paraphrases, as indicated by the TMRs once the inverse properties are used, are:

```

pred1
(theme(value (physical-object1
  (shape(value(sphere)))
  (color(value(black)))
  (above(value(physical-object2
    (shape(value(cube)))
    (color(value (green)))
  )))
)))

```

The union of the TMRs adds information only present in the third example, namely that of PUT, thus, producing

```

put1
(theme(value (physical-object1
  (shape(value(sphere)))
  (color(value(black)))
  (above(value(physical-object2
    (shape(value(cube)))
    (color(value (green)))
  )))
)))

```

If Figure 1 is described instead of paraphrases, and sentences like *a ball is smaller than a cube* happen to be added to the description, it is easy to see that the intersection of TMRs will remain the same, while the union will add the additional size information.

More Complex Pictures

As demonstrated in the previous sections, OST is capable of understanding the meaning of close paraphrases and represent it in such a way that the differences and similarities are shown. The next experiment aimed at stretching the similarities as far as possible, but asking the user to describe a picture instead of paraphrasing a text.

The picture shown to the user was selected to depict an unambiguous object in the foreground, while the background contains objects that can be described either very briefly, if at all, or be paid as much attention as possible. The hypotheses are:

- The description of the central element of the picture is affected by individual/personal schemata, and

therefore will partially differ from person to person. However, there should be an overlap in descriptions, focused on that central object, just as the paraphrases showed.

- The description of the background will differ from person to person to a much greater degree. A very small overlap is expected from pairs of participants since the background is not in focus (metaphorically).
- The activated schemata are not expected to be known to a computer, thus the computer will process only information explicitly stated by the subjects.

This is not at all an attempt to deal with the well-researched figure-ground phenomenon (see Talmy 2000, vol, 1: 311-344). Instead, we are only interested in the foreground display, but the background may provide individual distinctions.

Methodology

Once a picture was chosen, 3 subjects, unfamiliar with an experiment's goals and from unrelated occupations, were asked to describe the picture. The picture was visible to the subject all the time, thus the description is not effected by the accuracy of their recollection of the picture. The instructions requested to describe only what is seen on the picture, without alluding to any inferences or encyclopedic knowledge that the picture may activate. The subjects were not given any specific time frame to complete the task.

The described text was then entered into a machine for processing, and the union and intersection of information in individual texts were computed. Whenever the descriptions contradicted each other, the contradictions were also added to the union as alternative interpretation.

To check the validity of the found union and intersection, a person not participating in the description task and not involved in the OST part of the experimentation was asked to highlight the similarities in text. These similarities were then compared to the intersection of interpretations provided by a computer.

The foreground of a picture showed a moving elephant. The background of the picture contained trees, shrubs and other greenery, as well as a place where several cars were parked, as seen in Figure 2.

Figure 2: An elephant crossing the road

Results of Human Description

The descriptions of the submitted texts varied length (the first text used 54 words, the second text used 124 words,

and the third text used 151 words) and structure of sentences.

The following similarities were noticed by a human in all of the descriptions:

- Elephant's existence.
- Road on which the elephant is located.
- Trees in front of the cars, in some spatial relation to the elephant
- Cars parked in the background

The following information was included in at least one of the texts (author's summary below):

- A large African male elephant is shown on the picture and is moving either on the road or bare ground or crossing the road. The elephant has large tusks, 4 legs, one visible ear, one visible eye, a tail and a trunk. The front right leg of the elephant is bent at the knee.
- There is dust on road and some dirt or hard soil on the edges of the road. The road is wide and paved.
- A row of trees are between the elephant and the cars, past the cars and on the berm. The trees are large with extensive but not overwhelming foliage. The grass is mostly yellowish and dusty.
- Cars, red and light blue or white, are parked on the parking lot. The red car is a hatchback. The cars, either 4 or 2, are all compact models. All cars are parked behind the trees on what may be a parking lot.
- A building that has yellow corner is behind the cars.
- It is a bright sunny day; the sky is blue with light clouds.

From this description, it can be noticed that the hypothesis of the central element of the picture being similarly described between all participants could not be accepted. Interestingly, the descriptions varied in movement information—it could be argued that it is not salient to the central object itself—but not in the elephant's location on the road. The description of the elephant and its body parts did not vary as much between any 2 subjects as between all of them. It should also be noticed that there was no contradictory description of the elephant itself. Thus, perhaps a better metric would be to find overlap used by the majority of the participants, as opposed to all, for real-world applications.

The second hypothesis, namely the difference in the background descriptions due to focus on different elements could not be rejected based on this small set. Between the objects that were noticed by all participants, the description varied more than that of the central object, and often the information was contradictory. For example, there was no agreement on the number of cars in the picture or their colors and very different description of greenery.

Computational Description

Computational overlap, as expected, was clustered around objects. Thus, the following concepts were identified:

ELEPHANT, ROAD, CAR, TREE. Additionally, the following descriptions of the concepts were found:

```
undetermined_event
  (agent(value(elephant1)))
  (location(value(road1)))
car1
  (behind(value(tree1(number(greater-than(1))))))
put2
  (instrument(value(car1)))
  (location(sem(parking-lot)))
```

In plain English, it says that there is an elephant that is doing something on the road, there is a car behind trees, and somebody left a car in the parking-lot. Clearly, what is missing here from the overlap found by a human is that there are trees in some special relation to the elephant.

The union of information was not as successful due to coreference resolution mistakes (with STAN's coreference module not yet fully activated), however, the trivial unions of information were found. The number of unconnected clusters of information was small enough, that based on the concepts connected through the overlap above, it is possible to conclude that the three stories described similar information.

Perhaps it is worthwhile to demonstrate the computational process in the discovery of the overlap. Consider the following sentences:

- (1) A large grey elephant is moving on a road or bare ground.
- (2) This is a photograph of an elephant crossing a road. It is a large male African elephant.
- (3) Elephant is on asphalted road.

The sentences result in the following TMRs:

```
(1) land-animal-motion1
  (phase(value(continue)))
  (agent(value (elephant1)))
  (color(value(grey)))
  )))
  (location(value(road1 ground1)))
(2) pred1
  (theme(value(photograph
    (representation-of(value(change-location1
      (agent(value(elephant1)))
      (path(value(road1)))
    )))
  )))
pred2
  (theme(value(elephant1
    (size(value(large)))
    (gender(value(male)))
    (location(pnd(Africa)))
  )))
(3) exist1
  (agent(value(elephant1)))
  (location(value(road1
    (made-of(value(asphalt)))
```

)))

From the above descriptions, we know the following about the elephant:

From (1): $\langle \text{land-animal-motion1, elephant1} \rangle \in I[\text{agent}]$

From (2): $\langle \text{change-location1, elephant1} \rangle \in I[\text{agent}]$

From (3): $\langle \text{exist1, elephant1} \rangle \in I[\text{agent}]$

Taking the intersection of the events for which the elephant is an agent results in $x \in I[\text{event}]$. Thus, producing $\text{undetermined_event}(\text{agent}(\text{value}(\text{elephant1})))$.

Continuing with each TMR, we find the following:

From (1): $\langle \text{land-animal-motion1, road1} \rangle \in I[\text{location}]$

From (1): $\langle \text{land-animal-motion1, ground1} \rangle \in I[\text{location}]$

From (2): $\langle \text{change-location1, road1} \rangle \in I[\text{path}]$

From (3): $\langle \text{exist1, road1} \rangle \in I[\text{location}]$

It can be easily noticed that *ground1* occurs only in (1), thus the intersection with (2) and (3) results in an empty set. For *road1*, the calculation is similar to that of an elephant with the only addition of parent-child relationship of location and path.

It should also be noted that if we were to find an overlap of (1) and (2) and discarded (3), the event in question would have a considerably finer grain. According to the ontology, the most specific ancestor of both LAND-ANIMAL-MOTION and CHANGE-LOCATION is CHANGE-LOCATION. This means that while the sentences used different verbs to describe the movement of the elephant (crossing and moving), the OST understands what both mean and finds the general concept for both, as opposed to ignoring the similarity in meaning.

Similar processing is done for all sentences, resulting in the above relationship for *car1* and *put2* in addition to elephant.

The calculation of overlap is done in a similar manner, with the exception of the selection rules: each pair of concepts does not have to overlap in the found properties, instead uniquely found relationships are added to the existing set.

Conclusion

This paper was an attempt to investigate whether a computer is capable of finding similar information in structurally different texts that describe the same event, each focusing on potentially different parts of the event. The goal was not to find similar words in texts, which can be easily done, but to meaningfully connect the overlapping concepts and relationships used in the text descriptions. The approach is radically different from the machine-learning one. The performance of a machine in finding similarity was compared to human performance. The machine matched four out of five human findings.

It is too early to reach a conclusion that it is possible for computers to find overlap and difference between texts similarly to those that humans find, and, of course, more

extensive experiments should be conducted. However, it is promising that the first result is not negative.

Abstract

A set of studies examines whether domain knowledge for baseball will enable participants to overcome the fan effect from baseball-related sentence sets. In a first study, neither high nor low knowledge participants overcame the fan effect when baseball positions and locations were randomly paired together. In a second study, when positions and locations were consistent with baseball expectations, both high and low knowledge participants overcame the fan effect on target sentences. However only high knowledge participants showed no effect on foils. The results suggest that prior knowledge can affect both representation and decision phases underlying recognition memory.

Domain-related Knowledge and Memory

Research on expertise has generally found that possession of domain-related knowledge or experience leads to superior problem solving, learning, and memory performance (see Feltovich, Prietula, & Ericsson, 2006 for review). The superior performance is thought to be due to extensive, easily accessible and well-connected knowledge structures in long-term memory (Bedard & Chi, 1992; Ericsson & Kintsch, 1995; Ericsson & Staszewski, 1989) which allows for more connections or associations to be made with incoming stimuli. Interestingly, another body of research suggests that increasing the number of associations among incoming stimuli can lead to a detriment in memory performance (See Reder et al., 2007 for review). This phenomenon, called the *fan effect*, refers to the slowdown in verification time that occurs as a function of the number of associations with a presented concept (e.g., Anderson & Bower, 1973; Lewis & Anderson 1976; Reder, Donavos, & Erickson, 2002).

What is the Fan Effect?

Typically the *fan effect* is demonstrated by having participants study sets of sentences that vary in the number of associations stated between concepts such as objects and locations (Anderson, 1974; Reder et al., 2007). The number of associations that each object or location is paired with is the “fan” size, and it usually

varies between one and three.

For example, participants could be presented with the following sentences:

The lawyer is at the school.

The lawyer is at the park.

The lawyer is at the theater.

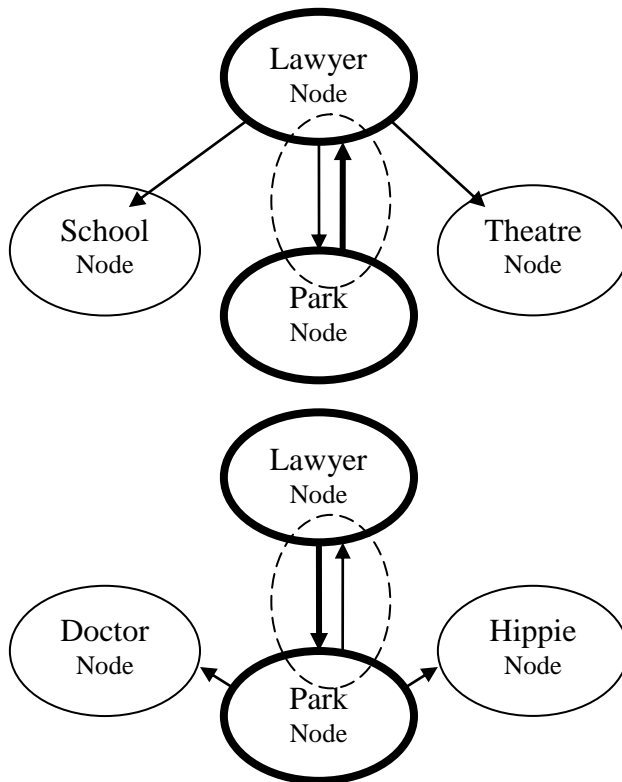

The doctor is at the museum.

In this example, the lawyer has a fan size of three and the doctor has a fan size of one. Participants are required to memorize these sentences to some criterion during the study phase. Then, after reaching criterion, participants move to a recognition test phase where they are asked to decide as quickly as possible whether or not sentences appeared in the study list. Typically, participants take longer to verify that the statement “The lawyer is at the school” appeared in the study list than “The doctor is at the museum,” due to the larger fan of lawyer in this set.

There are two main accounts that have been offered for the *fan effect*: the propositional network theory (Anderson, 1974; Reder et al., 2007) and the situation model theory (Radvansky, Spieler & Zacks, 1993; Radvansky, 1999).

The propositional theory suggests that the fan effect is a function of the number of pathways that branch from a target concept in a memory network and a corresponding reduction in the spread of activation. To illustrate this, imagine that nodes exist in memory that correspond to the presented concepts (e.g. lawyer, park, doctor, school, park, theater, museum). When participants are required to verify if they have seen a sentence such as “The lawyer is in the park,” the nodes “lawyer” and “park” are activated. As shown in the top of Figure 1, activation spreads along all connecting pathways that exist, represented by the arrows. For the “lawyer,” with the fan of three, activation is diffused among the pathways connected to “school,” “park,” and “theater.” Similarly, if three statements are presented involving “park”, as shown in the bottom of Figure 1, then activation would also be diffused in that case.

Figure 1:
Two models with fan sizes of three

In contrast, the sentence, “The doctor is at the museum,” has a fan size of one. As shown in Figure 2, there will be no diffusion of activation in this representation because there is only one pathway branching from each of the nodes “doctor” and “museum.”

Figure 2:
A model with fan size of one

In the fan of three examples, the partitioning of activation among associations decreases the amount of activation that spreads to each connecting pathway, which increases the amount of time it takes participants to become aware of the target pathway (Jones & Anderson, 1987). In this model, the distribution of activation to irrelevant pathways is called interference (Anderson, 1974), and indeed the empirical results have generally supported that the number of associations predicts verification time (Reder et al., 2007).

However, one exception in previous empirical results, has been the observation that not all fans of three are equal. The situation model account suggests that the type of fan represented by the bottom network in Figure 1 will experience less interference than the type of fan represented in the top panel. The situation model account posits that when people can integrate incoming information into a single representation then they will not be susceptible to the interference due to multiple associations (Radvansky, 1999). In this explanation, slower verification times are not the result of the number of associations that are present, but rather the number of models that need to be searched. From this perspective, one can imagine all three sentences in the second example could refer to a single situation in the park, perhaps with the lawyer meeting the hippie and the doctor. If these three sentences are integrated into one representation in memory, then even though there are three items associated with park, there is only one model to search. Consistent with this approach, several studies have demonstrated that the ability to integrate sentences into a single representation or model can eliminate the fan effect (Gomez-Ariza & Bajo, 2003; Moeser 1979; Myers, O'Brien, Balota & Toyofuku, 1984; Radvansky, Spieler & Zacks, 1993; Smith, Adams & Schorr, 1978).

Although it has not yet been tested, one implication of this model is that participants may be able to overcome the fan effect for domain-related information, as prior knowledge may allow readers to represent and integrate sets of sentences into a single model. Thus, the goal of this research was to investigate if the possession of prior knowledge related to the topic of the sentences would eliminate the fan effect in recognition memory.

Experiment 1

Method

Participants. Participants were 110 students in introductory psychology classes at University of Illinois at Chicago who received course credit for their

participation.

Procedure. Participants were administered a baseball-related fan task in groups ranging in size between 1 to 12. The sessions last approximately 1 hr. The stimuli were created by randomly pairing a type of baseball player (e.g., catcher) with a location on a baseball field (e.g., second base) to create sentences (e.g., The catcher is at second base). The task was analogous to the fan task used by Radvansky and Zacks (1991) with participants being presented 18 sentences and being asked to memorize them. The 18 sentences contained 4 at fan size 1, 4 at fan size 2 and 10 at fan size 3.

Each participant was seated at their own computer. During the study phase, the sentences were presented on a computer screen one at a time for 7-seconds each. After the study phase, participants were retested for their memory of the sentences. If participants were unable to remember 90 percent of the sentences correctly they repeated the study and test phase. Feedback was provided for incorrect answers during the test phase. This cycle was continued until participants reached the 90 percent criterion.

After the participants reached the 90 percent criterion, they completed a speeded recognition task. Twelve target sentences were presented from the studied materials (four sentences at each of the fan sizes of one, two, and three; Similar to Radvansky and Zacks (1993), studied sentences that had both a player and a location with more than one association were not used.).

Twelve foils were created by re-pairing the studied players and locations. The re-pairing was done within the fan size so fan 1 player/locations were re-paired with fan 1 player/locations. Participants pressed the “Z” key if the sentence was not studied and “M” if it was studied.

At the end of the study, participants completed a 45-item baseball knowledge questionnaire (Spilich, Vesonder, Chiesi & Voss, 1979). Average performance on the baseball questionnaire was 16.47 (SD 12.66) Range was 0 to 41. Two levels of domain knowledge were defined by a median split at 15. All participants’ accuracy was above 90% on the speeded recognition task and there was no significant difference for accuracy between high and low knowledge participants.

Results

A 2 X 3 mixed ANOVA was used to assess the effects of Fan Size (one, two or three), and Expertise (high,

low baseball knowledge) on correct verification RT. Similar to Radvansky, Spieler, and Zacks (1993) responses that were faster than 500 ms and slower than 10,000 ms were considered errors. The pattern of results is shown in Figure 1. The ANOVA revealed a main effect for Fan Size, $F(2, 216) = 7.36$, $p < .001$, $\eta^2 = .06$, and Expertise, $F(1, 108) = 8.24$, $p < .01$, $\eta^2 = .06$, but not a Fan Size X Expertise interaction, $F(2, 216) < 1$, $\eta^2 = .01$. As expected, participants experienced a slowdown in the recognition test as the number of associations increased from 1 to 3. There was also a main effect such that high knowledge participants made faster decisions than low knowledge participants. However, neither high knowledge nor low knowledge participants overcame the fan effect. Both high and low knowledge participants experienced increasing verification times as fan size increased. The same pattern of results was observed for the studied and foil sentences in this study.

Figure 1: Verification time per syllable (ms) with random pairings in Experiment 1. Error bars represent standard errors.

These results provide a replication of the basic fan effect finding. As fan size increased, so did verification times. Simply having prior knowledge for the topics of the sentences did not change this pattern. However, because the pairings were random, it is possible that this task did not test the situation model account. In order to support the construction of a single model, one may need sentences that “make sense” within the domain. According to the situation model theory, the fan effect should not be eliminated unless participants are able to integrate the multiple players and locations into a single model. Randomly pairing the players and locations together made pairs that were not consistent with baseball experience and which may not have made it any easier for high knowledge participants to integrate sentences into single situations. Thus, in Experiment 2, we presented sentences that were more consistent with baseball situations.

Experiment 2

The goal of this second study was to use sentences that were more consistent with real baseball situations, and to test whether prior knowledge might affect performance under those circumstances. For this study, players and positions were paired to reflect plausible situations, such as:

The reliever is at the mound.
The manager is at the mound.
The catcher is at the mound.

These sentences could represent a pitcher conference, an event that happens in the majority of baseball games.

Method

Participants. Participants were 110 students in introductory psychology classes at University of Illinois at Chicago who received course credit for their participation. These were new participants that had not participated in Experiment 1.

Procedure. Participants were administered a baseball-related fan task almost identical to the one administered in Experiment 1. The only difference was that the players and positions were not randomly paired together, but were paired to create plausible sentences by the researcher. The 12 foils were also consistent with baseball expectations. Some example foil sentences were:

The pinch runner is at second base.
The reliever is at first base.
The pitcher is at the bullpen.

Participants again completed a 45-item baseball knowledge questionnaire at the end of the study. Average performance was 14.53 (SD = 13.35). Range was 0 to 41. A median split of 15 was used similar to Experiment 1. All participants' accuracy was above 90% on the recognition task and there was no significant difference between high and low knowledge participants.

Results:

A 2 X 3 mixed ANOVA was used to assess the effects for Fan Size and Expertise on correct verification RT. Again responses that were faster than 500 ms and slower than 10,000 ms were considered errors. The pattern of means can be seen in Figure 2. The ANOVA revealed a main effect for Fan Size, $F(2, 216) = 7.82$, $p < .01$, $\eta^2 = .07$, but no main effect for Expertise $F(1, 108) < 1$, $\eta^2 = .01$. However, there was

a Fan Size X Expertise interaction, $F(2, 216) = 7.16$, $p < .01$, $\eta^2 = .07$.

Figure 2: Verification time per syllable (ms) with plausible pairings in Experiment 2. Error bars represent standard errors.

As in Experiment 1, participants experienced an overall slowdown in verification time as the number of associations increased from 1 to 3.

However, this effect was qualified by a significant Fan Size by Expertise interaction, with low knowledge participants showing the typical fan effect, and high knowledge participants showing a diminished fan effect. On the face of it, these results can be seen as consistent with the situation model account. They suggest that, now that the sentences are plausible, participants with prior knowledge may be able to create a single model for each set of sentences, which allows for efficient search of memory, regardless of the number of overlapping associations.

What is responsible for the elimination of the fan effect among high knowledge participants? To further examine this question, we performed some additional analyses and in particular we examined whether performance improved on both target and foil trials. If the better performance among high knowledge participants is due to the efficiency of needing to search only a single model, then this account would predict facilitation for both correct acceptance of targets and rejections of foils. However, as can be seen in Figure 3, different patterns were found across target (top panel) and foil (bottom panel) decisions.

Figure 3: Reaction times per syllable (Msec) for studied sentences (top panel) and foils (bottom panel). Error bars represent standard errors.

First, looking at performance on the studied sentences, here we can see that in fact, no fan size effect was found for either knowledge group. A 2 X 3 mixed ANOVA showed that there were no significant effects for Fan Size, $F(2, 216) = 1.91, p < .15, \eta^2 = .05$, or Expertise, $F(1, 108) = 1.31, p < .27, \eta^2 = .01$. Nor was there a Fan Size X Expertise interaction, $F(2, 216) = 1.60, p < .21, \eta^2 = .03$. Thus, neither high nor low knowledge participants experience a fan effect on correct verifications for plausible sentences.

Quite a different picture is seen when one examines the response times for the foils. Here another 2 X 3 mixed ANOVA revealed a main effect for Fan Size, $F(2, 216) = 20.16, p < .01, \eta^2 = .23$. Although there was no main effect for Expertise, $F(1, 108) < 1, \eta^2 = .02$, there was a Fan Size X Expertise interaction, $F(2, 216) = 8.17, p < .01, \eta^2 = .07$. Low knowledge participants were especially vulnerable to the slowdown on foils as fan size increased.

The results show that the fan effect was diminished for experts on both correct verifications and rejections, while novices experienced a fan effect, and this was driven by decision times on the foils.

DISCUSSION

According to the situation model account, the fan

effect should be eliminated when participants are able to integrate multiple associations from a set of sentences within a single situation model. Consistent with this approach, it appears that presenting participants with sentence sets representing plausible combinations of baseball players and positions enabled both high and low knowledge participants to respond quickly to studied sentences, regardless of the number of associations among them. This finding is consistent with the situation model account. It is also reminiscent of findings that have demonstrated that the fan effect is diminished when participants are able to integrate the sentence sets into stories (Ariza & Bajo, 2003; Myers, O'Brien, Balota & Toyofuku, 1984; Smith, Adams & Schorr, 1978).

In addition, the further analysis of the studied and foil sentences separately revealed the interesting result that the non-studied foils showed a different pattern of verification times than the studied sentences. When participants were presented with foil sentences that were also consistent with realistic baseball situations, the performance of high and low knowledge participants diverged. High knowledge participants experienced a diminished fan effect. However, low knowledge participants foil response times were more affected by fan size. Thus, it does not appear that the low knowledge participants were able to efficiently reject the foils. If both low and high knowledge participants were able to form single models from the sentence sets, decisions on foils should have been as easy as on targets. Only the high knowledge participants showed this advantage.

Thus, this result highlights another recent perspective from the fan effect literature which emphasizes that recognition memory results need to be thought of as both being a function of differential representation in memory, as well as being a function of decision making processes (Anderson, 1999). In essence, making a recognition judgment requires not just memory retrieval or search, but also an evaluative assessment or decision. This current dissociation between performance on targets and foils suggests that high and low knowledge participants may be achieving fast verification times to studied sentences via different means. While high-knowledge participants may have the advantage of a single model which allows for fast, direct retrieval for each set of sentences, the low-knowledge participants may have used some sort of plausibility heuristic during the verification task. This improved their performance for the studied items, but made it difficult for them to reject the foils.

An alternative explanation is that the quality of the

memory representations for the sentence sets differed among the low and high knowledge participants. It is possible that the high knowledge participants were able to create more detailed or distinctive traces for the sentence sets, which improved their ability to decide both what was studied and what was not (Hunt & Einstein, 1981). Low knowledge participants on the other hand, may have had “good enough” representations to aid performance on the studied items, but perhaps these traces were not detailed enough to aid them on the foils. Such a result would be consistent with a few recent findings that expertise can confer advantages in episodic memory (i.e. memory for words and order in domain-related word lists) (Rawson & Van Overshelde, 2006; Ricks & Wiley, 2009).

While most previous studies have suggested that reductions in the fan effect are due to unitized representations, the present results suggest that effects on decision processes are critical to consider. However, decision processes can only be explored when one uses plausible foils that require detailed memory for the studied sentences. In present study, thematic materials allowed all participants to avoid fan effects for the studied sentences, but only high knowledge participants were better able to detect foils. Thus the present design allowed for a clearer understanding of how prior knowledge may support both better integration and discrimination in recognition memory.

Prior expectations in pedagogical situations

Patrick Shafto¹, Noah D. Goodman², Ben Gerstle¹, & Francy Ladusaw¹

¹ Department of Psychological and Brain Sciences, University of Louisville

² Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology

Abstract

Much of human learning occurs in social situations, and among these, pedagogical situations may afford the most powerful learning. In pedagogical situations, a teacher chooses the concept that they are going to teach and the examples that they use to teach the concept. If learners know that a teacher is helpful and understands the implications, this could support strong inferences. In previous work, Shafto and Goodman (2008) proposed and tested a model of pedagogical data selection. We integrate special-purpose pedagogical expectations in this framework, and derive a task that allows independent assessment of pedagogical expectations. Two experiments contrast people's expectations about pedagogical and communicative situations. The results show that people's expectations differ in these situations, and that in pedagogical situations people expect teachers to present generalizable and semantically coherent knowledge. We discuss the implications for modeling learning in pedagogical settings, as well as for understanding human learning more broadly.

Keywords: Pedagogy; Learning; Bayesian Model

Much of human learning occurs in social contexts. We learn from siblings, parents, friends, and teachers by observing, imitating, and teaching. Among these social learning settings, pedagogical situations stand out as potentially the most important. Pedagogical situations are situations in which one person, a teacher, chooses information for the purpose of helping another person, a learner, arrive at some belief. Pedagogical situations might provide uniquely powerful learning situations, especially if learners are privy to, and understand the implications of, teachers' intentions to help.

Indeed, recent theories argue that an intuitive understanding of pedagogical situations may be what sets us apart from other animals (Csibra, 2007). Under this proposal, learners' intuitive understanding of pedagogical situations consists of two components: inferences how teachers choose examples to teach a concept, and expectations about what kinds of concepts teachers are more likely to teach.

The issue of how teachers choose information and learners' understanding of these situations have been investigated in detail (for a review, see Csibra and Gergely, 2009). Recently, Shafto and Goodman (2008) have proposed a computational model of reasoning in pedagogical

situations. This account provides a formal explanation of why and how teachers decide which examples to choose, and how learners can capitalize on the teacher's intent to make stronger inferences.

Researchers have also argued that young children come prepared with expectations about what kinds of knowledge to expect in pedagogical situations. Specifically, Csibra and Gergely (2009) argue that very young children expect that knowledge provided in pedagogical contexts is semantically generalizable. For instance, Topal et al. (2008) show that children make A-not-B errors in pedagogical contexts, but not in neutral contexts. They argue that the perseverative errors are a consequence of children misinterpreting initial pedagogical demonstrations as indicating that the A box is where the ball belongs. While these results are quite compelling, they contain influences of both the learner's inference about the teachers' choice of data, and the learners' expectations about what kinds of properties are likely to be taught.

In the current paper, we investigate the hypothesis that people expect semantically generalizable knowledge in teaching situations. We begin by discussing the role of prior knowledge in pedagogical reasoning, and how this can be integrated with Shafto and Goodman's (2008) model of pedagogical reasoning. We then use this framework to develop a method for separating the role of pedagogical priors from pedagogical data selection. Two experiments use this method to investigate whether adults expect generalizable knowledge (Experiment 1) and whether adults expect semantically coherent knowledge (Experiment 2). In each case, we contrast pedagogical situations with communicative situations to address whether these prior expectations are specific to pedagogical contexts. We conclude by discussing implications for modeling human learning and understanding reasoning in social situations.

The role of priors in pedagogical reasoning

The proposal that learners expect generalizable information can be integrated naturally into a Bayesian reasoning framework. From this perspective the problem of learning is one of inferring the probability of different hypotheses, h , given observed data, d . Bayes' theorem provides a way of updating our posterior beliefs about hypotheses, $P(h|d)$, given prior beliefs, $P(h)$, and as-

¹Please address correspondence to Patrick Shafto, p.shafto@louisville.edu

a particular hypothesis. Formally, the $P(d|h) = 1$ for the true hypothesis, and zero for all others. Equation 4 reduces to,

$$P(\theta|d) \propto P(h|\theta)P(\theta). \quad (5)$$

Given the fully labeled data, the learner’s judgments about the teacher’s systematicity depend on whether the learner expects that hypothesis to be chosen, and their prior expectations about systematicity.

To isolate the influence of learners’ prior expectations about hypotheses $P(h|\theta)$, we can ask learners to choose between two teachers. Because each teacher is equally likely to be systematic *a priori*, judgments about which of two teachers is preferred isolate the effects of a learner’s prior expectations. Formally, the judgment becomes a ratio of two inferences, each individually specified by Equation 5,

$$\frac{P(\theta_1|d_1)}{P(\theta_2|d_2)} \propto \frac{P(h_1|\theta)P(\theta)}{P(h_2|\theta)P(\theta)} = \frac{P(h_1|\theta)}{P(h_2|\theta)}. \quad (6)$$

In the following, we present two experiments in which people make judgments about which of two teachers they want to have teaching them in the future (presumably the one that chooses a hypothesis that is more consistent with their expectations). In our investigations, we have two goals: (1) identifying the prior expectations that people bring to pedagogical situations, and (2) establishing whether these expectations are unique to pedagogical situations. The experiments test two claims related to prior expectations about pedagogical situations: that learners expect more generalizable information, and that learners expect semantically coherent information.

Experiment 1: Testing the bias toward generalizability

Experiment 1 investigated whether people have an expectation that teachers would teach generalizable information. To investigate this question, we choose a domain for which we have a good understanding of the possible hypotheses, the domain of animals. Figure 1 shows the animals, and the intuitive taxonomic relations among these animals.² We operationalize generalizable concepts here as a concept that is true of a broader class of animals.

To investigate whether people expected generalizable knowledge, we presented participants with scenarios in which pairs of teachers taught concepts of different levels of generality. The generalizable teacher taught a property that was consistent with the tree structure and was true of a greater number of exemplars. For instance, the generalizable teacher might teach a property that was true of all 8 animals, while the less generalizable teacher might teach a property that was true of only ostriches and none of the other animals. If people expect teachers to teach generalizable information, we expect to find that people choose the teacher who teaches properties that were true of broader sets of examples.

²The tree was derived using the tree learning algorithm and a subset of the animals used in Kemp and Tenenbaum (2008).

Methods:

Participants: Twenty-four university undergraduates participated in this experiment in exchange for course credit. Participants were randomly assigned to the pedagogical or the communication scenarios.

Procedure: In the pedagogical situation, people were presented with a series of questions asking them to decide which of two teachers they would like to learn from in the future. Each teacher was presented as teaching about a novel enzyme, e.g. “Teacher 1 is teaching about enzyme P23T.” The names of the enzymes were random combinations of letters and numbers. This was followed by lists indicating which of the eight animals had the enzyme and which did not. Each question contrasted two teachers, where teachers differed in the generality of the properties taught. For instance, one teacher might teach a property that was true of owls, ostriches, leopards, and seals, but not of grasshoppers, ants, iguanas, and frogs, while the other was teaching a property that was true of all eight animals. Paired teachers always taught concepts where one was a subset of the other, so the more generalizable concept included all of the positive examples of the property in the less generalizable concept, with additional positive examples (e.g. ostrich versus ostrich and owl). Participants indicated which teacher they would rather have teaching them about new enzymes using a Likert scale ranging from -10 to 10 , where the extremes indicated the teacher on the left or the right and zero indicated indifference. Participants rated all possible pairings of teachers, resulting in a total of 34 questions. Order of the questions, as well as the side (right or left) of the more general concept, were randomized.

The communication condition was identical to the pedagogical condition, with the exception of some of the wording. Instead of teaching about enzymes, the situations described people who were talking about enzymes. For example, “Person 1 is talking about enzyme P23T.” Additionally, participants were asked to provide ratings about which one they would rather talk to in the future. Otherwise, the questions and response sheets were identical.

Results & Discussion

We coded people’s judgments as positive if they were in the direction of the more generalizable teacher and negative if they were in the direction of the teacher with the less general property. To test whether people expected more general properties, we compared the average ratings to chance (zero). In the pedagogical condition, people chose the teacher with the more general information, $mean = 0.66, t(407) = 2.06, p < 0.05$. In contrast, in the communication condition, people choose the less general information, $mean = -0.56, t(407) = -2.09, p < 0.05$. The difference between the two conditions was significant, $t(814) = 2.84, p < 0.01$. These results suggest that people expect that more general properties will be taught in pedagogical situations, in contrast with communicative settings, where people expect less general properties.

To follow up on these results, we investigated the pat-

Figure 2: Experiment 1 results: (a) Average human ratings in the pedagogy and communication conditions. Positive ratings indicate the more generalizable teacher. (b) Scatterplot showing the relationship between the difference in generalizability for pairs of teachers (x axis) and people’s ratings (y axis) for the pedagogy condition. The strength of people’s ratings increases with an increasing difference in generalizability, $r = 0.51$, indicating that they expect more generalizable concepts in pedagogical settings. (c) Scatterplot showing the relationship between difference in generalizability and people’s ratings for the communication condition. The strength of ratings decreases with an increasing generalizability, $r = -0.66$, indicating that people expect less generalizable concepts in communicative settings.

tern of ratings for individual items. If people choose more generalizable concepts, then pairs for which there was the greatest gap between the more and less generalizable teacher should have the strongest ratings. To investigate this question, we needed to quantify how general each hypothesis was. We consider two possible measures of generality: the number of positive examples, and the sum of the distances among items in the tree. To test whether ratings indicated an expectation that properties would be generalizable, we collapsed individual judgments into a single average rating for each question, resulting in 34 ratings. To investigate which measure of generality best predicted people’s judgments, we conducted a stepwise regression with item averages as the dependent variable. The independent variables included the number of positive examples in more general concept, the number of positive examples in the less general concept, the difference in number of positive examples, as well as the summed distances for the more and less general concepts, and the difference in the summed distance. The two difference scores allowed us to test whether people’s judgments take into account both teachers, or just a single teacher when making their judgments. Stepwise regression greedily selects the variable that accounts for the greatest variance, and iterates until no variables account for significant variance. Analysis of the pedagogy condition showed that the difference in summed distances accounted for the greatest variance, $r = 0.51$, $F(1, 32) = 11.49, p < 0.01$, and that no other variables accounted for significant residual variance. The correlation indicates that the bigger the difference in generalizability was, the stronger people’s ratings were toward the more generalizable teacher. In contrast, regression analyses on the communication condition showed that while the difference in summed distance was a significant predictor of ratings, the relationship was negative, $r = -0.66$, $F(1, 32) = 24.52, p < 0.001$. This suggests

that in communicative settings, people’s expectations about generalizability are the opposite of their expectations in pedagogical settings.

The number of positive examples, while a straightforward measure of generality for this task, is undesirable for two reasons. First, if this leads to an accurate characterization of people’s inferences, then one might wonder to what degree the results are a consequence of task demands (given that people were answering questions about lists of animals). Second, the number of positive examples is not a very good measure of generality because it bears no necessary relationship with actual semantic generalizability. As can be seen in Figure 1, many possible sets with the same number of positive examples differ markedly in their coverage of the tree. Instead, we prefer to measure the generalizability of a concept in terms of the sum of distances between all pairs of positive examples. This provides a measure that is not subject to task demands, and is related to the semantic generality of the concept. Our analyses show that distance in the tree provides a better description of people’s behavior, providing evidence that people’s judgments do not simply reduce to task demands, and that their judgments are based on semantic generalizability.

It appears that people have strong prior expectations that they bring specifically to pedagogical situations. In pedagogical situations, learners expect that teachers will choose to teach generalizable information. In contrast, when in communicative situations, people expect that speakers are likely to talk about specific information. Our analyses showed that people’s judgments are better predicted by distance in a semantic tree, consistent with a bias toward semantically generalizable information.

Experiment 2: Testing the bias toward semantic coherence

Experiment 2 investigated whether people have an expectation that teachers will choose semantically coherent concepts. To investigate this, we presented participants with scenarios in which two teachers each taught concepts with two positive exemplars. The semantically coherent teacher taught a property that was true of two tree-consistent exemplars, such as owl and ostrich. They were contrasted with a semantically incoherent teacher who taught a property that was true of two tree-inconsistent exemplars, such as ostrich and leopard. If people expect teachers to teach semantically coherent concepts, we expect to find that people choose the teacher who teaches tree-consistent properties.

Methods:

Participants: Twenty university undergraduates participated in this experiment in exchange for course credit.

Procedure: The procedure was identical to that used in Experiment 1 with the exception of the questions used. Each scenario provided information taught by two teachers. All properties were true of two animals, but were absent in the other six. In each scenario, one teacher taught a property that was semantically coherent – it was consistent with the structure of the tree – and the other taught a property that was semantically incoherent – it was inconsistent with the structure of the tree. For instance, a semantically coherent property might be true of owls and ostriches, but no other animals. Contrarily, a semantically incoherent property might be true of owls and leopards but no other animals. Questions were designed such that semantically coherent pairs were contrasted with all minimally different semantically incoherent pairs that overlapped one animal. For example, owls and ostriches were contrasted with owls and leopards, owls and seals, ostrich and leopards, and ostrich and seals. This resulted in a total of 16 questions. Order of the questions, as well as the side of the semantically coherent pair (left or right), were randomized.

Results & Discussion

Do people expect teachers to teach semantically coherent concepts? To address this question, we coded people's ratings as positive numbers if they were in the direction of the semantically coherent teacher, and negative numbers if they were not. We then ran separate t-tests comparing the means in the pedagogical and communicative conditions to zero. In the pedagogical condition, people tended to choose teachers of semantically coherent concepts, $mean = 0.97, t(159) = 2.04, p < 0.05$, one-tailed. In the communication condition, people also chose teachers of semantically coherent concepts, $mean = 2.21, t(159) = 6.76, p < 0.001$. The difference between the two conditions was also significant, $t(308) = 2.16, p < 0.05$.

To further investigate the role of semantic coherence, we computed the distance between all of the positive

examples in each scenario (see Figure 1). If people expect semantically coherent concepts, then more semantically coherent pairs – those with shorter distances – should have the strongest ratings. We ran a stepwise regression with people's ratings as the dependent variable, and independent variables including distance between the positive examples in the more and less coherent sets, and the difference in the distances. For the pedagogical condition, the distance between positive examples in the coherent concept was the only predictor selected, $r = -0.70, F(1, 14) = 13.24, p < 0.01$. Of the coherent hypotheses, the teachers teaching the more coherent concepts were rated more strongly. For the communication condition, regression analyses showed that distance between positive examples of coherent pairs did not strongly predict people's ratings, $r = 0.23, F(1, 14) = 0.80, p > 0.3$.³

Interestingly, unlike in Experiment 1, people's judgments in Experiment 2 were best predicted by the coherence of the more coherent hypothesis alone (as opposed to the difference in coherence). This suggests that the semantically incoherent hypotheses did not play a large role in people's judgments. This may reflect an explicit judgment that these cases are so unexpected that they, in effect, have zero weight.

The evidence suggests that people expect teachers to teach semantically coherent concepts: overall, people chose teachers of more semantically coherent concepts, and the strength of people's ratings decreased as the strength of coherence decreased. The evidence also suggests that people's expectation of coherence may apply across more than just pedagogical situations. Results from the communication condition showed that people tended to choose the more coherent speaker, but the strength of their ratings was not related to the degree of coherence. These results suggest that people's expectation of semantic coherence may not be limited to pedagogical situations.

Discussion

Pedagogical situations play a central role in human learning. In pedagogical situations, teachers choose which concepts to teach and which examples to use to teach the concept. We have presented an extension of Shafto and Goodman's (2008) model of pedagogical data selection that incorporates specific expectations about pedagogical situations. Using this framework, we have derived a method for isolating the effects of prior expectations about pedagogical situations. The results of Experiment 1 showed that people expect teachers to provide generalizable knowledge, and that this expectation does not apply in more general communicative settings. The results of Experiment 2 showed that people expect teachers to provide semantically coherent information, although this appears not to be specific to pedagogical situations. Taken together, these results provide evidence that people have specific expectations—intuitive

³A separate stepwise regression showed that none of the independent variables accounted for significant variance in people's judgments.

Figure 3: Experiment 2 results: (a) Average human ratings in the Pedagogy and Communication conditions. Positive ratings indicate the more semantically coherent teacher. (b) Scatterplot showing the relationship between distance among positive examples of coherent hypotheses (x axis) and people’s ratings (y axis) in the pedagogy condition. People’s ratings increase with decreasing distance, $r = -0.70$, suggesting that people expect coherent hypotheses in pedagogical settings. (c) Scatterplot showing the relationship between distance among positive examples of coherent hypotheses (x axis) and people’s ratings (y axis) in the communication condition. People’s ratings are only weakly related to distance, $r = 0.23$.

theories of pedagogical situations.

Our results provide additional evidence in support of Csibra and Gergely’s (2009) claim that people expect generalizable information in pedagogical contexts. Where previous results focused on young children, our results suggest that this expectation continues into adulthood. Our results also provide evidence that semantic coherence, while expected in pedagogical situations, is not specific to these contexts. Rather, the expectation of semantically coherent concepts extends to communicative, as well as pedagogical situations.

Here we have focused on learners’ expectations, but for these pedagogical expectations to be reasonable, it is important that teachers meet their expectations. Specifically, do people choose to teach concepts that are more generalizable and more coherent? If so, what are the implications of these matching (or mismatching expectations) in terms of the kinds of concepts that can be learned, the speed at which they are acquired, and the robustness of knowledge transmission? Future research will aim to answer these questions.

Our experiments have provided information about people’s prior expectations in pedagogical situations, but it is also important to explain why people have these biases. There is work to be done in formalizing computational models that explain why certain hypotheses would be more or less likely to be taught. This may not turn out to be entirely straightforward because while there is a reasonable motivation for teaching generalizable concepts, there are also motivations for teaching other kinds of concepts. For instance, one might also want to teach sparse concepts because they may be difficult to discover on one’s own. Further empirical research may help narrow down the possibilities and provide guidance for more explanatory models.

More generally, previous approaches to modeling human learning have focused on a single unitary set of prior expectations that apply generically across situa-

tions (but see Shafto et al., 2006). However, this approach seems obviously too simple. We all intuitively understand that we have different expectations that apply when, for example, we talk to children as opposed to adults. Pedagogical situations are but one case of a more general problem. Understanding how social situations affect learning will require understanding how different contexts affect both learners’ prior expectations and learners’ assumptions about how information is selected.

A Spiking Neuron Model of Serial-Order Recall

Center for Theoretical Neuroscience, University of Waterloo
Waterloo, ON, Canada N2L 3G1

Abstract

Vector symbolic architectures (VSAs) have been used to model the human serial-order memory system for decades. Despite their success, however, none of these models have yet been shown to work in a spiking neuron network. In an effort to take the first step, we present a proof-of-concept VSA-based model of serial-order memory implemented in a network of spiking neurons and demonstrate its ability to successfully encode and decode item sequences. This model also provides some insight into the differences between the cognitive processes of memory encoding and subsequent recall, and establish a firm foundation on which more complex VSA-based models of memory can be developed.

Keywords: Serial-order memory; serial-order recall; vector symbolic architectures; holographic reduced representation; population coding; LIF neurons; neural engineering framework

Introduction

The human memory system is able to perform a multitude of tasks, one of which is the ability to remember and recall sequences of serially ordered items. In human serial recall experiments, subjects are presented items at a fixed interval, typically in the range of two items per second up to one item every 4 seconds. After the entire sequence has been presented the subjects are then asked to recall the items presented to them, either in order (serial recall), or in any order the subject desires (free recall). Plotting the recall accuracy of the subjects, experimenters often obtain a graph with a distinctive U-shape. This unique shape arises from what is known as the primacy and recency effects. The primacy effect refers to the increase in recall accuracy the closer the item is to the start of the sequence, and the recency effect refers to the same increase in recall accuracy as the item gets closer to the end of the sequence.

Many models have been proposed to explain this peculiar behaviour in the recall accuracy data. Here we will concentrate on one class of models which employ vector symbolic architectures (VSAs) to perform the serial memory and recall. Using VSAs to perform serial memory tasks would be insufficient however, if the VSA-based model cannot be implemented in spiking neurons, and thus, cannot be used to explain what the brain is actually doing. In this paper, we thus present a proof-of-concept VSA-based model of serial recall implemented using spiking neurons.

Vector Symbolic Architecture

There are four core features of vector symbolic architectures. First, information is represented by randomly chosen vectors that are combined in a symbol-like manner. Second, a superposition operation (here denoted with a $+$) is used to combine

vectors such that the result is another vector that is similar to the original input vectors. Third, a binding operation (\otimes) is used to combine vectors such that the result is a vector that is dissimilar to original vectors. Last, an approximate inverse operation (denoted with $*$, such that A^* is the approximate inverse of A) is needed so that previously bound vectors can be unbound.

$$A \otimes B \otimes B^* \approx A \quad (1)$$

Just like addition and multiplication, the VSA operations are associative, commutative, and distributive.

The class of VSA used in this model is the Holographic Reduced Representation (HRR) (Plate, 2003). In this representation, each element of an HRR vector is chosen from a normal distribution with a mean of 0, and a variance of $1/n$ where n is the number of elements there are in the vector. The standard addition operator is used to perform the superposition operation, and the circular convolution operation is used to perform the binding operation. The circular convolution of two vectors can be efficiently computed by utilizing the Fast Fourier Transform (FFT) algorithm:

$$\mathbf{x} \otimes \mathbf{y} = \mathcal{F}^{-1}(\mathcal{F}(\mathbf{x}) \odot \mathcal{F}(\mathbf{y})), \quad (2)$$

where \mathcal{F} and \mathcal{F}^{-1} are the FFT and inverse FFT operations respectively, and \odot is the element-wise multiplication of the two vectors. The circular convolution operation, unlike the standard convolution operation, does not change the dimensionality of the result vector. This makes the HRR extremely suitable for a neural implementation because it means that the dimensionality of the network remains constant regardless of the number of operations performed.

The VSA-based Approach to Serial Memory

There are multiple ways in which VSAs can be used to encode serially ordered items into a memory trace. The CADAM model (Liepa, 1977) provides a simple example of how a sequence of items can be encoded as a single memory trace. In the CADAM model, the sequence containing the items **A**, **B**, and **C** would be encoded as in single memory trace, M_{ABC} as follows:

$$M_A = \mathbf{A}$$

$$M_{AB} = \mathbf{A} + \mathbf{A} \otimes \mathbf{B}$$

$$M_{ABC} = \mathbf{A} + \mathbf{A} \otimes \mathbf{B} + \mathbf{A} \otimes \mathbf{B} \otimes \mathbf{C}$$

The model presented in this paper, however, takes inspiration from behavioural data obtained from macaque monkeys. This data suggests that each sequence item is encoded using

ordinal information (Orlov, Yakovlev, Hochstein, & Zohary, 2000), rather than being “chained” together as in the CADAM model. To achieve this, additional vectors are used to represent the ordinal information of each item. In the subsequent equations, this ordinal vector is represented as P_i , where i indicates the item’s ordinal number in each sequence. The memory trace M_{ABC} would thus be computed like so:

$$M_A = P_1 \otimes \mathbf{A} \quad (3)$$

$$M_{AB} = P_1 \otimes \mathbf{A} + P_2 \otimes \mathbf{B} \quad (4)$$

$$M_{ABC} = P_1 \otimes \mathbf{A} + P_2 \otimes \mathbf{B} + P_3 \otimes \mathbf{B} \quad (5)$$

The encoding strategy presented above does not seem to have any mechanism by which to explain the primacy or recency effects seen in human behavioural data. In order to achieve these effects, additional components are added to the model. These components are discussed further below.

Neural Representation

To implement any of these models, we need to determine how a vector can be represented by a population of spiking neurons. In 1986, Georgopoulos et al. demonstrated that in the brain, 2D movement directions are encoded by a large population of neurons, with each neuron being most active for one specific direction – their preferred direction. The activity of each neuron would then indicate the similarity of the input vector to each neuron’s preferred direction vector. Since the movement direction is essentially a two-dimensional vector, this method of vector representation can be extended to multiple dimensions as well. For a population of neurons, the current J flowing into neuron i can then be calculated by the following equation.

$$J_i(\mathbf{x}) = \alpha_i(\tilde{\Phi}_i \cdot \mathbf{x}_i) + J_i^{bias} \quad (6)$$

In the above equation, the dot product computes the similarity between the input vector \mathbf{x} and the neuron’s preferred direction vector $\tilde{\Phi}$. The neuron gain is denoted by α , while J^{bias} denotes a fixed background input current. The current J_i can then be used as the input to any neuron model $G[\cdot]$ to obtain the activity for neuron i . In this model, we use the leaky integrate-and-fire (LIF) neuron model, characterized as such:

$$a_i(\mathbf{x}) = G_i[J_i(\mathbf{x})] = \frac{1}{\tau^{ref} - \tau^{RC} \ln \left(1 - \frac{J_i^{th}}{J_i(\mathbf{x})} \right)}, \quad (7)$$

where $a_i(\mathbf{x})$ is the average firing rate of the neuron i , τ^{ref} is the neuron refractory time constant, τ^{RC} is the neuron RC time constant, and J_i^{th} is the neuron threshold firing current. For a time-varying input $\mathbf{x}(t)$, the equations remain the same, with the exception that the activity of the neuron is no longer an average firing rate, but rather a spike train:

$$a(\mathbf{x}(t)) = \sum_n \delta(t - t_n) \quad (8)$$

Since the spike train represents the neuron’s response to the input vector \mathbf{x} , given the spike trains from all the neurons in

the population, it should be possible to derive decoding vectors ϕ that can be used to estimate the original input. Eliasmith and Anderson (2003) demonstrate that these decoding vectors can be found using the following equation.

$$\phi = \Gamma^{-1} \Upsilon, \text{ where} \quad \Gamma_{ij} = \int a_i(x) a_j(x) dx \quad \Upsilon_i = \int a_i(x) x dx \quad (9)$$

By weighting the decoding vectors with the post-synaptic current $h(t)$ generated by each spike, it is then possible to construct $\hat{x}(t)$, an estimate of the input vector. Equation (10) demonstrates how this is achieved. The parameters used to generate the shape of $h(t)$ is determined by the neurophysiology of the neuron population.

$$\begin{aligned} \hat{x}(t) &= \sum_{i,n} \delta(t - t_{in}) * h(t) \phi_i \\ &= \sum_{i,n} h(t - t_{in}) \phi_i \end{aligned} \quad (10)$$

The encoding and decoding vectors also provides a method by which the optimal connection weights between two neural populations can be. If for example, the transformation between two populations of neurons is a simple scaling operation, where the output of the second group of neurons should be Cx , then the connection weights w between the populations should be

$$w_{ij} = C \alpha_j \tilde{\Phi}_j \phi_i \quad (11)$$

Extending Equation (7) for linear operations is also straightforward. Consider three neural populations: one to represent the input x , another to represent the input y , and a third that we wish to have compute the linear combination $Cx + Dy$. The activity of the neurons in final population can be determined by

$$c_k(Cx + Dy) = G_k \left[\sum_i w_{ki} a_i(x) + \sum_j w_{kj} b_j(y) + J_k^{bias} \right], \quad (12)$$

where a_i , b_j , and c_k are the activities of the neurons in the first, second and third neural populations respectively. Employing Equation (11), the synaptic connection weights can also be determined. Letting w_{ki} be the connection weights between the first and third population, and w_{kj} be the connection weights between the second and third population, they work out to be:

$$w_{ki} = \alpha_k \tilde{\Phi}_k \phi_i^x \quad \text{and} \quad w_{kj} = \alpha_k \tilde{\Phi}_k \phi_j^y \quad (13)$$

Note that in the equation above, the superscripts serves to disambiguate the decoders, where ϕ^x signifies the decoders that represent x , and likewise for ϕ^y . Eliasmith and Anderson (2003) go into greater detail on how to use this general framework, known as the Neural Engineering Framework, to derive the appropriate decoders and connection weights to perform arbitrary non-linear operations as well.

The Neural Model

The neural model implemented in this paper is divided into two neural processes. One encodes an item sequence into a single memory trace, and the other decodes an encoded memory trace to retrieve its constituent items.

Sequence Encoder

Analysis of Equations (3) to (5) show that the memory trace for an arbitrary sequence of items can be constructed by computing the convolution of the last item vector with its ordinal vector, and then adding the result of the convolution to the memory trace of the sequence less the final item. From this, a generic sequence encoding equation can be derived (from here on referred to as the *basic encoding equation*).

$$M_i = M_{i-1} + P_i \otimes I_i \quad (14)$$

In the equation above, M_i represents the memory trace after encoding the i^{th} item. P_i and I_i represents the i_{th} item's ordinal vector and item vector respectively.

As mentioned previously, the encoding equation in its basic form does not account for the primacy and recency effects seen in human behavioural data. To achieve the primacy effect, rehearsal is simulated by adding an additional weighted copy of the old memory trace to the memory trace being calculated for the current item. In essence, as each item is rehearsed, a weighted copy of the item is added to the memory trace to “boost” the item's representation within the memory trace. In the equation below, the memory trace of the rehearsal-based encoding is denoted by R_i and the weight applied to the rehearsed contribution of the old memory trace is denoted by α . In the model implemented for this paper, α was set to 0.3.

$$R_i = R_{i-1} + P_i \otimes I_i + \alpha R_{i-1} \quad (15)$$

$$= (1 + \alpha)R_{i-1} + P_i \otimes I_i \quad (16)$$

To achieve the recency effect, an separate memory component is added to play the role of a sensory input buffer. The input buffer encodes items in a similar fashion to Equation (14) with a decay added to the old memory trace. This decay causes the input buffer to store only the most recently presented items, thus mimicking the basic recall characteristics of the human working memory system. In the neural implementation of this model, the decay is achieved by tuning the integrators used in the memory modules to slowly drift to zero if no additional input is applied to them. Equation (17) illustrates how this decay can be represented mathematically, with the memory trace of the input buffer represented by B_i , and the rate of decay represented by β .

$$B_i = \beta B_{i-1} + P_i \otimes I_i \quad (17)$$

The final memory trace of the encoded item sequence is then computed by combining the memory trace from the rehearsal component and the memory trace from the input buffer component.

$$M_i = R_i + B_i \quad (18)$$

From the above encoding equations, several issues become evident. First, two operations need to be implemented – a circular convolution and an addition operation. Second, a memory module is needed to hold the value of M_{i-1} while the new memory trace M_i is computed. With these components, and the rehearsal and decay mechanisms described above, a high level block diagram of the complete encoding network can be constructed, as shown in Figure 1.

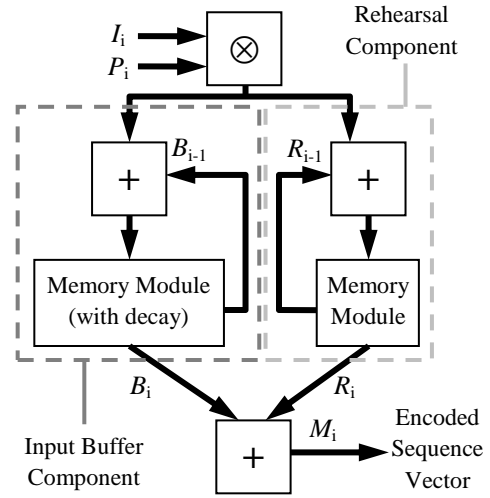

Figure 1: Encoding network functional block diagram.

Sequence Decoder

The decoding process is much simpler than the encoding process. The first step of the decoding process is to convolve the encoded memory trace with the inverse of the desired ordinal vector. For example, if the system is trying to decode the second item in the sequence, the encoded memory trace would be convolved with the inverse of P_2 . Next, the result of this convolution is fed to a cleanup memory module. The cleanup memory module contains a copy of all the item vectors in the original sequence, and when given an input, will determine which of the original item vectors best matches the input vector. An example of this decoding process follows. To simplify the example, only the basic encoding equation is used.

$$M_{ABC} = P_1 \otimes \mathbf{A} + P_2 \otimes \mathbf{B} + P_3 \otimes \mathbf{B}$$

$$C_B = M_{ABC} \otimes P_2^*$$

$$= P_1 \otimes \mathbf{A} \otimes P_2^* + P_2 \otimes \mathbf{B} \otimes P_2^* + P_3 \otimes \mathbf{B} \otimes P_2^*$$

$$\approx P_1 \otimes \mathbf{A} \otimes P_2^* + \mathbf{B} + P_3 \otimes \mathbf{B} \otimes P_2^*$$

$$I_B = \text{cleanup}(C_B) \approx \mathbf{B}$$

From the example above, we see that convolving the memory trace M_{ABC} with the inverse of P_2 results in a vector with the desired item vector \mathbf{B} combined with the unwanted vectors $(P_1 \otimes \mathbf{A} \otimes P_2^*)$ and $(P_3 \otimes \mathbf{B} \otimes P_2^*)$. However, since the cleanup memory module only contains the item vectors from

the original sequence and not the superfluous vectors, feeding the result of the convolution through the cleanup memory isolates the item vector B , producing the desired result. Figure 2 illustrates the high level block diagram used to implement the decoding network.

Figure 2: Decoding network functional block diagram.

Performing the Binding Operation Referring back to Equation (2) we see that the binding operation can be calculated using the FFT and IFFT algorithms, so the first step to implementing the binding operation in neurons is to implement these two operations. The equations that compute the FFT and IFFT algorithms are as follows:

$$\begin{aligned} \text{FFT : } X_k &= \sum_{n=0}^{N-1} x_n e^{-\frac{2\pi i}{N} kn} & k = 0, \dots, N-1 \\ \text{IFFT : } x_n &= \frac{1}{N} \sum_{k=0}^{N-1} X_k e^{\frac{2\pi i}{N} kn} & n = 0, \dots, N-1 \end{aligned} \quad (19)$$

Taking a closer look at the equations above, we see that they can be implemented efficiently as a multiplication between the input vector and a matrix containing the FFT (or IFFT) coefficients. From Equation (11), we can then set the synaptic connection weight matrix as the Fourier transform coefficients to calculate the required FFT and IFFT operations. The one caveat to this approach is that the real and imaginary components of the Fourier transform have to be calculated separately and then recombined (with the appropriate sign changes) when the final result is calculated.

With the neural implementation of the Fourier transforms solved, the implementation of the circular convolution binding operation becomes trivial since the only other operation needed is an element-wise multiplication. This can be achieved by utilizing multiple neural populations, each handling one element in the element-wise multiplication.

The Memory Module Since the circular convolution and addition operations are essentially feed-forward neural networks, the memory module in this model needs to be able to drive the network with a constant value and store the new value at the same time. This is achieved by the use of gated integrators. When the integrator is not being gated, it attempts to match the value of the input signal. When the integrator is gated, it no longer responds to the input value, and outputs the previously stored value. By placing two gated integrators in parallel controlled by complementary gating signals, the memory module is able to simultaneously store the new input value while outputting the previously stored value.

Cleanup Memory The cleanup memory network used in this model is an extension of the cleanup memory presented in (Stewart, Tang, & Eliasmith, 2009). In essence, the implementation of cleanup memory involves creating multiple neural populations, each assigned to one item vector from the original item sequence. The preferred direction vectors $\tilde{\phi}$ for each neuron in one population is predefined to match the item vector it is meant to clean up. From Equation (6), we see that the similarity (dot product) is calculated to determine the activity of the neuron. By predefining $\tilde{\phi}$, we can then determine the similarity of the decoded item vector to each of the original item vectors, thus determining which of the original item vectors best matches the decoded item vector.

Combining the Encoder and Decoder

Getting the spiking neuron model to encode a sequence, and subsequently decode the memory trace is achieved by chaining the encoder and the decoder together. Control signals are used to ensure that the decoding network only commences after the encoder has finished encoding the last item vector. Figure 3 shows the results of the complete network encoding and decoding an example twenty-dimensional 4-itemed sequence.

Figure 4: Plot of the recall accuracy data comparing results from human behavioural studies (from Henson et al. (1996), Figure 1), an ideal model implemented in Matlab®, and the spiking neuron model.

Results

The results of the simulation of the spiking neuron implementation of the ordinal serial encoding process is displayed in Figure 4. From the graph it can be seen that both the ideal Matlab®-implemented model and the spiking neuron model are a good match to the human data. The slightly reduced primacy in the neuronal implementation suggests that the simplistic implementation of the rehearsal mechanism can be improved. Figure 5 compares the transposition gradients – which is the count of the recall occurrences of each item for

Figure 3: Simulation results from the spiking neuron implementation of the sequence encoder network. A 4-itemed sequence of 20-dimensional item vectors was presented to the network at a half-second interval (two items per second). (Left) The output of the encoder, M_i , showing the encoded memory trace for each item vector presented. Referring to Equation (18), the graph at $t = 0.5$ seconds shows $M_1 = R_1 + B_1$, the graph at $t = 1$ second shows $M_2 = R_2 + B_2$, and so forth for. The final encoded memory trace for the entire sequence is the output of the encoder network at $t = 2$ seconds. (Center) The spike raster plot of the neurons in the output neuron population of the encoder network as it is encoding the sequence in the top figure. The spike raster is displayed for every 20th neuron. (Right) The similarity plot of each extracted item vector to each one of the four original item vectors. The similarity value between the vectors is obtained using the dot product operation. The graph shows the network correctly identifying the first, second, and last item. The third item is incorrectly identified because the similarity measures of the first three items are too close together for the system to accurately distinguish the correct answer.

Figure 5: Plot of the transposition gradients comparing results from human behavioural studies (from Henson et al. (1996), Figure 2, for non-confusable items), an ideal model implemented in Matlab®, and the spiking neuron model. Comparing the plots, both the ideal model and the spiking neuron model are able to replicate the transposition curves in the human data.

each serial position – also reveals that both the ideal implementation and the spiking neuron implementation are able to reproduce the transposition effects seen in humans. Both of these simulations were run using six-itemed sequences consisting of fifty-dimensional HRR vectors, and were run for an average of 200 trials each.

Discussion

From the results it can be seen that both the ideal implementation and the spiking neuron model demonstrate the ability to reproduce the primacy, recency, and transposition effects seen in human data. Furthermore, unlike other models which entail a host of tunable parameters to fit the human data, this model only utilizes two tunable parameters: the amount of contribution to the memory trace in the rehearsal component, and the decay rate of the input buffer component.

The model presented here also provides some insight into the neurophysiological requirements of serial memory. It demonstrates the need for a working memory system capable of simultaneous storage and retrieval. This model also maps on very well to Baddeley's model of working memory (Baddeley, 2007), with the input buffer component acting as the phonological loop, and the rehearsal component functioning as the episodic buffer.

Despite their complexity, there are advantages of creating a spiking neuron model in comparison to theoretical models, or models implemented using rate neurons. It provides the ability to compare the spike data of the model to data collected from neural recordings. For example, data collected in Warden and Miller's 2007 paper shows that the neurons change their preferred items as more items are introduced into the system. Although the analysis has yet to be completed at the time this paper was written, it can be inferred that because the encoded sequence vector changes as more items are added, a neuron that is responsive to one configuration of the sequence vector would either be less responsive or not responsive at all when a new item is added – changing the configuration of the encoded sequence vector – as it does in this model.

Several studies (e.g. Chein & Fiez, 2001) have also identified brain areas that are active during serial memory tasks. Moreover, the studies have demonstrated that there are similarities and more importantly, differences, between the areas of activity during the encoding phase and recall phase. By assigning different components of the model to different brain areas (for example, the input buffer component to the temporal lobe, near the auditory cortex, and the rehearsal component to the lateral prefrontal cortex), it would be possible to determine if the pattern of activities recorded in these studies matches the pattern of activities produced by this model.

Future Work

As mentioned in the results section, the performance of the rehearsal component needs to be improved slightly. Possible ways of doing this is by having an active rehearsal mechanism which decodes and then re-encodes the stored memory

trace within the inter-item interval (time between each item presentation). Such a rehearsal mechanism will also enable the model to be compared with serial recall studies involving list sizes that exceed the typical human memory span of 4 to 7 items.

Additionally, the current implementation of cleanup memory has a fixed vocabulary of item vectors that is predefined when the network is created. This means that the items in cleanup memory are static and do not change over time. It seems inconceivable that this is what occurs in the brain. Rather, future cleanup memory implementations should be dynamic, with the ability to “load” and “unload” arbitrary item vectors into its vocabulary.

Abstract

Two experiments examined the effect of semantic interference on visual lexical decision (vLD) in normal skilled readers. Experiment 1 employed a dual-task paradigm to test whether nonverbal semantic processing disrupts visual word recognition when the orthographic structure of words and non-words is controlled. Experiment 2 employed the same paradigm to test whether participants strategically shifted their reliance onto orthographic information when orthographic structure provided a cue to lexicality. The results showed (1) significant semantic interference in the vLD task in normal skilled readers when words and non-words were matched for orthographic well-formedness and (2) no semantic interference when words and non-words differed reliably in their orthographic well-formedness. The results are consistent with the view that accurate lexical decisions depend upon semantic activation, especially when judgments cannot be made on the basis of orthographic structure alone.

Keywords: semantics; lexical decision; dual-task; dual-route models.

Introduction

What is the relationship between semantic and lexical knowledge in the mind and brain? Neuropsychological investigations of this question have led to two contradictory conclusions. One long-standing tradition has emphasized neuropsychological dissociations to support the argument that knowledge of word forms and meanings are supported by functionally independent cognitive systems. For instance, patient EM performed poorly on semantic tasks such as picture naming but perfectly when reading or recognizing even irregular, low-frequency, and orthographically strange words (Blazely, Coltheart, & Casey, 2005; for similar cases, also see Cipolotti & Warrington, 1995; Schwarz, Saffran, & Marin, 1980). For some theorists, such evidence suggests that successful performance in lexical tasks like reading aloud or recognizing words does not depend on intact input from the word-meaning system (Coltheart, 2004).

A different tradition has emphasized that such classical dissociations are observed in only a tiny fraction of patients with semantic impairment, and that, in the vast majority of cases, lexical and semantic impairments go hand-in-hand (Woollams, Ralph, Plaut, & Patterson, 2007). For instance, Patterson et al. (2006) examined performance on four

lexical tasks—including reading aloud, lexical decision, spelling, and past-tense inflection—in fourteen patients with semantic dementia (SD), a progressive degenerative syndrome that produces a remarkably pure semantic impairment. Results revealed that, in all four tasks, all fourteen patients were seriously impaired at processing low-frequency items with atypical phonological, orthographic, or syntactic structure. Similarly Woollams and colleagues (2007) reported reading performance in a cohort of 51 patients with semantic impairment and found that only a vanishingly small proportion—3 out of 51—showed spared performance comparable to EM's (and see Graham, Patterson, & Hodges, 2000; Patterson & Hodges, 1992; Patterson, Lambon Ralph, Hodges, & McClelland, 2001; for similar accounts of association between semantic and lexical impairment). For these theorists, the strong association between semantic and lexical impairment suggests that, in most individuals, performance on lexical tasks depends importantly on intact input from the semantic system (Plaut, McClelland, Seidenberg, & Patterson, 1996; Seidenberg & McClelland, 1989).

Differentiating these views on the basis of neuropsychological evidence has proven challenging because both views can account for the major findings, that is, the strong association of lexical and semantic impairment in the majority of reported cases and the occasional dissociation in a small minority. For those who believe semantic and lexical processes are functionally independent, the strong association arises because the disease process in these individuals has affected both systems. Patterson et al. (2006) refer to this as the “Associated but unrelated deficits” (ABUD) view. Under ABUD, only dissociations provide useful information about the functional architecture of the language system, because they straight-forwardly disprove causal necessity: reading, word recognition, spelling, etc. cannot of necessity depend upon intact semantic input, because it is possible for these abilities to be completely spared in the face of degraded semantic knowledge.

The alternative view—that lexical processes depend importantly upon semantic input—was dubbed “It's All Semantics” (IAS) by Patterson et al. (2006). For proponents of IAS, the few cases that show strong lexical-semantic

dissociations are the exceptions that prove the rule. Such cases may deviate somewhat from the more typical pattern of associated deficits because they are exceptional in other ways. For instance, they may have had unusually good lexical skills in their premorbid state, so that, with mild semantic impairment, they remain capable of performing within the established norms for their age group, even if they have declined significantly from their premorbid peak. From this point of view, the fact that EM was a secretary for much of her life is potentially important—she presumably took dictation and as a result may have developed unusually robust orthographic and phonological representations.

Further complicating the picture is the fact noted by Plaut (1997) and others that some patterns of apparent dissociation in the literature may be attributable to poorly controlled stimulus materials. It is now well established that, when semantic knowledge degrades, patients can retain good knowledge of the “surface” structure of different domains. For instance, even when unable to retrieve the meanings of words, patients with semantic impairments can retain knowledge about orthographic structure, that is, which letter sequences are common and which unusual in the language. In tests of word-recognition, such patients can appear completely normal if the target words are all orthographically well-formed and the distractor words are all orthographically strange (Rogers, Ralph, Hodges, & Patterson, 2004). The same patients show serious impairments, however, if the orthographic structure of words and non-words is matched—indeed, some patients judge well-formed non-words to be real words at rates exceeding chance, showing a strong over-reliance on orthographic structure in making their decisions.

Taken together, the evidence from neuropsychological studies is arguably compatible with both ABUD and IAS and it is not clear that further neuropsychological evidence can adjudicate the different positions. Because the status of semantic knowledge cannot be manipulated experimentally in such studies the causal links between semantic and lexical processing are difficult to establish.

Experiment 1 of the present study tests the hypothesis that semantic processing contributes to one kind of lexical process—word recognition—using a dual-task paradigm. Healthy participants performed a visual lexical decision task while simultaneously performing a secondary nonverbal task (sound judgment) that either did or did not tap semantic memory. The key question is whether word-recognition is significantly more disrupted by the semantic than the non-semantic secondary task. According to ABUD, word recognition does not depend upon input from semantics, so there should be no effect of secondary task type as long as the two tasks are equally demanding. According to IAS, word recognition does depend upon semantics, so word recognition should be worse when participants simultaneously perform the nonverbal semantic task. Experiment 2 uses the same methods to test the hypothesis

that people show less or even no reliance on input from semantics when lexicality is confounded with orthographic structure—that is, when words and non-words differ reliably in their orthographic well-formedness.

Experiment 1

Method

Participants Fifty-one undergraduate students from UW-Madison participated in Experiment 1 for course credit or monetary compensation. All were native English speakers with normal or corrected-to-normal vision.

Materials and Design Participants were asked to perform two tasks simultaneously: a visual lexical-decision (vLD) task and a sound judgment task. The experimental manipulation concerned whether the sound judgment task did or did not draw upon semantic knowledge. In the non-semantic “Tones” condition, participants listened to a complex tone and judged whether it was ascending in pitch or not. The task is non-semantic because it does not require the participant to consult or draw upon stored knowledge about the sound. In the semantic “Birds” condition, participants listened to an animal sound and judged whether it was produced by a bird or not—hence this task required participants to draw on stored knowledge about the sounds produced by birds and animals.

The stimuli for the vLD task were adapted from a previous study (Hauk, et al., 2006) and consisted of 50 orthographically typical words (TW; e.g., “rot”), 50 orthographically strange words (SW; “yacht”), 50 orthographically typical non-words (TNW; “yot”) and 50 orthographically strange non-words (SNW; “racht”). Words and non-words were matched for the goodness of their orthographic structure as measured by summed bigram and trigram frequencies (for details, see Rogers, et al., 2004). This manipulation ensured that participants could not rely on the well-formedness of the letter string to decide whether the item was a word (Blazely, et al., 2005; Plaut, 1997). In all word items, only 11% of them referred to animal names. Since little is known about the semantic interference with non-word stimuli, we will examine the effect of sound-judgment tasks on word and non-word stimuli separately.

The sound judgment task included 50 items in each condition. The tones were complex sounds similar to a dial tone, half ascending in pitch and half descending, and varying in initial pitch and rate of change. The animal sounds included the vocalizations of 25 different birds and 25 non-bird animals. Items from the two conditions were matched on total duration. A pilot study with 28 participants who did not engage in Experiment 1 showed that the two tasks did not differ significantly by items or subjects in

mean accuracy and response time (all $ps > 0.10$). Thus the two sound-judgment tasks were closely matched for overall difficulty.

Procedure The 51 participants were randomly assigned to either condition, resulting in 25 in Tones and 26 in Birds. Every participant was tested individually and began with three short practice sessions. First, participants practiced the vLD task: on each trial they viewed a letter string on the computer monitor and pressed a button with their dominant hand to indicate whether it was a word or not. Next, they practiced the sound-judgment task alone: participants listened to a series of sounds presented over headphones and orally reported their response by saying “Yes” (for ascending tones in the Tones condition or for birds in the Birds condition) or “No” (for descending tones / non-birds). The oral responses were recorded by the experimenter. If any lexical processing was involved in the oral response, it should be equivalent across two conditions. In the third practice phase, participants performed both tasks simultaneously with a small number of stimuli. In this practice phase and in the experiment proper, the onsets of stimuli in vLD and sound tasks were asynchronous so participants could not get into a “rhythm” of doing one task then the other. After participants were familiarized with the dual-task procedure, they continued to the experiment proper, performing both tasks simultaneously until they had responded to all 200 items in the vLD task (presented in random order). In the sound task, sounds were selected randomly with replacement until participants had finished the vLD task. The study took about 40 minutes.

Results

The mean accuracy in the sound judgment tasks was generally high and did not differ significantly between groups: 0.90 (SD = 0.07) for Tones and 0.93 (SD = 0.03) for Birds, $F(1,49) = 2.329$, $MSE = 0.003$, $p = 0.133$.

Fig. 1: Mean accuracy of the vLD task in Experiment 1.

Figure 1 shows mean accuracy and standard errors for

words and non-words in each condition. A one-way ANOVA revealed that, for word items, accuracy was significantly lower in the Birds than in the Tones condition both by subject and by item (Tones, mean = 0.83, SD = 0.08; Birds, mean = 0.77, SD = 0.10), $F_1(1,49) = 5.410$, $MSE = 0.008$, $p = 0.024$, $F_2(1,99) = 50.996$, $MSE = 0.003$, $p < .001$) with no difference in response time (Tones, mean = 1079.36, SD = 358.67; Birds, mean = 1066.43, SD = 439.40, all $ps > 0.10$). For non-words neither accuracy (Tones, mean = 0.86, SD = 0.11; Birds, mean = 0.85, SD = 0.18) nor RT (Tones, mean = 1112.12, SD = 317.14; Birds, mean = 1108.26, SD = 451.54) differed reliably between conditions, all $ps > .05$. Thus, the participants made more errors recognizing words, but not rejecting non-words, when their semantic system was occupied with a secondary nonverbal categorization task compared to an equally-demanding but non-semantic task.

To further test the hypothesis that semantic processing interferes with vLD, we investigated the correlation in overall accuracy between the vLD and the sound judgment task across subjects in each group. If the two tasks do not share a critical resource, we expect a strong positive correlation in accuracy: participants who generally cope well with dual-task situations will perform well on both, whereas those who generally cope poorly with dual tasks will perform poorly on both. If, however, the two tasks share an important resource, this relationship should be altered: allocation of the resource to one task should boost performance in one task but should hinder performance of the other task, attenuating or eliminating the expected positive correlation between the two tasks.

Fig. 2: Correlation between mean accuracy in the vLD task and sound judgment tasks in Experiment 1.

Figure 2 plots the mean accuracy in vLD and the sound-judgment task for the two groups. Performance on vLD and the Tones task was positively correlated ($r = 0.700$, $p < .001$), while this relationship in the Birds condition was not reliable ($r = 0.201$, $p = .325$) and was significantly lower than that in Tones condition, $Z = 2.225$, $p = 0.026$. Thus some participants traded off accuracy on vLD for an acceptable level of accuracy on the semantic but not the

non-semantic sound judgment task.

Experiment 2

Experiment 1 found that healthy participants showed worse performance on the vLD task when their semantic knowledge was engaged in a concurrent task. Experiment 2 assessed whether this semantic interference is attenuated when orthographic structure provides a valid cue to lexicality. We hypothesized that, if words and non-words differed reliably in their orthographic well-formedness, participants could rely on this surface cue to guide their decisions, so that reliance on the semantic system would be reduced or eliminated.

Method

Participants Sixty undergraduate students who did not participate in Experiment 1 participated in return for course credit.

Materials and Designs We used identical materials but with two important differences in design. First, stimuli were grouped into two sets in such a way that, within each set, words and non-words differed systematically in their orthographic structure. Thus Set 1 (TW-SNW) included typical words (e.g., *rot*) and strange non-words (e.g., *racht*); while Set 2 (SW-TNW) included strange words (e.g., *yacht*) and typical non-words (*yot*). Participants completed either Set 1 or Set 2. Second, to maximize our power to detect an influence of semantic interference on word recognition, the secondary task condition (Tones vs. Birds) was manipulated within every subject. Each set was divided into two subsets closely matched for accuracy and response time (all the $ps > 0.05$) in a pilot study with 23 participants who did not participate in Experiment 2. Participants in each group then completed one subset paired with the Tones task and the other subset paired with the Birds task. The order of subsets and their combinations with Tones or Birds condition were counterbalanced across participants.

Procedure Participants were randomly assigned to one of the set conditions resulting in 30 participants in each. The dual-task procedure was identical to that in Experiment 1 except that the participants were exposed to both Tones and Birds conditions in a block design.

Results

Set 1 (TW-SNW) Unexpectedly, the mean accuracy in the sound judgment tasks differed reliably for this group (0.86, $SD = 0.10$ for Tones and 0.91, $SD = 0.04$ for Birds), $F(1,29) = 6.447$, $MSE = 0.006$, $p = 0.017$. Some participants performed especially badly in the Tones task, as implied by

the larger SD in this condition. We will return to this issue later in this section.

Neither mean accuracy nor RT in the vLD task differed significantly in the Tones versus Birds conditions— F values ranged between 0.005 and 2.04, all $ps > 0.16$ for all comparisons except response time to reject non-words for tones versus birds. In this contrast there was a trend toward an effect, but with somewhat *faster* response times in the Birds than the Tones condition (Tones, mean = 1026.45, $SD = 340.14$; Birds, mean = 956.34, $SD = 364.01$), $F_1(1,29) = 3.424$, $MSE = 21558.907$, $p = 0.073$, $F_2(1,49) = 2.400$, $MSE = 61468.119$, $p = 0.128$). Thus there is no evidence that performance of the nonverbal semantic task disrupted word recognition in this condition.

Could this difference from Experiment 1 somehow be attributable to the participants who performed poorly at Tone judgment? To address this question we identified 8 participants with accuracy lower than 0.80 in the Tones task and excluded them from all analyses to see whether the results would differ. With these participants excluded, mean accuracy in Tones condition was 0.91 ($SD = 0.07$) which was not significantly difference from the Birds condition (mean = 0.91, $SD = 0.04$), $F(1,21) = 0.242$, $MSE = 0.004$, $p = 0.628$). In the remaining 22 participants we still observed no reliable effect of sound-judgment task on either accuracy or response time in the vLD task (all the $ps > 0.05$). Thus when words are well-formed and non-words are ill-formed, there is no evidence that participants rely on semantic processing to make lexical decisions.

Set 2 (SW-TNW) For participants who completed Set 2, where words were orthographically ill-formed and non-words were orthographically typical, there was no significant difference in the sound judgment accuracy for Tones versus Birds (Mean accuracy = 0.91, $SD = 0.08$ for Tones and 0.93, $SD = 0.04$ for Birds, $F(1,29) = 0.781$, $MSE = 0.003$, $p = 0.384$).

Just as in Set 1, the mean accuracy and response time for the vLD task did not differ significantly in the Tones versus Birds conditions—all F ratios were between 0.001 and 1.17, all $ps > 0.28$. Thus even when words were orthographically strange and non-words were regular, participants showed no evidence of worse performance when simultaneously performing a semantic relative to a non-semantic task. Experiment 2 thus suggests that, when orthographic structure can serve as a reliable cue to lexicality, participants do not substantially rely upon semantic processing to recognize words.

Discussion

In a dual-task interference paradigm we found that nonverbal semantic processing disrupted word recognition in healthy adults (Experiment 1), especially when orthographic structure did not provide a useful cue to

lexicity (Experiment 2). These results are consistent with the view that word recognition depends upon semantic processing (Patterson, et al., 2006; Rogers, et al., 2004; Woollams, et al., 2007), and they also suggest, in accordance with other work (Plaut, 1997), that such effects can be attenuated in tasks that confound lexicity with orthographic structure.

Our results complement patient studies documenting a strong association between impaired semantic knowledge and disturbed performance on lexical tasks including word recognition (Patterson, et al., 2006; Rogers, et al., 2004; Woollams, et al., 2007). A natural interpretation of this patient work has been that semantic, orthographic and phonological representations of words are all represented within the same interactive system (Dilkina, McClelland, & Plaut, 2008; Plaut, et al., 1996) so that, when semantic representations degrade, so too does the stability of unusual phonological and orthographic forms. This hypothesis has proven difficult to test through patient studies alone, however, because it has been difficult to rule out the alternative hypothesis that lexical and semantic impairments occur as a consequence of a disease process that jointly affects two independent systems. The current study provides a stronger test of the hypothesis because there is no disease process—instead, the contribution of semantic processing to word recognition was functionally disrupted by engaging the semantic system in a secondary task. Moreover, the secondary task was a nonverbal sound-recognition judgment that arguably makes no demands upon lexical processes. Nevertheless, it led to poorer word-recognition when performed simultaneously with vLD.

Our results challenge the view that there exists “an orthographic lexicon that is distinct from the semantic system” (pp1163, Coltheart, 2004). On this view, normal participants with intact orthographic lexicons should show equivalent performance in dual-task conditions, regardless of nature of the secondary task, because accurate word-recognition can be accomplished solely by consultation of the orthographic lexicon.

Others have previously argued that the orthographic structure of targets and distractors might influence the extent to which accurate lexical decisions depend upon semantic processing (Plaut, 1997; Seidenberg & McClelland, 1989), and this hypothesis was corroborated in Experiment 2: using the same materials and procedure as Experiment 1, the semantic interference effect was eliminated simply by blocking stimuli so that orthographic well-formedness provided a reliable cue to lexicity. If participants could perform accurately simply by accepting (for Set 1) or rejecting (for Set 2) all well-formed letter strings, then they relied less or not at all on semantic input.

It is worth noting that this latter result also poses a puzzle for the view that there exists an orthographic lexicon that is independent of semantics. If lexical decisions are “...done at the level of the orthographic lexicon” (pp701, Blazely, et al.,

2005), it is not clear why one should observe different patterns of behavior for the exact same set of target words, depending upon how they are blocked with non-word distractors. Besides, the results from Experiment 2 eliminated the possibility that the semantic interference observed in Experiment 1 was due to difference in the extent of covert word reading across conditions. If so, some might expect to observe poorer performance on vLD in the Birds condition as well, since the same paradigm and sound stimuli were used in Experiment 2. However, this prediction is not supported by the result, suggesting that the covert articulation, if any, cannot be the alternative explanation for the observed semantic inference in Experiment 1.

The present study leaves at least one important question unanswered: How does one account for individual cases who, despite serious semantic impairment, can perform within the normal range on tests of word recognition or other lexical tasks? Recent computational modeling work has emphasized that individual differences in linguistic experience can influence the performance of lexical tasks and might account for the occasional lexical/semantic dissociations observed in neuropsychological studies (Dilkina, et al., 2008). For instance, Zevin and Seidenberg (2006) showed that variability in the model training regime can produce individual differences in non-word reading patterns similar to those observed in skilled readers. Dilkina et al. (2008) also demonstrated how differences in the frequency with which a model encounters orthographic versus visual inputs can produce dissociations between word reading and object naming in an interactive model of the lexico-semantic system.

In addition to such differences in experience, our results suggest that individuals may differ in other important respects. In Experiment 1, we found that, whereas some individuals coped well with the dual task scenario—performing near ceiling on both tasks—others struggled considerably and, in the “semantic interference” condition, appeared to trade off the accuracy of one task for another. Previous work (Herdman & LeFevre, 1992) has shown that a dual-task paradigm increases resource demands and affects different aspects of word recognition process, such as speed and efficiency. Presumably, participants with superior cognitive control are better able to manage the resource demands for both tasks and so may show little semantic interference. Understanding how individual differences in linguistic experience and in cognitive control may contribute to differential reliance on the semantic system in the performance of lexical tasks remains a goal for future research.

In conclusion, the present study demonstrates that normal participants’ performance on a visual lexical decision task is disrupted by a simultaneous sound judgment task that taxes semantic memory, suggesting that lexical processes draw upon semantic processes. Moreover, the semantic interference was affected by the orthographic structure of

the words and non-words, suggesting that reliance on semantic versus orthographic information in lexical decision is dynamic.

Abstract

One of the most challenging unsolved problems in cognitive science is lack of invariance in spoken language. We take the view that variability due to coarticulation is systematic and beneficial. Several recent eye tracking experiments have demonstrated listeners' sensitivity to local coarticulatory cues between adjacent phonemes. We examined sensitivity to longer-range, anticipatory vowel-to-vowel coarticulation, which can spread across multiple syllables. Using a variant of the Visual World eye tracking paradigm (Tanenhaus et al., 1995), we conducted the first on-line test of whether lexical access is sensitive to such subtle, long-range cues, and whether the impact of such cues is modulated by the coarticulation resistance of intervening segments. Lexical access was delayed when misleading anticipatory coarticulation was available in cross-spliced materials. This significantly extends the nature and temporal range of subcategorical cues known to influence on-line sentence comprehension, and demonstrates that lexical access is simultaneously constrained by information at multiple temporal grains.

Keywords: Coarticulation; anticipation; garden path; eye tracking.

Introduction

One of the hardest unsolved problems in cognitive science is *lack of invariance* in speech. There is a many-to-many mapping between acoustics and percepts, such that the same acoustic information can map to different speech sounds, while different acoustic information can map to the same speech sounds (depending on phonetic context, speaking rate, physical or indexical characteristics of talkers, etc.). This is true of production and perception even for clearly articulated segments and syllables (Ladefoged & Broadbent, 1957; Liberman, Delattre & Cooper, 1952; Peterson & Barney, 1952). The problem is compounded in mapping to words and beyond in conversational speech, where even more variation occurs. For example, Hawkins (2003) describes radical changes in the acoustics of the message "I do not know" in a progression from careful speech to casual speech ("I dunno", and even more reduced forms). The puzzle, then, is how we reliably map acoustics to words despite (or perhaps with the aid of) all this variation.

In order to make progress in studying spoken word recognition, psycholinguists have made the temporary simplifying assumption that the input to word recognition can be approximated by a phonemic transcription (as though this were the product of a speech perception mechanism). This allows one to sidestep the lack of invariance problem and related complications due to *coarticulation*. Coarticulation refers to the fact that the articulatory gestures of adjacent and even nonadjacent segments overlap, and therefore, so do their acoustic realizations. That is, as you produce one speech sound, you are simultaneously preparing your articulators for upcoming segments, and still experiencing effects of preceding articulations. Coarticulation is often viewed as destructive, as in Hockett's (1955) metaphor of a wringer squishing together a line of easter eggs on a conveyor belt, and a major contributor to lack of invariance.

Even when a scientist is cognizant of the fact that the phonemic input assumption is almost certainly incorrect, and she explicitly considers it provisional (until we solve the lack of invariance problem at the phonological level), it has the potential to hide constraints on word recognition (Magnuson, 2008). For example, Salverda, Dahan and McQueen (2003) reported that listeners use subtle prosodic cues (e.g., vowel duration) to anticipate word length and constrain lexical competition. They tracked eye movements as subjects followed spoken instructions to click on pictures on a computer display. When initial vowel duration was consistent with a bisyllabic word, subjects immediately began looking preferentially at items with bisyllabic names.

A phonemic transcription also abstracts away from coarticulatory information, which can specify qualities of upcoming segments. Dahan, Magnuson, Tanenhaus, and Hogan (2001) demonstrated that listeners are extremely sensitive to such information. They cross-spliced words (e.g., *neck* and *net*) to provide misleading coarticulatory cues to final consonants. Using the visual world paradigm, they found fast, robust effects of such mismatches on lexical activation and competition.

These examples are inconsistent with suggestions that coarticulation has a destructive impact on phonetic

information. Instead, coarticulation systematically provides anticipatory and redundant cues that afford rapid information transmission in speech. This optimistic view, that coarticulation is lawful and informative (Elman & McClelland, 1986; Fowler, 1986), is consistent with evidence that listeners compensate for coarticulation, taking into account the predictable structure of an ongoing speech event at the gestural (Fowler, 1980; Browman & Goldstein, 1992), phonological (Gow, 2001), lexical (Ganong, 1980; Magnuson et al., 2003), and sentential (Gaskell & Marslen-Wilson, 2001) levels.

All of these examples involve cases of local coarticulation, that is, coarticulation between adjacent segments. Subsequent work on speech production has revealed the existence of long-range coarticulation, in some cases spanning multiple segments or even syllables (Heid & Hawkins, 2000; Recasens, 1984; West, 2000). This raises the possibility that listeners have even richer information at their disposal -- cues specifying qualities of upcoming sounds even several segments in advance. However, these effects are subtle and subject to strong constraints. Among these constraints is *coarticulation resistance*, a finding of Bladon and Al-Bamerni (1976), who observed that intervening consonants could modulate the effects of vowel-to-vowel coarticulation. Specifically, light, palatal [l]s reduced coarticulation between surrounding vowels in comparison to dark, velarized [ɫ]s. The articulatory and perceptual effects of coarticulation resistance has been investigated in some detail (Fowler, 2005; Fowler & Brancazio, 2000; Recasens & Espinosa, 2009). Consonants with high coarticulation resistance prevent coarticulation between surrounding vowels. Typically, high coarticulation resistance consonants involve tongue body or tongue tip articulations (e.g., [t], [d]) and/or fine motor control (e.g., [s], [z]). That is, strong constraints on tongue tip or tongue body damp long-range, vocalic coarticulation. Low coarticulation resistance consonants allow coarticulatory information to spread further, as they do not involve the tongue body or tip and do not require particularly fine motor control (e.g., [p], [b], [f], [v]).

The current study is the first on-line study, to the best of our knowledge, to examine whether lexical access is sensitive to long-range coarticulatory information, and whether the impact of such information is modulated by the coarticulation resistance of intervening segments. If so, this will represent a substantial increase in the amount of detail listeners are known to use in order to constrain speech perception and word recognition.

Experiment

We examined whether coarticulatory effects would influence lexical access by manipulating two factors. The first was (*Coarticulatory*) *Match*. At the Match level, two instances of one utterance (e.g., "pick up a pole") were cross-spliced after the word "a". In the Mismatch condition, two utterances with different final vowels were

cross-spliced (e.g., "pick up a pole" and "pick up a pail"). This provides a potentially more powerful window on sensitivity to long-range coarticulation; the Mismatch stimuli should slow lexical access of the final target word, since the coarticulation is consistent with another word, which should compete more strongly for lexical access.

The second factor was (*Coarticulation*) *Resistance*. After low coarticulation resistance consonants such as [p], the full vowel in the final word in the utterance, "pick up a pole", is likely to influence the realization of the reduced vowels in "up" and "a." In contrast, [t] is high coarticulation resistant, so anticipatory coarticulation from the vowel would be less likely if the final word were "toll." Therefore, we selected words beginning with High Resistance ([t, s, ʃ]) or Low Resistance ([p, f]) segments.

Predictions

We used a variant of the visual world paradigm with two printed words as response choices (e.g., *pole*, *pail*), as subjects heard sentences like, "pick up a pole". Our first question is exploratory: whether and when subjects might begin to favor one word based on anticipatory coarticulatory cues. Given a low resistance consonant, it is possible that subjects could begin to pick up information about the final vowel as early as the vowel in "up." When Match and Resistance are crossed, an interaction is predicted: the effect of Match should be most apparent at the Low level of Resistance.

Methods

Participants Thirty-one undergraduate students at the University of Connecticut participated in this experiment for course credit. All were native English speakers with normal or corrected-to-normal vision and reported normal hearing.

Table 1: Low and High Coarticulation resistance items. Numbers indicate quadruple set membership.

Low Coarticulation Resistance Pairs		High Coarticulation Resistance Pairs	
1.pail,pole	6.fake,folk	1.tail,toll	6.sake,soak
2.pea,porch	7.fail,foal	2.tea,torch	7.sail,sole
3.paste,post	8.feel,fault	3.taste,toast	8.seal,salt
4.pan,pool	9.feet,fog	4.tan,tool	9.seat,sauce
5.peak,pork	10.feed,ford	5.teak,torque	10.seed,sword
	11.field,fall		11.shield,shawl
	12.feet,fort		12.sheet,short

Materials Twelve quadruples of words were chosen for the study. Each was composed of a pair of words starting with a low coarticulation resistance consonant (e.g., *pail/pole*), and a pair starting with a high coarticulation resistance consonant (e.g., *tail/toll*; see Table 1 for the full set). A number of constraints were observed in the selection of these quadruples. (1) The phonemes /p/ or /f/ were used as low coarticulation resistance consonants, and /t/, /s/, or /ʃ/ were used as the high coarticulation resistance consonants. (2) Highly discriminable front or back vowels were used to maximize acoustic differences

between words and also allow for maximal acoustic difference in anticipatory vocalic coarticulation. The front vowels used were: /i/, /e/ and /æ/. The back vowels were: /əʊ/, /ɑ/, /o/ and /u/. (3) When possible, we used the same final consonant in all words in a quadruple, while also varying length and frequency as little as possible. These constraints had to be relaxed in a few cases in order to find enough items. However, the most critical portion of any noun in our design is the initial consonant and vowel, which constrain the potential for long-range coarticulation. ANOVAs confirmed that items did not differ reliably in any of these characteristics.

Each word in a quadruple was recorded with the same sentence frame (e.g., “Pick up a”). This particular sentence frame was selected to be as naturalistic as possible, while also containing neutral vowels (/ə/ in “up” and “a”), thereby maximizing the chance of observing long-range coarticulatory effects. A male, native English speaker recorded all of the sentences at a moderately fast speaking rate, which produced observable long-range coarticulation. The auditory stimuli were recorded and presented in 16-bit resolution at a 44.1 kHz sampling rate.

The spoken sentences were all cross-spliced at the onset of the noun-initial consonant. In the Match condition, two tokens of the same recording were spliced together, to ensure that any effects in the Mismatch condition were not due to artifacts of cross-splicing. In the Mismatch condition, the carrier phrase from one recording (e.g., the “pick up a” portion of “pick up a pail”) was cross-spliced with the noun from another recording (e.g., the “pole” of “pick up a pole”). Average durations were 121 ms for “pick”, 171 ms for “up a”, and 317 ms for nouns.

Table 2: Mean F2-F1 (Hz) for *up* and *a* by condition.

	Coarticulation Resistance			
	Low		High	
	<i>up</i>	<i>a</i>	<i>up</i>	<i>a</i>
Front Vowels	789	793	811	1064
Back Vowels	772	612	808	938
ΔV	17	181	3	126

Acoustic analysis The formants of vowels of ‘up’ and ‘a’ of each target sentence were measured. Vowel formant center frequencies were measured using LPC and FFT spectra with reference to a wideband spectrogram. Measurements were made at the most stable portion of the middle of the vowel. Following Ladefoged (1993) we used F2-F1 (second formant - first formant) as a measure of vowel backness. The results are summarized in Table 2, collapsing over Front (/i, e, æ/) and Back (/əʊ, ɑ, o, u/) vowels. F2 and F1 are more widely spaced for front than back vowels, so F2-F1 should be greater for front vowels. High Resistant consonants should yield smaller vowel backness differences than Low Resistant consonants. All of these differences were observed in the mean F2-F1 values at both ‘up’ and ‘a’. Thus, we were successful in

providing long-range anticipatory coarticulation cues in the materials.

Procedure Participants were seated at a comfortable distance from a computer screen (approximately 60 cm). Eye movements were monitored with an SR Research EyeLink 1000 desktop-mounted (remote) system, sampling at 500 Hz. Spoken sentences were presented to participants through headphones.

Each trial started with a drift correction procedure (participants briefly fixated a central dot). Then, a central fixation cross appeared. Participants clicked on it to begin the trial. When the cross was clicked, the members of a word pair appeared on the screen, one on the left and one on the right, with target and distractor position counter-balanced and pseudo-randomized. (We did not use pictures because we were unable to find enough highly imageable words meeting our phonological constraints; see McMurray, Tanenhaus & Aslin, 2009, and Huettig & McQueen, 2007, for precedents of using printed words in the visual world paradigm to obtain fine-grained time course measures of speech perception and spoken word recognition.) After a delay of 500 ms, the spoken sentence was presented over headphones. Participants were instructed to click on the final word of each sentence. The trial ended when the participant clicked on a printed word.

Each participant was presented with all 48 experimental trials and 44 filler trials. Twenty-two fillers consisted of rhyming pairs (to direct attention away from the onset similarity of critical items), and the remaining twenty-two were non-rhyming pairs. Half of each of these sets were presented with an auditory sentence cross-spliced to produce mismatching coarticulation, and the other half were spliced with another token of the same sentence, using exactly the same procedure as for the experimental stimuli (due to space constraints, we do not report analyses of filler items here). Experimental and filler trials were presented in random order following four (filler) practice trials. Half the experimental trials were presented in the Match condition and half were presented in the Mismatch condition. Half the trials in the Match and Mismatch conditions were Low Coarticulation Resistance words and the others were High. Thus, participants were given 12 trials in each of the four possible conditions. The word pairs (*pail/pole*) were counterbalanced between participants, such that a participant heard one of the pair (*pail*) in the Match condition, and the other (*pole*) in the Mismatch condition. Across participants, each word pair was presented the same number of times in Match and Mismatch conditions, and each word appeared equally often on the left or right.

Results

Data from two participants was excluded from analyses because of poor eye tracker calibration. Mean accuracy was at least 0.99 in all conditions. Figure 1 shows the average time course of target and competitor fixation proportions (at 20 ms intervals). Qualitatively, one

Table 3: Growth curve analysis of competitor fixation proportions. See text for details.

	Model fit			Match			Coarticulation Resistance			Match x CR

Cubic	6151	53.9	<0.001	0.111	6.92	<0.001	0.033	2.04	0.041	-0.082	-3.60	<0.001

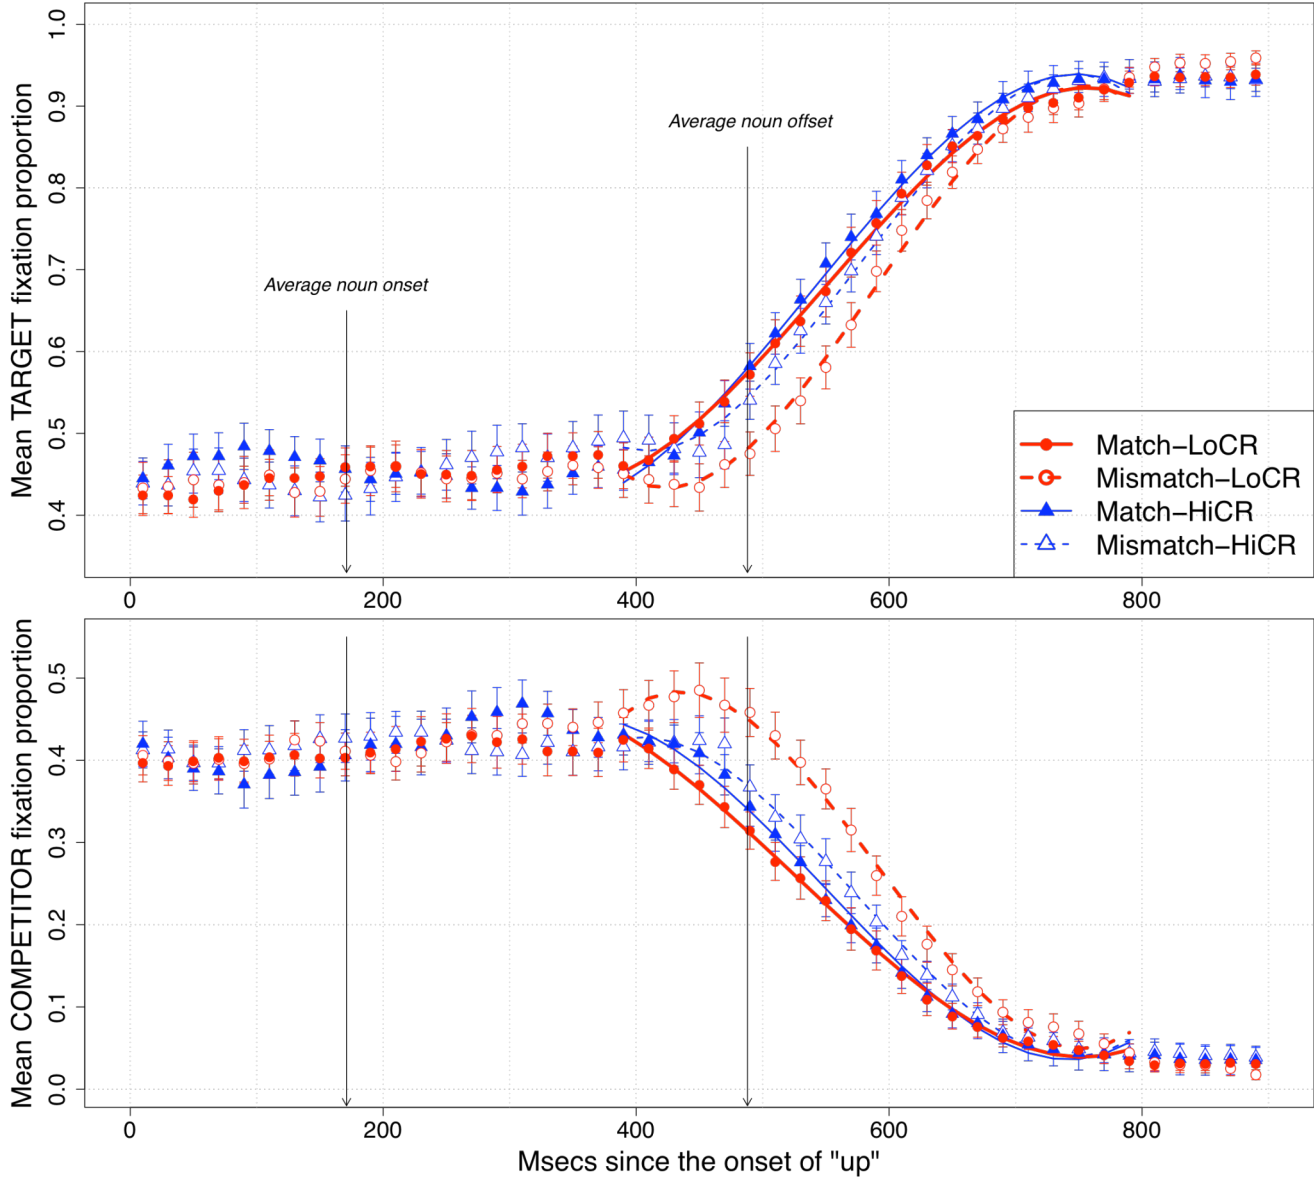

Figure 1: Mean fixation proportions to targets (top) and competitors (bottom). Symbols show observed data. Lines show growth curve fits for the 371-800 ms analysis window. Note different y-axis ranges.

condition stands out. The target is fixated most slowly in the Mismatch, Low Resistance condition, and a complementary increase in competitor fixations is also observed. The effect is not apparent until midway through the noun; however, the difference can only be due to coarticulatory detail available prior to word onset, since

the signal in that condition was identical to that in the Match, Low Resistance condition from noun onset onward. There was also a slight trend towards an effect of Match at the High level of Coarticulation Resistance.

For the statistical analyses, we applied *growth curve analysis* (GCA; Mirman, Dixon, & Magnuson, 2008).

GCA is a variant of multi-level modeling that fits orthogonal power polynomial terms to over-time data. Conceptually, curves are fit to subject mean proportions at the lowest level of condition combinations (e.g., the Match level at the Low level of Resistance), and GCA assesses whether the curve parameters differ. Notably, this approach is dynamically consistent: the average of subject-level fits is equivalent to the fit to averaged data.

It is clear from Figure 1 that there were no differences between conditions until midway through the noun. Therefore, we constrained the GCA to a window beginning 200 ms after noun onset, the approximately earliest point where noun-driven changes in fixation proportions could be observed (371 ms after "up" onset), and ending at target asymptote (800 ms).

While any order polynomial can be used, the first three terms are conceptually easiest to link to visual world data. The *intercept* is recentered, such that it is analogous to mean proportion in the analysis window, and so directly analogous to an ANOVA on mean fixation proportion (indeed, although standard ANOVAs are less powerful than the multi-level modeling afforded by GCA, ANOVAs on mean proportion in this analysis window converge with the GCA intercept analyses). The *linear* term is the mean slope over the analysis window, the *quadratic* term reflects bowing of the primary curve inflection, and the *cubic* term capture inflections at the tails (necessary for fitting the s-like curves here).

Table 4: Mean competitor fixation proportions in the 371-800 ms analysis window by condition.

	<i>Coarticulation Resistance</i>	
	Low	High
Match	0.198	0.209
Mismatch	0.271	0.225

Because effects on targets and competitors are logically complementary (since these categories represent the two primary objects of fixation), we will present just the competitor analysis. The analyses are summarized in Table 3, with main effects of Match on intercept (greater mean proportion in Mismatch than Match conditions), linear slope and quadratic curvature (due to more negative slope and greater curvature in Mismatch conditions that follows from the greater lag preceding the drop-off in competitor fixations), and the cubic term (due to the early initial rise in the Mismatch, Low condition). There were no main effects of Coarticulation Resistance, but there were interactions of Match and Coarticulation Resistance on intercept, quadratic, and cubic terms. The intercept interaction is crucial (and space does not permit discussion of the other interactions); simple effects analyses reveal a significant effect of Match at Low Resistance ($t=19.5$, $p<0.001$) but not at High ($t=1.5$). Relevant means are presented in Table 4. Thus, the predicted interaction was observed: the effect of

Mismatch was only reliable in the context of Low Coarticulation Resistance consonants.

Discussion

This study addresses the question of whether long-range coarticulatory information influences the time course of lexical activation and competition. We systematically varied (a) the Coarticulation Resistance (high vs. low) of the onset consonant of a monosyllabic target noun and (b) Coarticulatory "Match", i.e., whether the long-range anticipatory coarticulation matched or mismatched the vowel of the target noun that was ultimately heard.

While we observed trends associated with Coarticulatory Match and Resistance, the effects were driven largely by a difference in one condition: responses were slowed in the Mismatch, Low Resistance condition (though there was also a slight trend toward an effect of Mismatch at High Coarticulation Resistance).

The fact that the influence of anticipatory coarticulation was most apparent at low Coarticulation Resistance is consistent with phonetic analyses of long-range coarticulation, as those effects are simply more likely to propagate over segments (like [p]) that do not impose strong constraints on the position of the tongue tip or tongue body. The fact that influences of anticipatory coarticulation were most apparent in the Mismatch conditions is consistent with our expectation that these would be subtle effects and that misleading cues might be required to elicit detectable changes in lexical access (cf. Dahan, Magnuson, Tanenhaus & Hogan, 2001).

Notably, the effects do not emerge until midway through the final noun. This is surprising, as these effects must be due to anticipatory coarticulatory effects, since the nouns in the Match and Mismatch conditions were identical; those conditions differed only the "pick up a" portion of the instruction. It may be that anticipatory effects are detected as they occur, but require combination with confirmatory bottom-up evidence before they have a detectable impact. If front or back vowel qualities are detected on the vowel in 'up', this indicates that such a vowel is forthcoming, but it may still be several syllables away. This could prime appropriate phonological representations without driving strong lexical activation.

We do not mean to imply that lexical access initially proceeds based on local, bottom-up cues and other constraints are integrated after a delay (cf. Swinney, 1979). Instead, we note that when constraints are *gated* by bottom-up information but are integrated continuously, weak effects can appear to be late effects (Dahan, Magnuson & Tanenhaus, 2001; Shillcock & Bard, 1993).

Even though the effects we observed were relatively late and relatively modest, we did find a reliable influence of long-range coarticulatory anticipation. This reveals how extraordinarily sensitive listeners are to the rich sea of subphonemic details (some strong, some subtle) in which the islands of stability we describe as "phonemes" are embedded. This reinforces the view that coarticulation and other sources of variability in speech are not noise or

problems listeners must overcome. Rather, variability is largely lawful, enabling rapid rates of information transmission (Elman & McClelland, 1986; Fowler, 1986) due to local and anticipatory constraints it provides at multiple temporal scales.

Abstract

Previous studies have indicated cross cultural differences in conscious processes such that Easterners have a preference for a more global perspective and Westerners for a more analytical perspective. We investigated whether these biases also apply to implicit learning. In Experiment 1, Japanese and British participants were asked to attend to one of the two aspects of a set of GLOCAL strings, global or local. The results showed that they could learn the AG implicitly only from the attended level in both cultural groups. They also showed that the global superiority in implicit learning was found only for the Japanese. In Experiment 2, these cultural differences were examined without manipulating the participants' attention. The results indicated implicit learning only at the global and not the local level for the Japanese, but equal learning of both levels by the British. We concluded that cultural biases strongly affect the type of unconscious knowledge that people acquire.

Keywords: cultural differences; selective attention; implicit learning; artificial grammar learning; global/local.

Role of Selective Attention in Implicit Learning

When repeatedly exposed to large amounts of information, we can acquire some abstract knowledge, such as rules or covariations between variables, without being aware of it. This phenomenon has been known as *implicit learning*. Since Reber's pioneering work on it (Reber, 1967), implicit learning has been studied using several paradigms, for example, serial reaction time (SRT) task or artificial grammar (AG) learning (for reviews, see Dienes, 2008; Reber, 1989; Shanks, 2005).

Reber (1989) suggested that we can implicitly learn some knowledge with a minimal amount of attention. Several researchers have agreed with the claim (e.g. Perruchet & Vinter, 2002; Whittlesea & Dorken, 1993). Based on this claim, it can be supposed that some attentional selection should occur in implicit learning.

Previous studies on the role of selective attention in implicit learning (e.g. Cock, Berry, & Buchner, 2002; Jiménez & Méndez, 1999; Rowland & Shanks, 2006) have provided supportive evidence to Reber's claim. However, these studies have mainly used the SRT task and few studies have investigated the role of selective attention in AG learning.

Seger (1998) argued that different mechanisms may underlie learning in the SRT task and in AG learning. Specifically, SRT task involves the acquisition of perceptual motor implicit knowledge, whereas AG learning involves acquiring implicit knowledge for the purpose of making judgments. Similarly, Boucher and Dienes (2003) speculated that sequential tasks such as SRT involve error correction mechanisms based on prediction, whereas AG learning may involve an automatic chunking mechanism. Although some researchers suggest that there is a common mechanism in these two tasks (e.g. Perlman and Tzelgov, 2006), the roles of selective attention in implicit learning may differ in SRT and AG learning. This claim needs to be further tested.

The first attempt to investigate the role of selective attention in AG learning was conducted by Tanaka, Kiyokawa, Yamada, Dienes, and Shigemasa (2008). They developed a new method using GLOCAL strings (an example is shown in Figure 1) to manipulate selective attention. GLOCAL strings are chains of compound letters (Navon, 1977). A compound letter represents one large letter (i.e. a global letter) composed of a set of small letters (i.e. local letters). A critical feature of this stimulus is that while a GLOCAL string can be read as one string by using global letters (NVJTVJ in Figure 1), it can also be read as a string using local letters (BYYFLB in Figure 1). Since GLOCAL strings can simultaneously represent two different strings following different AGs, we can examine whether the participants can learn the two AGs—one is attended while the other is unattended—by manipulating their

Figure 1. An Example of GLOCAL Strings.

attention. Using the GLOCAL strings, Tanaka et al. revealed that participants could learn an AG only from the attended level of the GLOCAL strings. They concluded that selective attention plays a critical role in AG learning.

Tanaka et al. (2008) also found the global superiority in AG learning. In Experiment 1, the classification accuracy for the attended grammatical strings was higher in the global attention condition than in the local attention condition. In Experiment 2, they examined whether or not the information at the unattended level was encoded by using a Stroop paradigm. They found the global superiority again. These results suggest that there is a global/local asymmetry in implicit learning. This tendency is consistent with the claim for a general preference for processing at the global level (see Navon, 2003, for a review).

Cultural Differences in Attention

Cultural psychology literature has suggested that there are cultural differences in attention between Easterners and Westerners (for reviews, see Nisbett, 2003; Nisbett & Miyamoto, 2005; Nisbett, Peng, Choi, & Norenzayan, 2001). Specifically, Easterners tend to pay attention to a scene globally, whereas Westerners do so locally.

Masuda and Nisbett (2001) examined whether Easterners attend to context more than Westerners do. They presented Japanese and American participants with animated vignettes of underwater scenes (in Study 1) or with photos of an animal in the wild (in Study 2) and asked the participants to report the contents. In a subsequent recognition test, the participants were shown previously seen objects as well as new objects, either in their original setting or in novel settings, and were then asked to judge whether or not they had seen the objects. The results showed that Easterners made more statements about contextual information and relationships than Westerners did. They also found that Easterners recognized previously seen objects more accurately when they saw them in their original settings rather than in the novel settings, whereas this manipulation had relatively little effect on Westerners.

Kitayama, Duffy, Kawamura, and Larsen (2003) developed the framed line test (FLT). In this test, participants were presented with a square frame in which a vertical line was printed. They were then presented with another square frame of a different size and required to draw a line that was the same either in absolute length (absolute

task) or in proportional length (relative task). Kitayama et al. (2003) found that the performance of Westerners in the absolute task was better than that in the relative task, whereas for Easterners the pattern was reversed. The results indicated that Westerners are better able to filter out or to suppress contextual frame information, whereas Easterners are better at incorporating contextual information. Ishii and Kitayama (2007) extended the results to non-student participants and to auditory tasks.

Based on these studies, there is a possibility that the global superiority found by Tanaka et al. (2008) is limited to Easterners. In Tanaka et al. (2008), the participants were all Japanese. Because they tended to pay more attention to the information at the global level than that at the local level, they might have had difficulty filtering out the information at the global level when asked to focus on the strings at the local level. As a result, global superiority in AG learning emerged.

Present Study

In the present study, we determined whether or not the global superiority in AG learning found by Tanaka et al. (2008) would be obtained for Western participants. Based on the cross cultural literature, there ought to be cultural differences in attention. Since selective attention plays an important role in AG learning, we hypothesized that the cultural differences in attention would have an effect on AG learning: Easterners could learn AG from the global level more than from the local level, whereas Westerners could not.

We modified the procedures used by Tanaka et al. (2008) in the following ways. The first is the instructions in the learning session. In Tanaka et al. (2008), the participants were asked to write down the strings represented either by global or by local levels during their presentation. This procedure in the learning session might help the participants to learn the attended grammar more than otherwise because they can read the strings that they wrote down on the paper. In the present study, the participants were asked only to look at the strings carefully and sometimes write them down after the GLOCAL string had disappeared.

The second is in the procedure followed in the test session. In the previous study, the participants were not instructed regarding on which AG they should base their judgments. This procedure might cause the degree of each type of AG learning to be underestimated. In the present study, we divided the test into two sessions and the participants were explicitly told to judge the grammaticality based on one of the two AGs in each session. The order of these two test sessions was counterbalanced among participants.

In the third modification, the participants were asked to show the basis of their judgment in each grammaticality judgment trial. Although this point will not be discussed in this paper owing to space constraints, this procedure allows us to examine in more detail whether participants'

grammaticality judgment was based on an implicit or explicit basis.

Experiment 1

This experiment was designed to examine whether or not the global superiority found in Tanaka et al. (2008) could be replicated by Japanese and British participants.

Method

Participants Forty undergraduates from Chubu University and forty-two from the University of Sussex participated in the experiment and received a course credit following the completion of the experimental session. Assignments on types of GLOCAL strings and the order of the tests were counterbalanced. None of the students had previously participated in the same kind of experiment.

Stimuli The same AGs as those in Tanaka et al. (2008) were used. Grammar 1 comprised five letters (J, N, T, V, and X), as did Grammar 2, which used the letters B, F, L, Y, and Z.

Eighteen grammatical strings with a length of three to six letters were constructed from each AG. Two types of GLOCAL strings were constructed from these strings, following the two AGs. One type of GLOCAL string followed Grammar 1 at the global level and Grammar 2 at the local level; this was reversed for the other type of GLOCAL string, so grammar was counterbalanced across levels.

GLOCAL strings were presented as white uppercase letters against a black background. Small letters were used, printed in 12-point MS Gothic font. One large letter was the height of seven small letters. Eight small letters were arranged horizontally to obtain F, J, L, and X; nine to obtain B, N, T, and Y; thirteen to obtain V; and seven to obtain Z. The height of a large letter on the screen was approximately 3.2 cm and the width was approximately 1.8–3.0 cm. The distance between the display and the participants was approximately 60 cm.

Twenty strings following each grammar used in the test phase were composed of five or six letters. These were not GLOCAL but regular letter strings. Half of these were used in the learning phase and will be referred to as ‘presented grammatical strings’. The remaining strings were not identical to any of the strings presented in the learning phase and will be referred to as ‘novel grammatical strings’. All of these grammatical strings were used to construct nongrammatical strings that violated both of the grammars by placing one or two characters in nonpermissible locations.

Four types of string pairs were constructed for the test phase. The first type—Global_Old—paired a presented grammatical string at the global level of GLOCAL strings in the learning phase with a nongrammatical one based on the AG extracted from the global level of the GLOCAL strings. The second type—Global_New—paired a novel grammatical string at the global level of GLOCAL strings in the learning phase with a nongrammatical one based on the

AG that was extracted from the global level of the GLOCAL strings. Similarly, the third type was termed Local_Old, and the fourth Local_New. Each type comprised 20 pairs. Thus, there were 80 pairs in the test phase. Matching pairs of grammatical and nongrammatical strings in each type were randomized for each participant, subject to the constraint that the two strings should have the same length.

Procedure During the learning phase, 18 GLOCAL strings were presented on the display for 6 seconds. Half of the participants were asked to look at and memorize the GLOCAL strings represented by the large letters. The other half were asked to do so with respect to the strings represented by the small letters. The former was a global attention condition and the latter was a local attention condition. The participants were also required to write down the string represented by the attended level when the message was shown on the display. The message was presented about once in ten trials. Each GLOCAL string was presented six times. A mask stimulus comprising many ‘+’ signs in the area where the GLOCAL strings were intended to be displayed was presented for the 1-second interval between the presentation of GLOCAL strings.

At the beginning of the test phase, the participants were informed that two strings would be presented in the upper and lower regions of the display, each of the two levels of the training strings followed a set of rules, and each string of a pair followed one set of rules. The test phase consisted of two sessions: a test on the global level and one on the local level. Half of the participants were required to press the key associated with the string that they judged to be grammatical, extracted from the global aspects of the GLOCAL strings in the first test session and the local in the second one. The remaining participants were asked to do the same thing, first for the local and then for the global level.

Forty pairs were presented to each participant in a random order in each test session. A pair of strings remained on display until the participants pressed one of the two keys. The presentation of strings from a pair in the upper region was also randomized for each participant, subject to the constraint that one type of pair (i.e. the grammatical string) would be presented equally in each region.

After making judgments, the participants were asked what they based their judgments on and were required to choose one of the following five answers:

1. Random responding or guessing: Your judgment had no basis whatsoever; you could have just flipped a coin to make your judgment.
2. Intuition: You have some confidence in your judgment, but you have no idea why.
3. Familiarity: The sequence seemed familiar or unfamiliar for reasons you could not state.
4. Recollection: You recollected or failed to recollect seeing all or part of the sequence in the training phase.
5. Rules: You based the judgment on a rule or rules you could state if asked.

All of the instructions were presented in Japanese for the participants from Chubu University and in English for those from the University of Sussex. The English instructions were back translated and checked to make sure they had the same meaning as those in Japanese.

Design A $2 \times 2 \times 2$ mixed design was employed. The first factor was global/local. The participants were instructed to attend to the global or local level of the learning phase. This was a between-participants factor. The second factor was attended/unattended. In the test phase, half of the pairs could be judged correctly on the basis of the grammar extracted from the attended level of the GLOCAL strings, whereas the other half could be judged correctly on the basis of the grammar extracted from the unattended level. This was a within-participants factor. In addition, the third factor, presentation, indicated whether or not the grammatical string had been presented before in the learning phase. This was also a within-participants factor.

Results and Discussion

Figure 2 shows the mean classification accuracy for each condition in the test phase. First, the proportion of accurate classifications was subjected to a $2 \times 2 \times 2$ mixed ANOVA with global/local, attended/unattended, and presentation (old or new grammatical string) as factors for each cultural group.

For the Japanese participants, the main effect of the attended/unattended level was significant ($F(1, 38) = 231.43, p < .001$). Accuracy concerning the grammar of the attended level was higher than that of the unattended level. The interaction between the global/local and attended/unattended levels was also significant ($F(1, 38) = 11.04, p < .01$). The results of the simple main effect revealed that accuracy in the global attention condition was higher than that in the local attention condition at the attended level ($F(1, 76) = 10.67, p < .01$), whereas this effect disappeared at the unattended level ($F < 1$).

For the British participants, the main effect of the attended/unattended level was significant ($F(1, 40) = 69.03, p < .001$), indicating that accuracy concerning the grammar of the attended level was higher than that of the unattended level. The interaction between the global/local and attended/unattended levels was not significant ($F(1, 40) = 1.43$).

In order to examine the possibility that the participants could learn the AG from the unattended level to some degree, we compared the proportions accurately classified with chance (.5) in each condition. With respect to the Japanese participants, accuracy for Unattended_Old and Unattended_New in both the global and local conditions was not higher than chance ($ts < 1$). With respect to the British participants, on the other hand, accuracy for Unattended_Old in the global condition was significantly higher than chance ($t(20) = 2.91, p < .01$).

We replicated the results of Tanaka et al. (2008) for the Japanese participants. They were able to learn the AG from the global level more than from the local level only when

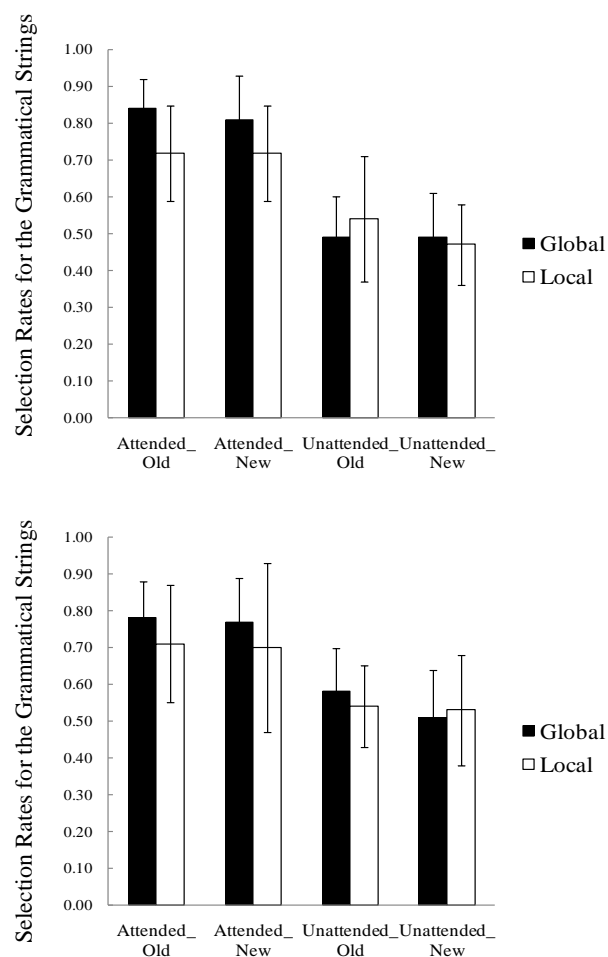

Figure 2. Mean Selection Rates for the Grammatical Strings in the Pairs of Attended_Old, Attended_New, Unattended_Old, and Unattended_New Grammatical Strings with Nongrammatical Strings in Each Attention Condition with Standard Deviations. Top panel: Japan; Bottom panel: UK.

they paid attention to the level itself. Global superiority, however, was not found for the British participants. In addition, the result of a t -test showed that they were able to learn the AG not only from the attended level but also from the unattended level when asked to pay attention to the global level. This might indicate that they have a tendency to process more information from the local level than from the global level.

In sum, the results suggest that there are cultural differences in implicit learning such as AG learning. This may be explained by attentional bias between Easterners and Westerners. In Experiment 2, therefore, we examined whether or not there would be cultural differences in implicit learning without manipulating the participants' attention.

Experiment 2

This experiment was designed to examine whether or not there would be cultural differences in attention and AG learning when the participants were free to manage their attention in the learning session.

Method

Participants Twenty undergraduates from Chubu University and eighteen from the University of Sussex participated in the experiment and received a course credit following the completion of the experimental session. Assignments on types of GLOCAL strings and the order of test were counterbalanced. None of the students had previously participated in the same kind of experiment.

Stimuli The same AGs as those in Experiment 1 were used.

Procedure The same procedures were used as in Experiment 1 except for the following points. First, the participants' attention was not manipulated in the experiment. They were asked to look at the GLOCAL strings not at one level but at both levels. Second, two questions were asked at the end of the experiment. The first question was, 'Which aspect—the bigger letters or the smaller letters—did you pay more attention to in the first session?' The second was, 'By how much more do you think you attended to your favorite aspect, e.g. twice as much, three times as much, etc.?'

Design A $2 \times 2 \times 2$ mixed design was employed. The first factor was cultural group. This was a between-participants factor. The second factor was global/local. This was a within-participants factor. In addition, the third factor was presentation. This was also a within-participants factor.

Results and Discussion

Figure 3 shows the mean classification accuracy for each condition in the test phase. First, the proportion of accurate classifications was subjected to a $2 \times 2 \times 2$ mixed ANOVA with cultural group, global/local, and presentation as factors.

The main effect of the global/local factor was significant ($F(1, 36) = 12.13, p < .01$). The interactions between cultural group and global/local and between cultural group and presentation were also significant ($F(1, 36) = 9.52, p < .01$; $F(1, 36) = 5.50, p < .05$, respectively). The results of the simple main effect revealed that accuracy in the global grammar was higher than that in the local one for the Japanese participants ($F(1, 36) = 21.57, p < .0001$), whereas this effect disappeared for the British participants ($F < 1$). The results of the simple main effect showed that accuracy in the new grammatical stimuli was higher than that in the old ones for the British participants ($F(1, 36) = 3.75, p = .06$), whereas this effect was not found for the Japanese participants ($F(1, 36) = 1.91, p > .10$).

In order to examine the possibility that the participants could learn the AG from each level, we compared the

Figure 3. Mean Selection Rates for the Grammatical Strings in the Pairs of Global_Old, Global_New, Local_Old, and Local_New Grammatical Strings with Nongrammatical Strings with Standard Deviations in Each Cultural Group.

Table 1. The ratio of participants who preferred each level in the learning session.

	Japan	UK
Global	90.0	50.0
Local	5.0	44.4
Equal	5.0	5.6

(%)

proportions accurately classified with chance (.5) in each condition. With respect to the Japanese participants, accuracy only for the Global_Old and Global_New strings was significantly higher than chance. With respect to the British participants, on the other hand, accuracy only for all types of strings was significantly higher than chance.

To examine the attentional bias in the learning session, we compared the ratio of the participants who paid more attention to each level between cultural groups. Table 1 shows the ratio of the participants who preferred each level. A *chi-square* test revealed that more participants preferred the global level to the local one in Japan, whereas this pattern was not found (*chi-square* ($N = 38$) = 8.36, $p < .05$). The result indicated that there were cultural differences in attention during learning sessions. It also indicated that this attentional bias might cause the cultural difference in AG learning.

General Discussion

In the present study, we examined whether or not there are cultural differences in implicit learning using an AG learning paradigm with GLOBAL strings. In Experiment 1, the global superiority in AG learning was obtained only for the Japanese participants. This indicated that there was a cultural difference in implicit learning between Easterners and Westerners. However, it was common that selective attention played a critical role in AG learning. Although the British participants could memorize the grammatical strings at the unattended level, in both cultural groups, the participants could learn only the AG extracted from the attended level. The results strongly support the necessity for attention in AG learning suggested by Tanaka et al. (2008).

The results of Experiment 2 revealed that the Japanese participants could learn the AG only from the global level, whereas the British participants could learn from both levels. It was also found that there was attentional bias in the learning session: most of the Japanese participants tended to pay more attention to the global level, whereas half of the British participants tended to pay more attention to the local level. Based on the cultural difference in attention, the results of AG learning should be interpreted as showing not that the British participants could simultaneously learn both AGs, but that some learned the AG only from the global level and others only from the local level, corresponding to their attentional preference.

It is necessary to examine whether or not there are also any cultural differences in learning or judging strategy between Easterners and Westerners based on the participants' judgment bases. Previous studies (e.g. Nisbett, 2003; Nisbett et al., 2001) have suggested that Eastern people prefer holistic processing, whereas Western people prefer analytic. It should be examined whether this tendency can be applied to implicit learning situations such as our task setting.

Conclusion

Selective attention plays a critical role in implicit learning in both Eastern and Western cultural groups. However, there are cultural differences in global/local asymmetry. Specifically, Japanese participants learned the AG extracted from the attended global level better than that from the local one, whereas British participants did not. The cultural difference in AG learning seems to be caused by cultural biases in attention between Easterners and Westerners.

Keywords: Numerical transcoding; number processing; number representation; network analysis.

Abstract

We explore the relationship between the lexical structure and the syntactical structure of numerical expressions in number transcoding from the oral verbal format to the Arabic digital format. The experimental setup included asking six to eight-year old Spanish-speaking children attending elementary school to write in Arabic format a set of dictated numerals. The method of analysis includes the construction of a relational representation of children's production and the use of clustering techniques to identify patterns. The model relates children and dictated numerals by children's accomplishment and generates a subsidiary similitude relation between dictated numerals with patterns that show differentiated structures. We find that the presence or absence of a verbal expression for the Hundred position digit in the dictated numeral marks one of the structures. The second structure comes from the role of two digit numbers (e.g. 20 or 34): homogeneous in the Decade position and heterogeneous in the Thousand position. We interpret these results as consistent with the semantic-lexical internal number representation model by R.J.D. Power and M.F. Dal Martello, *The dictation of Italian numerals, Language and Cognitive Processes*, 5, 237-254; 1990.

Introduction

McCloskey, Caramazza and Basili made in 1985 (McCloskey, Caramazza, & Basili, 1985) a pioneering proposal in adult neuropsychology of cognitive mechanisms in number processing and calculation. They posted the existence of a number comprehension mechanism, a number production mechanism and a calculation system with a numerical internal representation. The number comprehension mechanism translates a numerical input into the internal representation and the number production mechanism translates from the internal representation into the output format required. Comprehension and production mechanisms process both verbal and Arabic numerals and distinguish lexical-processing and syntactic-processing components. Lexical processing involves comprehension or production of individual elements in a number. Syntactic processing involves the relations among numerical elements

in order to comprehend or to produce a number as a whole. The number internal representation in this model is semantic-abstract, with numbers expressed in basic quantities associated to abstract forms of the base-10 representation (e.g. 2×10^1 and 5×10^0 for *twenty five*). The model specifies that the internal representation activates the syntactical production mechanism and that the highest power of ten in the central representation generates a syntactic frame with the appropriate number of slots or positions for the production of the Arabic numeral. This representation is independent of the structure of verbal representation. The semantic base-10 representation implies that the peculiarities of verbal stimulus do not exert any influence on the Arabic production mechanisms.

Number transcoding, defined as translating a numeral from one code to another one, has been used to explore number processing in impaired subjects and adolescents with mild retardation (Barrouillet, Camos, Perruchet & Seron, 2004; Granà, Lochy, Girelli, Seron, & Semenza, 2003; McCloskey, 1991; McCloskey & Caramazza, 1987; McCloskey *et al.*, 1985; McCloskey & Macaruso, 1995; Seron & Noël, 1995) and in groups of children (Barrouillet *et al.*, 2004; Power & Dal Martello, 1990; 1997; Seron & Fayol, 1994). From these works two main explanatory models for number processing in children arise: One proposes the existence of a semantic representation of numerical quantities, which can be either semantic-abstract (Macaruso, McCloskey & Aliminosa, 1993; McCloskey, 1991; McCloskey *et al.*, 1985) or semantic-lexical (Power & Dal Martello, 1990); the other perspective proposes an asemantic model where number processing results from assembling rules or algorithms (Deloche & Seron, 1982, 1987; Barrouillet *et al.*, 2004). Some models propose both routes.

In the semantic-lexical model posted by Power and Dal Martello (1990) working with children "the form of the representation reflects the structure of the subject's verbal numeral system." To these authors the internal representation is due to the interpretation of the verbal numeral and its internal structure tied to the verbal code. They propose sum and product structures as the main relationships between numerical concepts and, from the subject perspective, an overwriting rule for the sum operator and a concatenation rule for the product in Arabic

production. In this model a product relation produces numerals as 200 and 2000 from primitive numerical concepts as Ones, Teens, Tens and Hundred, and a sum relation to obtain composed numerals as 220, 2020, 20220. For Power and Dal Martello (1990) “Every non-primitive number is represented as the sum or product of two unequal numbers”. They show that syntactic errors, related to the numeral structure (e.g. 20045 for *two hundred forty five*), are more frequent than lexical errors related to the exchange of digits (e.g. 255 for *two hundred forty five*).

An asemantic model that predicts children production was developed by Barrouillet *et al.*, (2004), “ADAPT: A Developmental, Asemantic and Procedural Model for Transcoding from Verbal to Arabic Numerals”, with two versions: the basic (ADAPT^{BASIC}) and the advanced (ADAPT^{ADV}). The first version describes the transcoding process for numerals up to 99 and the second up to six digit numbers. The main proposal of the ADAPT^{BASIC} model is that when a verbal string for transcoding corresponds to a representational unit stored in Long Term Memory (LTM), this string is processed as such, whereas its transcription is the result of the direct memory retrieval of its digital form. In the ADAPT^{ADV} version, an algorithm is used to explain transcoding from the verbal numeral format to the Arabic digital format. For writing numerals the model assumes that the verbal expression is coded in a phonological code and analyzed by a parser. The results of the analysis are processing units that can be either elements whose digital transcription can be directly retrieved from LTM or separators, as Hundred and Thousand. These processing units trigger the transcoding rules that in a serial process generate either slots, digits or digit chains. (Barrouillet *et al.*, 2004)

The present work heads number processing by identifying patterns of relationship between the lexical (phonetic) structure of verbal expressions and one syntactical structure of the Arabic expressions in children’s production transcoding numbers from the oral verbal to the Arabic digital format. Our model includes a positional analysis using similarity, structural equivalence (Borgatti, Everett, Freeman, 2002; Johnson, 1967; Wasserman & Faust, 1994) and betweenness (Freeman, 1979; Girvan & Newman, 2002). The novelty of this analysis is the use of a relational representation children’s production. The most relevant findings are two syntactic structures: One pinned to the presence or absence of a verbal expression in the Hundred position of the dictated numeral, and other one which differentiates Decade forms (e.g. 20 or 70) and Decade-Unit forms (e.g. 34 or 76) when they are at Thousand position (e.g. 30.432 or 37.432).

Method

In this section we present the experimental setup and the model of analysis used in this study.

Participants

The experimental setup included the dictation of numerals to 207 children attending first, second and third grades of elementary school in Colombia. First grade children (65) were 6 years and 8.3 months old with standard deviation SD=2.9 months, second grade children (74) were 7 years and 7.0 months old (SD=3.0 months) and third grade children (68) were 8 years and 7.8 months old (SD=3.0 months).

Experimental procedure

The experiment consisted of asking children to transcode a set of dictated numerals from the oral verbal format to the Arabic one. Numerals were dictated in Spanish in a 20-minute testing session to each child. Dictated numbers were of a higher order than those traditionally taught at the corresponding school grade. Four dictation lists with the same set of numbers were generated randomly in each grade and assigned randomly to each child. The set of numbers included all lexical and syntactic forms for three, four and five digit numerals in Arabic code. The notation used to classify numerals is: *a*, *b*, *c*, *d* and *e* letters which represent the digital forms different from zero and correspond to the basic quantities of the numeral in the Arabic format (ex. 3789 is *abcd*). In all of the cases *a* represents the highest order quantity of the Arabic format. The 0 digit represents a null quantity. We use *x* to represent either a basic or a null quantity.

Method of analysis

Network analysis perspective uses graphs to represent and study complex systems in terms of relations between elements or parts. It gives a detailed account of structural and dynamical properties of systems by identifying patterns at the microscopic level and macroscopic phenomena. (Freeman, 2004; Wasserman & Faust, 1994)

Our model of analysis defines ties between numerals in terms of correlations in children’s production: Two numerals are tied with a strength equal to the number of children with production syntactically and lexically correct or incorrect for both numerals. The relation defined in this way does not have internal structure and therefore it is suitable for exploring elementary structures and patterns. As the relation expresses similarity, we use graph visual representations (Freeman, 2005), Johnson’s hierarchical clustering (Johnson, 1967), structural equivalence (Breiger, Boorman, & Arabie, 1975; Burt, 1976) and tie betweenness for cohesive subgroups (Girvan & Newman, 2002). These techniques have been implemented in computer codes as Netdraw (Borgatti, 2002) and UCINET (Borgatti, Everett & Freeman, 2002).

Visual exploration: Low dimensional graph representations of networks are often used to organize nodes and ties in landscapes where the location of a node is related to its actual location in the network. We use a spring embedded model with node repulsion, equal edge length and similitude

by geodesic distances. (Borgatti, 2002; Freeman, 2005; Wasserman & Faust, 1994)

Proximity clustering: Johnson's hierarchical clustering identifies clusters from correlations. (Borgatti, Everett, & Freeman, 2002; Johnson, 1967; Wasserman & Faust, 1994) It uses similarities or dissimilarities to find a series of nested partitions by departing from N partitions, each one with a node, and joining partitions in successive steps according to their relative distance from adding individual distances to other nodes.

Structural equivalence: Nodes with structurally equivalent positions in the network have identical relational profiles and are tied to the same nodes. We use two techniques to identify structural equivalence: Convergence of iterated correlations between profile vectors (CONCOR), based on Pearson's correlation (Borgatti, Everett, & Freeman, 2002; Breiger, Boorman, & Arabie, 1975; Lerner, 2005; Wasserman & Faust, 1994), and the Euclidean distance from each node to all other nodes (Borgatti, Everett, & Freeman, 2002; Burt, 1976; Wasserman & Faust, 1994).

Clustering by tie betweenness: Freeman (1979) defined betweenness centrality for a vertex or node as the number of shortest paths between any other two nodes passing by the node. Girvan and Newman (2002) extended this concept in order to identify cohesive subgroups by removing ties or links with the highest values of betweenness. This method relies on the fact that a tie linking two non-overlapping clusters must have the highest betweenness in the graph. In our analysis we combine successive weak strength and high betweenness ties removal to identify clusters.

Results

The results from applying the selected analysis techniques to children's production are presented for each grade including frequency analysis, visual exploration, proximity clustering, structural equivalence and tie betweenness.

First grade children's production included 1.047 (44.7%) correct answers from 2.340 dictated numerals (36 numerals to 65 children). The highest frequency of correct answers was for naught numerals (40%), then for *a0c* (25%), *ab0* (18%) and *abc* (17%) numerals. Table 1. The mean of correct answers for child is 29 (SD 11); for naught numerals 47 (SD 6.5), *a0c* 29 (SD 2.5), *ab0* 21 (SD 2.6), and *abc* numerals 20 (SD 2.7). All clustering techniques confirm the existence of three subgroups: 1) *a00*; 2) *a0c*; 3) *ab0* and *abc*. Figure 1 shows the graph obtained with Netdraw (Borgatti, 2002). The ties between numerals in the graph have at least 53 children each. Shapes of nodes indicate numeral classification: *abc*, *ab0*, *a0c*, *a00*.

Second grade children's production included 1.613 correct answers from 4.366 dictated numerals (37.0%). The highest percentage of correct answers was for naught numerals (*a000*) (78.8%), then for *a00d* (49.9%), *ab00* (45.8%), *abc0* (39.7%), *abcd* (34.0%), *a0c0* (27.4%) and *a0cd* numerals (24.2%). See Table 1. The mean and standard deviation (SD) of correct answers per child are: for naught numerals 51.2 (SD 4.2), for *a00d* 32.4 (SD 3.8), for

ab00 29.5 (SD 1.4), for *abc0* 25.8 (SD 4.1), for *abcd* 22.1 (SD 3.2), for *ab0d* 19.8 (SD 4.1), for *a0c0* 17.8 (SD 1.8) and for *a0cd* numerals 15.7 (SD 3.1). Numbers with verbal expressions in the Hundred position (*abxx*) have 38.2% of correct answers and numbers without verbal expression in the Hundred position (*a0xx*) have 31.4%. For *abxx* numerals the mean of correct answers per child is 24.8 (SD 4.5) and for *a0cx* numerals 16.4 (SD 2.5).

Frequency analysis, Johnson's hierarchical clustering, structural equivalence from Euclidean distances and tie betweenness indicates the existence of four main subgroups: Naught numerals, *a00d*, *a0cx*; and *abxx* numerals. However, structural equivalence from CONCOR gives four subgroups: two for naught numerals (one containing 3000, 6000, 8000 and 9000), one for *a0xx* and one for *abxx* numerals. Results from CONCOR have to be considered because the main ability of this technique is to recognize

patterns. Figure 2 shows the graph obtained with Netdraw (Borgatti, 2002). The ties between numerals in the graph have at least 55 children each. Shapes of nodes indicate numeral classification: *abcd*, *abc0*, *ab0d*, *ab00*, *a0cd*, *a0c0*, *a00d*, *a000*.

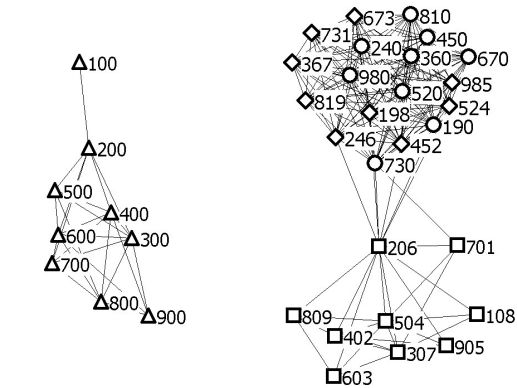

Figure 1: Graph for the relation between numerals in first grade children’s productions.

Third grade children’s production included 1.992 correct answers from 3.672 dictated numerals (54.3%). The highest achievement was for naught numerals (*a0000*) (73.8%). Numerals with verbal expression in the Hundred position (*axcxx*) are more frequently correct (55.8%) than numerals without verbal expression on this position (*ax0xx*) (39.7%), excluding naught numerals. The mean of correct answers per child for *axcxx* numerals is 38.2 with SD 3.8 and for *ax0xx* is 27.9 with SD 3.3. (See Table 1)

Figure 2: Graph for the relation between numerals in second grade children’s productions.

Frequency analysis, visual exploration (Figure 3), Johnson’s hierarchical clustering, structural equivalence from Euclidean distances and tie betweenness are consistent with the existence of three main subgroups: Naught numerals, *ax0xx* and *axcxx* numerals. Structural equivalence from CONCOR gives six subgroups: Naught numerals excluding 60000; *ax0xx* excluding naught numerals; *axcxx* excluding 90307, 24731 and 35246; 90307; 60000 and

24731; and 35246 (See Table 2). This classification is consistent with a differentiation between *axcxx* and *ax0xx* numerals.

Figure 3: Graph for the relation between numerals in third grade children’s productions.

Table 2: Numeral clustering for third grade.

										98367	3	4	3	3

Discussion

First grade results show the existence of three subgroups of numerals in children’s production: naught numerals, *a0c* and *abx* numerals. None of the analysis techniques shows any internal structure in the subgroups indicating that each one is homogeneous. Power & Dal Martello (1990) also

found differences in children's production between numerals ending in 00 (*a00*), numerals with internal zero (*a0c*), and numerals without internal zero (*ab0*, *abc*). Seron and Fayol (1994) predicted the following order of acquisition $a00 > a0c > abc = ab0$. They did not find other significant difference between the proposed forms. Their results are consistent with a higher frequency of errors for *ab0* and *abc* numerals than for *a0c* numerals. For Barrouillet *et al.*, (2004) the Decade-Unit form (*bc*) in *abc* numerals and the Decade form (*b0*) in *ab0* numerals are retrieved from LTM as representational units and the error rate did not present any significant difference between the two forms in three and four digit numbers. In our results *ab0* and *abc* numerals are both similar and equivalent.

For second grade, results indicate the existence of four main subgroups: 1) naught numerals, 2) *a00d*, 3) *a0cx*, and 4) *abxx*. One clustering technique, CONCOR, indicates that *a00c* and *a0cx* numerals should belong to the same subgroup, in agreement with Figure 2. Additionally, in our study the *a00d* numeral with the highest rate of correct answers was 2008, which has the same structure as the number of the year when the experimental testing was done. We consider that this fact might have influenced the production of *a00d* numerals.

We interpret these results as that the presence or absence of a verbal expression in the Hundred position of the dictated numeral determines the digital production. In the case of Spanish, three types of expressions are assigned to the Hundred verbal expression: *cien* for one hundred, *quinientos* for five hundred and *cientos* accompanied by a prefix in all other cases as in *trescientos* for three hundred. Note that *a1xx* numerals were more frequently correct than *abxx* ones (Table 1.).

An important difference between our results and Barrouillet *et al.*, (2004) is that they found higher rates of errors for the Unit form *0d* in *ax0d* than for the Decade form *c0* in *axc0* and the Decade-Unit for *cd* in *axcd*. Our results indicate the opposite situation in agreement with Power and Dal Martello (1990) and Seron and Fayol (1994).

In third grade production frequency analysis, visual exploration, Johnson's hierarchical clustering, structural equivalence and tie betweenness indicate the existence of three main subgroups: Naught numerals, *ax0xx* excluding naught numerals, and *axcxx* numerals. Note that *ax1xx* numerals were more frequently correct than *abxx* ones (Table 1.). Additionally, *ab00e* numerals obtained the lowest frequency of correct answers, in contrast with *a00d* numerals that obtained a high frequency in second grade children's production.

However, CONCOR neatly differentiates between *abcxx* and *a0cxx* numerals. This result is not consistent with Barrouillet *et al.*, (2004) proposal for Decade-Unit and Decade forms as being retrieved directly from LTM. Instead, it might be explained by considering that the difference between these forms is the number of operations for their construction (one product for Decade forms and one product and one sum for Decade-Unit forms), as

proposed by Barrouillet *et al.*, (2004) for complex Decade forms in French (e.g. *soixante-dix* for seventy and *quatre-vingt-dix* for ninety) or by Power and Dal Martello (1990).

Conclusions

First, the presence or absence of a verbal expression in the Hundred position of dictated four and five digit numerals generate differentiated structures in children's written production. This result indicates that the lexical (phonetic) structure in the oral verbal format interacts with the syntactic structure of Arabic digits in children's production in number transcoding.

Secondly, the difference found between *abcxx* and *a0cxx* numerals in children's production calls for new explicative efforts.

Finally, the method of analysis used gives valuable information that can not be obtained from frequency analysis or simple statistics.

Abstract

In this paper we will present evidence for language specific preferences in anaphor resolution from two series of experiments in English, German, and French. For within sentence anaphor resolution with “before” subclauses, we will show that English and German follow the generally assumed preference for the first mentioned NP or subject of the sentence, whereas French shows a clear preference for the object of the matrix clause. We will argue that our data can most easily be explained by a usage-based account, linking comprehension preferences to production preferences.

Keywords: Sentence processing; anaphor resolution; crosslinguistic differences; usage-based preferences

Introduction

It has been shown for many languages that the resolution of non-reflexive pronouns is strongly influenced by pragmatic factors such as topicality (in the sentence or in the discourse; Givon, 1983), the chain of causality, and other kinds of discourse relations (e.g. Kehler, 2002; Sanders & Noordman, 2000). On the sentence level, two of the factors that seem to play a role are a preference for the first mentioned antecedent (Gernsbacher, 1990), and a preference for the subject (Jaervikivi, van Gompel, Hyöna, & Bertram, 2005). These preferences are assumed to be valid across languages so that for subject-verb-object sentences like (1) a preference for the first noun phrase would generally be predicted, given that it is mentioned first and the subject at the same time.

(1) **English:** *The postman met the streetsweeper before he went home.*

French: *Le facteur a rencontré le balayeur avant qu'il rentre à la maison.*

German: *Der Briefträger hat den Strassenfeger getroffen bevor er nach Hause ging.*

More language specific predictions can be derived from accounts based on the availability of alternative constructions in the grammar of a particular language. According to the Gricean Maxim of Manner (Clarity), speakers should avoid ambiguous constructions in choosing unambiguous alternatives if they exist. If for an ambiguous construction an unambiguous alternative exists for one of the readings, listeners may thus assume that the speaker would have chosen this alternative for the respective reading. From this reasoning, a preference for the reading without an unambiguous alternative will result for the ambiguous construction.

In this paper, we will compare closely matched constructions in English, French, and German (see examples 2-5) to investigate cross-linguistic differences in pronoun resolution. What makes the comparison of these languages particularly interesting, is the distribution of alternative constructions for the different interpretations of an ambiguous sentence like (1): In French, a highly frequent construction exists for binding an anaphoric pronoun to the subject of the matrix clause (2) which does not exist for German.

- (2) **English:** *The street-sweeper met the postman before going home.*
French: *Le balayeur a rencontré le facteur avant de rentrer à la maison.*

Following the Gricean Maxim of Manner, the existence of this alternative predicts a preference for an object antecedent in sentences with full pronouns for French in contrast to the presumably saliency based preference for the subject for German. Listeners hearing a French sentence with “avant que” followed by a full pronoun will assume that the speaker would have used the unambiguous infinitival form in (2) had she intended the temporal clause to relate to the subject of the matrix clause. The pronoun is thus preferentially interpreted as relating to the object of the matrix clause for which no such alternative exists.¹

English is an interesting case for comparison, given that an alternative construction with a zero anaphor exists for subject antecedents (2). This construction is, however, used less frequently than the infinitival construction in French. Gricean accounts would thus predict that English patterns with French with respect to pronoun resolution.

An unambiguous alternative for one of the readings may also influence frequencies of usage. In a small scale corpus analyses (100 sentences per language) we established the following distribution: 77% subject antecedents for German (Frankfurter Rundschau), 64 % subject antecedents for English (Wall Street Journal) and 100 % (Le Monde) or 85% (Google News groups) object antecedents for French. Frequency based accounts would thus position English between German and French.

Experiments

Series 1: Visual World Experiments

In our first series of experiments, participants (32 native French speakers, 32 native English speakers, and 24 native German speakers) were presented with pictures such as in Figure 1 showing two characters while they listened to sentences such as (3-6). Their task was to judge whether a sentence presented aurally matched the picture or not. All 16 experimental trials were “match” cases. Half of the 4 practice items as well as of the 24 filler items were “mismatch” cases. Mismatches were realized by including characters in the sentence that were not in the picture (such as: “The florist prepared a bouquet for the street-sweeper”). Mismatches were realized at different positions during the sentence.

¹The same pattern would be predicted by Ariel’s (1990) accessibility hierarchy: less informative anaphora are predicted to prefer more salient antecedents. The zero anaphor in the infinitival construction in French, prefers the subject as the most salient antecedent. Using a full pronoun can thus be interpreted as a cue to search for a less salient antecedent which would be the object in sentences such as (1).

Materials: In our experimental materials, the subclause introduced by *before*, *avant que*, or *bevor*, was semantically biased for the High Antecedent (HA, the subject of the sentence which is situated higher in the phrase structural representation of the sentence, 3,5), or the Low Antecedent (LA) the object (4,6) of the main clause as antecedent of the pronoun. To control for visual scanning preferences, the first mentioned character was either on the left (3,4) or on the right (5,6) side of the screen. As a between participants factor, we also switched the position of the characters for half of the participants, so that, for example, the postman was on the right of the screen and the street sweeper on the left.

- (3) **French:** *Le facteur a rencontré le balayeur avant qu’il ramasse **les lettres**.*
English: *The postman met the street-sweeper before he picked up **the letters**.*
German: *Der Briefträger traf den Straßenfeger, bevor er **die Briefe** einsammelte.*
- (4) **French:** *Le facteur a rencontré le balayeur avant qu’il ramasse **la poubelle**.*
English: *The postman met the street-sweeper before he picked up **the trash**.*
German: *Der Briefträger traf den Straßenfeger, bevor er **den Abfall** einsammelte.*
- (5) **French:** *Le balayeur a rencontré le facteur avant qu’il ramasse **les lettres**.*
English: *The street-sweeper met the postman before he picked up **the letters**.*
German: *Der Straßenfeger traf den Briefträger, bevor er **die Briefe** einsammelte.*
- (6) **French:** *Le balayeur a rencontré le facteur avant qu’il ramasse **la poubelle**.*
English: *The street-sweeper met the postman before he picked up **the trash**.*
German: *Der Straßenfeger traf den Briefträger bevor er **den Abfall** einsammelte.*

Eight lists were created such that each item appeared in a different condition across lists, but only once in each list. Participants were first presented with four practice items followed by one of the eight lists of experimental items mixed with 24 filler items. The lists were randomized individually. Participants received course credits for their participations. Each experiment lasted less than 30 minutes including calibration. Eye movements were recorded using the Eyelink II® system by SR research.

Figure 1: Example of the visual stimulus material

Results: We calculated the likelihood of a gaze on either of the two critical picture elements by time steps of 20 ms starting from 500 ms before the onset of the pronoun (*he/she*) and ending at 2000 ms after the onset of the pronoun. From these data, we calculated the *logodds* for a gaze on the first-mentioned referent at each time step. Values below zero represent more fixations on the object, values above zero more fixations on the subject. Figure 2 shows the results for English, Figure 3 for German, and Figure 4 for French. HA means High Antecedent and corresponds to the subject, LA means Low Antecedent and corresponds to the object. “Left” and “right” correspond to the position of the subject on the picture.

Figure 2: Time course analysis for English; $\log_2(p(\text{sub}/p(\text{obj})))$, HA=High Antecedent, subject; LA=Low Antecedent, object

Figure 3: Time course analysis for German; $\log_2(p(\text{sub}/p(\text{obj})))$, HA=High Antecedent, subject; LA=Low Antecedent, object

Figure 4: Time course analysis for French; $\log_2(p(\text{sub}/p(\text{obj})))$, HA=High Antecedent, subject; LA=Low Antecedent, object

Before the onset of the pronoun, marked by the first vertical line in Figures 2 to 4, participants had a tendency to fixate the object more often than the subject (for German speakers, this tendency is somewhat modulated by the position of the object). This is not surprising, given that the object was the last mentioned entity in the matrix clause. After the onset of the pronoun, participants did not show any preference for a short period of time. This probably reflects the time needed to process the pronoun plus the time for planning a saccade (at least 230ms + 250 ms = 480 ms). After this period, German and English speakers fixated the subject more often than the object, whereas French speakers fixated the object more often. Disambiguation can only start playing a role after the onset of the disambiguating word plus at least 480 ms (given the time needed for processing and saccade planning). The dotted vertical line reflects the mean onset of the disambiguation, the third vertical line shows the earliest point possible for disambiguation to kick in. Participants start fixating the corresponding character more often after this point. Note that the onset of disambiguating is earlier in German due to German word order.

We defined three critical time periods for each individual trial: the 500 ms period before the onset of the pronoun (R1), the time period from the onset of the pronoun until 480 ms after the onset of the disambiguating region (R2), and the remaining time steps until 2000 ms (R3). For each participant and condition, respectively item and condition, we calculated a single *logodds* value per time period. The summarized data across conditions for English, German, and French are shown in Table 1.

Table 1: Average log odds for gazes on the first-mentioned referent, broken down by region. Ninety-five percent confidence limits are listed in parentheses (by subjects / by items).

Language	R1	R2	R3
English	-0.50 (±0.52/±0.43)	+0.34 (±0.28/±0.19)	+0.40 (±0.45 / ±0.32)
German	-0.09 (±0.51 / ±0.32)	+0.35 (±0.33 / ±0.34)	+1.14 (±0.22 / ±0.32)
French	-0.90 (±0.36 / ±0.28)	-0.38 (±0.30 / ±0.22)	-0.50 (±0.29 / ±0.29)

The eye movements show clear differences between the languages investigated. In the ambiguous region R2, we find a reliable preference to look at the subject of the matrix clause for English and German. In German, this extends even to the disambiguating region R3. In French, however, participants preferentially fixated the character corresponding to the object of the matrix clause.

One question remains to be answered at this point: Do the French fixation preferences reflect interpretational

preferences or possibly just differences in visual scanning patterns? Since the object of the matrix clause is at the same time the last entity mentioned before hearing the ambiguous pronoun, our French participants may have preferred to continue fixating the entity they just heard of until disambiguating information would be made available by the linguistic input. French participants did actually look at the character representing the object of the matrix clause more often than German and English participants even in Region 1. In order to test this possibility, we ran a further eye-tracking experiment with 32 native French speakers, using constructions with no structural alternative for either of the possible interpretations (7a-d). A subject preference would be predicted for these cases.

- (7) a. *Le facteur a rencontré le balayeur. Puis il a ramassé les lettres.*
The postman met the street-sweeper. Then he picked up **the letters**.
b. *Le facteur a rencontré le balayeur. Puis il a ramassé la poubelle.*
The postman met the street-sweeper. Then he picked up **the trash**.
c. *Le balayeur a rencontré le facteur. Puis il a ramassé les lettres.*
The street-sweeper met the postman. Then he picked up **the letters**.
d. *Le balayeur a rencontré le facteur. Puis il a ramassé la poubelle.*
The street-sweeper met the postman. Then he picked up **the trash**.

The set up of the experiment was identical to the earlier experiments. Since the preference for the more local referent could only be established for French, we will only present the French data here (see Figure 5).

Figure 5: Time course analysis for French between-sentence anaphor resolution; $\log_2(p(\text{sub})/p(\text{obj}))$, HA=High Antecedent, subject; LA= Low Antecedent, object

As in the earlier experiments, the French participants started with an increased number of fixations to the object of the first sentence. However, after a short period without any preferences right after the onset of the pronoun, they look

reliably more often at the character representing the subject of the matrix clause. Note, that the pictures we used in this experiment were identical to the ones used before. Clearly, French speakers do not have different visual scanning patterns. In cases where a subject preference is predicted, they clearly look at the character representing the subject more often, although the subject is the less local entity.

Figure 6 summarizes the results of all four experiments: Remember that values above zero reflect more looks to the subject, whereas values below zero reflect more looks to the object of the matrix/first clause. The most striking differences can be found in Regions 2 and 3: For within sentence pronoun resolution the subject is preferred as the antecedent for German and English, and likewise for between sentence anaphor resolution in French. The only deviating cases are French within sentence anaphors, showing a preference for the object.

Figure 6: Average log odds for gazes on the first-mentioned referent, broken down by region.

The fixation patterns are thus far compatible with the corpus frequencies mentioned above. We can, however, not be fully sure that they really reflect interpretational preferences and not just fixation preferences. We therefore ran a series of questionnaire studies in all three languages to clarify this issue.

Series 2: Questionnaires

Materials and procedure. In this series of experiments, we presented participants with ambiguous sentences derived from the materials used in the eye tracking experiments and asked them to fill a gap in a paraphrase following each sentence to indicate their interpretation of the pronoun.

- (7) **French:** *Le facteur a rencontré le balayeur avant qu'il rentre chez lui.*
Le _____ rentre chez lui.
English: *The postman met the street-sweeper before he went home.*
The _____ went home.

German: Der Briefträger hat den Straßenfeger getroffen, bevor er nach Hause ging.

Der _____ ging nach Hause.

We also included a cross-sentence condition (8), where the second sentence always started with “puis”, “then”, or “dann”.

(8) **French:** Le facteur a rencontré le balayeur. Puis il est rentré chez lui.

German: Der Briefträger hat den Straßenfeger getroffen. Dann ist er nach Hause gegangen.

English: The postman has met the street-sweeper. Then he went home.

To control for semantic/pragmatic biases, we switched the grammatical role of the characters as a between participants factor, so that, for example, the postman became the object of the matrix clause and the street sweeper became its subject. We created eight lists so that each item appeared in a different condition but only once in each list. The 16 experimental items were interspersed with 64 filler items mostly from unrelated experiments. Each list was randomized once. 32 native speakers of each language participated in the experiment.

Results. Figure 7 shows the results of the questionnaire experiments. All three languages showed a clear preference for the subject for between sentence pronoun resolution for sentences with “puis”, “then”, and “dann” (all ps < .01). However, whereas English and German participants chose the subject of the matrix clause more often as the antecedent of the pronoun for within sentence pronoun resolution as well, French participants chose reliably more often the object of the matrix clause.

Figure 7: Decisions in % for the subject or the object of the main/first clause as the antecedent of the pronoun.

Discussion

In our experiments, we established the following pattern:

- All three languages show a clear subject preference for between sentence pronoun resolution in sentences like (7) and (9).

- German and English, both show a subject preference for within sentence pronoun resolution (3-6, 7).
- French shows a clear object preference for within sentence pronoun resolution (3-6, 7).

An explanation of the differences between German and French before-sentences could be based on the Gricean Principle of Manner (avoid ambiguity). In French, the temporal clause can be unambiguously related to the subject of the matrix clause using an infinitival construction such as (2). In German, no such alternative construction exists. French listeners or readers might thus apply a Gricean logic taking the object of the matrix clause as the antecedent of the full pronoun in (1).

A Gricean account is, however, hard to reconcile with the English data: For English, an alternative construction relating the temporal clause to the subject is available as well (2). Still, the full pronoun in (1) consistently shows a clear preference for the subject across experiments. An experience-based account would be fully compatible with the results of the sentences with « before » as can be seen in the small scale corpus comparison study mentioned above (see Figure 8 for a direct comparison of off-line decisions and corpus data).

The Gricean Principle of Manner neither predicts production preferences nor comprehension preferences in English. This finding is very much in line with earlier evidence showing that speakers do not follow the Principle of Quantity (they very often produce more information than necessary in referring expressions, e.g., Pechmann, 1989), neither are they generally cooperative in using unambiguous alternatives for one of the possible interpretations of an unambiguous construction (Ferreira & Dell, 2000). Arnold, Wasow, T., Asudeh, and Alrenga (2004) likewise argue against sentence production as designed to be easily comprehensible for the audience, based on a consistent lack of ambiguity avoidance. The choice of linguistic expressions seems to be more affected by cognitive pressure than by cooperativeness (Wardlow & Ferreira, in press).

Figure 8: Decisions in % for the subject or the object of the main clause as the antecedent of the pronoun compared to corpus counts

However, we still have to explain why French and English should be different with respect to production

preferences: A reason why French speakers prefer producing an infinitival construction for subject antecedents may be the increased complexity of temporal clauses with « avant que »: The French conjunction “avant que” demands the subjunctive form as do many other conjunctions such as “puisque”, “pour que”, “bien que”, whereas others demand the indicative form, such as “après que”, “lorsque”, “parce que” and many others. The correct marking of the verb will thus have to be adapted to the respective conjunctions. Using the infinitival form avoids the necessity of checking which verb form to use in the actual utterance.² No such checking would be needed for English conjunction-plus-pronoun sentences which consistently demand the indicative form.

The results so far would thus be fully compatible with an approach linking comprehension preferences to production preferences (Cuetos & Mitchell, 1988; Gennari & MacDonalds, 2009, Konieczny, 2000). French speakers prefer using the infinitival form whenever possible, which is the case when the infinitival clause is related to the subject of the matrix sentence. “Avant que” plus pronoun will thus mostly be used in cases where the pronoun is related to a non-subject antecedent. These production preferences will result in the distributions observed in the corpora. Exposure to these distributions will consequently shape preferences in comprehension.

We do, of course, by no means imply that pronoun resolution preferences are based on exposure exclusively. Factors such as information structure, coherence relations and others are most certainly playing a role as well. An interesting question for further research will be, in how far the crosslinguistic differences established in our experiments extend to other conjunctions, and in how far they interact with factors influencing the prominence of antecedents such as first mention, topicality, prominence, and many more (Colonna, Schimke, & Hemforth, 2009; Schimke, Colonna, & Hemforth, 2009). We will also have to extend our research to other languages. Interestingly, European Portuguese provides a combination of alternatives highly comparable to what can be found in French. Recent self-paced reading experiments and questionnaire studies (Baumann, Konieczny, & Hemforth, 2010) show a clear object preference for pronouns in Portuguese constructions parallel to those under investigation in this paper.

Ariel, M. (1990) *Accessing Noun-Phrase Antecedents*. Routledge, London.

²French native speakers are actually not always fully sure of which form to use. A short questionnaire sent by mail to 20 doctoral students (mostly from the linguistics department) asking for the correct verb to use in sentences like “Le balayeur a appelé le facteur après qu'il _____ rentré à la maison.” (The street sweeper called the postman after he _____ gone home.), resulted in 56 % responses using the subjunctive and 44 % using the indicative. Following normative grammar, “après que” does not demand the subjunctive.

Abstract

State-trace analysis is a non-parametric method that can identify the number of latent variables (dimensionality) required to explain the effect of two or more experimental factors on performance. Heathcote, Brown, and Prince (submitted) recently proposed a Bayes Factor method for estimating the evidence favoring one or more than one latent variable in a state-trace experiment, known as Bayesian Ordinal Analysis of State-Traces (BOAST). We report results from a series of simulations indicating that for larger sample sizes BOAST performs well in identifying dimensionality for single and multiple latent variable models. A method of group analysis convenient for smaller sample sizes is presented with mixed results across experimental designs. We use the simulation results to provide guidance on designing state-trace experiments to maximize the probability of correct classification of dimensionality.

Keywords: State-trace analysis; Bayesian analysis; Bayes Factor; Encompassing prior method; Simulation.

State-Trace Analysis

State-trace analysis (Bamber, 1979), also known as dimensional analysis (Loftus, Oberg, & Dillon, 2004), is a method for determining whether a single latent variable is capable of explaining the joint effect of two experimental factors. Dimensionality is traditionally assessed by testing for an interaction between the two factors. However, interactions can be scale dependent (e.g., distorted by floor or ceiling effects) when response variables are bounded (e.g., accuracy data, see Dunn & Kirsner, 1988; Loftus, 1978). State-trace analysis overcomes this problem by assessing the ordinal relationships between the effects of experimental factors. One factor is comprised of a set of indicator variables, and is referred to as the *state factor*. A second factor is a variable thought to differentially influence performance over levels of the state factor, and is referred to as the *dimension factor*.

State-trace analysis is most easily described by an example. For this purpose we use the *disproportionate face inversion effect* (DFIE), the finding in perceptual and recognition memory studies that stimulus inversion has a more deleterious effect on faces than other mono-oriented stimuli (Valentine, 1988; Yin, 1969). This result has been taken to suggest that faces are encoded along a ‘configural’ dimension that is not available to mono-oriented non-face stimuli (e.g., houses; Maurer, Le Grand, & Mondloch, 2002). In this example, stimulus type (faces or houses) is the state factor and stimulus orientation (upright or inverted) is the dimension factor, as inversion is thought to differentially affect memory for faces and houses.

State-trace analysis results are shown in a state-trace plot: a scatterplot of the co-variation of performance for the levels of the state factor (e.g., faces or houses). Memory accuracy results for the two levels of the state factor form the two axes of the state-trace plot. Each point on the plot represents a pair of measurements, with a pair of (x,y) coordinates for each level of the dimension factor (e.g., upright and inverted). For our example there would be two coordinate pairs on the state-trace plot, one for upright stimuli and one for inverted stimuli. To infer dimensionality a third variable, referred to as a *trace factor*, is added to the state-trace design. The trace factor sweeps out a set of coordinate pairs for each level of the dimension factor. Levels of the trace factor within each level of the dimension factor are usually connected with a line in the state-trace plot, with each line referred to as a *data trace*.

Latent dimensionality is identified by assessing whether all of the data points in the state-trace plot fall on a single monotonic (i.e., always increasing or always decreasing) function, indicating evidence for a single latent variable. Monotonicity holds if all of the x axis values in a state-trace plot have the same order as the y axis values. Although a monotonic plot is necessary to infer a single latent variable, it is not sufficient: monotonicity cannot be diagnostic unless the data traces overlap on at least one axis. Hence, an assessment of whether data traces overlap is essential to a proper assessment of dimensionality. Similarly, it is important to establish that the trace factor does not itself affect dimensionality, so that results in favor of more than one dimension can be unambiguously attributed to the effect of the dimension factor. This can be checked by determining if the trace factor has a monotonic effect within each level of the dimension factor.

A Bayesian Approach to State-Trace Analysis

Given an observed state-trace plot, where the effects of the underlying latent variable(s) are perturbed by measurement error, how can we determine whether a monotonic curve best describes the data? A number of statistical methods for assessing departures from monotonicity have been suggested (see Loftus et al., 2004; Newell & Dunn, 2008). Recently Heathcote et al. (submitted) proposed a Bayes Factor approach to state-trace model selection, known as Bayesian Ordinal Analysis of State-Traces (BOAST), based on Klugkist, Laudy, and Hoijtink’s (2005) encompassing prior method. The encompassing prior method uses Bayes Factors to select

among models defined by inequalities. The advantage of this approach is that it automatically accounts for differences in flexibility amongst models, which is a key issue in state-trace analysis as a one-dimensional model is far less flexible than a multi-dimensional model.

BOAST assumes binomially distributed data (e.g., a binary two-alternative forced choice response used to measure recognition accuracy in the DFIE example), with state-trace models being defined by sets of inequality constraints on binomial probability parameters. For example, we define a ‘trace’ model, which instantiates the assumption that the trace factor does not change dimensionality, by specifying that the trace factor has a monotonic effect on performance within each level of the dimension factor. This specification implies that, for a trace factor with three levels and an overall increasing effect on accuracy, that accuracy is smaller for the first level of the trace factor than the second level, and smaller for the second level than the third. The trace model is, therefore, an order constrained special case of an ‘encompassing’ model that places no restrictions on the order of parameters.

When model M_i is an order constrained version of an encompassing model M_k , Bayes Factors can be estimated from prior and posterior samples from the encompassing model (Klugkist, Kato, & Hoijtink, 2005). The proportion of prior ($\hat{\pi}$) and posterior ($\hat{\Pi}$) samples that adhere to the order constraints of the more restricted model M_i are used to estimate a Bayes Factor from the ratio of the two sample counts,

$$BF_{ik} \approx \frac{\hat{\Pi}}{\hat{\pi}}. \quad (1)$$

This Bayes Factor indicates the strength of evidence in favor of M_i over M_k . Intuitively this is the case because it is the ratio of the probability that the model fits the data before the data are observed, which is proportional to the complexity of the model (e.g., the maximally complex encompassing model will always fit any data pattern), to the actual fit of the model to the data. If this ratio is greater than one it indicates that the model fits better than chance.

A set of such Bayes Factors, assuming the same encompassing model, can be used to compare a set of order-restricted models by calculating each models posterior model probability, $p(M_i|D)$, given observed data D . The quantity $p(M_i|D)$ is the probability that model M_i is the ‘true’ (data generating) model, on the assumption that one model in the set is the true model. Model selection based on $p(M_i|D)$ can also be justified on other grounds, even when the set does not contain the true model (e.g., it selects the model that is most likely to minimize a measure of error in predicting new data), so we refer to it simply as a method of selecting the ‘best’ model. For a set of models M_i , $1 \dots m$ that are assumed to have a probability p_i of being the best model prior to observing the data, the posterior model probability for M_i is:

$$p(M_i|D) = \frac{p_i \times BF_{ik}}{\sum_{j=1}^m p_j \times BF_{jk}} \quad (2)$$

for any $k = 1 \dots m$ which includes i . Throughout we assume each model is equally likely to be the best model before observing the data.

Our aim here is to assess, via simulation, how often BOAST analysis selects the correct number of latent variables, either one or more than one. We begin by simulating an individual participant analysis. We then examine a method of aggregating participant results to select the best characterization of dimensionality for a group of participants.

Simulations

Figure 1 shows state-trace data consistent with a single latent variable model (1D) and a two latent variable model (2D). In both cases the trace factor has a clear monotonic effect on performance; that is, as the level of the trace factor increases so too does the dependent variable. The two models also both exhibit moderate and equal data trace overlap. These two patterns were used to generate simulated data (by using their coordinates to specify binomial probability parameters) and we will refer to them as the 1D and 2D models.

Figure 1: The two models on which simulations were based. $p(\text{State 1})$ and $p(\text{State 2})$ refer to the proportion of correct responses for the first and second level of the state factor, respectively. The two lines on each plot represent data traces, one for each level of the dimension factor. The solid lines are identical for both models, and the dashed line for the 2D model is the same as the dashed line for the 1D model but transposed downward by 0.1.

We next elaborated the 1D and 2D models with 2 trace levels shown in Figure 1, which we call the $T2$ designs, by creating variants with three and four trace levels, $T3$ and $T4$ designs respectively. In $T2$ designs the two levels of the trace factor provided data for the end points of the data traces. For $T3$ and $T4$ designs the additional levels were evenly spaced between the end points of each data trace. One purpose of these simulations was to provide guidance on experimental design in terms of the trade-off between number of trials contributing to the estimates of each point in the state-trace plot and the number of levels in the trace factor. For a fixed sample size (number of trials) there is a trade-off between these two factors, with more trace levels resulting in fewer trials

per point. For each model and each T we explored 6 total trial numbers (n) with total n conserved across each T at 192, 384, 768, 1536, 3072 and 6144. For example, a model with $n = 192$ had 24 observations per coordinate of each point for $T2$, 16 observations for $T3$, and 12 observations for $T4$. In total we performed 36 simulations (2 models \times 3 trace levels \times 6 sample sizes). For each simulation 1000 Monte Carlo replicates were sampled from binomial distributions with parameters determined by the design and model. Sufficient posterior samples were obtained so that posterior proportions of monotonic samples had 90% credible intervals less than 0.025; prior proportions were determined analytically assuming a uniform prior (see Heathcote et al., submitted, for details).

BOAST Results

For each simulation we estimated Bayes Factors to test four mutually exclusive models, which we refer to as the non-trace (NT), no-overlap (NO), unidimensional (UD) and multidimensional (MD) models. Together these models account for all possible orders (i.e., together they constitute the encompassing model). Posterior model probabilities were calculated for each Monte Carlo replicate for each model by dividing each Bayes Factor by the sum of all four Bayes Factors (i.e., Equation 2), which we refer to as $p(\text{NT})$, $p(\text{NO})$, $p(\text{UD})$ and $p(\text{MD})$, respectively. Figure 2 illustrates results in terms of the proportion of comparisons selecting one of the four models (i.e., where the models posterior probability was greatest amongst the set of four models). Figure 2 can be interpreted by comparing the height of corresponding points across the panels in each row. In particular, the ‘highest’ point indicates which of the four models is most often supported.

The Trace Model

An important first check in any state-trace analysis is to determine whether the trace model is supported. For example, we described study duration as a possible trace factor. In this case the trace model indicates that accuracy increased as study durations became longer for both levels of the state and dimension factors. In contrast, support for the non-trace model indicates that the order dictated by the trace factor was violated. Even when the trace model is the data generating model, measurement noise can cause violations of the trace model (i.e., support for the non-trace model) to arise more frequently when differences between levels of the study duration factor produce only small changes in accuracy. Support for the non-trace model clouds any conclusions about underlying dimensionality of the state factor since the effects of the dimension and trace factors are confounded, and can suggest that the experimental design needs to be improved by using more widely spaced trace factor levels.

The non-trace model results are shown in the left column of Figure 2. The figure demonstrates a number of key points. As expected, evidence for the trace model is similar across both 1D and 2D simulations, since the trace factor should

have a consistent effect irrespective of underlying dimensionality. Secondly, as total sample size increases the lines always approach zero, indicating consistent selection of the trace model. That is, BOAST recovers the trace model with increasing reliability as measurement error decreases due to an increase in sample size. Finally, the probability of selecting the non-trace model approached zero with lower total trials for $T2$ compared to $T3$ and $T4$. As seen in Figure 2, selection is approximately zero for $T2$ at $n = 768$, whereas this increased to $n = 1536$ for $T3$ and $T4$ in the 1D model, and to $n = 3072$ for $T4$ in the 2D model. Thus, for smaller n , the trace model had a greater chance of being supported in $T2$ designs compared to $T3$ and $T4$ designs. This occurs because the combination of a smaller sample size (and hence greater measurement noise) and closer spacing between results for adjacent trace levels as T increases makes a violation of monotonicity within a data trace more likely.

The No-Overlap Model

When the trace model holds it implies that one of the three remaining models best describes the data, as they are each trace models. A monotonic state-trace plot is a special case of the trace model where all data points have the same ordering for both levels of the state factor. A non-overlapping monotonic plot is a case where data traces for both levels of the dimension factor do not cross over at any point along either axis of the state-trace plot. In this case, monotonicity is not diagnostic of dimensionality, as both one-dimensional and multi-dimensional data generating models produce monotonic state-trace plots when there is a failure of data trace overlap. Hence, an important second check in a state-trace analysis is to determine whether the no-overlap model holds.

Results for the no-overlap model differed between the 1D and 2D data generating models. The 1D simulations results generally give some support for the no-overlap model, which is perhaps not surprising given the the 1D model produces monotonic data. Of more concern is the fact that this support was inconsistent as a function of sample size, n , for $T4$ and to a lesser degree for $T3$. That is, support for the no-overlap model initially increased with n , but then decreased, from $n = 1536$ for the $T4$ design and from $n = 768$ for the $T3$ design. In contrast, the no-overlap model consistently received little support across all T and n in the 2D simulations. Overall, these results suggest that when there is in fact trace overlap in a one-dimensional data generating model, the no-overlap model is more often rejected in designs with fewer trace levels.

The Unidimensional and Multidimensional Models

For both data generating models the unidimensional and multidimensional posterior model probabilities provided support for the true model dimensionality. For the 1D case support for the unidimensional model (middle right column of Figure 2) increased with sample size, but the level of support was smaller for larger T . For the 2D case support for the multidimensional model (right column of Figure 2) also in-

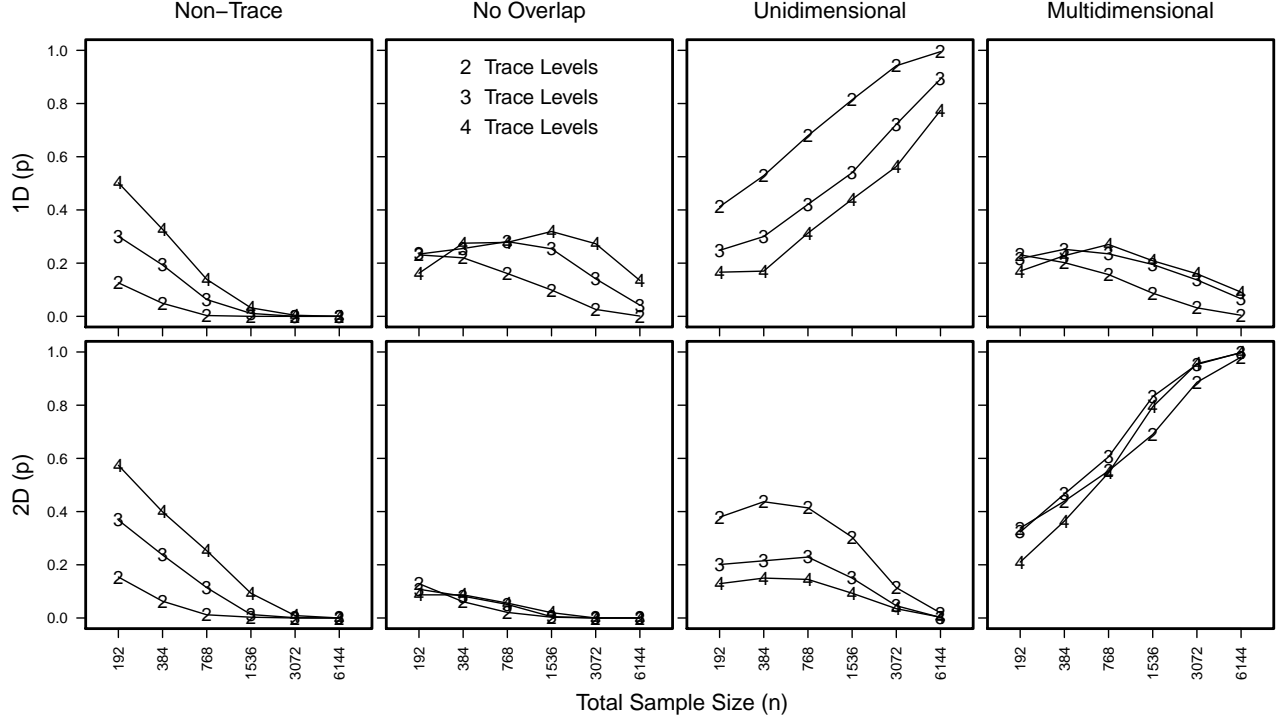

Figure 2: Model selection results for both data generating models, type of comparison, number of trace levels, T , and number of ‘trials’, n . Columns correspond to each of the mutually exclusive models being tested and rows to the type of the data generating model. On each plot the x axis represents the six levels of n and the y axis represents the proportion of simulations in which posterior model probability favored the model specified for each column. The lines group designs with the same T .

creased with sample size. In contrast to the 1D case, the level of support was similar for all T , although it was slightly less for the $T4$ design for smaller n (likely reflecting the larger level of support for the non-trace model) and slightly less for the $T2$ design for the second and third largest value of n , with all T designs perfectly selecting the true model for the largest sample size. Across the 1D and 2D data generating models support for the wrong dimensionality was generally low and decreased with sample size, although there was some inconsistency for the three smallest sample sizes.

Overall, the results of the simulation study indicate that accurate results for all comparisons can only be guaranteed for quite large sample sizes. This indicates that analysis of individual participant data may not produce clear results in applications where it is not possible to measure performance on a large number of trials for each individual. In such situations it would be desirable to have a method of combining results over participants in a way that improves correct identification at the group level. In the next section we extend the analysis of our simulation results to assess the performance of one such method suggested by Heathcote et al. (submitted), the group Bayes Factor.

Group Bayes Factors

A Bayes Factor for a group of participants, assuming each participant contributes independent evidence, can be obtained

by taking the product of each participants Bayes Factor. Hence, a group Bayes Factor for a model M_i is given by $GBF_i = \prod_{j=1}^N BF_{ij}$, where N is the number of subjects. Group Bayes Factors can then be combined to obtain a posterior model probability for model M_i at the group level. Again we assume each model is equally likely to be the best model before observing the data, and so:

$$p(M_i|D) = \frac{GBF_i}{\sum_{k=1}^m GBF_k} \quad (3)$$

for a set of $k = 1 \dots m$ models that includes model i .

We examined the utility of group Bayes Factors using the simulations from the previous section. For each simulation we sampled with replacement (i.e., resampled) sets of individual Bayes Factors from the 1000 available. The sets were of sizes (N) 8, 16 and 32, representing experiments with different numbers of participants. These N 's cross with total trials n in a balanced manner. For example, a set of $N = 32$ with $n = 192$ trials provides results from a total of 6144 trials, equivalent to the set $N = 16$ with $n = 384$ trials, and $N = 8$ with $n = 768$ trials. The resampling procedure was repeated 500 times for each possible grouping: two data generating models (1D, 2D), with three trace levels ($T2$, $T3$, $T4$), three total trial sizes ($n = 192, 384, 768$), and three participant sample sizes ($N = 8, 16, 32$), for each of the four comparisons (non-trace, no-overlap, unidimensional, multidimensional), a

Figure 3: Group level results for the 216 comparisons. The rows and columns represent the same data generating models and comparisons as Figure 2. On each plot, the x axis represents the three levels of N that were resampled for each of $n = 192, 384, 768$, and the y axis represents the proportion of cases in which the posterior model probability at the group level favored the model specified for each column.

total of 216 combinations ($3^3 \times 2 \text{ models} \times 4 \text{ comparisons}$). For each of the 500 repetitions of the 216 combinations we estimated group Bayes Factors, and then calculated the proportion of comparisons selecting one of the four models (i.e., where the models posterior probability was greatest amongst the set of four models), with results shown in Figure 3.

For the no-overlap model the group Bayes Factors results were much the same as for the individual analysis, except that the inconsistent effect of sample size for the individual analysis of the 1D data generating model disappeared in the group analysis. For the trace model performance was excellent when $n = 768$ but the wrong (non-trace) model received increasing support when there were fewer observations per participant for all but the $T2$ design. These problems with the trace model caused corresponding failures to identify the correct dimensionality for lower values of n , whereas for $n = 768$ performance in identifying dimensionality was similar to that of the largest samples sizes in the individual analysis. In particular, the 2D data generating model was almost perfectly identified, but with higher T designs being slightly better, whereas performance in classifying the 1D data generating model was very good for $T2$ designs but decreased markedly for the $T3$ and $T4$ designs.

Conclusions

We aimed to investigate the ability of BOAST analysis to identify latent dimensionality. The results of individual par-

ticipant data indicated that large sample sizes produced strong support for the correct outcome for both 1D and 2D data generating models across designs with two, three and four levels in the trace factor. Classification for the 1D data generating model was most reliable in designs with two trace levels, whereas the opposite tendency was evident for the 2D data generating model; dimensionality assessment was more accurate with larger numbers of trace levels. Overall these results indicate that a design with three trace levels provides the best compromise for accurate diagnosis of both single and multiple latent variable data generating models.

We also explored a group analysis procedure that is advantageous where it is practically difficult to obtain a large number of responses from each individual participant, such as in cases where the number of available stimuli is limited, but where larger numbers of participants are available. Generally, this method was found to be very effective in identifying the 2D data generating model. However, our results indicate that it should be used with caution as it could be biased against detecting cases in which only one latent variable is present in certain experimental designs. When each participant contributed a smaller number of responses (192 or 384) results could be inaccurate even for the largest number of participants (32). For 768 observations per participant performance was more accurate and improved with group size for the 1D

data generating model. In contrast to the individual participant results, the group level analyses indicate that designs with two levels in the trace factor produce the best compromise of most accurate classification across number of trials per participant and different numbers of participants for both 1D and 2D data generating models. However, these results should be used with some caution given the three and four trace level designs demonstrated a large proportion of cases supporting the non-trace model (possibly due to the small experimental effects of the trace factor in these larger trace level designs), which had strong consequences for the correct classification of dimensionality.

Our individual and group analyses indicate that the ideal number of trace levels in a state-trace experiment is dependent on the intended approach to data collection. If only a small number of trials per participant are obtainable it seems wiser to use a trace factor with few levels so as to maximise data per point, and then combine across participants with group Bayes Factors. In contrast, if many trials per participant can be obtained, correct classification of dimensionality is possible with a three level trace factor through individual participant analysis, which confers additional benefits such as the exploration of individual differences in performance.

In summary, these results indicate that the success of BOAST analysis, and likely any state-trace analysis method, depends strongly on the particular model producing the state-trace plot. This highlights a caveat on our group analysis, which assumes all participants have an identical underlying model (rather than just having the same dimensionality but possibly different magnitudes of the effects of experimental factors). As well as being unrealistic, this assumption likely magnifies the effects of a particular data pattern. In ongoing research we will simulate groups of participants that vary in the effects of experimental factors (while maintaining a consistent dimensionality) in order to check the generality of the group analysis results reported here.

Abstract

Recent work has shown that individual differences in language development are related to differences in procedural learning, as measured by the serial reaction time (SRT) task. Performance on this task has also been shown to be associated with common genetic variants in *FOXP2*. To investigate what these differences can tell us about the functional properties of language processing, we present a computational model of the SRT task. We varied parameters in the model to observe their effects on performance in the task. We found that the combined effect of several model parameters produced changes in the learning trajectory that were similar to those observed behaviorally.

Keywords: language processing; specific language impairment; *FOXP2*; procedural learning; serial reaction time task; computational modeling; simple recurrent networks

Introduction

The mechanisms that underlie language use emerge over the course of development through the integration of multiple biological and environmental factors (Elman et al., 1997). Much previous research has focused on whether these mechanisms are language-specific or domain-general (Christiansen & Chater, 2008). Regardless of which is the case, we must specify how different factors interact to give rise to language.

One way to study the mechanisms involved in language is to look at individual differences in language ability. Recently, the use of molecular genetics has emerged as a tool for investigating these differences. However, the use of genetics to study complex cognitive processes, like language, presents a challenge: how do we address questions regarding the role of genes when they are so far removed from language processing? Similarly, how do we assess the role of individual genes when it is unlikely that there is a one-to-one correspondence between genes and specific characteristics of language?

As a first step, we need a way to observe the effects of functional properties of language processing on behavior. Computational models offer a tool for doing this. The units in a neural network model, for instance, correspond to functional (rather than structural) units in the system. Thus, computational models may be useful for examining how genetic factors relate to the functional organization of cognitive systems.

The aim of the current paper is to investigate the relationship between individual differences (both differences in language ability and genetic differences) and functional properties of language processing using a computational model of the serial reaction time (SRT) task. The SRT task measures participants' ability to learn pattern sequences. Variation in performance on the SRT task has been associated with both language ability (Tomblin, Mainela-Arnold, & Zhang, 2007b) and genetic differences (Tomblin, Christiansen, Bjork, Iyengar, & Murray, 2007a). Given this, and the fact that sequence processing is a critical component of language use, this task provides a useful paradigm for studying these relationships.

Individual differences in language abilities

One area in which differences in language ability have been extensively studied is specific language impairment (SLI). SLI is a relatively common developmental disorder characterized by difficulty acquiring language in the absence of gross cognitive or sensory impairments, and despite adequate experience and educational opportunities (Tomblin, Records, & Zhang, 1996). Typically, research criteria for SLI classification require that the individual falls 1.15 SD below the mean on a range of standardized assessments of language while falling in the normal range for non-verbal intelligence (Tomblin et al., 1996).

Children with SLI have deficits in various language abilities, such as morpho-syntactic processing, phonological processing, word learning, and spoken word recognition (Leonard, 1998; McGregor, Newman, Reilly, & Capone, 2002; McMurray, Samelson, Lee, & Tomblin, 2010). In many ways, these children demonstrate language abilities associated with typically developing younger peers. They have smaller vocabularies, use shorter, simpler syntactical constructions, and make more morphological errors than would be expected for children their age (McGregor, Friedman, Reilly, & Newman, 2002).

A range of possible hypotheses for SLI have been proposed, and include deficits in temporal-perceptual processing, generalized slowing, problems with phonological processing, and deficits in working memory (Bishop, North, & Donlan,

1996). Thus, the underlying causes remain unclear, though it is likely that SLI is multiply determined.

Genetic factors and language

Genetics is now commonly employed as a tool for investigating differences in language development. Initial molecular studies centered on the KE family, a multigenerational pedigree that appears to show an autosomal dominant pattern of language impairment (Hurst, Baraitser, Auger, Graham, & Norell, 1990). Affected individuals have been characterized as having apraxia of speech, as well as expressive and receptive language problems (Vargha-Khadem, Watkin, Alcock, Fletcher, & Passingham, 1998). They also have a rare genetic mutation in the *FOXP2* (forkhead box P2) gene (Lai, Fisher, Hurst, Vargha-Khadem, & Monaco, 2001). More recently, Mueller, Bjork, Tomblin, and Murray (in preparation) investigated the role of more common genetic variants in *FOXP2*. These variants were single nucleotide polymorphisms (SNPs), which represent differences in a single base pair in the genome. They examined multiple SNPs in a population with a range of language abilities and found an association between SNPs in the promoter region and language ability as a discrete phenotype. This suggests that these common variants of *FOXP2* also play a role in language development.

FOXP2 is expressed in multiple species as well as several different organs, including the lungs and brain (Shu et al., 2007; Fujita et al., 2008). This has led some to argue that the link between *FOXP2* and language is weak. However, the fact that *FOXP2* is neither species- nor domain-specific means it is likely to play a role in multiple cognitive processes. In addition, since *FOXP2* is a transcription factor (i.e., encodes a regulatory protein that affects gene expression), it is possible to identify other elements of the gene pathway (and therefore the systems) in which it exists (Vernes et al., 2008).

A more general role for *FOXP2* fits with the hypothesis that language itself is shaped by domain-general processes (Christiansen & Chater, 2008). Statistical learning plays an important role in language acquisition (Saffran, Aslin, & Newport, 1996), and it is closely related to procedural learning (Perruchet & Pacton, 2006). *FOXP2* remains a candidate gene involved in language because of its association with procedural learning and the basal ganglia (Enard et al., 2009).

Procedural learning and the SRT task

Given the links between language ability, *FOXP2*, and procedural learning, researchers have examined sequence learning to better understand these relationships and mechanisms associated with language. The SRT task is a sequence learning task designed to measure participants' ability to implicitly learn sequences. Participants are presented with blocks of trials that are either random or repeat in a particular sequence. As sequence processing is fundamental to language and statistical learning provides a useful mechanism for learning language (Saffran et al., 1996), this task allows us to measure some of the key functional properties of language.

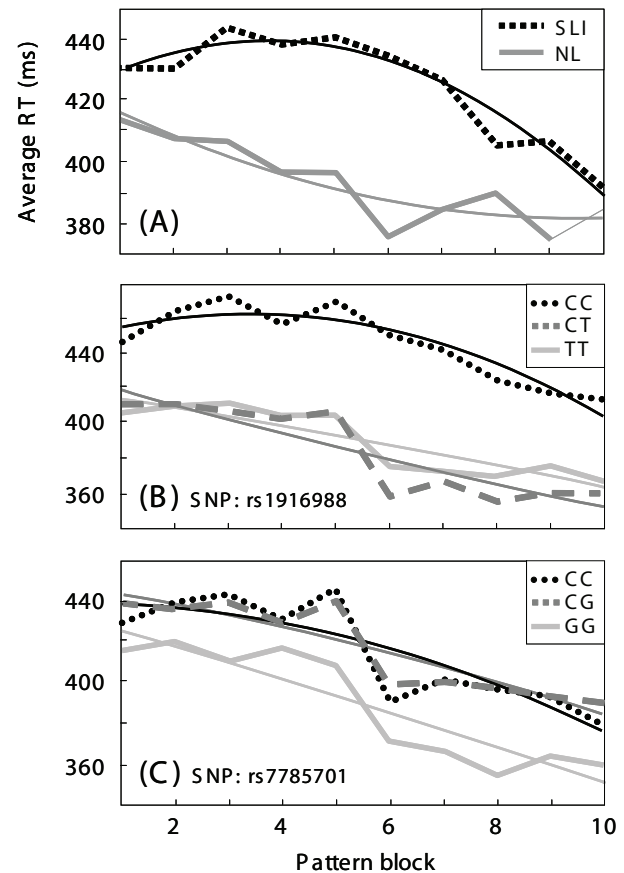

Figure 1: Behavioral data for pattern trials in the SRT task. (A) Data from Tomblin et al. (2007b) comparing SLI and NL groups. (B & C) Data from Tomblin et al. (2007a) for individuals with different genotypes of SNPs rs1916988 and rs7785701.

Tomblin et al. (2007b) used an SRT task to examine differences between children with normal language (NL) and children with SLI. In their task, participants were shown four boxes on a computer screen. On each trial, a picture of a cartoon creature appeared in one of the boxes, and the participant's task was to choose the box containing the picture as quickly as possible.

For the first 100 trials, stimuli were presented randomly. Then, 200 trials were presented in which the sequence [1, 3, 2, 4, 4, 2, 3, 4, 4, 2, 4] was repeated (pattern trials). Finally, 100 additional random trials were presented. Participants were not informed which trials were random and which were pattern trials during the course of the experiment. The experiment was divided into blocks of 20 trials each for data analysis (blocks 1-5 were the first set of random trials, blocks 6-15 were pattern trials, and 17-20 were random trials).

Tomblin et al. found that, overall, the SLI group had longer RTs than the NL group (Fig. 1A). During the pattern trials, performance of both groups improved, indicating that they learned something about the sequence. However, the learn-

ing trajectory differed for the two groups. For the NL group, RT decreased rapidly after the first few blocks of pattern trials and then leveled off. In contrast, for the SLI children, RT remained flat (or increased slightly) during the first few pattern blocks before decreasing. The difference between these two learning trajectories can be approximated by a quadratic function (small differences between the two groups at the first and last blocks; large differences in the middle blocks).

In another study, Tomblin et al. (2007a) examined the relationship between multiple SNPs and performance in this SRT task. They found that the CC genotype of SNP rs1916988 (Fig. 1B) and the CC genotype of SNP rs7785701 (Fig. 1C) were associated with slower RTs over the course of the pattern trials. The CC genotype of SNP rs1916988 was also associated with a learning curve that was similar to the SLI children.

These results suggest that both language impairment and genetic variation in *FOXP2* have similar effects on performance in the SRT task. Given previous work showing a link between *FOXP2* and language, these effects may be related to common functional differences evident in language impairment and some variants of *FOXP2*.

Computational model

We used a neural network to examine whether some of the functional properties of procedural learning are related to the differences observed with human participants. In particular, we would like to capture the difference in the shape of the learning trajectory observed between some of the fast RT groups (children with NL [Fig. 1A] and the CC and CT genotypes of SNP rs1916988 [Fig. 1B]) and slow RT groups (SLI children and the CC genotype of that SNP). By exploring the parameter space of the model, we can determine which functional properties are associated with these differences in the learning trajectories.

Model architecture

The model is a simple recurrent network (SRN; Elman, 1990; c.f. Misyak, Christiansen, & Tomblin, 2009, for an adaptation to the SRT task). The network has three layers: an input layer, an output layer, and a hidden layer with recurrent connections. The input and output layers each have four units (corresponding to the four possible stimulus locations). The hidden layer's recurrent connections provide it with information about the state of the hidden units on the previous trial (context units). This allows the network to learn sequences, like those in the pattern trials of the SRT task. Connection weights are updated using backpropagation (Rumelhart, Hinton, & Williams, 1986). Logistic activation functions are used for the hidden and output units.

Simulation procedure

The network was trained on a task based on the one used by Tomblin et al. (2007b). On each trial, a stimulus was presented to the network by activating a particular input unit and setting the rest to zero, and activation flowed to the output

units. Luce choice ratios were computed by dividing each output unit's activation by the total activation. These values were then used to compute an RT for the network according to the equation

$$RT = \frac{1}{C - \frac{\sum I}{n-1}} \quad (1)$$

where C is the activation of the correct output unit, I is the activation of each of the three other output units, and n is the number of output units (four for these simulations). This gives an estimate that is analogous to RT; a lower value corresponds to a lower RT in the SRT task. Thus, when one unit is significantly more active than all the others (i.e., the network is confident in a single response) the RT will be low. When all the units are similarly active (the network is unsure what the response is) the RT will be high.

The correct unit on each trial is the output unit that corresponds to the one that was activated at the input layer. This corresponds to the SRT task in which participants respond by selecting the location containing the stimulus.

For the first 100 trials, a random location was chosen and presented as input. Then, for 200 trials, the sequence [1, 3, 2, 4, 4, 2, 3, 4, 4, 2, 4] was repeated. Finally, an additional 100 random trials were presented. Only trials on which the correct output unit had the highest activation were included in the analysis. The entire simulation run was divided into 20 blocks of 20 trials.

Simulation 1

In the first simulation, we varied several parameters individually to gauge their effect on performance in the SRT task: *context strength*, *input strength*, *learning rate*, *number of hidden units*, and *temperature*.

Context strength determines the strength of the connections from the hidden to context units (i.e., hidden unit activations are multiplied by this amount when setting context unit activations). A lower context strength may have an effect on the network's ability to learn sequences, which could influence learning in the SRT task.

Input strength controls the fidelity of the stimulus presented to the network. The input unit corresponding to the chosen location is set to the value of the input strength and the others are set to zero. A lower input strength makes the stimulus location less distinct from the others.

Learning rate is the value that the weight change term is multiplied by each time the weights are updated. Models with lower learning rates require more trials to learn the task, but may have more stable learning. This could affect the network's ability to learn over the course of the pattern trials.

Number of hidden units affects the amount of information the network can hold about the sequence. If the network has too few, its ability to encode the sequence will be impaired.

Temperature corresponds to the temperature parameter of the logistic activation function. This activation function constrains the hidden and output units to have activations between zero and one. A higher temperature makes the logistic

more nonlinear. Thus, if the correct output unit has the highest activation, a high temperature parameter will make this value more distinct from the values of the incorrect units, resulting in a lower model RT. The temperature parameters for the hidden and output units were varied separately.

Five hundred repetitions of each condition were run.

Results

The network was able to learn the SRT task and showed an overall learning trajectory similar to the ones observed in the behavioral data. The network's performance improved over the course of the simulation and was faster during the pattern trials than the random trials.

Fig. 2 shows the performance of the model on the SRT task for different values of each parameter. A range of values for the parameters were tested to find a set that produced responses similar to those observed for the fast RT groups in the behavioral data. Each parameter was then varied individually, holding the others constant at those values. For example, in Fig. 2A, *context strength* was varied. The other parameters were held constant for both *context strength* conditions at the baseline values (i.e., *learning rate* = 0.10, *hidden units* = 12, *input strength* = 1.0, *hidden unit temperature* = 1.0, *output unit temperature* = 1.0).

Context strength (Fig. 2A) had very little effect on the network's RT. This suggests that the network can still perform the task with limited information from the previous trial.

Input strength (Fig. 2B) had an effect on overall RT and an effect on the shape of the learning trajectory. Models with a lower input strength showed a small increase in RT at the beginning of the pattern trials, but this did not persist to the middle blocks.

Learning rate (Fig. 2C) also had an effect on the shape of the learning trajectory. This was due to the fact that the network initially shows an increase in RT at the beginning of training. By decreasing the learning rate, this increase was pushed forward in time into the pattern trials. Thus, one reason that some groups show an increase during the pattern trials in the SRT task might be that they are still in this initial learning phase.

Number of hidden units (Fig 2D) had an effect similar to *input strength*. Fewer hidden units resulted in longer overall RTs and a small increase at the beginning of the pattern trials.

Temperature (Figs. 2E & 2F) had an effect on the overall RT at the beginning of the pattern trials, but did not capture the change in the shape of the learning curve.

Discussion

Several parameters produced changes in the network's median RT and learning trajectory. Changes in *input strength*, *learning rate*, and *number of hidden units* can account for some of the changes in the shape of the learning trajectory observed behaviorally. As discussed above, however, specific SNPs and individual differences in language ability are likely to have multiple functional effects. Thus, we may find a better

Figure 2: Results of Simulation 1. For each simulation, the set of parameters producing effects similar to those seen in the fast RT groups was used as a baseline (solid lines in figures), and individual parameters were varied (dashed lines).

fit to the behavioral data by examining the combined effects of multiple parameters. This was done in Simulation 2.

Simulation 2

In the second set of simulations, we varied multiple parameters in the model simultaneously, allowing us to explore the parameter space of the network further. Five values were tested for the number of hidden units, and four were tested for each other parameter, yielding a total of 5,120 combinations. The simulation procedure was the same as Simulation 1, except that 50 repetitions of each combination were run.

Results

In order to determine which parameter sets reflected the fast and slow RT groups in the behavioral data, pairwise comparisons were made and the difference scores were fit to quadratic functions (the pattern of the differences in the learning trajectories). Thus, for each comparison there was a set of parameters corresponding to the slow RT groups and a set corresponding to the fast RT groups.

Several pre-processing criteria were used to exclude sets that did not show correct performance on the SRT task (i.e., better performance over the course of the pattern trials) and comparisons that would not yield a pattern consistent with the difference between groups in the behavioral data (i.e., quadratic). The remaining pairs were then fit to quadratic functions using the least squares method, and R^2 was used to determine the goodness of fit.

R^2 values greater than 0.9 were found for 0.47% of the pairs. To determine which parameters drove the effect, we computed the mean parameter values for the slow and fast RT groups for these pairs. The mean values for each parameter for the two groups are shown in Table 1. Some parameters did not differ between the groups, whereas others differed greatly. We found that the parameters in Simulation 1 that produced changes in the learning trajectory (*learning rate*, *number of hidden units*, and *input strength*) had similar effects when varied in conjunction with *temperature*. Fig. 3A shows the responses of the model when these parameters are varied simultaneously.

Adjusting the parameters by hand allowed us to distill the set of parameters down to two, *learning rate* and *temperature*, that accounted for the difference in learning trajectories for the first half of the pattern trials, but not the second half (the

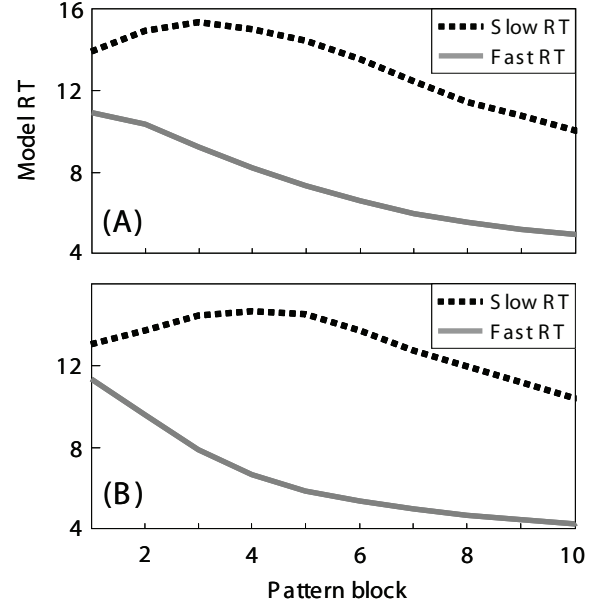

Figure 3: Results of Simulation 2. (A) Responses of the model when *learning rate*, *input strength*, *number of hidden units*, and *temperature* are varied simultaneously. (B) Responses when *learning rate* and *temperature* are varied simultaneously. Five hundred repetitions of each condition were run to produce the figures.

slow RT model did not reach the same RT by the end of the pattern trials). Fig. 3B shows the responses of the model when these parameters are varied together.

Discussion

The results of this simulation show that the combined effects of several parameters together can better approximate the difference in learning trajectories. This suggests that this approach can be used to determine which combinations of parameters mirror the behavioral data. Additional exploration of the parameter space (i.e., testing a larger range of values) may allow us to find a better fit.

General discussion

The results of these simulations suggest that several functional aspects of sequence processing contribute to the differences in SRT performance observed behaviorally and that by examining multiple factors at the same time, we can get a better estimate of the effects of language impairment and genetic variation. This fits with the notion that genetic differences are likely to have multiple functional consequences.

Recently, McMurray et al. (2010) used a similar approach to determine which parameters in TRACE (McClelland & Elman, 1986) corresponded to differences between NL and SLI children in a spoken word recognition task. They found that variation in the network's decay parameter produced differences similar to those between the SLI and NL groups. This parameter is related to competition. In the SRN used here,

Table 1: Simulation 2 results.

Parameter	Slow RT	Fast RT
Context strength	0.48	0.53
Input strength	0.83	0.90
Hidden units	5.9	9.5
Learning rate	0.13	0.18
Temperature (hidden)	0.39	0.52
Temperature (output)	0.38	0.44

the *temperature* parameter corresponds to competition (e.g., a lower temperature parameter for the output unit activation function leads to greater activation for the competitor units). Thus, these two sets of simulations, modeling different tasks with different networks, provide converging evidence that competition between internal representations may be a critical mechanism in language processing that produces differences between NL and SLI children.

The simulations presented here provide a first step towards assessing the role of genetic variation and language ability in procedural learning, and they suggest several functional properties that may be influenced by these differences. More broadly, they show that exploring the parameter space of a computational model may offer an approach to studying the effects of genetic factors on cognitive systems.

Acknowledgments

We would like to thank Morten Christiansen and Jennifer Misyak for theoretical discussion of these topics and Cheyenne Munson for help preparing the figures.

Abstract

Previous research indicates that adult learners are able to use co-occurrence information to learn word-to-object mappings and form object categories simultaneously. The current eye-tracking study investigated the dynamics of attention allocation during concurrent statistical learning of words and categories. The results showed that the participants' learning performance was associated with the numbers of short and mid-length fixations generated during training. Moreover, the learners' patterns of attention allocation indicated online interaction and bi-directional bootstrapping between word and category learning processes.

Keywords: Eye-tracking; statistical learning; word learning; category learning.

Introduction

Over the past few decades, researchers have found that humans are sensitive to statistical regularities in the environment. People are able to use statistical information in non-linguistic tasks, such as making inferences (e.g., Xu & Denison, 2009) or finding predictive features of complex visual scenes (e.g., Fiser & Aslin, 2001). They can use statistical information in linguistic tasks as well, such as learning phonetic distributions (e.g., Maye *et al.*, 2002), word boundaries (e.g., Saffran *et al.* 1996b), word and meaning mappings (e.g., Smith & Yu, 2008), and rudimentary syntax (e.g., Gomez & Gerken, 1999). These studies suggest that statistical learning is a domain-general ability in human cognition.

An earlier cross-linguistic study conducted in our laboratory (Chen *et al.*, 2009) also showed that adult English and Mandarin speakers were able to use co-occurrence information to learn word-to-object mappings and to form object categories at the same time. However, even though these two groups of learners had comparable performance in learning word-to-object mappings, they showed different levels of sensitivity to the cues associated with category learning. Participants were better at learning the types of regularities that were present in their native language than the ones that were incongruent with their linguistic input. In Experiment 1 of the study, objects from the same category had similar attached object parts and their labels ended with the same final syllable. This syllable-to-category association simulated a prevalent linguistic feature in Mandarin in that the final syllables of object names often indicated category membership. The results showed that Mandarin speakers were able to learn individual word-to-object mappings and to form syllable-to-category associations under cross-situational learning contexts. On

the other hand, English speakers tended not to use the final syllables of labels as cues in category learning. In Experiment 2 of that study, the category markers were moved to the beginning of labels to simulate a more frequent feature in English (e.g., the adjectives in noun phrases). As the structures of the training stimuli were more congruent with the input in the naturalistic environment, the English speakers' category learning performance became significantly better. More importantly, they also had better performance in the word learning task. One possible explanation of the improvement of word learning performance is that category learning bootstraps word learning. That is, learning which objects belong to the same category helps the learners to focus on relevant features of the stimuli and to rule out certain distractors as possible referents of a word. However, from the design of that study, we were not able to draw a conclusive link between the English speakers' success in forming categories and their improvement in word learning.

The present study was designed to address this issue by using eye-tracking techniques. Category learning studies using eye-tracking techniques have shown that learners generally attend to all possible dimensions early in learning. But during the process of learning, they gradually shift their attention to relevant dimensions (e.g., Rehder & Hoffman, 2005; Blair *et al.*, 2009). Based on previous studies, similar patterns might be observed in statistical word learning and category learning. Our prediction is that at the beginning of training, learners will pay attention to all objects on the screen when hearing a word. Across learning, they will gradually tune their attention to the most probable referent of a word. Moreover, after successfully forming a few word-to-object mappings, the learners should notice that the objects (and their labels) can be grouped into different categories, each having its own distinctive feature. After establishing primitive category structures, the learners should then use this information to rule out certain distractors as possible referents of a word. The goals of the current study are to examine the dynamics of attention allocation in statistical learning of words and categories and to investigate the real-time interaction between word learning and category formation.

Method

Participants

Participants were 23 undergraduates (14 females, mean age: 19.1 years) who received course credit for volunteering.

None had previously participated in any cross-situational learning experiments.

Design and Stimuli

The experimental design in this study was the same as the one used in Experiment 2 of Chen *et al.* (2009) with slight modification in the length of training trials. Participants were trained under a cross-situational learning paradigm, which was first proposed by Yu and Smith (2007). In each training trial, the participants viewed four novel objects on a computer screen and heard four novel words. However, the temporal order of the word presentations was not related to the spatial locations of the words' target referents. In order to find the correct word-to-object mappings, the participants had to track the co-occurrence regularities between objects and words across different trials. There was a total of 18 object-word pairs to learn. Over the training, there were 12 repetitions per object-word pairing, yielding a total of 54 trials (18 pairs * 12 repetitions / 4 pairs per trial). The length of each trial was 14 seconds and the whole training lasted for 12.6 minutes.

The to-be-learned objects were divided into three different categories, with six items in each category. Members in a category had an attached part that looked similar to each other. As an example, Figure 1 shows two items from a category in which all members had an attached spiral part that spread at the end. Moreover, these objects all had labels that began with the same syllable (e.g., *la-* in this case).

Figure 1 Sample objects and labels used in the study

Apparatus

The course of the experiment was controlled by a computer using E-prime. The visual stimuli were presented on a 17 inch monitor with a resolution of 1280*1024 pixels. The learners' eye gaze was measured by a Tobii 1750 near infrared eye-tracker (www.tobii.se). The eye-tracking system recorded gaze data at 50Hz (accuracy = 0.5°, and spatial resolution = 0.25°).

Procedure

Before the experiment, the eye-tracker system was calibrated. We used a procedure including nine calibration points. The experiment consisted of a Training session, followed by a Testing session. In the Training session, the participants were presented with 4 novel objects and 4 novel words in each trial without any information about which

word referred to which object. The learners had to keep track of the co-occurrences between objects and words across trials to find the correct word-to-object mappings. Once they formed several correct word-to-object mappings, we expected they would be able to detect the associations between the first syllables of words and the attached object parts and to form object categories accordingly. The syllable-to-category associations should in turn facilitate word-to-object mappings, because the learners would be able to use the first syllable of a label to determine its possible referents. Eye movements were recorded during the Training session.

There were two tasks in the Testing session, a word-to-object Mapping task and a Generalization task. The Mapping task tested how well the participants learned the names of the training objects. The participants were instructed to select the referent of a training word from 4 alternatives. There were 18 trials in the Mapping task.

In the Generalization task, the participants were asked to select the referent of one novel word from three alternatives, each containing the object-part that corresponded to the particular feature of one category. The first syllable of the novel word was the same as the labels from one of the three categories. If the learners had formed the syllable-to-category associations, they should be able to use the first syllable of the novel word to find its referent. There were 9 trials in the Generalization task (3 for each category).

Eye-tracking dependent variables

To derive eye movement measures, we defined four rectangular region-of-interests (ROIs) that covered the objects displayed on the screen for each trial. We took the onset of a series of gaze data that fell within an ROI as the onset of a fixation and the end of the fixation was determined when the gaze fell outside of the same ROI. The minimum length of a gaze was 20ms (i.e., the length of 1 data point recorded by the eye-tracker). All gaze data outside the ROIs were viewed as saccadic eye movements and not included in the analyses.

Based on the remaining gaze data, we computed two dependent measures. The first variable was the *number of fixations* per trial. We set the thresholds at 100ms, 500ms, and 1000ms and counted the numbers of fixations exceeding these thresholds. Moreover, fixations with a length between 100ms and 500ms were defined as Short fixations; fixations between 500ms and 1000ms were viewed as Mid-length fixations; and those longer than 1000ms were taken as Long fixations. The reason for setting different thresholds was that previous category learning studies using eye-tracking techniques have found that looking more at the correct or relevant features during training was positively correlated with behavioral performance (e.g., Rehder & Hoffman, 2005; Blair et al., 2009). This indicates that more looking at the relevant features during training might lead to better learning. However, more looking could result from either having a few long fixations or having many short fixations combined together. Setting different thresholds would allow

us to examine whether longer looking also leads to better learning.

The second measure was *proportion looking time* (ranging from 0 to 1), which took the time spent fixating on one object divided by total time spent fixating on all objects. Moreover, based on the word being presented, we divided the objects into 3 categories: Correct Object, Within-Category Distractor, and Between-Category Distractor. Because there were 4 objects in each training trial while there were only 3 categories to learn, there could be more than 1 object from a specific category in a trial. Therefore, for each word, the Correct Object was the target referent while a Within-Category Distractor was an object from the same category. On the other hand, the Between-Category Distractors were the ones from a different category. Figure 2 illustrates a situation in which there are two objects from the *la-* category, one from the *jo-* and one from the *mu-* category. The label of each object can be found above it (please note that in real training, the labels were presented auditorily). For the word “*lati*”, there is one Within-Category Distractor and two Between-Category Distractors in this trial. In contrast, for the word “*joler*”, there are three Between-Category Distractors. However, in this case none of the objects is a Within-Category Distractor for this word. The mean numbers of Correct Object, Within-Category Distractor, and Between-Category Distractor for the training words in each trial are: 1, 0.74, and 2.26, respectively.

Figure 2 Sample stimuli in Training

Behavioral Results

On average, more than 50% of the participants' responses were correct in the Mapping task and in the Generalization task as well (see Figure 3). Consistent with earlier findings, participants learned more word-to-object mappings than expected by chance ($t(22) = 4.211, p < .001$). They also performed significantly above chance in the Generalization task ($t(22) = 3.227, p = .004$). That is, they could use the first syllable of a novel label to find its referent. In addition, we found a strong positive correlation between the learners' Mapping and Generalization performance ($r = .773, p < .001$). This suggests that the more words participants

learned, the more likely they were to use the first syllable as a cue in categorizing novel objects.

Figure 3: Proportion of accurate responses in Mapping and Generalization tasks

Eye Movement Data Analyses

According to the participants' performance in the Mapping task, we divided them into three groups. The participants that had more than 70% correct responses were viewed as High Learners. The people that made less than 35% correct responses were viewed as Low Learners. People having 35% to 70% correct responses were viewed as Mid Learners. There were 8, 6, and 9 people in the High, Mid, Low group, respectively. We compared the *number of fixations* and *proportion looking time* to different types of objects of the High, Mid, and Low Learners to see if there were differences in their eye movement patterns during the training.

Number of Fixations

As mentioned previously, we counted the numbers of fixations exceeding 100ms, 500ms, and 1000ms for each participant. The results can be found in Figure 4. The solid lines indicate the numbers of fixations exceeding 100ms. The High, Mid, and Low Learners had comparable numbers of fixations at the beginning of training. Across the Training session, the numbers of fixations of the Mid and Low Learners gradually decreased and the decreasing rate was slightly higher for the Low Learners. The dashed lines show that when the threshold was set at 500ms, the High Learners tended to have more fixations than the other two groups, especially in the second half of training. When the threshold was set at 1000ms, there did not seem to be group differences.

The patterns observed above were confirmed by statistical analyses. We compared the numbers of Short (100ms-500ms), Mid-length (500ms-1000ms), and Long fixations (>1000ms) of different groups of learners. With regard to Short fixations, trial-by-trial ANOVAs showed that group differences were significant between Trial 38 and Trial 42 ($ps < .05$). Pair-wise comparisons showed that the High Learners generated more Short fixations than the Low Learners ($ps < .05$). For Mid-length fixations, Trial-by-Trial ANOVAs revealed that significant group differences occurred between Trial 31 and Trial 39 at p level of .05. Pair-wise comparisons showed that the High Learners generated more Mid-length fixations than the Mid and Low Learners ($ps < .05$). In addition, the Mid Learners also generated more Mid-length fixations than the Low Learners

in Trial 13, 16, 39 and 40. When the threshold was raised to 1000ms, all three groups had about equal numbers of fixations across trials. Significant group differences were only found at Trial 26, in which the High Learners generated more fixations than the Mid and Low Learners ($p < .05$).

Figure 4 Number of Fixations of High, Mid, and Low Learners. The number of fixations was counted separately with 100ms, 500ms, and 1000ms as thresholds of minimal eye fixation length.

To summarize, the major differences between the High, Mid, and Low Learners were caused by the decreasing Short and Mid-length fixations of the Mid and Low Learners. The High Learners had more Short and Mid-length fixations than the other two groups, especially in the second half of training. The Mid learners also generated more Mid-length fixations than the Low learners.

Proportion Looking Time

Proportion Looking Time By Trial We first looked at the dynamics of attention allocation during the course of statistical learning. For ease of comparison, Figure 5 to Figure 7 present the normalized Proportion Looking Time of the High, Mid, and Low Learners across training trials. The Proportion Looking Time to a certain type of object is normalized so that the chance level is 25%. As can be seen from Figure 5, there was a drastic increase in the High Learners' Proportion Looking Time to the Correct Object. There was also a decreasing trend in their looking at the Between-Category Distractors. Starting from Trial 34, the High Learners looked at the Correct Object significantly more than expected by chance ($p < .05$). They also looked at the Between-Category Distractors significantly less than chance from Trial 35 on ($p < .05$). As to the Mid Learners in Figure 6, even though there was an increasing trend in their Proportion Looking Time to the Correct Object, it did not reach statistical significance. As can be seen in Figure 7, the Low Learners had chance level performance across the training. Though they had above- or below-chance performance in a few trials, the patterns were not reliable.

We also conducted trial-by-trial ANOVAs to compare group performance. Starting from Trial 38, the High Learners looked at the Correct Object more than the Mid and Low Learners (at $p < .05$). The pattern can be seen in

Figure 8. There was also a trend that the Mid Learners looked at the Correct Object more than the Low Learners at the last third of training. But the pattern was not reliable. As to Within-Category Distractors, there were significant group differences in a few trials in which the High and Mid Learners looked at the Within-Category Distractors more than the Low Learners. But the patterns were not reliable either. With regard to Between-Category Distractors, there were significant group differences starting from Trial 24. Compared to the High Learners, the Low Learners looked more at the Between-Category Distractors in the second half of training. Additionally, they looked more at the Between-Category Distractors than the Mid Learners in the last third of training.

Figure 5 Proportion Looking Time of High Learners

Figure 6 Proportion Looking Time of Mid Learners

Figure 7 Proportion Looking Time of Low Learners

Figure 8 Proportion Looking Time to the Correct Object

Proportion Looking Time By Occurrences Across the Training session, each word-object pair occurred 12 times. For each participant, we calculated the Proportion Looking Time by word-object occurrences. For example, we took their Proportion Looking Time at the first occurrence of individual objects and averaged it across objects to get the Proportion Looking Time at Occurrence 1. This gave us 12 values for each participant. We then compared the High, Mid, and Low Learners' Proportion Looking Time to the Correct Object by occurrence.

Figure 9 illustrates that at about the third time the High Learners heard a word, they looked more at the Correct Objects than the Mid and Low Learners. Trial-by-trial analyses showed that group differences became significant at the third occurrence of a word ($ps < .05$). Except for the 6th occurrence, the High Learners were more likely to look at the Correct Object than the other two groups. The Mid Learners looked more at the Correct Objects than the Low Learners from Occurrence 10 to Occurrence 12.

Figure 9 Proportion Looking Time to Correct Object by Occurrences

Compared to chance, the High Learners looked at the Correct Objects significantly above chance from the 7th to the last time they encountered a word ($ps < .05$). The Mid Learners looked at the Correct Objects significantly above chance from the 10th to the last time they heard a word ($ps < .05$). As for the Low Learners, they did not look at the Correct Objects more than chance. This indicates that it took only a few repetitions for the High Learners to detect the word-to-object co-occurrence regularities and that they could quickly tune their attention to the most probable referent of a word. However, it took longer for the Mid Learners to find the correct referent of a word.

Predictive Looking

Because the first syllable of a label indicated an object's membership, another question we were interested in was whether the participants made predictive looking and attended to objects from a relevant category even before the whole word was finished. For example, if the learners formed the association between the syllable *la-* and the spiral part, they might be able to use the syllable *la-* as a cue to rule out Between-Category Distractors even before the word "*lati*" was completed.

We calculated Proportion Looking Time to objects from a relevant category (i.e., the Correct Object and Within-category Distractor) and objects from irrelevant categories between 600ms and 900ms after the onset of a word. We

chose the time between 600ms and 900ms based on the approximation that it took at least 200ms to generate stimulus-driven fixations and 600ms is about 200ms after the end of the first syllable while 900ms is about 200ms after the end of the word¹. The Proportion Looking Time to object from a Relevant Category of the High, Mid, and Low Learners can be seen in Figure 10. For ease of comparison, the results were normalized, so that the chance value was .5. In the first half of training, all three groups had similar performance. In the second half of training, the Mid and the High Learners started to fixate on objects from a Relevant category even BEFORE the whole word was completed. However, for the Mid Learners, the trend was not as reliable as the High Learners.

It is noteworthy that the High Learners' predictive looking could only be reliably observed in the last third of training, which occurred after their reliable above-chance looking at the Correct Objects. This indicates that prior to forming syllable-to-category associations, the learners needed to establish at least a few correct word-to-object mappings in order to extract the regularities across objects.

Figure 10 Proportion Looking between 600ms and 900ms after the onset of a word

Predictors of Behavioral Performance

As mentioned, the participants were grouped based on their performance in the Mapping task, which is a behavioral task administered after training. The above analyses showed that group differences could be observed from eye movement data during training. This suggests that eye gaze patterns during training might be used as predictors of behavioral performance.

Table 1: Correlations between Eye Gaze and Behavioral Measures.

		Mapping	Generalization
Number of Fixation	Short	.167	.107
	Mid-length	.339	.400*
	Long	.150	.118
Proportion Looking	Correct	.803**	.586*
	Within-category	.046	.278
	Between-category	-.749**	-.609**

* $p < .05$

** $p < .001$

¹ We also tried 500ms-800ms and 500ms-900ms. The trends are similar to the patterns observed here.

To find the best predictor of behavioral performance, multiple linear regression analyses were conducted. As can be seen from Table 1, there is a positive correlation between the number of Mid-length fixations and Generalization performance. The learners' Proportion Looking Time to the Correct Object is positively correlated with their Mapping and Generalization performance. In contrast, Proportion Looking Time to the Between-Category Distractors is negatively correlated with Mapping and Generalization performance. Stepwise regression showed that the best predictor of the Mapping performance is Proportion Looking Time to the Correct Objects during training. Consistent with the findings of previous studies, the more the learners looked at the correct features during training, namely the correct object, the better they performed in the following behavioral task. On the other hand, the best predictor of the Generalization performance is Proportion Looking Time to the Between-Category Distractors. The less the learners looked at the Between-Category Distractors, the better they did in the following Generalization task. This suggests that less looking at the Between-Category Distractors can be viewed as an indicator of category learning.

General Discussion

This study replicates previous findings that adult learners are able to use co-occurrence information to simultaneously learn word-to-object mappings and to form object categories. In addition, the current study shows that the learners' behavioral performance in the Mapping and Generalization tasks can be predicted from their looking patterns during the course of learning. Learners who generated more short- and mid-length fixations tended to perform better in the following behavioral tasks. However, there was no difference in the numbers of long fixations generated by different groups of learners. This indicates that more looking was not due to longer looking. Instead, the good learners tended to shift their attention back and forth among objects to check the possible referents of a word. Thus, rapid gaze shifts between several concurrent visual objects suggest a real time competition process which leads to better learning.

Patterns of attention allocation of the High, Mid, and Low Learners could be detected during the course of learning in addition. After accumulating certain statistical information, learners tended to shift their attention to objects containing relevant features. Moreover, at the third encounter with a word, the High Learners appear to have (partially) formed the association between a word and its referent. On the other hand, it took about 10 times for the Mid Learners to form correct mappings. This suggests that from eye movement data, we might be able to observe the accumulation of partial knowledge and how it leads to successful learning.

After forming a few individual word-to-object mappings, the High and Mid Learners shifted their attention to relevant categories BEFORE a word was completed. This suggests that after establishing syllable-to-category associations, they

use the first syllable of a word to eliminate Between-Category Distractors as possible referents of the word. Together, the results of the present study reflect online interaction of word learning and category learning. It also provides evidence that word learning and category learning bootstrap each other.

Abstract

We examined adult and child performance on two numerical, geometric estimation tasks. In both tasks adults demonstrated greater accuracy than children as well as more mature representations, in general. Furthermore, evidence from mouse tracking data demonstrates that adult strategy includes the application of discrete landmark values while child strategy, generally, does not. This evidence suggests that adults construct mental representations of landmark values and successfully integrate them into analog tasks. Implications for future intervention studies are discussed.

Keywords: numerical estimation, embodied cognition, mathematical development, cognitive assessment

Introduction

Numerical estimation tasks provide researchers with a powerful means of assessing individuals' mental representation for number. Evidence from brain scans demonstrates that approximate numerical tasks, such as less-than/greater-than judgments, activate cortical regions associated with spatial processes, while activities that rely exclusively upon recall, such as single-digit multiplication, do not (Dehaene, Piazza, Pinel, & Cohen, 2003). According to Dehaene (1997) our ability to map numerical values to spatial magnitudes is what is commonly referred to as "number sense," and grounds all mathematical reasoning.

Yet, the study of number sense extends beyond theoretical interest as recent evidence suggests a link between estimation and mathematical achievement. Along these lines Halberda, Mazocco, and Feigenson (2008) discovered that 14-year-olds' ability to discriminate between dot displays of varying cardinalities was highly correlated with achievement scores extending back to kindergarten. Likewise, Siegler and Booth (2004) found that individual differences on a number line estimation task are correlated with standardized test scores.

In the case of number line estimation individual differences may embody large, qualitative shifts in representation (Siegler & Opfer, 2003). Dehaene (1997) asserts that numerical symbols implicitly recruit a logarithmic representation that is more precise at smaller values. Siegler and Opfer (2003) found that young children, especially with larger numerical ranges, tend to apply this kind of logarithmic representation while estimating the position of a given value on a number line. Specifically, data of estimated magnitude over actual magnitude are best fit by a logarithmic function for these younger children. On the other hand, older children's data, in many cases, is best fit by a straight line.

The emergence of a linear representation has several possible causes and implications. In particular, Siegler and Opfer (2003) differentiate between two models of linear representation. In the *accumulator* model, adopted from Gibbon and Church (1981), noise in the mental representation for a numerical value increases in proportion to the mean. This representation implies increasing variability in the estimates as the magnitude increases. In the *linear-ruler* model – which was found to be a better fit for the data – variability in estimates has a constant relation to magnitude.

The authors suggest that the mature, linear representation is developed through cultural, particularly school-based, experience. Furthermore, evidence of less variability near landmark values along the number line (e.g. quartiles) demonstrates a specific means for implementing the linear-ruler model. One may even speculate that at the lowest-level number representation may be logarithmic or accumulator in nature, but at the level of conscious-level processing number concepts are modulated for specific tasks.

If the appeal of number line estimation tasks is due, in part, to its high ecological validity, one might then find it

surprising that although number lines are a ubiquitous feature of elementary school classrooms, many students maintain immature, logarithmic representations. Yet, recent evidence suggests that the development of mature representations may be promoted through simple, economical interventions, such as playing linear board games (Siegler & Ramani, 2008) or providing corrective feedback (Opfer & Siegler, 2007) on values that maximize the logarithmic-linear difference. In the latter case many children demonstrated a logarithmic to linear shift within a few feedback trials.

Yet, the ease with which some children transition from a logarithmic to linear representation begs the question of whether these children already maintain a linear representation of whole numbers and simply learn to recruit it for the given task. From this perspective, “development” of a linear representation in these interventions may capture only the tail end of this learning process, only made possible through years of informal experience with numerical concepts (Ginsberg, 1983).

At the cost of ecological validity, an alternative approach to cognitive developmental research might imply the adoption of a task utilizing a novel, unique spatial representation of number. Within such a paradigm researchers would observe as children (or adults) struggle to construct meaning out of the task, although the task may be meaningless beyond the research setting. This research model would afford psychological researchers with a level of control that is unobtainable with common concepts.

As a compromise between ecological validity and control this study applies the numerical estimation paradigm to degree measure, which is an important element of mathematics, but is under-utilized in elementary school curriculum and therefore relatively unfamiliar to children (Clements & Battista, 1992). Considering that degree measure does not become a major component of curriculum, generally, until high school, research with degree measure provides an opportunity to study numerical development of older children.

Yet, degree measure is not a unitary concept, but is rather composed of two psychologically distinct spatial representations: degree as angle of intersection between lines and degree as rotation. While some tasks, such as LOGO programming, may confound the two concepts (Clements, Battista, & Sarama, 2001), other activities clearly demonstrate that children perceive physical models of each concept distinctly (Mitchelmore, 1998).

Given the unique spatial qualities of each representation, we should expect courses of development for rotation and angle concepts that may differ from whole number concepts. For example, Clements and Burns (2000) found that fourth grade students physically modeled angle values and curtailed the degree of embodiment with increasing expertise. Furthermore, both students and instructors focused on the representation of “benchmark” (or landmark) magnitudes, such as 90° . Although one might perform a degree estimation task by applying the same linear

representation developed for the number line, albeit in a circular form, the emphasis on standard landmarks for degree measure suggests that performance with number lines and degree measure is likely to be quite different. Specifically, the mental representation for degree measure might rely upon the integration of continuous models of numbers and discrete abstractions of landmark values.

While the nature of a mental abstraction is a constant source of debate, the grounded or embodied cognition framework (Barsalou, 2008) asserts that all mental representations are composed of sensory-motor elements of experience. Specifically, perceptual symbols develop from frequent encounters with a meaningful type of object. In turn perceptual simulators develop to provide individuals a means of representing a concept in its perceptual absence (Barsalou, 1999).

In the case of angle and rotation, perceptual symbols are likely to embody landmark values. Given the perceptual salience of perpendicular lines – which can be discriminated from non-perpendicular lines by Amazonian tribesman (Dehaene & Izard, 2006) – we should expect that 90° angles are represented in this form. However, the perceptual symbol encoding 90° angles may only account for a limited range of valid right angles, such as right angles with sides oriented horizontally and vertically from the ground. Thus, perceptual symbols may develop in both robustness for particular symbols, and in number, overall.

In the case of rotation, the spatial mapping of language may play an important role in the embodiment of this numerical concept (Lakoff & Nunez, 2000). For example, the directives “turn around” or “turn to your right” may ground landmark values of 180° and 90° , respectively. Older students may develop other landmark values for common spatial transformations, such as a rotation of 45° .

Yet, all numerical tasks involving degree measure do not, explicitly, require landmark values. An angle measure of 117° , for example, is unlikely to have its own unique representation. However, individuals may shuttle between analog, continuous models and discrete, abstract models (Schwartz & Black, 1996). In this case one is likely to apply this process to numerical estimation by searching for relevant landmarks (e.g. 90°) and then applying an analog procedure, in a form of divide-and-conquer. As stated above, Siegler and Opfer (2003) suggest that this is the specific mechanism used by adults to implement a linear-ruler representation on the number line. However, since number lines may utilize an arbitrary range of values, linear representation may reflect the online development of landmarks, rather than the application of perceptual symbols from memory.

Although evidence for the application of landmark strategies is suggested by the pattern of variability in accuracy across numerical range, these accuracy measures reflect only the final judgment of the participant and may hide strategy-relevant features of the estimation process. On the other hand continuous, online measures of performance afford researchers a view of the specific process undertaken

by a participant (Spivey, 2007). In this study we adapt a mouse-tracking paradigm in which mouse position and time is recorded at continuous, fine intervals. Specifically, as participants perform the estimation task the mouse's rotational orientation about the center of the screen is recorded to facilitate the analysis of inflections near landmark values.

In the following study we analyze estimation performance of relative experts (graduate students in education) to novices (middle-to-upper elementary school students). Given the adults likely experience with relevant geometric concepts, we expect that these participants are likely to use apply a process of shuttling between landmark and analog representations, which should result in a high proportion of mouse stops near landmark values and an overall linear representation.

The children, on the other hand, are less likely to be familiar with landmark values and may struggle to integrate them into the estimation task. Therefore we suspect that linear representations will be rare. Although these students, mostly in fourth grade, should clearly maintain a linear representation on the number line, we expect that, given the novelty of this task, they are likely to adopt a logarithmic representation. Furthermore, we expect there to be clear differences between adults and children in overall accuracy.

Method

Participants

Sixteen adults (mean age = 28.9, SD = 8.7) were recruited from an introductory cognitive psychology course as part of a research requirement. Sixteen children (mean age = 9.5, SD = .73) were recruited from an after-school program located in a low-SES neighborhood of a large city. The children consisted of two third-graders, one fifth-grader, and thirteen fourth graders.

Tasks

Both adults and children performed two distinct numerical estimation tasks on Apple MacBooks. Both tasks were programmed with Adobe Air 1.1 in the Adobe Flash CS3 development suite. The application covered the entire height of the screen (23 cms) and approximately 87% of the width (32.5 cms).

Both tasks required a single click (and release) on a circle within the display to initiate each trial. Upon completing each trial participants were required to click-and-hold the mouse button for a half second to "lock-in" their answer to reduce the frequency of accidental clicking. Although there was no time limit, if the participant made no motion with the mouse for more than ten seconds the trial was terminated.

In *angle construction* (Figure 1) the participant maneuvers the mouse to rotate one leg (9.2 cms long) of an isosceles triangle clockwise about a fixed vertex, while the other leg remained motionless – opening and closing the triangle. Participants were asked to manipulate a target

angle, marked with a red arc, to reflect a target number of degrees. At 0° and 180° the figure becomes a straight line. Motion beyond 180° maintained the appearance at 180° and was recorded as 180°. Participants could move directly from 0° to 180° by moving the mouse counter-clockwise from the initial position.

Figure 1: The top pane shows the initial display for an angle construction trial. Participants clicked within the circle to begin the trial. The lower pane shows a triangle that has been formed to match the target value. The arced arrow is superimposed here to demonstrate the vector of motion of the non-stationary vertex from its original position.

In *triangle rotation* (figure 2) the participants maneuvered the mouse to rotate an isosceles triangle about the center of the triangle. Participants were asked to rotate the triangle, clockwise, a target number of degrees from the triangle's initial orientation. A light gray triangle in the initial orientation of the triangle remained throughout the trial to provide a reference. The shape of the triangle was varied between trials by randomizing the angle measure at intersection of the triangles legs from 10° to 170°, although the length of the legs was constant (9.2 cms). Varying the shape was necessary to avoid the use of strategies involving static relationships between the moving triangle and the gray reference triangle. Participants could maneuver the triangle between 0° and 180°. Motion beyond 180° did not affect the appearance of the figure. Like angle construction, in some cases participants moved directly from 0° to 180° by moving the mouse counter-clockwise.

Figure 2: The top pane shows the initial display for a triangle rotation trial. Participants clicked within the circle at the vertex to begin. The lower pane shows how the triangle has been rotated to match the target value.

Procedure

Both children and adults were split into two groups of eight, varying task order. The children received a block of 20 non-feedback trials in both *angle construction* and *triangle rotation*. The adults received 120 trials, organized into six blocks, for each task. However, for the purpose of directly comparing adult and child performance, only the adults' first block for each task were analyzed here. The task was individually administered to adults in a private room. Children performed the task in a dedicated section of a classroom as their classmates completed homework.

Prior to the first block of each task participants received 5 practice trials. Each practice trial required the participant be within 15° of the target and displayed written, verbal feedback suggesting an increase or decrease. The practice values of 90° , 45° , 135° , 15° , and 180° were selected to represent a wide distribution of the range. However, in angle estimation the 180° trial was replaced with a 165° trial to maintain a triangular appearance of the display.

Each block was populated with target values in the range of 10° to 170° . Target values were selected randomly from 20 intervals of 8° over this range. In the interest of directly comparing the two tasks, angles greater than 180° were not used as they cannot form internal angles of a triangle.

Data Analysis

Prior to all analyses outlier trials were removed to eliminate cases of accidental clicks, which prematurely terminated

trials. From observation of performance accidental clicks generally occurred near either extreme value (0° or 180°) or within a short time period (e.g. double-clicking). Therefore trials in which the participant moved the mouse less than 5° from the initial position, ended the trial within a degree of the 180° endpoint, or completed the trial in less than one second were removed from analysis. To reduce the likelihood that subjects intended degree measures in the outlier range we only used targets between 10° and 170° .

During each trial the current value of the manipulated degree measure was sampled at approximately every 40 msec. Degree over time data was fit to a function and smoothed using the 'fda' package within R (Ramsay, Wickham, Graves, & Hooker, 2009). The first derivative of smoothed data, degree change over time, was then searched for values at or near zero for an extended period of time (500 msec), indicating a stop point.

Stop points within 10° of specific landmark values were tallied and are referred to as *landmark stops*. Likewise stop points in 10° ranges just above and below the landmark ranges were tallied and are referred to as *near-landmark stops*. For example, 90° landmark stops included all stops between 80° and 100° , while 90° near-landmark stops occur in the ranges 70° to 80° and 100° to 110° . For 180° landmark stops were tallied between 170° and 180° , while near-landmark stops range between 160° and 170° .

Although stops in a landmark or near-landmark range could represent random behavior, subjects consistently applying a landmark strategy are more likely to stop within landmark than near-landmark range, while subjects stopping at random should be equally likely to stop within either range. Therefore we suggest that a high proportion of landmark to near-landmark stops indicates the explicit use of a landmark strategy. This landmark-to-near-landmark proportion was calculated as a statistic ranging from -1 (all near-landmark) to 1 (all landmark) by subtracting the count of near-landmark stops from the count of landmark stops and dividing by their total. For example, three landmark stops to one near landmark stop is a value of .50 [i.e. $(3-1)/(3+1)$]. On the other hand, one landmark stop to two near-landmark stops is a value of -.33 [i.e. $(1-2)/(1+2)$]. A value of zero indicates either an equal number of landmark and near-landmark stops or no stops.

Results

To determine the nature of a participant's representation of estimated magnitude vs. actual magnitude data was fit to a linear and logarithmic model. Participants were classified to "linear" or "log" representation to indicate the model that accounted for a larger proportion of their variance. In the case where neither model was a significant predictor of estimates participants were classified as "other." Also, the absolute deviations (residuals) from estimated to actual magnitudes of "linear" participants were fit to a linear model to determine the presence of scalar variability. Those

participants with a positive slope, significantly different from zero ($p < .05$) were classified as “accumulator”, while those with no trend of increasing deviations were classified as “linear-ruler.” Table 1 indicates the distribution of models for adults and children in each task.

Table 1: Model frequencies across task and age.

Model:	Linear-ruler	Linear-accum.	Log	Other
Adult–Angle	11	5	0	0
Child – Angle	4	2	5	5
Adult–Rotation	10	2	4	0
Child–Rotation	4	1	1	10

A chi-square test of this distribution indicates that adults and children vary significantly in both angle construction and triangle rotation [$\chi^2(3, N=32) = 14.55$ and 14.7 , respectively, $ps < .01$]. Model frequencies between tasks, within age groups, did not differ significantly, $ps > .05$.

Furthermore, the means of all absolute deviation from estimated magnitude to target magnitude (error), indicating overall accuracy, showed a similar pattern (Table 2).

Table 2: Mean and standard deviation of absolute deviations from estimated and actual magnitudes.

	Mean Error	SD
Adult–Angle	9.78°	2.69
Child – Angle	35.7°	16.7
Adult–Rotation	16.5°	4.93
Child–Rotation	41.0°	13.9

A two-way ANOVA with task-type as a within subjects factor and age as a between subjects factor reveals a strong main effect for age [$F(1,31)=29.8$, $p<.000$] and a weaker, yet significant, effect for task type [$F(1,31)=4.6$, $p<.05$], indicating better performance for angle construction. Interaction between task and age was non-significant.

To analyze the use of landmarks each participant’s trials were divided into 4 quadrants with target values in the ranges 0° - 45° , 46° - 90° , 91° - 135° , and 136° - 180° . For each participant the 180° landmark to near-landmark statistic was calculated for trials in quadrant four (136° - 180°) and 90° in quadrant two and three (46° - 135°). We then applied t-tests to determine whether these values differed significantly from zero, suggesting explicit use of the landmark. The means and p-values are shown in Table 3 below.

Table 3: Mean ratios of landmark to near-landmark stops and associated p-values.

Angle Construction	Mean Ratio	Triangle Rotation	Mean Ratio
Adult – 90° Q2-Q3	.37*	Adult – 90° Q2-Q3	.19
Child – 90° Q2-Q3	-.06	Child – 90° Q2-Q3	.25
Adult – 180° Q4	.25+	Adult – 180° Q4	.48**
Child – 180° Q4	-.06	Child – 180° Q4	.25*
+ $p < .1$		* $p < .05$ ** $p < .01$	

For the rotation task both children and adults applied the 180° landmark strategy, while neither did so in the angle construction task. In angle construction only adults utilized a 90° landmark strategy. We applied two ANOVA models to compare age and task for each landmark within its associated region. With 90° landmarks there was a significant main effect of age [$F(1,31)=5.0$, $p < .05$], but not task-type ($p > .05$). With 180° landmarks there was a significant main effect for task-type [$F(1,31)=4.9$, $p < .05$], but not for age.

Discussion

Clearly, there is a large difference between adult and child performance in both tasks. This is certainly not surprising, given the difference in experience between the adults and children in the domain of geometry. Yet, considering that 10 of the 16 children’s data for the rotation task could not be fit by either a linear or logarithmic function, the extent of this difference was surprising.

The graphs for individual subjects who were classified as “other” show either general randomness, crowding towards some arbitrary magnitude, or (in one case) a *negative* linear relationship. For these students, the mapping between numerical value and the chosen spatial representation was either meaningless or completely misconceived.

Another explanation is that these children simply refused to “play the game” correctly, and were simply applying their own, idiosyncratic rules. Yet, considering that only half as many children were classified as “other” for angle construction, it is unlikely that this behavior emerged from general disinterest. Rather, many students expressed their frustrations, especially during the rotation task, by telling test administrators that, “I don’t know how to do this.” Furthermore, in both tasks, several students were unsure as to which direction represented an increase in value.

Adults and children also differed greatly in the application of landmarks. While adults clearly used 90° landmarks for targets ranging from 45° to 135° in angle construction, children showed little evidence of this strategy. In fact, the children were slightly more likely to stop at near-landmark values (albeit at non-significant level). Both adults and

children used the 180° landmark in the rotation task, but this may be an effect of the particular environment as 180° represents a clear physical boundary.

One may also reasonably claim that near-landmark stops were, in some cases, attempts at using specific landmarks. Yet, due to a general lack of precision, and difficulty with mouse control, children often stopped outside of the accepted landmark range suggesting that, with practice, landmark stops may replace near-landmark stops.

While, this data demonstrates relative extremes in numerical representation it cannot inform us about the path of development from novice to expert. Rather, we are left to ask whether adult performance result from a wealth of exposure to degree measures in particular or from a flexible understanding of the linear nature of numbers? From the latter perspective one might imagine that adults are able to imagine a curved number line with endpoints at 0° and 180° – which would enable linear performance with relatively little experience with degrees, specifically. Furthermore, given the important role that landmark values holds in adult performance, should child instruction focus on strategies incorporating landmark values or will mental representations for these landmarks emerge from exposure to the entire range of magnitudes?

Such questions suggest the potential of intervention studies to elucidate paths of development. Possible interventions to promote understanding of degree measure may include measuring angles, playing games aimed specifically at these numerical constructs, or situated activities such as LOGO programming. In particular our research team is currently investigating the latter two means of developing numerical understanding.

In a preliminary intervention study applying a LOGO-like environment and geometry curriculum with thirteen children (from this study), we have found a trend towards improvement in overall accuracy measure for angle construction [$t(12) = 2.1$, $p = .059$]. Furthermore, of these 13 students the number of students demonstrating a linear representation increased from four to nine.

Although the study of relatively novel numerical concepts is of theoretical interest, one might argue that if these concepts are so under-represented in curriculum then interventions at this level may be unnecessary or inappropriate. However, the National Council of Teachers of Mathematics (2000) stresses the important of geometric and spatial reasoning for children of all ages. We suspect that mastery of basic concepts, such as angle measure, serves as a grounding for higher-level conceptual skills, such as geometric constructions and proofs

The Disproportionate Face Inversion Effect in Recognition Memory

Melissa Prince (Melissa.Prince@newcastle.edu.au)
Andrew Heathcote (Andrew.Heathcote@newcastle.edu.au)
School of Psychology, The University of Newcastle
University Drive, Callaghan, 2308, NSW Australia

Abstract

The Disproportionate Face Inversion Effect (DFIE), the finding that inversion disproportionately affects face recognition, provides a primary piece of evidence to suggest that faces are processed in a qualitatively different way to other visual stimuli (i.e., along configural as well as featural dimensions). However, when Loftus, Oberg and Dillon (2004; also Prince and Heathcote, 2009) examined the DFIE using state-trace analysis (Bamber, 1979) they found evidence for a one-dimensional encoding of unfamiliar faces when inversion only occurred during the study phase of a recognition memory task. We further examine this one dimensional result with more precise individual measurement and more specifically, Prince and Heathcote's suggestion that the use of configural encoding may not be automatic in recognition memory.

Keywords: Disproportionate Face Inversion Effect; Recognition Memory; State-trace analysis.

Over the course of a human lifetime, thousands of faces can become so familiar that they can be recognized after only a glance, when seen in an unfamiliar context and even after undergoing significant physical changes (Maurer, LeGrand & Mondloch, 2002). Indeed, the common experience of recognizing a familiar face in a crowd or involuntarily imagining a face in scenic features seems to indicate that humans possess an innate aptitude for face processing. However, this expertise is less evident when the faces are unfamiliar (Hancock, Bruce & Burton, 2000), and even more so when they are viewed upside-down.

It is widely found that perception and memory performance for all mono-oriented stimuli (i.e., objects usually viewed in a specific "upright" orientation) are strongly disadvantaged by inversion; called the *Inversion Effect*. However, in his seminal paper, Yin (1969) observed that this inversion effect was disproportionately stronger for faces compared to mono-oriented control stimuli (e.g., houses) that were matched as closely as possible to faces in terms of familiarity, complexity and difficulty in applying a verbal label; known as the *Disproportionate Face Inversion Effect* (DFIE). Although the inversion effect is taken to indicate there is a general factor affecting the processing of all mono-oriented stimuli, the DFIE suggests there is an additional face specific factor. Hence the DFIE has become one of the primary pieces of evidence to suggest that face processing is "special".

In this paper, we aim to explore the evidence for the DFIE in recognition memory accuracy for unfamiliar faces. In particular, we will focus on an alternate statistical method for testing the effect of inversion called *State-Trace Analysis* (Bamber, 1979). Using this technique, Loftus, Oberg and Dillon (2004) found that, in contrast to results

from traditional analyses that revealed a weak DFIE, state-trace results indicated that unfamiliar faces were not special relative to other mono-oriented stimuli when inversion was only manipulated during the encoding stage of a recognition memory task. Loftus et al. therefore suggested that the DFIE only occurs during memory retrieval. Although Prince and Heathcote (2009) replicated this state-trace result, as well as ruling out several potential caveats on Loftus et al.'s methodology and state-trace analyses, they questioned the memory retrieval interpretation. Here we examine an alternate explanation for these results, namely Prince and Heathcote's *Strategic Hypothesis*.

The Disproportionate Face Inversion Effect

Since Yin's (1969) initial demonstration, the DFIE in recognition memory has been replicated numerous times and with various procedural variations. Although many studies have followed Yin's original design where items were studied upright or inverted and tested in the same "matched" orientation, a DFIE has also been found when images were tested using a different viewpoint from study (Valentine & Bruce, 1986) as well as when all images were studied upright but tested upright or inverted (Yarmey, 1971). Consequently, the DFIE has been taken to indicate that face processing is qualitatively different from the processing of other visual stimuli.

It has been suggested that the two factors (or dimensions) underlying the DFIE might be two types of information that can be extracted from the images. The first, *featural information*, is common to all mono-oriented stimuli and refers to the isolated features of an object that can be specified without reference to its other parts. In contrast, the second type, *configural information*, is mostly or only available to faces and enables good discrimination despite the highly similar structure and features that all faces share (McKone & Yovel, 2009). At least three types of configural information have been proposed: (a) *holistic information*, which captures the overall look of a face; (b) *first order relational information*, which refers to the arrangements of features that define a face; and (c) *second order relational information*, which refers to distances between internal features. However, the differences between these sub-types are not of critical importance here. Rather, what is important is the general finding that inversion differentially affects two broad classes of largely independent information.

Although both featural and configural information are affected by inversion, it is typically found that the extraction of configural information is particularly disrupted. Hence, it is often believed that upright faces are processed using both

featural and configural information, whereas only featural information is available for inverted faces. Recent evidence, however, suggests a more graded relationship, such that inversion decreases the rate at which both featural and configural information can be extracted from a face, but to a greater degree for configural information (Valentine & Bruce, 1986).

Identifying Dimensions of the DFIE

Evidence for the DFIE, and hence for the existence of two underlying dimensions for face processing, is traditionally provided by a dissociation quantified by an interaction test comparing the size of the inversion effect for faces (the *face inversion effect*; FIE) to that for a mono-oriented control stimulus, such as houses (the *house inversion effect*; HIE). However, it has been argued that such dissociation logic at best makes the rejection of a one-dimensional account more plausible or parsimonious. Moreover, where response measures are bounded (e.g., accuracy data), interactions may be scale dependent (e.g., influenced by floor and ceiling effects; Loftus, 1978). An alternate method proposed to overcome the caveats on dissociation logic is *State-trace analysis* (e.g., Newell & Dunn, 2008). State-trace analysis provides a rigorous method for determining whether a single dimension (i.e., a single latent variable) is able to explain the joint effect of two or more experimental factors, and assumes only that the mapping between the latent variable and response is monotonic (i.e., that the response and latent variable consistently change in the same direction).

The results from state-trace analysis are assessed using a *state-trace plot*, which is essentially a scatterplot showing the covariation of two factors, namely the *state* and *dimension* factors. As shown in Figure 1, the state factor defines the axes of this plot, while each level of the dimension factor typically defines a set of points within the plot. In particular, the dimension factor is manipulated with the aim of differentially influencing the latent variables. In applications examining the DFIE, the state factor is defined by recognition accuracy for face and house images and the dimension factor manipulated to differentially influence the latent configural dimension is the image orientation.

The crucial diagnostic feature of this plot concerns whether or not the data fall on a single monotonic function; that is, whether the ordering of the x-axis values is the same as the ordering of the y-axis values. At least three data points are required to potentially violate monotonicity, and thus a third factor, called the *trace factor*, is introduced to sweep out a set of points (i.e., a “data trace”) within each level of the dimension factor. Importantly, the trace factor must itself have a monotonic effect if we are to unambiguously attribute dimensionality evidence to the interaction between the state and dimension factors (i.e., that $A < B$ and $a < b$ in Figure 1). Loftus et al. (2004), for example, manipulated the study presentation time, which can reasonably be assumed to have a monotonic effect on accuracy; shorter study durations always lead to poor recognition in all conditions (within measurement limits).

If the two levels of the state factor depend on the same underlying dimension, the points on a state-trace plot will fall on a single monotonic function (e.g., in Figure 1a the x- and y-axis order is a,A,b,B). If, however, performance for each state is determined by more than one dimension (e.g., along featural and configural dimensions), the resulting state-trace plot will be non-monotonic (see Figure 1b). It is important to note that although a non-monotonic plot cannot have been produced by a one-dimensional model, the converse does not necessarily hold. Monotonic evidence is only diagnostic of dimensionality when there is overlap of the data traces on at least one axis. Where data-trace overlap fails (such as in Figure 1c), a state-trace plot can be monotonic even if two separate dimensions exist.

Despite the simplicity of state-trace analysis graphically, the best statistical method for testing departures from monotonicity remains an open question (e.g., Newell & Dunn, 2008). Recently Heathcote, Brown and Prince (submitted) proposed a method for assessing dimensionality in state-trace designs based on a Bayes Factor method of selecting amongst models defined by ordinal constraints: namely, (a) a *non-trace* (NT) model, which assumes the trace factor does not have a monotonic effect on performance: that is that the trace model is violated; (b) a *no overlap* (NO) model, which given the trace model holds, assumes the data traces do not overlap and hence cannot be

Figure 1: Example state-trace plots for a design where the state, dimension and trace factors each have two levels. The thin dotted lines show the underlying dimension or processes revealed in the plot, with examples of (a) a one-dimensional plot, (b) a two-dimensional plot and (c) a non-diagnostic state-trace plot (i.e., due to the data traces having no overlap)

considered diagnostic of dimensionality; (c) a *uni-dimensional* (UD) model, which assumes the state-trace plot is monotonic, given that both trace monotonicity and data trace overlap hold; and (d) a *multi-dimensional* (MD) model, which assumes the state-trace plot is non-monotonic, again given that both trace monotonicity and data trace overlap hold. Together these four models account for all possible orders. The aim is then to find the model with the highest posterior probability; that is, the model with the highest probability of being the data generating model.

A Memory Retrieval Phenomenon?

Using state-trace analysis, Loftus et al. (2004) reported an apparent exception to the otherwise robust DFIE result; evidence for a single dimension in accuracy averaged over participants in recognition memory for unfamiliar faces (Experiment 1). In contrast, when the faces were famous (i.e., familiar; Experiment 2), they found evidence for more than one dimension. In both experiments, images were studied upright or inverted and all tested upright. This design was utilized to examine Valentine's (1988) assertion that "the orientation of the inspection [study] series does not appear to be critical" (p.474) to produce a DFIE. Loftus et al. concluded that a DFIE would only emerge when inversion was present at the time of memory retrieval, because familiar faces cause memory retrieval at study (and so produce a DFIE when inversion occurs during study), but unfamiliar faces do not (so inversion occurring at study cannot cause a DFIE).

Although, Prince and Heathcote (2009) replicated the one-dimensional state-trace result with unfamiliar faces, the conclusion that a DFIE only occurs at memory retrieval goes against the general opinion in the literature which would suggest the DFIE "is really a perceptual phenomenon rather than a memory phenomenon" (Freire, Lee & Symons, 2000; p.160). Consequently, Prince and Heathcote proposed an alternate explanation more compatible with this perceptual view, whereby participants may be able to strategically use configural information, but only when they know it will improve performance for all items. That is, that the use of configural information may not be automatic in recognition memory.

Here we aim to further examine the one-dimensional state-trace result for unfamiliar faces, as well as Prince and Heathcote's (2009) strategic hypothesis. To do so we ran new experiments that greatly increased the number of observations obtained from each participant (78 observations per design cell), by increasing the number of trials and reducing the number of study durations. Our first condition partly replicated Prince and Heathcote's *Test Upright* design, with both upright and inverted study trials mixed in each study list and all items tested upright. However, it used a two-alternative forced choice (2AFC) recognition memory test, rather than the single-item testing used in the original study (i.e. on each test trial participants chose between a studied and unstudied face, or between a studied and unstudied house). This condition was run to

check if Prince and Heathcote's result was replicable with a different testing procedure and with a slightly different, and more powerful, design. We denote this condition *TUM2* (*Test Upright, Mixed study lists, 2AFC*).

In *TUM2* (thus also Prince and Heathcote's, 2009, *Test Upright* design), an old item can either be studied and tested upright or studied inverted and tested upright. The former case has a matched (configural) encoding available at study and retrieval. However, when an image is studied inverted it only (or at least mostly) can be encoded using featural information, yet configural information is available from the upright test presentation. As suggested by the encoding specificity effect (i.e., the improvement in memory when study and test conditions match; Tulving & Thomson, 1973), if only featural information was available at study, performance would benefit from a matched (featural) test encoding and be hurt by a mismatched (configural) encoding. Hence it may be detrimental for participants to use configural information when an item had been studied inverted.

In these upright test conditions, upright and inverted items were mixed together at study. Therefore, when all items are presented upright at test, participants have no way of knowing for which test items the use of configural information may be detrimental (i.e., those studied inverted). As these experiments used multiple study-test cycles participants would quickly become aware that all test items were upright. Hence it is possible that they decided to rely purely on featural information, either by not encoding upright study items along a configural dimension, or choosing not to use the configural information available at test. In either case, both faces and houses would only be encoded along a single (featural) dimension, producing the one-dimensional state-trace plots observed by Loftus et al. (2004) and Prince and Heathcote (2009).

To test this possibility, in our second condition, participants viewed two types of study-test lists where: (a) all items were studied and tested upright or (b) all items were studied inverted and tested upright. By blocking study orientation in this manner we hoped that participants would become aware of when configural encoding was advantageous (in type 'a' lists) and hence make use of it. If this occurred, we should observe a multi-dimensional state-trace plot, and hence evidence against Loftus et al.'s (2004) memory retrieval hypothesis. We denote this condition *TUB2* (*Test Upright, Blocked study lists, 2AFC*).

Method

Participants

The 38 participants were recruited from members of the wider community, who had normal or corrected-to-normal vision. They received cash reimbursement for their time (total AUD\$30.00). Two subjects in *TUM2* were excluded due to their raw percentage correct falling below 55%, leaving 18 subjects in *TUM2* and *TUB2*.

Stimuli

Stimuli were black and white bitmap images (120 x 105 pixels) displayed at twice their original size. A total of 936 face stimuli were sourced from the FERET database (Phillips, Wechsler, Huang & Rauss, 1998), excluding images with averted gaze, distinctive facial expressions or blemishes (either natural or the result of photographic process). These face stimuli were divided into homogenous blocks based on race, gender and any other distinctive feature (i.e., glasses or facial hair). An additional 36 Caucasian males without facial hair or glasses were included for the practice phase.

A total of 936 house stimuli (with an additional 36 for practice) were sourced using real estate websites and internet search engines. Houses were excluded if located in New South Wales in order to reduce potential familiarity effects given that participants were largely drawn from this region. Following Prince and Heathcote (2009), house stimuli were also divided into homogenous blocks based on their most distinctive feature (e.g., fence, two-storey).

Apparatus

Testing was completed either at individual computer terminals equipped with 17inch LCD monitors or at an external location using laptop computers. All stimuli and text were presented on a black background with white font. Prospective and retrospective confidence judgments were made using the computer keyboard with the keys “z”, “x”, “.”, “/” labeled “1”, “2” “3” and “4” respectively.

Procedure

It was emphasized during the instructions for the task, that the orientation of a stimulus was irrelevant to a recognition decision; that is, participants should identify an image as being “old” even if the test item had been studied in a different orientation. In *TUB2*, participants were further informed that study lists would be comprised of either all upright or all inverted images and a warning was displayed prior to each study list indicating the study orientation to be used. Before commencing the main experiment, participants completed two full length practice blocks; one for faces and one for houses, with order counterbalanced over participants.

A study list (comprised of 18 trials) was initiated by pressing the space bar, following which the warning “*Prepare for study ... of ... Place your fingers on the keys*” was displayed for 2000ms. For each study trial a centrally placed fixation cross was displayed for 1000ms, followed by a 300ms blank screen. The target stimulus was then presented for its designated duration (upright: 33, 100, 267ms; inverted: 267, 800, 2048ms), with durations selected to maximize data trace overlap and each duration level used equally often in every study list. After each study presentation, participants had a maximum of 2500ms to rate their prospective confidence by responding to the question “*How confident are you that you will remember this image later on?*” using a four-point scale from “definitely no” to

“definitely yes”. The purpose of this prospective confidence judgment was to encourage participants to attend to the stimulus and this data will not be considered further.

The test list (again comprised of 18 trials) was marked by a 300ms blank screen, followed by the warning “*Prepare for test ... of ... Place your fingers on the keys*” displayed for 2000ms. Each test trial was preceded by a blank screen following which the test item and retrospective confidence response scale were presented for a maximum of 5000ms. For our 2AFC design, a pair of test images (one old and one new, with the old item appearing equally often on the left and right) were presented above the question “*Which image was previously studied and how confident are you that you have seen this image earlier?*” Again participants responded using a four-point scale from “definitely left” to “definitely right”. For the entire length of the study and test lists, the words “STUDY” and “TEST” were respectively displayed in the top left corner of the screen.

Following the practice study-test lists, participants received feedback on the number of times they used each of the confidence levels. The purpose of this feedback was to encourage participants to use the full range of the confidence scale.

Participants were required to attend three one hour sessions, preferably on consecutive days. Participants completed 12 study-test lists in their first session and 20 study-test lists in the later two. At the end of each list participants were able to take a self paced break (minimum of 30s), while three longer breaks (minimum of 5min) occurred within each one hour session.

Results

The retrospective confidence rating was used to determine a participant’s probability correct (i.e., the number of trials correct divided by total number of trials). Accuracy was then quantified by the inverse cumulative normal probability (z) transformation of the probability correct.

We first report a preliminary analysis to ensure the present study was able to replicate previous findings that accuracy is linear as a function of the logarithm of study duration. One-way repeated measures ANOVAs were performed on the effect of the logarithm of study duration for upright and inverted houses and faces in each condition with polynomial trend analyses. Linear trends were all statistically reliable ($p < .05$) and accounted for almost all (minimum 88%) of the variance in accuracy as a function of study duration. The only quadratic trends to approach significance were for *TUM2*’s upright faces ($p = .045$) and upright houses ($p = .075$).

Evidence for the DFIE was first assessed by the traditional test of an interaction between orientation and stimulus type. As the 267ms duration level was the only study duration common to both upright and inverted stimuli, the DFIE was tested by a two-way (orientation by stimulus type) ANOVA using only the 267ms data. Table 1 also shows estimates of the inversion effect (i.e., the difference between upright and inverted) for faces (FIE) and houses

(HIE), the corresponding DFIE estimates (DFIE=FIE-HIE) and the results of associated *t*-tests.

Table 1: Estimates of the FIE, HIE, and DFIE and results associated *t*-tests, for the 267ms data.

	FIE	HIE	DFIE
<i>TUM2</i>	0.281**	0.270***	0.011
<i>TUB2</i>	0.274***	0.215***	0.059

Note: ****p* < .001, ***p* < .01, **p* < .05

For *TUM2* there was no reliable difference in accuracy between houses ($M=0.479$) and faces ($M=0.411$), $p=.152$. However, accuracy was reliably higher for upright items ($M=0.582$) than inverted items ($M=0.307$), $F(1,17)=30.50$, $p<.001$. Although a slightly greater inversion effect was observed for faces than houses (DFIE=0.01), this effect was not statistically reliable, $p=.91$. Similarly for *TUB2*, accuracy was higher for houses ($M=0.421$) than faces ($M=0.409$), but not reliably so, $p=.83$. Upright items were again reliably more accurate ($M=0.537$) than inverted items ($M=0.293$), $F(1,17)=41.93$, $p<.001$. However, there was no reliable DFIE (DFIE=0.059; $p=.42$).

State-trace plots for each condition are shown in Figure 2. Results for upright study are joined, as are the points for inverted study. These lines are clearly monotonically increasing, and consistent with the requirement that the trace factor has a monotonic effect, both conditions' posterior model probabilities favored the trace model being true, $p(\text{NT})<.001$. The plots also show excellent data trace; for both *TUM2* and *TUB2* $p(\text{NO})<.001$. In assessing the overall dimensionality, *TUM2* showed positive evidence for a multi-dimensional model, $p(\text{MD})=0.910$, however, *TUB2* showed equivocal evidence suggestive of a one-dimensional account, $p(\text{UD})=0.733$.

Discussion

We replicated Loftus et al.'s (2004) and Prince and Heathcote's (2009) finding of a linear increase in accuracy consistent with the suggestion that there was no abrupt change in strategy (i.e., no switch from featural to configural processing) associated with longer study durations. Additionally, we replicated the lack of evidence for a DFIE using the traditional interaction measure (although the DFIE estimates were of the same magnitude as Loftus et al., and Prince & Heathcote). Our state-trace findings, however, were mixed.

We found clear multi-dimensional evidence consistent with the use of both featural and configural information for *TUM2*, where inversion was only manipulated during initial encoding and upright and inverted items were mixed together at study. However, for *TUB2*, where study lists were blocked by orientation, we observed evidence suggestive of a single underlying dimension (although at an equivocal level). In this blocked condition, participants were informed of an item's study orientation if it was old and therefore, according to Prince and Heathcote's

Figure 2: State-trace plots showing the 50% credible regions for the (a) *TUM2* and (b) *TUB2* conditions. The numbers 1...3 indicate shorter to longer study durations.

(2009) strategic hypothesis, may have been able to reinstate the use of configural information. The observed one-dimensional result, however, does not offer support for this proposal. This is not to say that our results are consistent with Loftus et al.'s (2004) memory retrieval hypothesis. Indeed the strong multi-dimensional result for *TUM2* cannot be explained by a memory retrieval interpretation, as orientation was only manipulated during initial encoding.

It is important to note that the posterior model probabilities on which we are basing our interpretations, are not simply the average result over participants. Rather they examine, for example, the probability that *all* individual state-trace results are one-dimensional versus *all* being multi-dimensional. Hence these probabilities can sometimes be influenced by outlying subjects. To ensure our results were not influenced in this way, we re-examined the dimensionality results, excluding participants with poor evidence ($p>.5$) for trace monotonicity and data trace overlap (four participants from *TUM2* and seven from *TUB2*

were excluded using this criteria). However, both conditions revealed the same pattern of results; that is, multi-dimensional evidence for *TUM2* and equivocal evidence for *TUB2*. Although *TUB2* showed a decrease in the probability supporting a one-dimensional model, $p(\text{UD})=0.691$.

One possible explanation for observing multi-dimensional evidence, even though inversion was only manipulated during the initial stimulus encoding, is that our more precise individual measurement also produced higher accuracy performance overall and consequently an improved effect size. Although state-trace analysis is not affected by floor and ceiling effects to the same degree as traditional dissociation analyses, if accuracy is not high enough to reveal the decrement caused by inversion then it will also not be able to reveal the underlying dimensionality. Consistent with this suggestion, we can observe from the *TUM2* state-trace plot that the data traces do not depart from monotonicity (indicating multi-dimensional evidence) until the longer study duration levels (where accuracy is also higher). This same pattern can also be seen to a lesser degree in *TUB2*.

Although not reported here, we also ran these same mixed and blocked conditions using a yes/no testing procedure (i.e., participants were shown a single test item and asked to indicate if that item had or had not been studied), and in contrast to our 2AFC results, observed equivocal one-dimensional evidence. Interestingly, it has been found that memory performance is advantaged by a 2AFC procedure over a yes/no procedure (Deffenbacher, Leu & Brown, 1981), which could explain why our 2AFC conditions tended toward multi-dimensional evidence. It should also be noted that recognition memory studies in general tend to show a smaller inversion effect than perceptually based studies (e.g., *TUM2* showed a 9.97% drop in accuracy, but perceptual tasks can show a drop double this magnitude; see McKone & Yovel, 2009). Hence evidence for more than one dimension underlying face processing may only emerge when performance is high enough to reveal the decrement caused by stimulus inversion.

We will pursue two avenues in future research. First, as our results did not offer strong insight into Loftus et al.'s (2004) memory retrieval hypothesis we will examine state-trace evidence for the DFIE in recognition memory using a paradigm in which unfamiliar faces are all studied upright and tested either upright or inverted. In this paradigm, Loftus et al.'s (2004) memory hypothesis predicts that evidence for multiple dimensions should emerge, because inversion occurs at test where memory retrieval is required. Second, we will extend the use of state-trace analysis to a perceptual paradigm, such as a sequential same-different task, in order to investigate whether evidence for more than one dimension emerges with larger inversion effects.

Acknowledgments

Decomposing Externally Cued Task Switching Costs

Christina Wasylyshyn (christina.wasylyshyn@nrl.navy.mil)

Naval Research Laboratory, 4555 Overlook Ave., S.W.
Washington, DC 20375 USA

Abstract

The double-cued task switching procedure has recently been introduced as a new way to measure externally cued switch costs. In the present individual differences study, two hundred fifty young adults completed measures of task switching, inhibition, and long-term memory. A latent variable approach was taken to examine the relationships among these cognitive measures. Decomposing the externally cued task switching costs into a cue switch component and a task switch component indicated that individual differences in these costs could be explained by benefits of repeated cues rather than by changes in tasks. Individual differences in the cue switch component were predicted by long-term memory scores.

Keywords: cued task switching; switch costs; individual differences; long-term memory; inhibition

Introduction

Recent interest in understanding how people shift their mental sets in response to external cues has led to the development of a new method of measuring task switching costs: the double-cued procedure. In traditional, single-cued procedures, cues and tasks are mapped one-to-one, leading to the possibility that the components of cue switching and task switching are confounded. When there is a change in cue, there must be a change in task; when there is no change in cue, it follows that the task will repeat from the previous trial. Both cue switching and task switching then contribute to the overall switch cost in an undifferentiated manner.

One way to distinguish between cue switching and task switching is to use a double-cued procedure, that is, to have two cues to indicate each task. This leads to three types of trials: cue repeat, cue switch, and task switch. In cue repeat trials, both the cue and the task repeat; this is a traditional nonswitch trial. In cue switch trials, the cue changes but the task remains the same; this is also classified as a nonswitch trial. In task switch trials, both the cue and the task change. The latency differences between cue switch and cue repeat trials are thought to indicate encoding benefits from repeated cues. The latency differences between task switch and cue switch trials are thought to reflect the act of task switching.

In task switching paradigms, responses to the current stimulus trial are slower (and typically less accurate) if the task differs from that completed on the previous trial. Switch costs are thought to indicate how flexibly one can change his/her cognitive configurations, or task sets, to accommodate newly relevant task demands. In order to establish a task set, one must activate relevant task rules (e.g., Mayr & Kliegl, 2003; Rubinstein, Meyer, & Evans, 2001) and minimize interference from competing task sets,

possibly through inhibition processes (e.g., see Mayr & Keele, 2000). It has therefore been suggested that one's task set reflects the interaction of task set inertia from previous trial(s), exogenous task set activation from the stimulus itself, and endogenous control input needed to overcome the other two biases and to reconfigure the cognitive system for a change in task (Aron, Monsell, Sahakian, & Robbins, 2004).

Mayr and Kliegl (2003) suggest that performance in double-cued procedures can be explained by two processes: cue-based retrieval of task rules from memory and the application of task rules to the target. The retrieval of task rules produces the cue encoding benefit, while the time involved in applying the mapping rules produces the actual switch cost. Retrieval and loading of task rules from long-term memory is necessary for both nonswitch and switch trials. A repetition of the immediately preceding cue leads to a reactivation of the most recent retrieval process (i.e., positive priming); a cue change, however, requires activation of a new (or less recently activated) retrieval process.

Logan and Bundesen (2003) offer a similar explanation, but one that assumes there is no endogenous control component. The explicit task cue provides enough information to uniquely indicate a response on each trial. There is no task set reconfiguration process between the cue and the target stimulus. Instead, any switch costs that remain beyond the act of cue switching are the result of encoding benefits on nonswitch trials, or priming from related cues, not task switching (see Logan & Bundesen, 2004, for explanation of the process of mediator repetition, and see Schneider & Logan, 2005, for formal model).

Using double-cued procedures, several studies have shown evidence for cue encoding benefits (i.e., responses were faster for cue repeat trials than for cue switch trials). However, after cue encoding effects have been accounted for, the remaining task switch costs have been negligible in some studies (e.g., Logan & Bundesen, 2003, 2004; Monsell & Mizon, 2006 Experiment 1) and substantial in others (e.g., Mayr & Kliegl, 2003; Arrington & Logan, 2005 Experiment 3; Monsell & Mizon, 2006 Experiments 2-6). There are several procedural differences between these studies that may explain some of the differences in results, including type of task cue and frequencies for task switches. Evidence that switch costs result from the processing of the task cue rather than from the switching of tasks has been shown in studies that use salient verbal or pictorial task cues and/or 50% task switch frequency. Evidence for substantial task switch costs over and above any effect of a cue change

has been shown in studies that employ arbitrary task cues and/or 33% or less task switch frequency.

Most of the research in task switching and executive control functioning has been experimental in nature. The present study, however, takes a novel individual differences approach to decompose switch costs to determine whether a cue switch component can be differentiated from a task switch component. The overall goal is to establish a representation of the structure of individual differences in the double-cued procedure to determine whether switch costs are more likely to reflect processes involved in the interpretation of instructional cues (i.e., trial to trial change in retrieval path) or the switching of task sets (i.e., trial to trial change in the task itself). In this way, it will be possible to test, at the latent level, if individual differences in the costs incurred reflect a benefit for cue repetition instead of, or as well as, a cost for task switching.

Method

Participants

Two hundred fifty Syracuse University students (169 females, 81 males, mean age = 18.92, SD = 1.21) participated. All students were native English speakers and non-colorblind.

Tasks

There were three task categories: task switching, long-term memory, and inhibition.

Task Switching Switch costs were measured in three task domains: digits, shapes, and verbal. For the digits task, magnitude and parity judgments were made on a series of digits (1, 2, 3, 4, 6, 7, 8, 9). In the shapes task, participants determined either the form or color of an image. Stimuli consisted of combinations of two shapes and two colors. For the verbal task, participants determined if a word shown could be classified as an animal or a non-animal or if it could be classified as something that was smaller or larger than a basketball. Stimuli consisted of 64 high frequency and high imagery nouns obtained from the Toronto Word Pool.

Each task consisted of 120 trials. Cues and targets were combined randomly, with the constraint that cue-repeat, cue-switch, and task-switch trials each occurred on one-third of the trials. In each task, there were four cues. Two meaningful and salient cues distinguished each sub-task, so that one cue noted category membership and the other noted response mapping. In the digits task, participants were presented with one of four cues on each trial: Magnitude, High-Low, Parity, or Odd-Even. Depending on the cue shown, participants pressed the 'z' key if the target digit was higher than five or odd, and the '/' key if the target digit was lower than five or even. In the shapes task, one of four cues was presented on each trial: Shape, Triangle-Circle, Color, or Red-Green. Participants pressed the 'z' key if the target image was a triangle or was colored red, and the '/' key if the target image was a circle or was colored green. In the

verbal task, either the cue Creature, Animal-Nonanimal, Size, or Smaller-Larger was presented on each trial. Participants pressed the 'z' key if the target word was an animal or was smaller than a basketball, and the '/' key if the target word was a non-animal or larger than a basketball. On cue repeat trials, both the cue and the task repeated from trial n to trial $n+1$ (e.g., in the digits task, magnitude followed by magnitude). On cue switch trials, the cue changed but the task repeated (e.g., magnitude followed by high-low). On task switch trials, both the cue and the task changed (e.g., magnitude followed by parity). Participants were given 150 ms for preparation during the cue-stimulus interval and 300 ms for passive dissipation during the response-cue interval.

Inhibition In the flanker task (Eriksen & Eriksen, 1974), participants were asked to identify a centrally presented target letter (either an 'S,' 'C,' 'H,' or 'K'). This target letter was either presented alone or with three noise letters flanking it on each side. Participants pressed the 'z' key when the target letter was S or C, and the '/' key when the target letter was H or K, as quickly as possible. There were four stimulus conditions: (1) no noise (e.g., S), (2) noise same as target (e.g., SSSSSS), (3) noise response compatible (e.g., SSSCSSS), and (4) noise response incompatible (e.g., SSSKSSS). After completing 32 practice trials, participants completed 160 trials (4 blocks of 40 trials). Trials began with a 500 millisecond fixation cross presented in the center of the screen, followed by a blank screen for 50 milliseconds. The stimulus was then presented until a response was made. The latency difference between the noise response incompatible condition and the no noise condition served as the dependent measure.

Long-Term Memory Participants were asked to learn a list of 30 words. Words were presented one at a time in the center of the screen at a rate of 3 seconds each. After approximately 15 minutes, participants were given a recognition test of all 30 words randomly mixed with 30 foil words. Participants pressed the 'z' key if the word was part of the original study list and the '/' key if the word was not presented in the original list. Stimuli were obtained from the Toronto Word Pool and consisted of highly familiar 1 syllable words that were 3, 4, or 5 letters in length. Scores were obtained using a nonparametric form of the discriminability index (i.e., a'), and participants with an a' score below .5 were excluded from analysis.

Results

Descriptive Statistics

Descriptive statistics are presented in Table 1. All of the measures meet the criteria for univariate normality (Kline, 1998); skews are all less than 3 and kurtosis values are all less than 4. All measures therefore displayed adequate distributional properties for being subjected to latent variable analysis.

Table 1: Descriptive statistics

Variable	M	n	SD	Skew	Kurtosis
Digits					
CR	808.72	241	118.72	0.16	-0.41
CS	1204.26	241	251.99	0.48	0.05
TS	1299.25	241	290.04	0.51	0.49

Note: CR = cue repeat trial, CS = cue switch trial, TS = task switch trial

Cue Switching vs. Task Switching: Accounting for Individual Differences in Switch Costs

Figure 1 presents the mean encoding costs and task switching costs (errors bars indicate SE) by task domain (digits, shapes, verbal). Encoding costs were calculated as latency differences between cue switch and cue repeat trials, and task switch costs were computed as latency differences between task switch and cue switch trials. Across task domains (please refer to Table 1), cue repeat trials were the fastest ($M = 847$ ms), followed by cue switch trials ($M = 1182$ ms), and finally task switch trials ($M = 1280$ ms). Cue switch trials were more like task switch trials than cue repeat trials, suggesting that cue repetition effects account for most of the switch cost. Indeed, the majority (77%) of the switch cost is accounted for by the cost of encoding the cue (335 ms cost). However, there is an overall mean residual task switching cost of 98 ms. Planned contrasts indicated that task switch trials were significantly slower than cue switch trials, $t = 8.04$, $p < 0.0001$. Therefore, from the means analysis, we can conclude that there is an effect of task switching. Partial correlations between cue repeat and cue switch trials, controlling for performance on task switch trials, were also computed. Controlling for task switch trials did not significantly attenuate the relationship between cue repeat and cue switch trials in any of the task domains; this suggested that the residual effect of task switching might not be useful as an individual differences variable. The next goal was to use Structural Equation Modeling to test for reliable individual differences.

Two models were contrasted to test whether, after accounting for cue encoding, the process of cue-switching is

Figure 1: Mean encoding costs and task switching costs (\pm SE) by task domain (digits, shapes, verbal)

sufficient to explain individual differences in switch costs, or whether an additional task switching process is needed to fully account for these costs. The former will be called the 2-factor model, and the latter will be referred to as the 3-factor model. In both models, the manifest measures are the RTs from the cue repeat, cue switch, and task switch trials from the digits, shapes, and verbal tasks. Residual variances of trial type measures employing the same task domain were correlated.

Model fit was assessed using the chi-square test for goodness of fit, the comparative fit index (CFI; Bentler, 1990), the Tucker-Lewis index (TLI; Tucker & Lewis, 1973), and the root mean square error of approximation (RMSEA; Browne & Cudek, 1992). Acceptable model fit is reflected by a nonsignificant chi-square test for goodness of fit, relative fit indices (i.e., CFI and TLI) above .90, and a RMSEA value below .08 (Bentler, 1990; Bentler & Bonnet, 1980). A RMSEA value below .05 indicates excellent fit. Analyses were conducted with AMOS 5 software (Arbuckle, 2003) using maximum likelihood estimation. For all of the SEM models, the factor loadings and interfactor correlations were allowed to vary (Anderson & Gerbing, 1988).

In order to capture what was common, all nine measures were free to load on the first factor, that is, an encoding baseline, because all types of trials (cue repeat, cue switch, and task switch) involve encoding the external cue and thus should have systematic differences in the encoding process. A 1-factor encoding model, however, did not sufficiently account for individual differences in switch costs, $\chi^2(18) = 108.88$, $p = .000$, TLI = .881, CFI = .952, RMSEA = .142. The second factor, cue switch, was then introduced to reflect the systematic individual differences associated only with switching a cue; it represents the common variance of the cue switch and task switch trials, once baseline encoding has been accounted for. The 2-factor model (please see

Figure 2; note that the correlations among the residual variances are not included in the figure for ease of interpretation) provided an acceptable fit to the data, $\chi^2(12) = 22.76$, $p = .030$, TLI = .979, CFI = .994, RMSEA = .060. In Figure 2, the larger circles represent the latent variables, and the rectangles represent the scores on the individual indicator tasks that were used to measure each of the latent variables. The smaller circles represent the residual variances of the indicator tasks.

A third factor, task switch, was then introduced to determine if a task switching process, in addition to encoding baseline and cue switching, could better explain individual differences in switch costs. This third factor was equal to the residual common variance of task switch trials only. The 3-factor model (please see Figure 3) provided an excellent fit to the data, $\chi^2(9) = 12.62$, $p = .181$, TLI = .991, CFI = .998, RMSEA = .040. At first glance, this suggests that there is an effect of task switching, over and beyond the processes of cue encoding and cue switching.

Because the 2-factor and 3-factor models are not nested, the Akaike Information Criterion (AIC) and the Expected Cross-Validation Index (ECVI) were used to compare overall model fit (Note: unlike the chi-square difference test, these indices do not provide a statistical comparison of competing models). In general, a model that has the lowest AIC and ECVI values is judged to fit the data better than the alternative model(s) tested (Brown, 2006). For the 2-factor model, AIC = 106.76 and ECVI = 0.429; for the 3-factor model, AIC = 102.62 and ECVI = 0.412. In terms of the AIC and ECVI indices, the 3-factor model best fits the data, however, the 3-factor model was deemed unacceptable due to non-interpretable and ill-fitting parameter estimates of the task switch factor. The variance of the task switch factor was not significant, $p = 0.272$. Only the path loading for the task switch trials in the Shapes task to the task switch factor was significant ($\beta = 0.18$, $p = 0.015$); the path loadings for the Digits and Verbal tasks were not significant.

Therefore, the 2-factor model was accepted. The lower (i.e., better fitting) AIC and ECVI values for the 3-factor model seem to simply reflect adjustment for model complexity compared to the 2-factor model, so that the 3-factor model does not account for any additional systematic differences in switch costs. The act of task switching does not provide reliable information that was not already available from cue switching.

Using Cognitive Measures to Explain Individual Differences in Task Switching

Further support for this claim comes from additional modeling of possible cognitive predictors (inhibition and long-term memory) that might serve to explain some of the systematic differences in each of the latent factors. Please see Table 2 for standardized effects and model fits. It should be noted that because only single indicator predictors are being employed, the following effects are small, but significant. Individual differences in inhibition significantly predict individual differences in encoding, but not cue

switching or task switching. That is, individuals who are quicker at encoding the present, most relevant information are also faster at inhibiting previous and/or distracting information. Individual differences in long-term memory

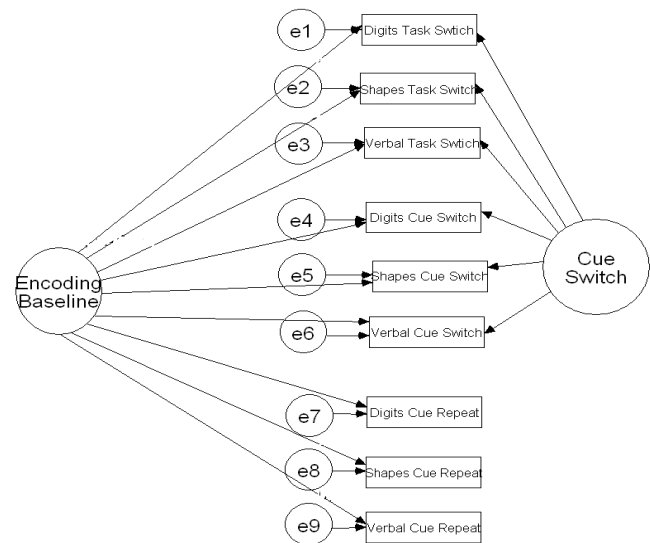

Figure 2: 2-Factor latent variable model to account for switch costs

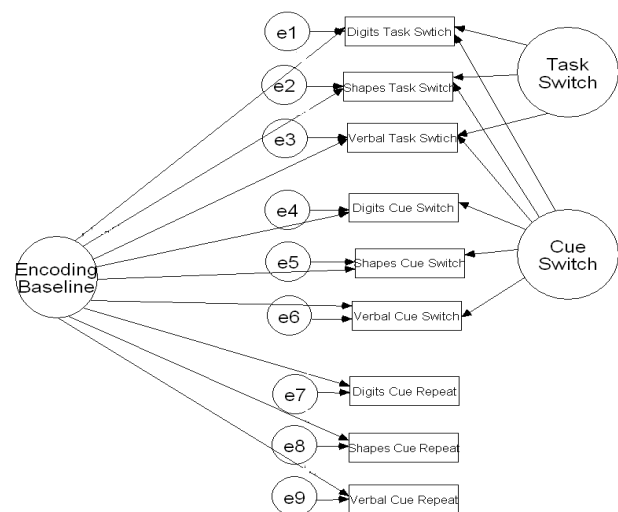

Figure 3: 3-Factor latent variable model to account for switch costs

significantly predict individual differences in cue switching, but not encoding or task switching. That is, individuals who are able to efficiently switch between trials that require a change in information, or change in instructional cue, have higher long-term memory scores.

Table 2: Standardized effects of inhibition and long-term memory on the task switching factor components and model fit statistics

	Inhibition		Long-Term Memory	
	β	p	β	p
Encoding Baseline	.203*	.005*	-.039	.586
Cue Switch	-.099	.274	-.187*	.036*

CFI	.996		.999	
TLI	.986		.995	
RMSEA	.044		.025	

Discussion

The overall goal of the present study was to establish a representation of the structure of individual differences in the double-cued procedure. There were two specific aims. The first aim was to examine if individual differences in performance on cue switch and task switch trials could be distinguished at the level of latent variables to determine whether switch costs reflect processes involved in interpreting instructional cues rather than, or in addition to, switching task sets. The second aim was to examine the relationships of the decomposed costs with measures of long-term memory and inhibition to determine the underlying mechanisms or processes that might explain some of the variance in each of the components.

In the aggregate trial-type RT analysis, cue switch trials ($M = 1182$ ms) appeared more like task switch trials ($M = 1280$ ms), than like cue repeat trials ($M = 847$ ms). Although 77% of the switch cost was accounted for by encoding the cue (335 ms), the mean overall residual task switching cost of 98 ms was significant. That is, average performance on task switch trials was significantly slower than average performance on cue switch trials. Using partial correlation, it was found that the first-order correlation

between cue repeat and cue switch trials in the digits task was reduced from .76 to .40 after controlling for performance on task switch trials. The correlation between cue repeat and cue switch trials in the shapes task reduced from .80 to .52, and the correlation for the verbal task cue repeat and cue switch trials reduced from .76 to .35. This implied that 63%, 72%, and 59% of the variance shared between the cue repeat and cue switch trials in the digits, shapes, and verbal tasks, respectively, was associated with performance on task switch trials. However, controlling for task switch trials did not significantly attenuate the relationship between cue repeat and cue switch trials in any of the task domains, suggesting that the residual effect of task switching might not be useful as an individual differences variable.

The results of the present study showed that task switching did not serve as a reliable individual differences variable; task switch trials did not provide any additional information that was not already accounted for by the cue switch and cue repeat trials. The residual common variance for the task switch factor was not significant, lending support to the claim made by Logan and Bundesen (2003) that efficient performance does not require an actual act of task switching. It should be noted that this claim can only be made for externally cued paradigms that employ short preparation intervals, as this study only used one interval. Yehene and Meiran (2007) suggest that this may not be the case at longer preparation intervals. However, it should also be noted that in an individual differences study, Friedman and Miyake (2004) could not distinguish switch costs incurred at short preparation intervals from those incurred at longer preparation intervals at the level of latent variables.

That there were no reliable individual differences to account for the act of task switching cannot be attributed to participants' preparatory strategies in response to a high probability of a task switch trial. Recent studies (e.g., Schneider & Logan, 2006; Monsell & Mizon, 2006) have indicated that the frequency of switch trials is related to the magnitude of switch costs, so that the higher the probability of the occurrence of a task switch trial, the smaller the overall switch cost. In the present study, the overall probability of a task switch, $p(\text{task switch})$, was 0.33, and the probability of a task switch given a cue switch, $p(\text{task switch}|\text{cue switch})$ was 0.5. In the Logan and Bundesen (2003) studies, $p(\text{task switch}) = 0.5$, and $p(\text{task switch}|\text{cue switch}) = 0.67$. Unlike the Logan and Bundesen experiments, the present study can rule out the possibility that participants might have strategically controlled their task-set readiness as a function of expectation for a task switch trial, thereby reducing their overall switch costs. Moreover, other procedural precautions were taken in the design of the current study, as suggested by Monsell and Mizon (2006), to capture an endogenous control process, or actual act of task switching, if there was one. For example, the response-stimulus interval was kept constant to avoid confounding active preparation with passive decay, and highly salient cues were used. Finally, the present study can

make the claim that increasing the number of target stimuli from 4 in the shapes task, to 8 in the digits task, to 64 in the verbal task did not lead to a task switching effect; participants did not resort to switching task sets in response to the cue as the mapping combinations between cues, targets, and responses got larger.

Conclusions

In summary, individual differences in switch costs were attributed to changes in cue initiated retrieval; switch costs were a consequence of cue priming effects, not a consequence of task changes. The further modeling of cognitive measures to predict individual differences in the component factors indicated that the single inhibition measure was associated with individual differences in the encoding baseline factor, and the single long-term memory measure was related to individual differences in the cue switching factor. It should be noted that although these effects were small, they were theoretically grounded. These results lend support to the claim that the loading of task rules from long-term memory was necessary even on nonswitch trials (Mayr & Kliegl, 2003). Because only one preparation interval was included, the reduction in the switch cost effect across increasing preparation intervals cannot be measured. Therefore, it is not possible to completely rule out an endogenous task set reconfiguration process. The present study can, however, conclude that at short preparation intervals, reliable variance in switch costs could be explained by a cue repetition benefit; an additional task switching process was not needed to fully account for individual differences.

Abstract

Bayesian models of cognition are typically used to describe human learning and inference at the computational level, identifying which hypotheses people should select to explain observed data given a particular set of inductive biases. However, such an analysis can be consistent with human behavior even if people are not actually carrying out exact Bayesian inference. We analyze a simple algorithm by which people might be approximating Bayesian inference, in which a limited set of hypotheses are generated and then evaluated using Bayes' rule. Our mathematical results indicate that a purely computational-level analysis of learners using this algorithm would confound the distinct processes of hypothesis generation and hypothesis evaluation. We use a causal learning experiment to establish empirically that the processes of generation and evaluation can be distinguished in human learners, demonstrating the importance of recognizing this distinction when interpreting Bayesian models.

Keywords: Approximate Bayesian Inference; Hypothesis Generation; Hypothesis Evaluation; Causal Learning

Introduction

Learning causal relationships, categories, and languages all require solving challenging inductive problems, using limited data to assess underdetermined hypotheses. In the last decade an increasing number of papers have argued that people solving inductive problems act in ways that are consistent with optimal Bayesian inference (e.g., Griffiths & Tenenbaum, 2005; Goodman, Tenenbaum, Feldman, & Griffiths, 2008; Xu & Tenenbaum, 2007). However, most of these analyses operate at what Marr (1982) termed the *computational* level, using Bayesian inference to identify the hypotheses that an ideal learner with particular inductive biases would choose to explain the observed data. An important question for this approach is what learners are doing at the *algorithmic* level: identifying the psychological processes by which learners solve inductive problems, and understanding how these algorithms connect back to the computational level.

Connecting the algorithmic and computational levels involves two challenges: identifying algorithms that can produce behavior consistent with Bayesian inference, and determining how the assumptions of a computational-level analysis relate to the components of these algorithms. In this paper, we take up these two challenges for one class of algorithms for inductive inference. The most naïve translation of Bayesian inference into an algorithm for inductive inference would be to assume that learners implement Bayes' rule directly, having a fixed set of hypotheses and updating a probability distribution over all of those hypotheses simultaneously

as data are observed. However, the assumption that learners possess all relevant hypotheses before seeing data is at odds with numerous findings suggesting that generating appropriate hypotheses can be one of the hardest parts of inductive inference (e.g., Kuhn, 1989; Klahr, Fay, & Dunbar, 1993). We thus consider the consequences of separating the processes of generating hypotheses and evaluating those hypotheses, assuming that learners perform Bayesian inference with only the set of hypotheses they generate.

To investigate this, we present a mathematical analysis of a simple algorithm in which hypothesis generation and evaluation are separated. This produces a surprising result: This algorithm results in behavior that can still be analyzed in terms of Bayesian inference, but with a prior that conflates the plausibility of a hypothesis with the ease of generating that hypothesis. This result suggests that we should be cautious when interpreting the priors of Bayesian models estimated from behavioral data. Such priors will always reflect the inductive biases of human learners – those factors that lead people to select one hypothesis over another when both are equally consistent with the data. However, human inductive biases can include components that result from processes at the algorithmic level, such as generating hypotheses.

To demonstrate the importance of taking into account algorithmic-level factors in interpreting Bayesian models, we present an experiment exploring the separability of hypothesis generation and evaluation. In the task, we conduct a causal learning experiment in which we manipulate the hypotheses that people generate: by “priming” an appropriate hypothesis, we increase the probability of people producing responses consistent with that hypothesis; however, when we employ a more standard Bayesian reasoning task, providing a set of hypotheses and asking participants to evaluate them, the effect of priming goes away. A computational-level analysis would require postulating different prior distributions in order to explain behavior on these two components of the task. However, an algorithmic-level analysis shows that this difference can be explained as the result of the separate effects of hypothesis generation and evaluation. Finally, we discuss the implications of this work for future models of human cognition and for studies of developmental changes.

Analyzing inductive inferences

Bayesian inference indicates how a rational learner should change his or her beliefs about a set of hypotheses in light

of observed data. Let h be a hypothesis belonging to a set of hypotheses \mathcal{H} . Assume that the learner has different degrees of belief in the truth of these hypotheses, and that these degrees of belief are reflected in a probability distribution $p(h)$, known as the *prior*. Then, the degrees of belief the learner should assign to each hypothesis after observing data d are given by the *posterior* probability distribution $p(h|d)$ obtained by applying Bayes' rule

$$p(h|d) = \frac{p(d|h)p(h)}{\sum_{h' \in \mathcal{H}} p(d|h')p(h')} \quad (1)$$

where $p(d|h)$ indicates the probability of observing d if h were true, and is known as the *likelihood*.

Bayes' rule provides a computational-level theory of inductive inference, being a component of the optimal solutions to a variety of problems of reasoning under uncertainty (Anderson, 1990; Anderson & Schooler, 1991; Freeman, 1994; Geisler, Perry, Super, & Gallogly, 2001; Griffiths & Tenenbaum, 2007; Huber, Shiffrin, Lyle, & Ruys, 2001; Knill & Richards, 1996; Körding & Wolpert, 2004; Shiffrin & Steyvers, 1997; Weiss, Simonvelli, & Adelson, 2002). As an account of inductive inference, the prior $p(h)$ captures the inductive biases of the learner, indicating which hypothesis a learner will favor when multiple hypotheses are equally consistent with the observed data (ie. which hypothesis will have higher probability when multiple hypotheses have equal likelihood). This account is attractive in that it can potentially allow us to identify the inductive biases of human learners, comparing different Bayesian models to find an appropriate prior. However, as we show in the remainder of this section, one should be cautious in interpreting such a prior: Considering algorithms by which people might be making inductive inferences shows that multiple processes can be reflected in a prior estimated from behavioral data.

Inferences with a reduced hypothesis space

As a computational-level theory of inductive inference, Bayesian models make no commitments about the psychological mechanisms by which people actually learn and reason. The most naïve interpretation of experiments demonstrating that people produce behavior consistent with Bayesian inference is that people are actually computing Bayes' rule in their heads. There are many reasons why such an algorithm is implausible, not least the requirement that people have all relevant hypotheses available whenever they make an inductive inference. However, this naïve algorithm provides a good starting point for exploring the consequences of different psychological processes that could play a role in inductive inference. Here we explore the consequences of modifying one aspect of this algorithm: rather than considering all possible hypotheses in the hypothesis space, considering only a subset of these hypotheses.

Research in inductive inference and scientific reasoning has shown that hypothesis generation is a challenging component of solving inductive problems (e.g., Kuhn, 1989; Klahr

et al., 1993). Hypotheses can be generated in many different ways, including detecting cues from context, recognizing similarities to previous experiences, and making analogies to other domains (e.g., Gick & Holyoak, 1980; Gentner, 2002; Nersessian, 1992; Koslowski, 1996). We will not attempt to model these processes here, but for our purposes, it is sufficient to assume that the result of all of these processes can be summarized in a single probability distribution over hypothesis spaces. Using this probability distribution, $q(\mathcal{H}^*)$, we define the *Generate-Evaluate* (GE) algorithm for Bayesian inference with a reduced hypothesis space:

Step 1: Generate Sample a reduced hypothesis space $\mathcal{H}^* \subseteq \mathcal{H}$ from the probability distribution $q(\mathcal{H}^*)$.

Step 2: Evaluate Evaluate the hypotheses in the reduced hypothesis space \mathcal{H}^* by applying Bayesian inference, using a prior distribution on \mathcal{H}^* proportional to the prior on the full hypothesis space \mathcal{H} . Using $p(h)$ to denote the prior on the full hypothesis space, as in Equation 1 we obtain the reduced posterior distribution

$$p^*(h|d) = \frac{p(d|h)p(h)}{\sum_{h' \in \mathcal{H}^*} p(d|h')p(h')} \quad (2)$$

for $h \in \mathcal{H}^*$, with all other hypotheses receiving a posterior probability of zero. Because we are only sampling a subset of hypotheses, those that are not sampled will never be considered.

Mathematical analysis

Having defined an algorithm that takes into account the process of hypothesis generation, we can now analyze the consequences of using this algorithm. We have two questions of interest. First, will a learner using the GE algorithm produce behavior that appears to be consistent with Bayesian inference? Second, how does the process of hypothesis generation influence the interpretation of the resulting Bayesian model? We can answer both of these questions for a special case of this algorithm by exploiting its relationship to a Monte Carlo method known as importance sampling.

Monte Carlo methods are a class of algorithms that are used to approximate probabilistic computations by substituting samples from a probability distribution for the distribution itself. For example, if we wanted to perform computations involving a distribution $p(x)$, we could instead substitute a set of m values x_1, \dots, x_m drawn from $p(x)$, each with weight $1/m$. Importance sampling is a Monte Carlo method that takes this one step further, substituting samples from another distribution (the *surrogate* distribution) for samples from the target distribution (for details, see Neal, 1993). Thus, if we wanted to perform computations involving $p(x)$, we would generate a set of samples x_1, \dots, x_m from the surrogate distribution $q(x)$. We can get away with doing this if we no longer assign those samples equal weights. Instead, we give each sample x_i a weight proportional to $p(x_i)/q(x_i)$. The approxi-

mation to $p(x)$ is thus

$$p^*(x) = \frac{p(x_i)/q(x_i)}{\sum_{j=1}^m p(x_j)/q(x_j)} \quad (3)$$

for $x_i \in \{x_1, \dots, x_m\}$, and zero otherwise. Intuitively, the weights proportion to $p(x_i)/q(x_i)$ reflect the “importance” of each sample. If x_i is more probable under $q(x)$ than $p(x)$, it will be over-represented in the sample, and thus should receive lower weight. If x_i is more probable under $p(x)$ than $q(x)$, there will be fewer such values than there should be, and it receives higher weight to compensate. This yields an asymptotically unbiased approximation to probabilistic computations involving the target distribution, provided certain constraints are observed (for example $q(x)$ has to be greater than zero wherever $p(x)$ is greater than zero).

Importance sampling gives us the tools we need to analyze the GE algorithm. If we assume that the samples are drawn independently, with $q(\mathcal{H}^*) = \prod_{h \in \mathcal{H}^*} q(h)$, then the GE algorithm is an importance sampler for the target distribution

$$\frac{p(d|h)p(h)q(h)}{\sum_{h \in \mathcal{H}} p(d|h)p(h)q(h)} \quad (4)$$

which is the posterior distribution obtained when using a prior proportional to the product of $p(h)$, the prior on the original hypothesis space, and $q(h)$, the probability of generating that hypothesis. It is straightforward to check that this is the case: if we approximate the distribution given in Equation 4 using $q(h)$ as the surrogate distribution, then we should generate a reduced hypothesis space \mathcal{H}^* by sampling from $q(h)$ and then assign each sampled hypothesis a weight proportional to $p(d|h)p(h)q(h)/q(h) = p(d|h)p(h)$. This is exactly the procedure followed in the GE algorithm, with Equation 2 being equivalent to Equation 3.¹

This analysis answers our two questions about the GE algorithm. First, it shows that a learner using this algorithm will still produce behavior consistent with Bayesian inference, albeit with a modified prior. Second, it indicates how the process of hypothesis generation affects behavior: If we estimate a prior by assuming people are performing Bayesian inference, that prior will reflect both the a priori plausibility of hypotheses, $p(h)$, and the probability of generating those hypotheses, $q(h)$. One needs not consider $q(h)$ when hypotheses are provided to the learner to evaluate, and thus no generation is required. However, the analysis indicates that we should be careful in interpreting priors estimated using Bayesian models: if we do not take algorithmic processes into account, hypothesis generation and evaluation are confounded. This can be problematic, as processes that change the way people generate hypotheses, such as priming a particular hypothesis, will influence the distribution $q(h)$ and hence the estimated prior, without influencing the plausibility of a hypothesis $p(h)$. Critically, ignoring the algorithmic level could

therefore lead to counter-intuitive results where we need to use different priors to explain behavior across contexts where all that differs is the ease in which hypotheses are generated.

Generation and evaluation in human inferences

Our analysis assumes that the spontaneous generation of hypotheses can be separated from the evaluation of a given hypothesis. Thus, if the analysis is correct, generation and evaluation should be separable components of human inductive inference. If a learner does not sample the correct hypothesis, she will never consider it and thus cannot evaluate it; however, if a hypothesis is given to her (e.g., supplied by an experimenter), she should be able to evaluate the hypothesis just as if she generated it herself. We can empirically explore whether confounding generation and evaluation is a problem for Bayesian models in practice.

Testing the assumption that generation and evaluation are separable requires finding a task that allows us to manipulate the ease of generating different hypotheses. Previous work suggests that priming of a hypothesis can help people solve complex reasoning tasks. For example, Schunn and Dunbar (1996) found that even though participants do not spontaneously make an explicit analogy between domains, knowledge from one domain can influence reasoning in the other. Encouraged by this finding, we predicted that participants should generate different samples of hypotheses if primed differently. Priming hypotheses would thus modify the probability of generating those hypotheses, $q(h)$. However, such priming should not affect the evaluation of hypotheses provided for a learner.

In order to test whether the processes of generating and evaluating hypotheses are separable, we designed a priming task and a two part causal learning experiment. Prior to the causal learning experiment, half the participants read a vignette that primed them to think about the correct causal rule; the other half of the participants were given a “neutral” vignette. In the causal learning experiment, participants were given experience with sets of blue blocks (individuated by a letter on the block) that sometimes lit up when they interacted with each other. In the first part of the causal learning experiment, as participants encountered data, they were asked to make predictions about the result of new block interactions², and following all evidence, participants were asked to describe the rule they had discovered that best captured the pattern of lighting/nonlighting blocks. The actual rule by which evidence was generated was a “rank order” rule, which meant that a latent feature of “block strength” dictated which blocks could light others. The evidence was ambiguous such that the rule was not immediately obvious, but still potentially discoverable. In the second part of the causal learning experiment, participants completed a more standard task, traditionally taken as reflecting the posterior in Bayesian learning paradigms; participants were given several rules and asked

¹Technically, we also require that \mathcal{H}^* be a multiset, allowing multiple instances of the same hypothesis.

²The block task was inspired by a similar method used by Tenenbaum and Niyogi (2003).

to evaluate the degree to which each rule seemed plausible, given the blocks' interactions previously demonstrated in the learning phase.

Note that because the participants are required to discover the correct causal rule in the first part of the causal learning experiment, their ability to produce the correct predictions and the correct description require both steps of the GE algorithm: the subjects must generate a set of possible hypotheses and evaluate those hypotheses to discover the causal rule that best captures the observed data. In contrast, the second part of the causal learning experiment requires only evaluation, because the set of possible hypotheses is already provided for the participant. If generation is an important factor in determining people's inferences, we should observe a difference between the two parts of the experiment, and in particular, a difference in participants' sensitivity to the prime manipulation. Specifically, if the prime affects only generation, it should only affect participant responses in the first part of the experiment: participants given a strong prime should be more likely to generate the correct hypothesis than participants who are given a weak prime, but strong prime and weak prime participants should be equally likely to correctly rate the explanations provided to them in the second part of the experiment because this task only requires evaluation and does not require generation. However, if the prime affects other things, like the prior, it will affect both parts of the experiment: the strong prime participants should not only be more likely to generate the correct causal explanations in the first part of the experiment, but they should also be more likely than the weak prime participants to provide a higher rating of the provided, correct explanation in the second part of the experiment.

Methods

Participants and Design Participants were 40 undergraduates from the University of California, Berkeley who participated either for pay or for course credit. Participants were randomly assigned to either a *Strong Prime* or *Neutral Prime* condition. About half the participants completed an unrelated experiment prior to completing this experiment.

Stimuli The *Strong* and *Neutral Prime* vignettes were given to participants on a single sheet of paper with instructions. The target experiment included six small (6cm × 6cm) cardboard cutouts that the participants could manipulate as they completed the task and a 12 page booklet that included instructions, descriptions of the blocks, and sections to write in answers (see Figure 1).

Procedure The procedure involved a priming stage and a two part causal learning task, we outline each in turn.

Priming: Participants were first given an "unrelated" survey, which included a vignette about teachers watching children interacting on a playground and learning about rules that governed which children would win a game. In the *Strong Prime* condition the story suggesting that the rule governing which children would win was related to the childrens

height. The text read, in its entirety: "Teachers at an elementary school taught their students a game for two children to play. They observed the results of pairs of students playing the game and tried to come up with a way to predict (for any given pair of students) who was going to win the game. At first it was difficult for the teachers to notice anything that would help them correctly predict the outcomes of the games. Then the teachers started organizing the children by the height of the children and the pattern of results quickly became apparent. The teachers were able to use the height of the children and make very accurate predictions as to who (for any given pair of students) was going to win the game." The *Neutral Prime* vignette was identical, except that instead of organizing the children by height, children were organized by the shirt color. Shirt color was chosen because pilot work suggested that numerous possible orderings may be plausible (e.g. sorting by the color wheel; bold colors vs. neutral colors; arranging from lightest to darkest colors, etc.), and thus the primed causal rule was somewhat arbitrary. Following the vignettes, participants were asked to respond to two simple questions about the story on the back of the sheet.

Causal Learning: In the first part of the causal learning task, participants saw sets of blue blocks (individuated by a letter on the block) that sometimes lit up when they interacted with each other. The actual rule, unbeknownst to the participants, was that the blocks could be ordered by "strength" with the "stronger" blocks always causing the "weaker" blocks to light (i.e. a variable like "height" given in the *Strong Prime* vignette, that would result in causal relations following a rank order³). As participants encountered data, they were asked to make predictions about the result of new block interactions ("Will this block light? Yes or no?") and provided confidence ratings on a scale of 1 to 7 (see Figure 1). Following all evidence, participants were asked to describe the rule they had discovered that best captured the pattern of light-

³Pilot work suggested that causal relations that follow a rank-order (e.g. dominance hierarchy) are not immediately obvious, but still potentially discoverable to participants, following suggestive evidence.

ing/nonlighting blocks and whether they could organize the blocks to best capture the rule.

In the second part of the causal learning task, participants were asked to evaluate four different explanations describing how the blocks should interact. Two explanations captured some, but not all of the data (e.g. “The blocks can be organized into two groups: blocks *s*, *k*, & *m* have the power to light up the other blocks (*y*, *w*, & *g*). Blocks in the same group do not light each other.”) One explanation was non-descriptive: “The blocks can not be organized. They will light or not light randomly, but only one block can be lit at a time.” And the final explanation was the target explanation, which correctly described the data: “The blocks can be organized by ‘strength’. The stronger blocks will light the weaker ones. Strongest *s k m y w/g* Weakest”. Participants rated the explanations on a scale from 1 (“not good”) to 7 (“very good”).

Results

Data were coded by the first author and reliability coded by a research assistant blind to condition and hypothesis outcomes. Explanation generation responses were labeled as “correct” or “incorrect”. Agreement was 98%; the single disagreement was resolved conservatively with respect to predictions. Two participants were excluded and replaced for failing to provide a sensible response to the comprehension questions. Otherwise, all participants completed the comprehension questions for the priming vignettes.

Results confirmed that the ability to generate a hypothesis is separate from the evaluation of hypotheses. As predicted by Bayesian inference, there were no differences in evaluating the hypotheses between conditions: Both the Strong Prime and Neutral Prime participants readily rated the correct explanation equally likely: (*Strong*: 5.3; *Neutral*: 5.6; $t(38) = .48, p = ns$), and both groups ranked it well above the other (incorrect) provided rules (*Strong*: 2.8; *Neutral*: 3.0) (Wilcoxon Signed-Rank: *Strong*, $z = 3.07, p = .001$; *Neutral*, $z = 3.60, p < .001$) (Figure 2). However, there was a significant effect of condition: Participants in the *Strong Prime* condition were significantly more likely to answer the prediction questions correctly (Wilcoxon Signed-Rank: $w = 45, p < .01$; Figure 2a) and were more likely to generate the correct rule, Pearson $\chi^2(N = 40, 1) = 3.6, p = .058$. 65% of the participants in the *Strong Prime* condition provided the correct hypothesis, whereas only 35% of participants in the *Neutral Prime* condition generated the correct hypothesis (Figure 2b). That is, even though participants in the *Neutral Prime* condition were able to correctly evaluate the rules when they were provided, they were not necessarily able to generate the correct rule from the evidence alone.

We also looked at participant explanation ratings with the dependent factor being whether or not the participant generated the correct prediction on their own. Participants who did not generate the correct rule on their own still provided a significantly higher rating to the correct explanation (mean = 4.9) than to the incorrect explanations (mean = 3.3) (Wilcoxon Signed-Rank: $z = 2.63, p < .01$). That is, even though these

participants were not able to generate the correct rule on their own, they were perfectly able to evaluate the good and bad explanations, being more likely to rate the correct explanation higher than the incorrect explanations.

Discussion

Connecting the computational and algorithmic levels is a significant challenge for Bayesian models of cognition. We have shown that considering the algorithms by which people might perform inductive inference can provide insight into how different psychological processes influence the conclusions that we can draw when using Bayesian models. Mathematical analysis of a simple algorithm in which learners first generate and then evaluate hypotheses indicates that while the resulting behavior is still consistent with Bayesian inference, estimation of a prior distribution from this behavior will confound the probability of generating a hypothesis and its a priori plausibility.

The responses of participants in our experiment provide some empirical support for the assumptions behind our analysis: While priming influenced whether participants could *generate* the correct explanation, it did not affect participants ability to correctly *evaluate* explanations that were provided. That is, one interpretation of our results is that the prime affected the distribution $q(h)$ from which hypotheses are generated, but it did not affect the prior probability of any particular hypothesis $p(h)$, since there were no differences between conditions when participants were asked to evaluate hypotheses that were provided to them. In the remainder of the paper, we consider some of the implications of these results and directions for future work.

Errors and approximations

Approaching inductive inference from the algorithmic level results in additional implications and predictions that may be valuable to explore in future work. For example, the algorithmic approach taken in this paper offers some reconciliation between computational level theories that suggest people are carrying out rational inference, with approaches that show people performing in seemingly “irrational” ways, such as not coming to the correct conclusion despite unambiguous or compelling evidence. By suggesting that people may be *approximating* rational inference by sampling a subset of hypotheses, these failures of inductive inference can be explained as the result of not generating appropriate hypotheses.

This makes predictions about the factors that should influence the errors that people make in inductive inference. For example, as the hypothesis space becomes large, the probability of sampling the correct hypothesis decreases. Thus, we should observe a trade-off between the size of the space and the probability of generating the correct explanation. Similarly, if cognitive limitations are imposed (for example increasing participant computational load, with additional tasks) then the set size of samples generated should decrease, and thus decrease the probability of generating the correct

Figure 2: (a) Participants' responses to the final four prediction questions in the Neutral and Strong Prime conditions. (b) Percentage of participants who generated the correct explanation. (c) Average rating (1 weakest - 7 strongest) of the provided explanations by participants in both conditions.

sample. It may also be valuable to explore these questions in a developmental setting, examining how changes in information processing capacity influence the conclusions that children reach.

Conclusion

Bayesian models of cognition provide a computational-level account of inductive inference. Here, we have presented an analysis that shows how taking an algorithmic-level approach can allow us to tease apart two processes that are confounded in computational-level models: hypothesis generation and evaluation. We also present experimental results that suggest that these two processes are separable in human inductive inference. Together, our analysis and empirical findings indicate that we should take both the probability of generating a hypothesis and its a priori plausibility into account when interpreting prior distributions estimated using Bayesian models. More generally, these results illustrate that understanding human inductive inference will require working at both computational and algorithmic levels of analysis, and establishing the connections between them.

Abstract

The current study looks at preschoolers' ability to discover higher-order patterns spontaneously, without being explicitly taught to do so. The higher-order pattern of interest was the degree of transitivity among the relations of three arbitrary dimensions. Preschoolers and adults were taught two relations (i.e., $A = B$; $B = C$), and they were asked to guess the third relation (i.e., between A and C). In each case, a relation was a perfect correlation between two arbitrary relations (e.g., heavy = large). The crucial manipulation pertained to how difficult it was to learn the two relations. The two relations either matched in direction (which was conceived as low learning difficulty), or they had opposite directions (which was conceived as high learning difficulty). Our prediction was that the higher-order pattern of transitivity becomes apparent when learning difficulty is high. The argument is that a local mismatch makes it difficult for children to focus merely on the isolated relations, and thus sets the stage for higher-order insights. Results confirm our hypothesis, both for preschoolers and adults. Participants were more likely to engage in higher-order transitive reasoning in the case of a local mismatch between the to-be-learned relations than in the case of a local match.

Keywords: learning; preschoolers; reasoning

Introduction

It is commonly believed that young children learn best when the content is broken down into 'digestible' pieces of information. The implicit expectation is that the pieces of information are combined into a whole later on, when the child is thought to be cognitively ready. For example, to teach children about an overarching principle, say in physics, one might introduce children to the constitutive parts of the principle first. When ready, the child might then put the pieces together and infer the overarching principle.

Basic-level research casts doubt on this logic, however. In particular there is evidence that children have difficulty combining pieces of information into larger units (e.g., Morris & Sloutsky, 2002; Ruffman, 1999). Therefore, teaching them piece-meal information might not lead to the desired success. Take for example a context in which participants are presented with the three physical dimensions size, loudness, and grayness (Smith & Sera, 1992). The task is to relate each dimension to the next, such

as to determine whether something small goes with something loud or quiet, whether something loud goes with something dark or light, and whether something dark goes with something big or small. Children at preschool age had no difficulty relating the dimensions in a consistent way (e.g., if they decided that small goes with light, they also related dark with big). However, preschoolers were not constrained by the higher-order transitivity among these relations. Children believed, for example, that a big object was related to a loud sound ($A = B$), that the loud sound was related to the light gray ($B = C$), and that the light gray was related to the small object ($C = \text{not } A$). Figure 1 shows these three relations in schematic form. While they are normatively possible, they do not respect transitivity.

Figure 1. Representation of three features relations (combining two dimensions each) that lack transitivity among each other.

There is another reason why a piece-meal teaching approach might not work. Children not only fail to combine pieces of information into a desired higher-order structure, they impose an incorrect structure, ignoring pieces of information that conflict with it. In other words, children might fail altogether to learn a piece of information if it does not match with other beliefs they might hold. Consider, for example, children's beliefs that heavier objects sink faster in water than lighter objects. When this belief is somehow elicited in a teaching protocol, children will have difficulty learning that small objects sink faster than large objects (Kloos, 2007). There is nothing particularly difficult about the latter volume-speed relation, and children can easily learn it if it is the only thing children think about. But as soon as mass is varied in a salient way, children impose an overarching belief that mass and volume correspond in their

effect. They believe that, if heavy objects sink fastest, large objects should sink fastest too.

If learning the individual parts of the whole does not necessarily set young children up to spontaneously discover an overarching principle, and if young children might even fail to learn individual parts, what could help them learn higher-order patterns?

To address this question, we used a transitive-inference task similar to the one used in Smith & Sera (1992) described. While transitive inference is not a concept commonly taught to children, it is seen as a basic reasoning process that might underlie all learning of higher-order structure (Inhelder & Piaget, 1958). Furthermore, young children are not incapable of making a transitive inference (e.g., Adams, 1978). When preschoolers were taught the length relation between five sticks in a series (e.g., stick A is taller than stick B, stick B is taller than stick C, and so on), they were able to incorporate a new stick into the series and guess its relative size, integrating the sticks into one continuous dimension.

Of course, Adams' transitive-inference task on how sticks relate to each other in their lengths differs from Smith & Sera's transitive-inference task on how the alignment of poles respects higher-order Gestalt. Most notably, transitivity pertains to a logical necessity in the former case, but not in the latter case. If Stick A is larger than Stick B, and Stick B is larger than stick C, then stick A has to be larger than stick C – by logical necessity. Conversely, if big goes with loud, and loud goes with dark, it is not logically required that dark goes with big. Nevertheless, despite these differences in context, findings from Adams (1987) shed light on what it is that might help children discover the higher-order pattern of transitivity.

In particular, preschoolers in Adam's study were more likely to make a transitive inference when the length differences between the sticks were small (approximately 1 cm.). The small difference in length might have allowed children to think of the series as a whole, rather than to focus on each pair individually if the length differences were larger. Based on the findings, we predict that children are more likely to attend to a higher-order pattern when a narrow focus on an isolated pattern hinders learning of isolated parts. In Adams' (1978) transitive-inference task, a 1cm length difference between adjacent sticks made it difficult to narrowly focus on isolated sticks (none of them stuck out as particularly long or particularly small).

Similar arguments have been made in mathematical reasoning, when 11-year-olds spontaneously discovered a mathematical rule after being presented with individual instances (Kaminski, Sloutsky, & Heckler, 2009). Learning was markedly improved when individual instances were maximally abstract, possibly because it made it difficult for children to sustain a local focus on the separate instances. In the current paper, we apply this idea to transitive inferences.

In particular, we adapted a version of the Smith and Sera (1992) task that involved relations between three physical dimensions (size, shading, and depth). Given that

dimensions are polar (they have a 'more' pole and a 'less' pole), a relation can be considered positive or negative. For example, 'big' aligning with 'dark' is a positive relation, while 'big' aligning with 'light' is a negative relation¹. Transitivity exists when the three relations are congruent among each other. For example, in a congruent set, 'big' is aligned with 'dark' ($A = B$), 'dark' is aligned with 'deep' ($B = C$), and 'deep' is aligned with 'big' ($C = A$). Figure 2 shows the congruence among these relations graphically.

Figure 2. Representation of the three feature relations that are congruent among each other.

Preschool children were taught two of the relations (e.g., how size relates to darkness and how darkness relates to depth), and they had to guess the third relation (e.g., how size relates to depth). Adults were included for comparison purposes.

We tested the idea that children might attend to a higher-order pattern of transitivity in situations in which focusing of isolated parts was hampered in the task. The crucial manipulation was whether the two to-be-learned relations matched in direction or not. Relations that matched in direction were either both positive (e.g., 'big' goes with 'dark', and 'dark' goes with 'deep'), or they were both negative (e.g., 'big' goes with 'light', and 'light' goes with 'deep'). And for relations that did not match in direction, one was positive and one was negative (e.g., 'big' goes with 'dark', and 'dark' goes with 'shallow').

Our reasoning was that children could easily learn relations that match in direction. Children might therefore merely focus on learning the isolated relations, without regard for the higher-order pattern of transitivity. Conversely, children should have more difficulty learning the two relations of opposite direction. As a result, they might be more likely to spontaneously integrate the two into the higher-order patterns of transitivity.

¹ Note that the 'more' pole is ambiguous for shadings (more grey vs. more white), and for depth (deeper vs. wider). On an absolute level, it is therefore arbitrary whether a relation is considered positive (big = more gray) or negative (big = less white). However, the chosen 'more' pole was always labeled as such (i.e., darkest; deepest) resulting in the prescribed direction of the relation.

Method

Participants

A total of 63 children, aged 4 to 5 years ($M = 5.0$ years, $SD = 3.6$ months) were recruited from daycares and elementary schools located around the Cincinnati, OH and Northern Kentucky areas. Three children were tested and excluded from the experiment because they did not meet the learning criterion (see Procedure), and five children did not finish due to loss of interest. In addition, we tested 60 undergraduate students ($M = 21.4$ years, $SD = 5.7$ years), recruited from the University of Cincinnati, in return for class credit.

Materials

Materials were pictures of four cartoon mice, four clouds, and four bowls, presented on a computer screen. Mice differed in size (from 1 to 4 cm), clouds differed in achromatic color (from the lightest shade of gray to the darkest gray), and bowls differed in depths (from shallow to deep). Figure 2 shows the four pictures of each element. The resulting relations are between mouse size and cloud darkness (MC), mouse size and bowl depth (MB), and between cloud darkness and bowl depth (CB).

Relations between features were labeled either positive or negative, depending on how the poles of features size, darkness, and depth were introduced. For example, for a positive mouse-cloud relation (MC+), the bigger mouse was paired with the darker cloud; for a negative mouse-cloud relation (MC-), the bigger mouse was paired with the lighter cloud.

Design

There were three conditions that differed in the direction of the relations presented to participants. Participants were taught two relations: two positive relations (e.g., MC+CB+) in the Plus-Plus condition, two negative relations (e.g., MC-CB-) in the Minus-Minus condition, or a negative and a positive relation (MC+CB-) in the Plus-Minus condition.

Table 1 shows, in schematic form, how the relations were combined to create the three different conditions. The first column contains the two to-be-learned relations participants were presented with. The second column shows the relation that participants were asked to guess. Finally, the last column shows the expected direction of the third relation if participants pay attention to transitive congruence. For example, if participants learned a positive cloud-bowl relation (CB+) and a positive mouse-cloud relation (MC+), then the direction of the third relation is expected to be positive as well.

Procedure

The cover story involved an explorer, Toto, who found a machine on a far-away planet. The machine was said to transform things. In particular, participants were told that this machine transformed objects: "If something is put it on

one end, something completely different comes out on the other end."

Table 1: How the combinations of the relations create each condition.

To-be-Learned Relations	To-be-Inferred Relation	If congruent...
Plus-Plus (two positive relations)		
Minus-Minus (two negative relations)		
Plus-Minus (one positive and one negative relation)		

The next step was to introduce the objects that could go into the transformer. Six pictures of differently-sized mice were placed in front of the participant in random order. The difference in dimension was pointed out (e.g., "See how some mice are big and some are little"), and participants were asked to point to the biggest mouse. Help was provided as needed. The chosen picture was moved to the side, participants had to point to the next biggest mouse, which again was moved to the side, and so on. Next, participants were presented with six pictures of differently colored clouds, and they were asked to order them from darkest to lightest. Finally, participants were presented with six pictures of bowls and the required ordering was from deepest to most shallow. Children and adults had no difficulty completing this task, suggesting that they could focus on the dimensions in question.

To prepare participants for the learning task, the experimenter provided the following information, accompanied by pictures on the computer:

"A mouse will either turn into a cloud or a bowl, a cloud will turn into either a mouse or a bowl, and a bowl will turn into either a mouse or a cloud. Sometimes the biggest mouse will turn into the darkest cloud, and sometimes the biggest mouse will turn into the lightest cloud. Sometimes the darkest cloud will turn into the deepest bowl, and sometimes the darkest cloud will turn into the shallowest bowl. Sometimes the deepest bowl will turn into the biggest mouse, and sometimes the deepest bowl will turn into the smallest mouse. Toto is very confused and doesn't know what's going on. But he made some movies for us showing us what the transformer is doing. Can you help him figure it out?"

The experiment proper started immediately and had two phases: a demonstration phase and a testing phase (see Table 2). During demonstrations, participants watched a set of movies that conveyed the feature relations. For each movie, two transformers were displayed above each other, in the middle of the screen. Two objects entered simultaneously on one side of each transformer, and another two objects came out simultaneously on the other side of the transformer. For example, a big mouse and a small mouse each entered a transformer, and a dark and a light cloud each come out on the other end.

Table 2: The experiment phases in step-by-step form.

Phase 1: Demonstration		
Relation 1		
3 movies		
Pretest: 4 trials		
3 movies		
Pretest: 4 trials		
Relation 2		
3 movies		
Pretest: 4 trials		
3 movies		
Pretest: 4 trials		
Phase 2: Testing		
Learning Trials		
Relation 1: 4 trials		 
Relation 2: 4 trials		 
Inference Trials		
Relation 3: 4 trials		 

To convey a relation, there were two sets of three movies, each followed by pre-testing to gauge initial learning. Movies pertaining to the same relation differed in the way items were combined with each other. The order in which movies were presented was randomized across children. Pre-testing started with a reminder of the relation presented during the set of movies. For example, if the movies showed a bigger mouse turning into a darker cloud, the experimenter explained: "The biggest mouse will always turn into the darkest cloud." Four pre-testing trials followed, each asking what an object turned into. For example, if the movies showed a bigger mouse turning into the darker cloud, the question was: "What cloud did the bigger mouse turn into?" Participants had to perform consistently, either correct or incorrect, on at least three of the four trials. They were excluded otherwise.

After participants watched two sets of movies for one relation and then two sets of movies for the second relation, the testing phase started, with the following instructions:

"I think you know everything there is to know about the transformer. But just to make sure, Toto wants to ask you a few more questions."

Then four trials per relation were presented. The learning trials, for the first and second relations, were identical to the pre-testing trials presented earlier. The inference trials came last, following the same format as the other trials. Participants were asked to make a guess about the third relation that was not presented. For example, if the mouse-bowl relation was never shown, the experimenter would ask "what will the big mouse turn into?"

The demonstration phase lasted about 10 minutes, with the introduction and testing phases each lasting another 2-3 minutes. Overall, the experiment lasted around 15 minutes.

Results

In a preliminary analysis, we looked at children's learning of the two relations presented to them. For each participant, we calculated an average proportion-correct score across the eight learning trials. A 3 by 2 between-subjects ANOVA was conducted, with condition (Plus-Plus, Minus-Minus, Plus-Minus) and age (preschoolers, adults) as the factors. It revealed a significant effect of age, $F(1,117) = 31.27$, $p < .01$, in that adults performed better on learning trials ($M = .96$) than preschoolers ($M = .77$). There was also a difference in condition, $F(2,117) = 5.49$, $p < .01$, suggesting that participants had some difficulty learning the relations presented to them. However, there was no interaction with age and condition, $F < 1.85$, $p > 0.16$. Figure 3 shows the degree of learning (represented as mean % correct), as a function of age group and condition.

Figure 3. Mean performance correct on learning trials (to test the degree of learning), as a function of age and condition. Standard errors are shown as error bars.

To determine if participants were congruent in their inferences about the third relation, we considered only those participants who performed consistently on each set of four learning trials per relation. 'Consistent' here means either correct performance on at least three learning trials of a

relation, or incorrect performance on at least three learning trials of a relation. Eighteen children (29%) and 4 adults (7%) did not meet this criterion and were not included in the transitivity analysis. Of the included participants, 13 of the children and 3 of the adults performed consistently incorrect on one set of learning trials, and nobody performed consistently incorrect on both sets of learning trials.

If children make congruent inferences, then the inferred relation should be negative if one of the learned relations is positive and the other is negative. The inferred relation should be positive if the learned relations are either both negative or both positive. To what degree did participants' inferences follow this pattern across the four inference trials? Figure 4 shows participants' transitivity performance as a function of age and condition. A score of 1 means that performance was congruent on all four inference trials, while a score of 0 means that performance was incongruent on all four inference trials. As can be seen in the figure, both children and adults were more likely to give congruent answers in the Plus-Plus and Plus-Minus condition than the Minus-Minus condition.

Figure 4. Mean proportion transitive inferences, as a function of age and condition. Standard errors are shown as error bars.

The transitivity scores were submitted to a 3 by 2 between-subjects ANOVA, with conditions (Plus-Plus, Minus-Minus, Plus-Minus) and age (preschoolers, adults) as factors. There was a significant effect of age, $F(1,95) = 30.11$, $p < .01$, with adults having higher transitivity scores ($M = .95$) than children ($M = .69$). More importantly, there was a significant effect of conditions, $F(2,95) = 3.59$, $p = .03$. There was no significant interaction, $F < .05$, $p > .95$, meaning that this pattern stayed the same for both children and adults. For both children and adults, guesses were transitive in the Plus-Minus and Plus-Plus conditions, but less so in the Minus-Minus condition. Learning score was uncorrelated with transitivity score.

Summary & Discussion

Our prediction was that children would be more likely to attend to the higher-order pattern of transitivity when the learning of the local elements (the single relations that make

up the whole) did not afford a narrow focus. Learning two positive relations did not interfere with a local focus: children could pay attention to only one of the two relations and still be able to learn the second one (because the direction matched). The same was true for learning two negative relations: focusing locally on one negative relation did not hinder (and might have even helped) the learning of the second negative relations. But when children were asked to learn a positive and a negative relation, a local focus on a single relation hindered learning.

Results support our prediction – with a twist. Inferences of children in the Minus-Minus condition were less transitive than of children in the Plus-Minus condition. And the lower transitivity performance was not related to the participants' learning scores (i.e., the degree of transitivity of the guessed relation cannot be explained by the degree of learning of the two presented relations). This finding is consistent with our hypothesis: when children had to learn non-matching relations that hindered an overly local focus, the overarching pattern of transitivity was likely to emerge. Importantly, the patterns of transitivity appeared spontaneously for an age group that is commonly known for having difficulties with transitive inferences.

Adults were more likely to make a transitive inference than children. However, they were also affected by the learning manipulation. Transitivity was lower in the Minus-Minus condition than the Plus-Minus condition. As was found with preschool children, when single relations were difficult to learn with a narrow focus on each separate relation, adults spontaneously applied the higher-order transitivity to the relations.

A surprising finding pertained to performance in the Plus-Plus condition. We predicted transitivity to be low in this condition, because the two to-be-learned relations matched in direction, and thus afforded a local focus. Nevertheless, children and adults made higher-order transitive inferences when asked to guess the direction of the third relation. What could explain this performance?

A closer look at the specifics of the Plus-Plus condition might shed light on participants' inferences. Recall that two positive relations are congruent with another positive relation. If 'big' goes with 'dark' (positive), and 'dark' goes with 'deep' (positive), then 'deep' should go with 'big' (positive). But guessing a positive relation might be a default (cf., Inhelder & Piaget, 1958). Therefore, participants might have guessed a positive relation in this case with little regard to transitivity among all three relations.

If this is the case, participants' bias toward a congruent set of relations in the Plus-Minus condition is even more impressive evidence of transitive inference. In the case of a positive and a negative relation, the congruent third relation is negative (e.g., if 'big' goes with 'dark', and 'dark' goes with 'shallow', then 'deep' should go with 'little'). Thus, to make a congruent guess, participants (including preschool children) had to go against a default of guessing a positive relation and guessed a negative relation. Note that this

interpretation of the results needs to be qualified until we gain a better understanding of how children match the poles a priori.

Taken together, the results suggest that higher-order transitivity is an emergent property, employed as a means of reducing learning complexity. With higher complexity of individual elements, a local focus was compromised, helping children to note the larger whole. In future studies, it may be useful to follow up with different conditions, such as other cover stories or other objects. It remains to be seen if these claims hold across different domains.

Abstract

Researchers in both educational and developmental psychology have suggested that children are not particularly adept hypothesis testers, and that their behavior can often appear irrational. However, a growing body of research also suggests that people do engage in rational inference on a variety of tasks. Recently researchers have begun testing the idea that reasoners may be sampling hypotheses from an internal probability distribution when making inferences. If children are reasoning in this way, this might help to explain some seemingly irrational behavior seen in previous experiments. Forty 4-year-olds were tested on a probabilistic inference task that required them to make repeated guesses about which of two types of blocks had been randomly sampled from a population. Results suggest that children can sample from a probability distribution as evidenced by the fact that, as a group, they engaged in probability matching and that the dependency between successive guesses decreased over time.

Keywords: Cognitive Development; Causal Learning; Approximate Bayesian Inference; Sampling Hypotheses

Introduction

Young children are faced with a variety of novel situations on a daily basis. They encounter countless episodes in which they must reason about why particular events unfold the way they do, what this means in terms of how related events might unfold in the future, and how this newly acquired information fits into the knowledge they already possess. Humans revise their beliefs throughout development, often beginning with relatively flawed beliefs and progressing towards an increasingly accurate portrayal of the world. However, no current theory provides a satisfactory explanation of how children decide which hypotheses to test. Somehow they must search through the potentially infinite number of hypotheses that exist at the beginning of the learning process. Here, we investigate this question by asking whether young children can make probabilistic inferences via a process of sampling hypotheses from probability distributions.

The question of whether children and adults are capable of using rational inference to search through a hypothesis space and revise their beliefs has drawn mixed empirical findings. To begin, Piaget noted that children tend not to reason systematically about hypotheses, at least until they reach the formal operational stage in late childhood (Piaget, 1983). Since Piaget, some researchers have found evidence to corroborate this claim, stating that children often appear to navigate randomly through a selection of predictions and explanations (Siegler & Chen, 1998). For example, researchers in educational psychology have revealed evidence suggesting that young children and even non-expert adults are not particularly skilled hypothesis testers (e.g., Kuhn, 1989; Klahr, Fay, & Dunbar, 1993). Furthermore, developmental psychologists have found that children often revise their beliefs surprisingly

slowly, suggesting a struggle to efficiently update theories (e.g., Carey, 1991; Wellman, 1990).

On the other hand, at least two kinds of evidence exist to suggest that children might be capable of using rational inference to generate, search through and evaluate hypotheses. First, recent research in cognitive psychology suggests that people reason in ways that are consistent with optimal Bayesian models in a variety of tasks (e.g., Griffiths & Tenenbaum, 2005; Goodman, Tenenbaum, Feldman, & Griffiths, 2008). Although most of this work examines adult reasoning, a growing body of evidence suggests that children can also reason in a way that is consistent with Bayesian inference (e.g., Gopnik et al., 2004; Kushnir & Gopnik, 2005; Schulz & Gopnik, 2004; Schulz, Bonawitz, & Griffiths, 2007; Goodman et al., 2006). For example, Xu and Tenenbaum (2007) found that preschoolers can systematically integrate prior knowledge regarding hierarchical information with evidence in order to apply the correct labels to a variety of objects in a word learning task and Schulz et al. (2007) and Kushnir and Gopnik (2007) found that children's causal inferences rationally depend on both their prior beliefs and the observed evidence. Second, many researchers advocate the theory-theory of conceptual development, which states that children's knowledge is organized into abstract, coherent conceptual systems, similar to those found in science (Carey, 1985; Gopnik & Meltzoff, 1997; Murphy & Medin, 1985; Wellman & Gelman, 1992). This framework predicts that children will engage in hypothesis testing in ways similar to scientists during learning, and much evidence has accumulated in support of this view (e.g. see Karmiloff-Smith & Inhelder, 1974; Bonawitz, Lim, & Schulz, 2007; Legare, Gelman, & Wellman, in press). However, the theory-theory does not specify where the hypotheses are derived from in the first place or how children could be expected (albeit unconsciously) to compute full Bayesian inference over (often) infinite hypothesis spaces.

The sampling hypothesis

Although Bayesian inference corresponds well to the theory-theory of conceptual development, researchers who advocate a rational approach to human inference do not suggest that adults and children actually work through the steps of Bayes' rule in daily life. Evaluating all possible hypotheses each time new data are observed would not be feasible both from a formal and a practical standpoint, given the large number of hypotheses that would require consideration. One way to think about how the mind may be approximating Bayesian inference is to start with good engineering answers to this problem. Techniques for approximating Bayesian inference have

already been developed in the fields of machine learning and statistics and we can see whether humans are also using some version of these strategies.

One strategy for implementing Bayesian inference is sample-based approximation (Shi, Feldman, & Griffiths, 2008; Sanborn, Griffiths, & Navarro, 2006). This approach states that people might be approximating Bayesian inference by evaluating a small sample of the many possible hypotheses. This “sampling hypothesis” has been supported by additional empirical data that suggest people often base their decision on just a few samples (Goodman et al., 2008; Mozer, Pashler, & Homaei, 2008). Indeed, in many cases an optimal solution is to take only one sample (Vul, Goodman, Griffiths, & Tenenbaum, 2009). Sampling partly involves picking a hypothesis at random from the distribution. However, the process is not entirely random in that distributional information may be used to generate hypotheses that are highly likely more often than those that are less likely. This strategy allows the learner to entertain a variety of hypotheses, ensuring that they will spend more resources testing likely hypotheses but will not overlook a lower probability hypothesis that could turn out to be correct.

The sampling strategy predicts “probability matching”: aggregating over numerous samples, generated by different individuals in a group, should return the original distribution; as the number of samples approaches infinity, the closer the result will be to the distribution. This benefit of averaging is called the “wisdom of crowds”. If instead people generate a “best guess”, then aggregating over numerous samples should result in an inaccurate reflection of the distribution, characterized by an overweighting of the most likely hypothesis. Sampling also depends on independence between guesses; the more independent the draws from the distribution, the more accurate the sample will be. However, we might expect that if a single individual is generating multiple guesses, then there may be dependence between guesses, but this dependence may decrease as time between guesses increases.

Recently, Vul and Pashler (2008) tested the sampling hypothesis in adults. They asked individuals to make guesses about a variety of real-world statistics such as: What percentage of the world’s airports are in the United States? In an *Immediate* condition, participants were asked to make guesses about a variety of real-world statistics and then asked the questions a second time directly after. In a *Delayed* condition, the question was asked for the second time two weeks later. It was found that an individual’s error was reduced when their guesses were averaged compared to each of their individual guesses in both the Immediate and Delayed conditions. There was also a greater benefit of averaging guesses in the Delayed group than in the Immediate group; the independence of guesses and, therefore, accuracy was greater after a time delay. This suggests that adults were most likely sampling guesses from an internal distribution rather than always providing an optimal guess.

The results from Vul and Pashler (2008) suggest that

adults may be approximating rational solutions when making guesses about frequencies, in accordance with the sampling hypothesis. We turn to the question of whether or not children are drawing samples from probability distributions in a similar way. We explore two predictions of the sampling hypothesis. First, if children use a strategy of sampling hypotheses from a distribution, we should see that the probability with which they select hypotheses should match the distribution. This contrasts with a strategy of maximizing (always choosing the most likely answer) or guessing (randomly providing responses, independent of their probability), which make different predictions. We will refer to this as the *probability matching* prediction. Second, because sampling depends on independence, we can predict that increasing dependencies between guesses will decrease the degree to which responses accurately reflect the distribution. We will call this the *dependency* prediction.

While results of several studies seem to suggest that children do in fact probability match in numerous situations (e.g. see Kam & Newport, 2009; Kushnir, Wellman, & Gelman, 2008; Bonawitz, Chang, Clark, & Lombrozo, 2008; Sobel, Tenenbaum, & Gopnik, 2004), to our knowledge, no research has demonstrated the dependency prediction, or analyzed results in terms of the sampling hypothesis. While much research has demonstrated the sophisticated graded response of children on average, any particular child’s response is often, paradoxically “non-optimal.” That is, often developmental studies involve forced-choice responses, and so the predictions of any single child seem in conflict to rational models: Why wouldn’t children simply always choose the most likely response, rather than some fraction of children choosing the likely response and some smaller fraction choosing the unlikely response? If children are in fact approximating rational inference by sampling hypotheses at least in some situations, this may provide an account of these data. More importantly, the sampling hypothesis may also provide an account of how children navigate through potentially infinite hypothesis spaces during learning: rather than computing full Bayesian inference over the whole hypothesis space, children sample a subset of hypotheses. We now turn to our experiment to explore this question.

Do children sample hypotheses?

We investigate the sampling hypothesis in preschool-aged children by testing their ability to use probability information to make guesses about which of two colored blocks was most likely to be sampled from a population (consisting of a 4:1 ratio) on a single random draw. This design allows us to investigate whether children demonstrate the first of two sampling signatures: probability matching. First, we predict that if individual children are sampling from a distribution of hypotheses, their responses will be closer to the correct distribution (i.e., 80% red blocks) than would be predicted by random guessing (50% red, blue guesses) or maximizing (100% red guesses). Second, the dependency prediction suggests that

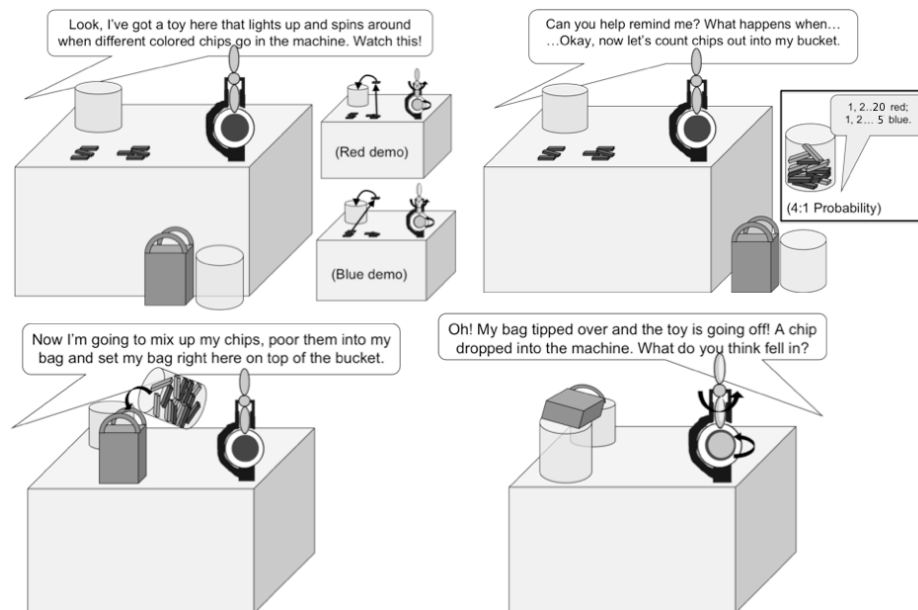

Figure 1: Stimuli and method used to test the sampling hypothesis in children.

children who are given a long delay between guesses will demonstrate greater independence of guesses across trials than children who provide guesses following only a very short delay and we can model these dependencies via a Markov process. As a result of differences in independence between guesses, the distribution over guesses in the *Long Wait* condition should be closer to the predicted distribution than the distribution over guesses in the *Short Wait* condition.

Methods

Participants Forty 4-year-olds were recruited from preschools located on the U.C. Berkeley campus. The children were randomly assigned to one of two conditions, each consisting of 20 children: the *Long Wait* condition, which included 8 males and 12 females ($M = 54$ months; $R = 48$ mos – 62 mos) and the *Short Wait* condition, which included 11 males and 9 females ($M = 53$ months; $R = 48$ mos – 59 mos). On additional child was tested and excluded due to failure to pass an initial comprehension check (see procedure below). The children's ethnicities reflected the composition of the area.

Stimuli A large box (12in \times 12in \times 18in) constructed out of cardboard and covered in yellow felt previously used in Bonawitz et al. (2008) was used. All five surfaces excepting the back side of the box were intact and covered with felt. A hole was cut out of the top of the box in the front right corner where a toy with a transparent sphere with lights and a spinner inside connected to a cylindrical shaft was inserted such that only the sphere was visible to the children. The toy activated by pressing a button on the shaft, causing it to light up and play music. An opaque activator bin was placed on the back left corner of the box. Additional stimuli included

red, blue, and green domino sized wooden blocks; one red, one yellow and one green paper cup; a rigid green bag; and a transparent container. (See Figure 1).

Procedure *Short Wait Condition.* Each testing session was videotaped for data retrieval and a second experimenter recorded all responses online. The experiment began with the child and experimenter sitting across from one another with the large yellow box in between them—the front side facing the child and the back side facing the experimenter. The experimenter introduced children to the large yellow box saying, “This is my big toy and I’m going to show you how it works.” The experimenter then took two blocks of each color (red, blue, and green) and placed them on the table. She showed the children that when a red block or a blue block is placed in the activator bin, the toy lights up and plays music and when a green block is placed in the bin, the toy does not activate. In reality, the experimenter was surreptitiously activating the toy by pressing a button. Previous work suggests that children (and even adults) find this manipulation compelling (Bonawitz et al., 2008). A comprehension check was then performed to ensure children remembered that the blue and red blocks make the toy activate and that green blocks did not. Next, the experimenter began Trial 1 by having the child count 20 red blocks and 5 blue blocks one at a time and placing them into a transparent container. The order of block color was counterbalanced. After counting the blocks, the experimenter shook the blocks in the container to mix them and poured them into the rigid bag. She then placed the container upside down in front of the activator bin on the yellow box and placed it on top of the container. She then accidentally knocked it over toward the activator bin. Just after the bag fell

over, the experimenter activated the toy and said, “Oh, I think one of the blocks must have fallen into the toy! Can you tell me which color it was?” Once the child answered the question, the experimenter pretended to remove the block while turning off the toy. Finally she asked, “and why do you think it was a [red/blue] chip?” Once children provided an answer, the experimenter began Trial 2 by saying, “That was kind of funny how I accidentally tipped the bag over and it made the toy go off. Should I try to make that happen again? First we have to count our blocks again.” The second and third trials progressed exactly the same as Trial 1. At the end of Trial 3, the majority of children were asked three follow-up questions: the experimenter asked which color they guessed fell into the activator on the first, second, and third trials.

Long Wait Condition. The *Long Wait* condition was identical to the *Short Wait* except that children completed Trial 1 in the first testing session, Trial 2 in a second testing session one week later, and Trial 3 in a third testing sessions one week after Trial 2.

Results

There were no age differences between groups ($t(38) = 0.11, p = ns$). Responses were coded by first author and reliability coded by a research assistant blind to experimental hypotheses. All responses uniquely and unambiguously were either “red” or “blue” and agreement was 100%.

Probability Matching As expected, looking only at the first responses, there were no differences between conditions, $\chi^2(1, n = 40) = 1.9, p = ns$. To assess whether or not children probability matched, we averaged the first response of children in both the *Long Wait* and *Short Wait* condition. Overall, children’s responses reflected probability matching (70% providing the more probable chip response). That is, results suggest that children were not simply randomly guessing, as responses were significantly different from chance ($p < .05$; binomial test), but not significantly different from the predicted distribution of .8 ($p = ns$, binomial test). Similarly, children were not “maximizing” by always providing the most probable response (i.e. always choosing the red chip), or responses would have approached ceiling.

Dependency Measures To assess whether children’s responses were independent from one another across trials, we first assessed what the independent sampling assumption would predict. That is, given probability θ of sampling a particular chip, what should the distribution of three responses look like? Because there are two possible responses (red (r) or blue (b)) and there are three trials, there are simply 2^3 or eight possible hypotheses ($rrr, rrb, rbr, rbb, \dots, bbb$). Thus, assuming independence between trials, the probability of any particular hypothesis (e.g., rrb) is simply the probability of sampling each chip (i.e. $(.8) * (.8) * (.2)$). In this way, we can compute probabilities for all eight hypotheses. We compared the expectation to the observed distribution of children in the *Short Wait* and *Long Wait* conditions (see Table 1).

Table 1: Pattern of responses expected under independent sampling compared with frequencies in the *Long Wait* and *Short Wait* conditions.

Responses	Expectation	<i>Long Wait</i>	<i>Short Wait</i>
red,red,red	.512	10	1
red,red,blue	.128	1	1
red,blue,red	.128	2	10
red,blue,blue	.032	3	0
blue,red,red	.128	0	1
blue,red,blue	.032	1	6
blue,blue,red	.032	1	1
blue,blue,blue	.008	2	0

Chi-squared tests revealed a significant difference between children’s responses in the *Short Wait* condition to both the *Long Wait* condition, $\chi^2(7, N = 40) = 22.3, p < .05$, and to the expected distribution, $\chi^2(7, N = 20) = 18.6, p < .05$.¹ However, the difference between the *Long Wait* condition and the expected distribution was not statistically significant, $\chi^2(7, N = 20) = 6.57, p = ns$. This suggests that while children in the *Long Wait* condition were providing responses that followed the predictions of independent samples, children in the *Short Wait* condition were doing something else. Indeed, a quick examination of Table 1 suggests that children in the *Short Wait* condition were simply alternating responses. To directly compare the two conditions, we coded children’s responses in terms of whether they repeated a response (e.g. “red” then “red” again) or alternated (e.g. “red” then “blue”). Comparing condition by repetition/alternation revealed significant differences both when we coded for repetition/alternation over all three responses, Fisher Exact ($N = 33$), $p < .0001$, and when we coded for repetition/alternation over two responses, $\chi^2(1, N = 80) = 29.5, p < .0001$.

Another way to think about dependency is to model children’s responses as a Markov process and consider the transition matrix. We computed the empirical frequencies with which children moved from a “red chip” response to a “blue chip” response, and so forth (see Table 2). If children are producing independent samples, the probability of producing a particular response should be the same regardless of the previous response. However, this analysis revealed a strong dependency between responses in the *Short Wait* condition, Fisher Exact ($N = 20$), $p < .0001$, and a much weaker dependency in the *Long Wait* condition, Fisher Exact ($N = 20$), $p = .03$. These results suggest that although children’s pattern of responses in the *Long Wait* condition were close to the predicted distribution, there were still dependencies between a single child’s guesses.

¹Because the approximation to the χ^2 distribution is unreliable with small cell entries, we computed the null distribution numerically. We generated 10,000 contingency tables with these frequencies, computed χ^2 for each, and then computed p values by examining the quantile of the observed χ^2 value.

Table 2: Transition matrices in the two conditions.

	<i>Long Wait</i>		<i>Short Wait</i>	
	Next <i>r</i>	Next <i>b</i>	Next <i>r</i>	Next <i>b</i>
Current <i>r</i>	21	7	4	17
Current <i>b</i>	4	8	18	1

We conducted one final analysis to rule out the hypothesis that children in the *Short Wait* condition showed more dependency in responses than children in the *Long Wait* condition purely because children in short wait were more likely to remember their guesses. If children in the *Long Wait* condition had simply forgotten their previous responses more often than children in the *Short Wait* condition, they would be much less likely to show dependencies between guesses simply due to memory differences between trials. Recall that at the conclusion of the experiment children were asked which color block they had said fell in on each of the three previous trials. Looking at whether children answered all questions correctly, we found no difference in memory between conditions, $\chi^2(1, N = 32) = 3.14, p = .08$. However, because there was arguably a marginal difference between conditions, we also gave the children a memory score from 0-3 depending on how many memory questions children answered correctly; comparing memory scores also revealed no significant differences, $t(30) = -1.52, p = ns$.

Discussion

Our experiment examined whether children's responses in a simple causal reasoning task could be accounted for in terms of sampling from a probability distribution. The results of the experiment provide evidence in support of the sampling hypothesis in children. First, children's behavior reflected probability matching. That is, as a group, children provided a percentage of red and blue guesses that corresponded with the actual distribution of red and blue blocks in the population, rather than maximizing and choosing the red block on every guess or randomly guessing 50% of each color. Second, children's responses reflected the predicted patterns of independence and dependence across conditions. After delays of one week, children showed a greater amount of independence between guesses than did children who did not experience a delay. Furthermore, in contrast to results from the *Long Wait* condition, analyses of the *Short Wait* condition revealed that individual children showed strong dependence between their three guesses; thus these children were not randomly sampling from the distribution.

One might ask whether the findings suggesting that children are probability matching in our experiment were an artifact of our particular design. If children were aware that they would be asked the same question multiple times, they might not have been motivated to provide an optimal response, knowing that they would have two more chances to provide guesses. However, children were not aware that they would be playing the game multiple times in either the *Long*

Wait or the *Short Wait* conditions. Furthermore, it is unlikely that such young children would be capable of engaging in such sophisticated planning. Moreover, at the conclusion of the three trials we asked children whether they remembered the guesses they had provided on each trial. Across both conditions children's memories were fuzzy, with the majority of them only being able to accurately report one or two of their initial responses in both the *Long Wait* and *Short Wait* conditions and there was no difference between conditions on the memory check.

Although our findings were consistent with the sampling hypothesis in that children both probability matched and displayed greater independence of guesses given a time delay, we did not find evidence for a "wisdom of crowds" effect. The wisdom of crowds predicts that when guesses are aggregated across individuals, this should provide a score that is closer to the actual distribution than the individual guesses alone. Instead, we found no differences between children's first guess and the majority of three responses, $\chi^2(1, N = 40) = .23, p = ns$. Given that Vul and Pashler (2008) found this benefit with adults, we might have expected to find a similar increased advantage of aggregation with children. However, we elected to use a forced choice paradigm due to the young age of our participants, and this may have reduced the sensitivity of our measure such that we were unable to detect the effect. In future work we may explore this further by designing a task that would allow children to make more fine-grained responses.

Future Work

Future work will continue to evaluate the sampling hypothesis in children to investigate the role of evidence in children's hypothesis generation and sampling. For example, we are looking at whether young children are capable of rapidly updating hypotheses based on evidence during a causal learning task. The prediction following the Sampling Hypothesis is that children will update their hypothesis space following either confirming or disconfirming evidence and will adjust their predictions accordingly, and should sample their next hypothesis from the remaining possible hypotheses.

Another future direction will involve investigating the sampling hypothesis in even younger children and current research suggests some possible appropriate methods. In an experiment examining single-event probability, Denison and Xu (in press) used a crawling procedure to show that 13-month-old infants can make predictions about single-event probability. They used two trials, one to establish which of two object-types individual infants preferred and another to test probabilistic inference. They showed infants two large populations of objects, one with a 4:1 ratio of desirable: not-desirable objects and the other with the opposite ratio. The experimenter removed a single item from each of the two populations one at a time and placed them into separate opaque containers. The infant was then encouraged to crawl to the container of their choice. Findings suggested that infants could predict which of the two populations would most likely yield a single-item

sample of their preferred object.

Finally, although other work suggests that children do demonstrate graded sensitivity to probabilities with similar designs (Bonawitz et al., 2008) and we chose a sample probability that maximized the difference between chance response and a strategy of maximizing, further conditions could strengthen our findings here by demonstrating that children's responses match probabilities across an array of values. For example, ongoing studies in our lab suggest that preschool-aged children's first responses do also match to samples where the probabilities are 19:1, 15:5, 12:6, and 10:10. Furthermore, we can demonstrate that children can sample from probability distributions in a more complex hierarchical sampling task. We have adapted the current procedure to show children an overall population of blocks that is physically separated into two sub-populations with different distributions. This design allows assessment of children's ability to make valid probabilistic inferences when they must take into account the condition that the block is being sampled from only one of the two sub-populations.

Conclusions

The current experiment provides a first step in examining the sampling hypothesis in children. Children in our experiment engaged in probability matching and demonstrated increased independence of guesses when given a time delay, suggesting that they may have engaged in a process of sampling from probability distributions. This sampling behavior may begin to explain how children navigate through the potentially infinite number of hypotheses they face at the outset of a learning process. More generally, the sampling hypothesis may also begin to explain how it is that children's behavior can appear irrational when examined individually but may actually reflect a rational strategy overall.

Abstract

Current cognitive models of Web navigation (e.g., Information Foraging Theory, IFT, Pirolli, 2007) are based on the assumption that users' behavior is guided by evaluating the topical relevance of information encountered on the Web. This "information scent" has been successfully used to model Web search behavior. In this paper, however, we claim that topicality-oriented theories like IFT need to additionally consider the evaluation of information quality in order to address a broader class of realistic search tasks. For instance, when search tasks are complex and the quality of available Web information is highly variable, Web navigation will also depend on evaluating information quality, in addition to evaluating topical relevance. In this paper we first provide a theoretical framework of quality evaluation during Web search. Second, we review two experimental studies to substantiate this theoretical framework. Finally, we propose an extension of IFT using the concept of *epistemic scent* to incorporate evaluations of quality into the theory.

Web search and information quality

With the exponential growth of information available on the World Wide Web (WWW), the Web has evolved into one of the most important information sources. Besides searching for simple and uncontroversial facts or researching product purchases, the Web increasingly serves as a rich information source for conducting research on more complex academic or science-related topics (cf. Horrigan, 2006). For instance, in the context of personal concerns of individuals, such as medicine and health care, using the Web as a supplement to the interaction with experts has achieved great popularity (Moharan-Martin, 2004).

However, as anyone can publish virtually any information on the Web, the WWW is characterized by a large variability of information quality with information sources differing dramatically with regard to Web authors' expertise and motives. As a result, the trustworthiness of online information on topics like medicine or healthcare varies considerably, with many Web sites containing misleading or even false information (Eysenbach, Powell, Kuss, & Sa, 2002). Despite this variability, different Web sources (e.g., scientific and other institutions, journalists, lay people, or companies) are usually interspersed in the results lists returned by search engines. Moreover, in many cases popular commercial or social Websites (e.g., shops or forums) that

may be doubtful with regard to their motives or expertise fit exactly to search terms entered by users, so that they are listed among the highest-ranked search results on a search engine result page (SERP). Thus, even the information contained in the top search results of a SERP might turn out to be biased and one-sided, leading to premature or even wrong decisions. Accordingly, Web users may not only be required to critically evaluate the topical relevance of search results but also their quality (cf. Taraborelli, 2008) - especially when dealing with controversial issues such as the effectiveness of specific medical treatments. Contrary to this claim, however, most current cognitive models of information search on the Web focus on evaluating the topical relevance of search results, thereby neglecting issues of information quality.

In this paper, we propose an extension of one of the most influential theories of search and navigation on the Web - the Information Foraging Theory (IFT, Pirolli, 2007) - based on the results of two experimental studies. These results will be reviewed following a theoretical introduction of Web-search models and quality evaluations.

Topicality-oriented models of Web navigation

In the last decade, various computational cognitive models of Web navigation have evolved. These models are based on concepts like semantic similarity and topical relevance, such as SNIF-ACT by Fu and Pirolli (2007), CoLiDeS by Kitajima, Blackmon, and Polson (2000), MESA by Miller and Remington (2004), and CoLiDeS+ by Juvina & Van Oostendorp (2008). Although several models exist, they have all ignored the evaluation of information quality.

In this paper we will focus on the SNIF-ACT model, which is based on IFT. IFT postulates that the selection of hyperlinks (e.g., from a SERP or Web page) is determined by the strength of a so called "information scent". Information scent reflects the perceived semantic similarity between *proximal cues* (i.e., keywords or trigger words available in link labels or search results) and the current *search goal* of the user, which is defined by a desired distal information source (e.g., a Web page). A strong information scent of a hyperlink indicates a high likelihood that the source accessible via the hyperlink contains the desired information and thus increases the likelihood that the hyperlink will be selected. As IFT explains Web searching behavior based on this notion of information scent, the theory presupposes that Web searching is exclusively guided by the topical rele-

vance of Web information. The computational modeling of information search in SNIF-ACT uses spreading activation in semantic memory as a mechanism for determining semantic similarity. A strong information scent occurs when the encoding of proximal cues in semantic memory results in a substantial spread of activation to the representation of the current search goal. Activation spread according to the associative strength between concepts in memory is a standard measure to represent semantic similarity in the underlying ACT-R architecture. Figure 1 illustrates the concept of information scent (IS) for a user pursuing the goal of finding information about “medical treatments for cancer” (this is the desired distal information defining the search goal). It is assumed that the user encounters a search result like the one depicted in Figure 2, which includes the terms “cell, patient, dose, beam” (these are the available proximal cues). The arrows represent the spread of activation from the search result to the goal representation, which is used to calculate the information scent of the search result.

Figure 2: Example of a search result link.

Topically-oriented computational models like SNIF-ACT have been able to predict Web search and link selection in a wide range of different tasks. Thus, at first sight they seem to allow for a successful and precise modeling of Web navigation of any kind. However, we claim that all tasks that were used for modeling forced users to focus their attention on the topical fit of available information: Users either had to engage in simple fact-finding tasks or they had at their disposal a selection of Web information that was restricted to uncontroversial and consistent information of established

quality. For these types of task, quality evaluations are not an important issue. Moreover, previous studies used search environments that provided users with more or less salient topicality cues but not with salient cues pointing to the quality of search results.

Preconditions for quality evaluations on the Web

Given the search tasks and search environments used in previous studies on information scent, it seems plausible that users' Web navigation in these tasks was mainly a function of the perceived topical relevance of available information (i.e., its information scent), because quality evaluation are neither required nor supported. However, we hypothesize that the role of quality evaluations on search behavior might change considerably when certain preconditions are given with regard to task characteristics, user prerequisites, and search interface. The hypothesized interplay of these preconditions, which is illustrated in Figure 3, will be used as a theoretical framework throughout this paper.

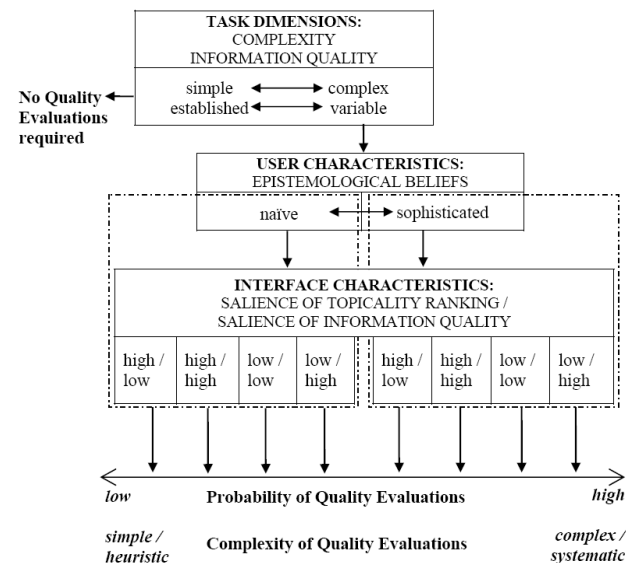

Figure 3: Preconditions of quality evaluations

Task complexity and variability of information quality

We assume that the evaluation of information quality (e.g., in terms of credibility, accuracy, and completeness) becomes of major importance (1) when the search task is sufficiently complex and, even more important, (2) when the available information is highly variable with regard to its quality. Search tasks loading high on these two task dimensions have become an increasingly important activity on the Web, for instance, when users search for controversial science-related topics or personal concerns like medical or health issues. In such search tasks, inconsistent and potentially contradictory Web information of variable quality is often encountered, so that searchers should not take the accuracy of the available information for granted. Despite the growing popularity of research on Web information quality in the last decade (for a review see Rieh & Danielson, 2007), to the best of our knowledge, the fit of topicality-

oriented models of Web navigation with users' search behavior in tasks that require the evaluation of information quality has not yet been investigated.

User prerequisites: Personal epistemology

Once the user is confronted with a search task that requires quality evaluations, both the probability and the complexity of these quality evaluations will strongly depend on the searcher's cognitive prerequisites, for instance on his or her personal epistemology. In line with dual-process theories (e.g., Chen & Chaiken, 1999), quality evaluations can range from simple, non-elaborated, intuitive, and spontaneous "heuristic" evaluations, on the one hand, to complex, cognitively elaborated, conscious, and reflected "systematic" evaluation processes on the other hand. In order to systematically evaluate the quality of Web information, searchers need to consider how credible a source of information is, how certain and consistent with other sources the information itself is, and how strongly the information might be influenced by the motives of the information provider. According to Hofer (2004) this kind of reasoning is closely connected to a person's epistemological beliefs (EBs), that is, to one's personal beliefs about the nature of knowledge and knowing. EBs have been shown to guide users' cognitive and metacognitive activities during Web search (Hofer, 2004). For instance, it has been demonstrated that users with naïve EBs are less critical Web searchers and that EBs influence search techniques and the ability to recognize authority (Hofer, 2004; Whitmire, 2003). Certainly, there exist other important cognitive prerequisites beyond EBs that support systematic quality evaluations of Web information, such as domain expertise or Web expertise. These prerequisites were, however, not investigated as factors in the studies reviewed in this paper and will therefore not be discussed in greater detail.

Search interface: Salience of topicality and quality

A third precondition for quality evaluations – beyond task requirements and user prerequisites – is related to the affordances and information provided by the search interface. We assume that even if a user is able to engage in quality evaluations required by a search task, the concrete enactment of these processes during Web search might depend on two aspects of the search interface: first, whether the search interface affords quality evaluations and second, whether it comprises quality-related information. In our opinion, the interface of popular search engines usually does not support quality evaluations with regard to these two aspects.

First, search engines usually present search results in a list, with the most topically relevant and most popular Web pages being the highest-ranked ones (cf. Cho & Roy, 2004). This list format provides a strong affordance for users to start reading at the top of the list and to follow the strict and non-ambiguous order when reading and selecting the search results presented. Thus, no affordances are provided for users to take over the responsibility for evaluating and selecting search results on their own. Rather, searchers' aware-

ness of the ongoing selection process is hindered by the SERP layout.

Second, search engines usually display only very little information for each search result (e.g., a title, an excerpt from the respective Web page, a URL) on which evaluation processes aimed at deciding which search results to select for further inspection must be based. Moreover, the search result descriptions are typically confined to topical information, whereas quality-related source information is sparse and non-salient. Accordingly, the interface design of standard search engines does not support users to engage in quality-related evaluation processes on their own.

It can be expected that (1) the salience of topicality rankings of search results and (2) the salience of proximal cues in search results pointing to the quality of information are two important factors that determine whether quality evaluations take place or not. We assume that a search interface that provides salient proximal cues for information quality and refrains from making the topicality ranking of search results the most salient feature will stimulate more quality evaluations than a search interface without these characteristics. Thus, within the limits of users' individual cognitive prerequisites, a proper search interface might lead to navigational decisions that are based to a substantial degree on evaluating information quality in addition to evaluating topical relevance.

Hypotheses and review of experimental studies

Based on the framework describing the preconditions of quality evaluations during Web search (Figure 3), a couple of hypotheses were derived and tested in two studies reviewed in this section. In both studies, fine-grained process data (combination of eye-tracking methodology and log file data) were used to test the relationship between the probability and complexity of quality evaluations in a science-related search task and the design of the search interface and users' EBs. The task of both studies addressed a controversial medical topic. The collection of Web pages made available in the studies represented the variability of information quality on the Web and included Web pages provided by official institutions, scientific authorities, journalists, companies, and lay people (e.g., discussion pages). All Web pages were topically relevant to the respective search topic. We hypothesized that a search task with these characteristics would cause users to engage in quality evaluations, at least when their cognitive prerequisites and the search interface used would allow for these processes. Users' EBs were measured to test whether users with naïve and sophisticated EBs differ in the quality evaluations they engage in.

Two different interface design approaches were implemented to test whether they stimulate quality-related evaluation processes. In study 1 (Kammerer, Wollny, Gerjets, & Scheiter, 2009) participants either used a standard Google search result list or an augmented search result list additionally containing source categories for each search results (cf. <http://www.clewwa.de/>). This approach aimed at providing salient quality-related cues. In Study 2 (Kammerer & Ger-

jets, 2010) a standard list format was compared to a grid format with search results arranged in multiple rows and columns (cf. www.viewzi.com). This approach aimed at decreasing the salience of the topicality ranking and at increasing users' awareness of the selection process.

We hypothesized that both experimental interfaces would lead to more and better quality evaluations than a standard search interface with a high salience of the topicality ranking and a low salience of information quality.

Study 1: Display of search results with source categories

In this study (for details see Kammerer et al., 2009) participants were confronted with a fictitious request from an overweight friend, who wants to loose weight by changing her diet. Participants were asked to conduct a 20-minute Web search to make an informed decision between low fat and low carb diets in order to recommend one of the two diet methods. Participants were provided with three prearranged Google-like SERPs with ten search results each.

Method. Thirty university students participated in the experiment by either using a standard Google search result list or an augmented search result list (15 participants per group). The augmented list additionally contained source category labels printed in bold next to the URL. The labels indicated to which of five different source categories a search result belonged. The five source categories were Science/Institutions, Portals/Advisors, Journalism/TV, Readers' Comments, and Shops/Companies. We assumed that these source categories provided users with cues regarding the quality of the respective Web pages without changing the topical information available for each search result. Furthermore, searchers' EBs were obtained with the Epistemic Beliefs Inventory (EBI; Schraw, Dunkle, & Bendixen, 1995). In order to study participants' evaluation processes, their eye movements and mouse clicks during Web search were captured. We assumed that the amount of attention (i.e. total fixation duration) spent on a search result reflected evaluative processes with regard to this search result. As the topical information did not differ between the experimental conditions we assume that group differences in the amount of attention indicate differences in quality evaluations. Similarly, selection differences between groups cannot be traced back to differences in topicality but indicate that searchers evaluated the quality of sources differently.

Results and discussion. The results showed various differences between the two search interfaces and between naïve and sophisticated users with regard to the attention distribution on SERPs and the selection of search results. First, augmenting SERPs with source categories resulted in less linear viewing sequences than standard SERPs. Second, the availability of source categories influenced students' evaluation and selection behavior, such that they gave less attention to commercial search results ("Shops/Companies") and were more likely to select search results from the category Portals/Advisors. Third, beyond these effects of the interface design, the results revealed that source categories stimulated users with sophisticated EBs to pay more atten-

tion than naïve users to search results that were rather ambiguous with regard to their information quality (Portals/Advisors, Journalism/TV, and Readers' Comments) compared to the remaining categories Science/Institutions (high quality) and Shops/Companies (low quality). Fourth, with regard to EB effects on standard SERPs, the results indicated that sophisticated users paid less attention than naïve users to search results linked to social or commercial Websites. A possible explanation is that searchers with sophisticated EBs might be able to identify such search results as being of rather low quality by having only a quick look on the search result descriptions (e.g., the URLs). To conclude, Study 1 revealed several effects of (1) enriching search interfaces with salient quality-related cues and (2) of the personal epistemology searchers bring to the task. These two factors would be difficult to model with topicality-oriented theories of Web navigation like the IFT because the differences in attention distribution and selection behavior were not associated with differences in topical relevance.

Study 2: List interface versus grid interface

In this study (for details see Kammerer & Gerjets, 2010) users had to decide between two competing therapies for Bechterew's disease. They were given eight minutes to conduct a Web search regarding the pros and cons of both therapies and to make an informed decision between them. Participants were provided with two prearranged SERPs, one for each therapy, with nine search results each.

Method. Eighty university students participated in the experiment by either using a standard Google search result list or a grid interface with search results arranged in three rows and three columns. Furthermore, the trustworthiness order of search results on a SERP was experimentally manipulated in order to test participants' sensitivity to information quality (cf. Pan et al., 2007). The trustworthiness order of the search results presented in this study was obtained empirically in a pilot-study. Based on these data, the nine search results per SERP, which were all of high topical relevance, were either presented in an *optimal* order, with the most trustworthy search results presented first and the least trustworthy ones presented last, or in a *reversed* order, so that the least trustworthy search results were presented first. For the grid interface, trustworthiness of search results was arranged line-by-line, that is, from left to right in each of three rows. Twenty participants were assigned to each of the four conditions with trustworthiness order (optimal vs. reversed) and search interface (list vs. grid) varied as between-subjects factors. Searchers' epistemological beliefs were obtained with the Internet-Specific Epistemology Questionnaire (ISEQ, Strømsø & Bråten, 2010). Searchers' eye movements and mouse clicks were captured during Web search. Additionally, retrospective verbal protocols were obtained by asking participants post-hoc to think aloud while watching a replay of their own eye movements during search.

Results and discussion. The results showed numerous differences between the two search interfaces, between the two

trustworthiness orders, and between naïve and sophisticated users with regard to the attention distribution on SERPs, the selection of search results, and the occurrence of quality-related verbal utterances. First, the grid interface caused less homogenous and less linear viewing sequences on SERPs than did the list interface (for both trustworthiness order conditions). Second, when using the list interface most attention was given to the search results on top of the list – independent of their trustworthiness. In contrast, with a grid interface, nearly all search results on a SERP were attended for equivalent durations. Consequently, when search results were presented in a *reversed* order, participants using the list interface attended significantly longer to the least trustworthy search results and selected the most trustworthy search results significantly less often than participants using the grid interface. Third, with regard to verbal utterances, the grid interface stimulated quality-related utterances compared to the list interface, although these utterances mostly reveal simple and heuristic quality evaluations rather complex and systematic ones. Fourth, EB results showed that, with regard to searchers' selection behavior, sophisticated users better identified trustworthy sources than naïve users. With regard to verbal data, naïve users reflected less on the type of sources they had encountered. With regard to attention distribution, naïve users paid less attention to the URLs of the search results. To conclude, Study 2 revealed several effects of (1) the presentation format and presentation order implemented in the search interface and (2) of searchers' personal epistemology. These factors influenced verbal behavior, attention distributions, and selection behavior, providing evidence that at least sophisticated searchers using an interface with a low salience of the topicality ranking (i.e., the grid interface) substantially engaged in quality evaluations to guide their web navigation. Again, because the search results displayed in all experimental conditions were equivalent with regard to topical relevance, the findings obtained would be difficult to model with topicality-oriented theories of Web navigation like the IFT.

Extending Information Foraging Theory

Based on the theoretical framework illustrated in Figure 3 we predicted that – given certain preconditions – Web navigation would be substantially guided by quality evaluations in addition to topicality evaluations. The two experimental studies reviewed confirmed these expectations. Searchers in different experimental conditions were presented with search results that were equivalent with regard to topical relevance. Experimental manipulations involved the presentation format (list versus grid), the trustworthiness order (optimal versus reversed) and the availability of quality-related proximal cues (source categories). Additionally, we distinguished searchers with naïve and sophisticated EBs. The results yielded various effects of quality-related manipulations and of searchers' EBs on attention distribution, selection behavior, and verbal utterances. IFT and other topicality-oriented models of Web search would not have predicted these effects, because the topical relevance of

search results remained unaffected by the manipulations. We propose to extend IFT in three ways to account for the data we obtained. Our suggestions are illustrated in Figure 4, which refers to the example introduced in Figures 1 and 2 (medical treatments for cancer).

Figure 4: Extension of Information Foraging Theory

Tasks that require quality evaluations. IFT claims that Web search is guided by a topical goal, namely the goal of finding topically relevant information irrespective of its quality. In order to account for our data, however, it is necessary to introduce more complex goal structures that comprise an additional epistemic goal component (e.g., find *trustworthy* information of topical relevance). In order to decide which tasks require an epistemic goal component leading to quality evaluations, additional procedural knowledge is necessary to trigger the epistemic goal component (e.g., in cases in which contradictory information or information of variable quality is encountered during Web search).

Epistemic scent as a guiding parameter. When an epistemic goal component is active due to the characteristics of the search task and the nature of the search results encountered, a second scent parameter becomes available, namely the spread of activation from proximal cues for information

quality (e.g., the words “scientific”, “journal” or “.org” in a search result description) to the representation of the current epistemic goal component (e.g., reliable and trustworthy information provided by experts). This epistemic scent (ES) based on information quality, can be taken into account in addition to the topicality-based information scent for guiding Web navigation. An open issue might relate to the integration of information scent with epistemic scent (e.g., by summing up activations, applying “metacognitive” rules).

Epistemic knowledge: Concepts and rules. To account for effects of EBs and quality-related cues on SERPs we suggest not only to model searchers’ domain knowledge but also their epistemic knowledge. Epistemic knowledge comprises conceptual knowledge (e.g., knowing that information in a scientific journal provided by experts is trustworthy, see the lower part of Figure 4). Conceptual epistemic knowledge is necessary to interpret quality cues on SERPs and to judge the epistemic scent of search results. Epistemic knowledge also comprises procedural rules that guide systematic quality evaluations (e.g., recognizing good and unbiased Web information) and allow to handle information of variable quality (e.g., selection and attention behavior). These procedural rules will, however, strongly depend on whether search interfaces provide the information necessary for their application. Conceptual and procedural components of epistemic knowledge together can be used to model the influence of searchers’ EBs on Web navigation. The proposed extensions of IFT would broaden its scope to include search tasks that require quality evaluations. Based on these extensions, IFT could be used to model aspects of users’ Web navigation behavior that are not determined by topicality alone. Furthermore, these extensions are in line with the general assumptions of IFT and with our framework on the preconditions of quality evaluations (Figure 3). Moreover, they are consistent with the pattern of results obtained in the two experimental studies reviewed in this paper. Finally, they would allow for novel predictions on how domain and epistemic knowledge in combination can affect quality evaluations due to their associations in semantic memory.

Simulating the Elimination and Enhancement of the Plosivity Effect in Reading Aloud

Qiang Liu (qxliu@ucsc.edu) & Alan H. Kawamoto (ahk@ucsc.edu)

Department of Psychology, University of California at Santa Cruz
Santa Cruz, CA 95064 USA

Abstract

In this paper, we consider articulatory processes in a connectionist model of reading aloud to account for effects of manner of articulation of the initial segment in a variety of tasks. We first describe experimental results showing how flexibility in articulation can completely eliminate the *a priori* acoustic latency difference between plosives and non-plosives in some tasks, and exaggerate this difference in other tasks. We then simulate an expanded version of the Connectionist Incremental Articulation Model that incorporates Stevens' (1998) 3 phases involved in articulating a speech segment.

Keywords: Phonological Priming; Word Naming; Speech Production; Segment Duration; Jordan Network; Minimal Unit of Articulation; Response Criterion

The Precise Articulatory Sequence in the Production of Individual Sounds

Researchers have known that the onset of the articulatory response occurs long before the onset of the acoustic response (Bell-Berti & Harris, 1981). This asynchrony between the onset of articulatory and acoustic responses is due to the fact that individual sounds are produced in three distinct articulatory phases: (1) the movements of the articulators toward the formation of the oral constriction; (2) the flow of air behind or around the oral constriction; and (3) the release of the current constriction and movement toward the next constriction (Stevens, 1998).

The exact point at which the acoustic event is produced in the sequence above for initial segments that differed in manner can be distinguished according to their specific articulatory requirements. For non-plosive segments such as /m/, /l/, /r/, /s/, etc., acoustic energy can be generated shortly after their respective oral constriction are formed. However, for plosive segments such as /p/, /t/, /k/, etc., acoustic energy can be generated only after (a) the buildup of sufficient intra-oral pressure, and (b) the release of the current oral constriction. That is, acoustic onset for non-plosive segments occurs during the second phase, whereas for plosive segments, it occurs during the third.

The Plosivity Effect

This differential requirement for the production of the acoustic events of plosive and non-plosive segments is the basis for the Plosivity Effect. Because the acoustic event for plosive segments requires the buildup of the intra-oral pressure, the onset of acoustic energy (acoustic latency)

for responses beginning with plosive segments is typically 50 – 100 ms slower than responses beginning with non-plosive segments, although this difference can be as short as 20 ms in speeded naming tasks (see Kawamoto, Kello, Jones & Bame, 1998). Notably, the plosivity effect can be completely eliminated in some tasks (Kawamoto, Liu, Mura, & Sanchez, 2008), or enhanced in others (Liu, Kawamoto, & Grebe, 2009).

The Elimination of the Plosivity Effect

In a study examining the temporal relationship between the onsets of the articulatory and acoustic responses in the delayed naming task, participants were presented with the complete stimulus (a monosyllabic word) at the beginning of a trial and were told to respond as quickly and accurately as possible only after a signal to respond was given, which was given after a delay. Using stimuli that began with the segments /p/, /t/, /m/, and /n/, Kawamoto and colleagues found that what constituted the initiation of the response to participants was the onset of the acoustic response, despite the fact that for long delays, the onset of the articulatory response occurred before the signal to respond. In essence, participants were moving their articulators into the optimal position for the phonation of the acoustic response while they were waiting for the signal to respond. For sufficiently long delays, that meant holding the acoustic response in abeyance until the signal to respond was detected. For responses beginning with non-plosive segments (/m/ and /n/), that meant holding the response at the cusp of the second articulatory phase, whereas for responses beginning with plosive segments (/p/ and /t/), it was held at the cusp of the third articulatory phase.

Basically, when participants were afforded the opportunity (i.e., long delays) to not only form the appropriate oral constriction (phase 1), but also build the required intra-oral pressure (phase 2) for plosive initial segments, the plosivity effect disappeared completely. But when there was insufficient time for the first two phases to be completed for plosive initial segments (i.e., short delays), a plosivity effect could still be observed, although the magnitude of the plosivity effect diminishes as a function of delay.

The Enhancement of the Plosivity Effect

In a different study, which examined the minimal unit of phonological information needed to initiate articulation (i.e., minimal unit of articulation), participants again produced monosyllabic utterances that began with the

segments /p/, /t/, /m/, and /n/ under a variant of the delayed naming task, called the pair-wise priming task (Liu, Kawamoto, & Grebe, 2009).

Procedurally, the pair-wise priming task is identical to the delayed naming task except that instead of presenting the complete stimulus at the beginning of the trial, only the initial letter was presented (e.g., *m*__). The complete stimulus (e.g., *mood*) was presented only after a variable delay (i.e., stimulus onset asynchrony or SOA) of 300 ms or 600 ms.

The key issue was whether or not the initial segment was sufficient for a participant to initiate the articulatory response or even the acoustic response. Liu and colleagues (2009) found that participants could in fact initiate the articulatory response on the basis of the initial segment alone. In fact, in the 600 ms SOA condition, articulatory onset for both plosive and non-plosive segments on average occurred before the presentation of the complete stimulus.

The next issue is whether knowledge beyond the initial segment is required to initiate the acoustic response. If the acoustic response can be initiated on the basis on the initial segment alone in certain conditions, one can lengthen the acoustic event for these segments until the subsequent segment becomes available. Indeed, for nasals, a 10.08 ms increase in the mean acoustic segment duration was observed in the 600 ms SOA condition compared with the 300 ms SOA condition (see Figure 1). In fact, in certain trials, acoustic onset occurred prior to the presentation of the complete stimulus. Although the total number of trials where this was observed was limited to 6 out of 474 trials in total, they represent a clear existence proof that for non-plosive initial segments, the acoustic response can be initiated based on knowledge of the initial segment alone.

Figure 1: The acoustic segment durations (left) and acoustic latencies (right) of plosive and nasal initial segments across priming conditions reported by Liu et al., (2009).

However, the results for plosive initial segments differed from those for nasals. For plosives, acoustic onset corresponds to the explosive release of pent up pressure that require knowledge of the following segment (i.e., phase 3), and thus acoustic onset always occurs some time after the complete target is presented. Moreover, because this release of pressure occurs more or less in an all or none fashion, plosive segments are relatively resistant to acoustic lengthening. Indeed, acoustic duration for plosive

segments were almost identical across the different priming conditions (58.91 ms and 58.72 ms for the 300 ms and 600ms SOA, resp.). So, despite the fact that initiation of the articulatory response for plosive initial segments does not require knowledge of the subsequent segment, the initiation of the acoustic response is contingent on the following segment.

Given that the initiation of the acoustic response for plosive initial segments must wait until the next segment is known but it does not for non-plosive segments, the onset of the acoustic response for non-plosive initial segments can be initiated much earlier than plosive initial segments, particularly in the 600 ms SOA condition. This differential constraint is what was driving the 16.64 ms enhancement of the plosivity effect on acoustic latency observed across the different priming conditions (i.e., the difference between the 17.77 ms plosivity effect in the 300 ms SOA condition and the 34.42 ms plosivity effect in the 600 ms SOA condition as illustrated in Figure 1).

Individual Differences: A Case for multiple Response Criteria. Although the results of Liu and colleagues' (2009) study represent the strongest evidence to date that participants can initiate both the articulatory and acoustic responses before the full phonological code of a word is generated, not all participants behaved in this manner. In fact, there is a wide range of individual differences.

Figure 2: Data for two participants (1 and 12) reported by Liu et al., (2009). The articulatory onset to acoustic onset interval (AAI) is shown in red, and the acoustic segment duration is shown in green.

At one extreme (e.g., participant 1 in Figure 2), there are participants who initiated the articulatory response shortly after the prime is processed and long before the complete stimulus is presented. In a sense, data from these participants typified a response strategy where articulation is based on a segmental criterion (cf. Kawamoto et al., 1998). For these participants, articulation of the initial segment was necessarily lengthened because articulation of the initial segment was initiated before the subsequent segment was available. Since information for the next segment comes much later in the 600 ms SOA condition, these participants showed the largest AAI and acoustic segment duration effects (for nasals). When the difference in the SOA is taken into account, there is virtually no difference in when the articulatory response is initiated (articulatory latency)

Table 1: Examples of the input and output representations used in the current model. Input for the Articulatory Control structure (in bold), with the “-” denoting the Unspecified Segment unit (used only for priming), and the “\$” denoting the Metrical Slot unit (specified or not). The first and last sweep represents the neutral state.

relative to the presentation of the prime.

At the same time, there are also participants who, despite the fact that the prime provided sufficient information to initiate articulation, chose to wait until more information becomes available. These participants (e.g., Participant 12 in Figure 3) typified a response strategy where articulation is based on the whole word criterion (cf. Kawamoto et al., 1998). For these participants there was little or no difference in when and how the response was executed across priming conditions.

The Incremental Articulation Account: An Expanded Implementation

In this section, we describe an expanded implementation of the Incremental Articulation Account (Kawamoto et al., 1998). The core assumptions of the incremental account are that (1) the minimal unit of articulation is the segment, (2) multiple response criteria can be used, and (3) when articulation is initiated on a segment by segment basis, the articulation of the current segment/s may be lengthened to accommodate the time needed to process the subsequent segments.

The goal of the initial implementation of this model was to account for anticipatory coarticulation and segment duration effects (Kawamoto and Liu, 2007). The goal of the current implementation is to expand the generality of this model by demonstrating how the elimination and enhancement of the plosivity effect can be accounted for when the precise sequence of articulatory events involved in articulation is considered.

The Representations Used

The input representation for the current implementation, as in Kawamoto and Liu (2007), is a slot based local representation scheme that specifies the segmental content, syllabic frame, and encoding status of a metrical slot (see Table 1). The output and state representations in the current implementation correspond

to the current articulatory phase, the syllabic position of the segment being produced, and a small set of articulatory dimensions: the velar opening, the positions of the tongue tip and tongue body, the vertical and horizontal lip separations, the degree of intra-oral pressure, the constriction of the glottis, and acoustic intensity. Phase 1 of a word medial segment overlaps in the current output representation with phase 3 of the previous segment to convey the fact that these two phases are one and the same (see Table 1).

Model Architecture

The current model consists of two linked networks — a phonological network that provides the input to an articulatory network (see Figure 3).

The Phonological Network

The phonological network consists of three distinct components: a Phonological Buffer, a Response Criterion layer, and a Buffer Control structure. The Phonological Buffer functions simply as a temporary storage mechanism for the phonological code generated by the preceding processes such as phonological encoding (not modeled here). The Response Criterion layer denotes the particular set of response criteria used. In the current implementation there are three sets of units: (1) the Instruction units, (2) the Lengthening Criterion units, and (3) the Articulation Criterion units.

The Instruction units were designed to mimic the effect of instructions on the precise articulatory juncture that participants decide to hold the response in abeyance (i.e., {1, 0, 0} denotes articulatory onset, {0, 1, 0} denotes the acoustic onset, and {0, 0, 1} denotes vocalic onset). Their specific function in this implementation is to simulate the results of the delayed naming task. The Lengthening Criterion units dictate the manner in which a verbal response will be lengthened (i.e., {1, 0} for articulatory lengthening, and {0, 1} for acoustic lengthening).

Testing the Network

Simulation of certain key results of the delayed naming experiment reported by Kawamoto et al., (2008) and the pair-wise priming task reported by Liu et al., (2009) were carried out. For the delayed naming task, our interest focused on simulating the elimination of the plosivity effect at long delays. For the pair-wise priming task, the result of interest to us was the enhancement of the plosivity effect driven by participants using the segment response criterion. To demonstrate the malleability of the plosivity effect as well as the differential lengthening of the articulatory and acoustic responses, the outputs of the Articulatory Network were computed offline from the weight matrices of the Jordan net and the Articulatory Control Structure.

Delayed Naming. The test sequences for delayed naming were simply the training sequences lengthened to 17 sweeps for test sequences beginning with plosive segments and 18 for non-plosive sequences. For both test sets, the neutral state was presented for the first 4 sweeps to represent the time that it takes for the phonological code to be generated. The complete syllabic code is presented in the 5th sweep and remained so until the 14th sweep for plosive test sequences and the 15th sweep for non-plosive sequences, after which both sets of test sequences returned to neutral state on the final sweep. Input from the Instruction units to the Articulatory Control units were set at {0, 1, 0} (indicating that the acoustic response will be held in abeyance) from sweeps 2-10 to indicate the time for the signal to respond to be detected, after which the input was switched to {0, 0, 0} for the remainder of each test sequence set.

The outputs of these test sequences clearly show that for sequences beginning with plosive and non-plosive segments, the articulatory phase prior to the generation of

acoustic energy is lengthened until the signal to respond is detected (i.e., sweep 10). Specifically, the Sigma-Pi connections to the Output-to-State connections were turned “on” and the connections to the State-to-State connections were turned “off” on the 5th sweep for non-plosive sequences and on the 6th sweep for plosive sequences. These actions turn the Jordan net into a feed forward network that simply updates the output of the earlier sweep. In essence, the articulation of the first articulatory phase for non-plosive sequences was lengthened until sweep 10, whereas for plosive sequences it was the second articulatory phase. When the Sigma-Pi units switch back to their default state on sweep 10, the articulatory network turned back into the Jordan net and produced the next articulation phase (phase 2 for non-plosives and phase 3 for plosives) in sweep 10 and for the remainder of the response in subsequent sweeps.

Since acoustic energy is generated in Phase 2 for non-plosive initial segments, and phase 3 for plosive initial segments, the output of the test sequences demonstrate that, due to the input from the Instruction units, acoustic energy for these test sequences are generated in synchronicity in sweep 8 — an elimination of the plosivity effect.

Pair-wise Priming. Two different sets of test sequences were used for the pair-wise priming task to simulate the behavior of participants using different response criteria: (1) the whole word, and (2) the segment criteria. The sequence lengths for these input sets were 17 and 15, respectively. For both test sets, the first 4 sweeps represent the neutral state. On sweeps 5-9, a fragmentary syllabic code consisting of information for the initial segment only (e.g., *m*___ or *p*___) with the unspecified segment represented by the “-” unit in the appropriate metrical slots. From sweeps 10 to the penultimate sweep,

Table 2: Example of the test sequences *m*___ → *mood* for the pair-wise priming task. The values of the Current Articulatory Phase Units from the Output Layer, the input from the Lengthening Criterion units, and the actions of the Articulatory Control units are to show the sequence of events under the **Segment Criterion**.

the test sequences contained the complete syllabic code (e.g., *mood* or *pit*); and neutral state on the final sweep (see Table 2).

Inputs to the criterion units, specifically, the Articulation Criterion and Lengthening Criterion units, for the whole word criterion test set were set to {0, 1} and {0, 0}, respectively. For the segment criterion test set, the input was set to {1, 0} and {1, 0} on sweeps 1-7, and switched to {1, 0} and {0, 1} for the remaining sweeps.

The output of the whole word test sets show that the first articulatory phase of the initial segment for both plosive and non-plosive test sequences was not produced until sweep 10, and subsequent articulatory phases were produced in each successive sweep until the entire response was completed on sweep 16. This is because the input from the Articulation Criterion units (i.e., {0, 1}) to the Buffer Control units coupled with input from the Unspecified Segment units (i.e., “-” units) in the Phonological Buffer turned “on” the Sigma-Pi connection from the Buffer Control units to the Buffer-to-Plan connections, which effectively shut off input from the Phonological Buffer units to the Plan units until the full phonological code became available on sweep 10. Once the Sigma-Pi connections to the Buffer-to-Plan connections were turned “off”, the entire syllabic code was then fed into the articulatory network, and the syllabic response is produced uninterrupted. Because the acoustic event for the initial segment was produced on the 11th sweep for non-plosive sequences, and on the 12th sweep for plosive sequences, a plosivity effect of 1 sweep was observed.

For the segment criterion test sets, the first articulatory phase was produced on sweeps 5-7 for both the plosive and non-plosive sequences because the initial segment only became available on sweep 5. On sweep 8, the input from the Lengthening Criterion units was switched to {0, 1}, at which point the action of the Articulatory Control units reverts the Sigma-Pi connections to their default state, thus, allowing the next articulatory (phase 2) to be produced. However, on sweep 9, based on the input from the Current Articulatory Phase units within the State units (values offset from those within the Output Layer, shown in Table 2, by 1 sweep), the Articulatory Control units again turned “on” the Sigma-Pi connections to the Output-to-State connections and turned “off” the Sigma-Pi connections to the State-to-State connections. Thus, phase 2 was repeated on sweep 9 (see Table 2). When the entire syllabic code became available on sweep 10, the Sigma-Pi connections again revert back to its default state allowing the remainder of the syllabic response to be produced in subsequent sweeps. Accordingly, the acoustic event for non-plosive sequences (phase 2) was produced on sweep 8, whereas, for plosive sequences (phase 3), it was produced on sweep 10, resulting in a plosivity effect of 2 sweeps.

Although the output of these two test sets taken together produced a mean plosivity effect of 1.50 sweeps

— a net plosivity enhancement of 0.50 sweeps, the exact magnitude of the enhancement ultimately depends on the proportion of participants using the segment criterion and the whole word criterion.

Conclusion

The results of the current simulations demonstrate that a single network using a sub-syllabic minimal unit and different response criteria can account for both the elimination and enhancement of the plosivity effect, as well as the differential lengthening of the articulatory and acoustic responses when the precise sequence of articulatory events involved in the generation of the individual sounds is taken into consideration. This approach can easily be extended to other latency and duration effects, both articulatory and acoustic, that can arise from a variety of processing difficulties in speech production. Moreover, with slight modifications, the current network can be easily coupled to existing models, such as the one described by Dell, Juliano, and Govindjee (1993) to account for a wider range of empirical data (e.g., latency data). Such an extension provides a way to explore the intricate coordination between different processing stages, and how potential asynchronies in the flow of information may reveal themselves in the interplay between different dependent measures such as articulatory latency, acoustic latency, and the duration of various components of a verbal response.

Abstract

The present study provides an empirical evaluation of the ideal representation view of concept representation. We compared the ideal representation view with the more established exemplar and prototype views both in common taxonomic categories and in ad hoc categories. All three views are modeled based on underlying spatial similarity representations. Results suggest that the ideal representation is the better representation in ad hoc categories, and that the exemplar model is the better representation in the common taxonomic categories.

Keywords: concepts; category representation; computational models of concept representation; typicality; ad hoc concepts

An important and robust observation in concept representation research is that not all members of a category are equally representative of the category. For example, while a platypus is a mammal, it is not a good example of a mammal. It has many features that do not fit our image of what a mammal should be like: it has webbed feet, a beak and it lays eggs. A cow on the other hand, is a good example of a mammal to most people. In the same way, a spoon is a bad example of the category *weapons*, and a gun is a good example.

Previous research suggests that people are in agreement as to what are representative, good examples of a certain category and which examples are not (Rosch & Mervis, 1975). This graded membership structure is often referred to as the typicality gradient and has been reliably observed in a broad range of natural language categories, including common taxonomic categories (e.g. De Deyne et al., 2008) and ad hoc categories, such as goal derived categories (Barsalou, 1983, 1985)

Typicality is assumed to be closely linked to the representation of a concept (e.g., Murphy, 2002; Rosch, 1978). Theories of concept representation should therefore be able to explain the observation of a typicality gradient. The observation of a typicality gradient in different kinds of categories however, does not necessarily imply that the same processes and the same kind of concept representation underlies typicality judgments. The present study aims at evaluating different views on concept representation in different kinds of categories.

Kinds of concept representations

Two contrasting views on category representation have dominated the computational research on categories and concepts, each giving a different account of the graded internal structure of categories. In both approaches typicality is related to similarity of a category member to the category representation. The two views differ in what the category representation is assumed to consist of.

On the one hand, the prototype view states that a category is represented by an abstract summary representation, referred to as the prototype (e.g., Hampton, 1979; Posner & Keele, 1968). In this view, the concept *vehicle* is represented by a summary of what vehicles are like on average, abstracted from specific instances of vehicles, containing information such as ‘moves people or cargo from point A to point B’. The typicality of *car* for the category *vehicle* then is the similarity of *car* to this abstract prototype.

On the other hand, the exemplar view proposes that a category is represented by previously encountered instances of the category, instead of an abstract summary (e.g., Brooks, 1978; Medin & Shaffer, 1978). According to this view, typicality is conceptualized as the summed similarity of a category member to all stored members of the category. For example, the concept *vehicle* consists of memory traces of previously encountered instances of vehicles, such as *train*, *plane* and *metro* (i.e. member-categories at a lower level of abstraction). The typicality of *car* is then its summed similarity to all stored instances of *vehicle*.

Barsalou (1985) has proposed a third approach to account for the typicality gradient. Focusing on ad hoc categories – categories constructed ad hoc to serve a specific purpose, for example *things you rescue from a burning house* or *things you eat when on a diet* – he proposed the idea of an ideal representation. Like a prototype representation, an ideal representation is a summary representation. Unlike a prototype which is based on average, central tendency values on the stimulus dimensions, an ideal contains extreme values on relevant dimensions. For example, a typical member of the category *things to eat when on a diet* has an extreme value on the ideal dimension ‘fat percentage’ – typical examples being at the extreme low end of that dimension, with a zero percentage of fat as an extreme ideal representation.

Barsalou (1985) compared a number of determinants of the typicality gradient in both common, taxonomic categories and ad hoc categories – including a prototype measure and an ideal representation measure. He found that whereas in common taxonomic categories the prototype measure was the dominant determinant of typicality, the ideal measure determined the typicality gradient of the ad hoc categories significantly.

This notion of ideal representation provides an excitingly new perspective on concept representation, but, unlike the exemplar and prototype views, it has not yet made its way into a computational model of concept representation. Recently we developed a model that attempts to translate the idea of an ideal representation to a computational model (Voorspoels, Vanpaemel & Storms, submitted) that is based on an underlying spatial similarity representation. To test whether this model is a proper translation of the notion of ideal representations, we aim at replicating the findings of Barsalou (1985) using computational models. We will compare the performance of the model that implements ideal representations to an exemplar model and a prototype model (also based on underlying similarity spaces) in common taxonomic categories and ad hoc categories. If our model is a proper implementation of ideal representations, we expect an interaction between the type of model and the kind of category. The ideal representation model should be the lesser model in the common taxonomic categories and the better model in the ad hoc categories.

Models

The models considered in the present paper are all based on underlying spatial similarity representations. In a spatial representation of a category, the members are represented by points in a M-dimensional space, and the distance between two members (i.e., between two points) is inversely related to the similarity between the two members. Such a representation is typically derived using multidimensional scaling (MDS) techniques, based on pairwise similarity data. The axes that span the similarity space of a category can be considered dimensions that are important to determine the similarity relations between members in the category. In the present study, we do not attempt to interpret the axes.

Ideal Dimension Model

The ideal dimension model (IDM) posits that an ideal dimension exists in the underlying similarity space. Each exemplar of a category has a certain value along the ideal dimension, obtained by an orthogonal projection on this dimension. The further this value is located along the dimension in the ideal direction, the more typical an exemplar is.

It is useful to think of the ideal dimension as a specific combination of (unarticulated) features. The more a member has of this combination of features, the more typical it is for the category. In the case of *things to eat when on a diet*, the ideal dimension possibly is made up by a combination of

features such as fat percentage, sweetness and calories. For taxonomic categories, it is more difficult to articulate the specific combination of features that might make up the ideal. To put it somewhat trivially: a car is typical for the category of *vehicles* if it has a lot of the combination of features that make up “vehicle-ness”.

Formally, the IDM assumes that judging the typicality of an item i for a category A comes down to evaluating the value of i on a certain dimension V_A . In an M-dimensional space, the typicality of item i for category A , is then given by:

$$T_{iA} = \frac{\sum_{k=1}^M x_{ik} x_{Ak}}{\left(\sum_{k=1}^M (x_{Ak})^2 \right)^{1/2}}, \quad (1)$$

where x_{Ak} are the coordinates spanning the ideal dimension V_A , x_{ik} are the coordinates of item i , and M is the number of dimensions. We restrict x_A to be at a fixed distance from the origin. This does not pose a restriction for the ideal dimension.

The model orthogonally projects item i on the ideal dimension V_A , and returns a dimensional value relative to the origin that rises when the projection is farther in the ideal direction (i.e., the direction determined by the vector V_A). This value is considered the typicality of item i for category A .

Generalized Context Model

The generalized context model (GCM; Nosofsky, 1984, 1986) assumes that categorization decisions are based on similarity comparisons with individually stored category exemplars. Originally, the model was developed to account for categorization decisions, but it has successfully been adapted for typicality judgments (Nosofsky, 1991; Voorspoels, et al. 2008a).

Typicality of an exemplar is calculated by summing the similarity of that exemplar to all other exemplars in the category. Formally, the typicality of an exemplar i for category A is then given by:

$$T_{iA} = \sum_{j=1}^n \eta_{ij}, \quad (2)$$

where η_{ij} is the similarity of exemplar i to exemplar j , with j belonging to category A .

The similarity between two exemplars is a function of the distance of the exemplars in the M-dimensional psychological space, adjusted by attentional weights – that specify which underlying dimensions are important in the similarity calculation – and a sensitivity parameter – which magnifies or shrinks the psychological space. Formally, the scaled psychological distance between two exemplars i and j is given by:

$$d_{ij} = c \left(\sum_{k=1}^M w_k |x_{ik} - x_{jk}|^r \right)^{1/r}, \quad (3)$$

where x_{ik} and x_{jk} are the coordinates of exemplars i and j on dimension k , w_k a parameter reflecting the attention weight for dimension k , M is the number of dimensions, and c is the sensitivity parameter. Since Euclidean distances are generally accepted to be more appropriate for integral dimensions (Shepard, 1964), we fixed r at 2 for the present studies.

Similarity of a stimulus i to another stimulus j , is related to psychological distance as follows:

$$\eta_{ij} = \exp(-d_{ij}), \quad (4)$$

where d_{ij} is the scaled psychological distance between exemplar i and j . The free parameters in the GCM consist of $M-1$ dimension weights and a scaling parameter c .

MDS-based Prototype Model

Within the framework of the GCM, one can easily define a prototype model (MPM; Nosofsky, 1992). Typicality of a category member then is the similarity towards the prototype of the category:

$$T_{iA} = \eta_{iP_A}, \quad (5)$$

where P_A is the prototype of category A . The position of the prototype in the similarity space is determined by averaging the coordinates of all category members on each axis.

The free parameters in the model are identical to the free parameters in the GCM (i.e., $M-1$ dimension weights and a scaling parameter).

Data

Construction of the psychological space relies on similarity data. Evaluation of the models relies on typicality data. For the common categories we used data from a recent norm study De Deyne et al. (2008). For the ad hoc categories, we collected the data. We will discuss the data for both category types in turn.

Common taxonomic categories

Eleven common taxonomic categories, from two semantic domains (animals and artifacts) were used in the present study (from de Deyne et al., 2008): *birds, fish, insects, mammals, reptiles, clothes, kitchen utensils, musical instruments, tools, vehicles and weapons*. The categories contain between 22 and 30 members.

Typicality measure The exemplars of each category, presented as verbal stimuli, were rated by 28 participants for goodness-of-example for the superordinate category they belonged to on a Likert-rating scale ranging from 1 for very bad examples to 20 for very good examples. The reliability

of the judgments was evaluated by means of split-half correlations corrected with the Spearman-Brown formula, and ranged from .91 to .98 across the 11 categories (De Deyne et al., 2008, Table 1, p. 1033). The ratings were averaged over participants.

Similarity measure Pairwise similarity ratings were also available in de Deyne et al. (2008). Similarity of each member pair within a category was rated by 15 to 25 participants (varying across categories, not within categories). Estimated reliability of the ratings ranged from .88 and .96 across categories.

Ad hoc categories

Ten ad hoc categories were constructed, including those of Barsalou (1985): *things you put in your car, things you rescue from a burning house, things not to eat/drink when on a diet, wedding gifts, things you use to bake an apple pie, things you take to the beach, means of transport between Brussels and London, properties and actions that make you win the election, weapons used for hunting and tools used when gardening*.

For each of the categories, 80 participants generated at least eight members. From the resulting potential members pool, we sampled 20 to 25 members, covering the production frequency dimension.

Typicality measure The members of each category were rated for goodness-of-example by 30 participants on a Likert-rating scale ranging from 1 for very bad examples to 20 for very good examples. The reliability of the judgments was evaluated by means of split-half correlations corrected with the Spearman-Brown formula, and ranged from .94 to .98.

Similarity measure Since the members of an ad hoc category can be very divers and seemingly irrelevant to each other (e.g., tissues and candy), we did not ask participants to directly rate the similarity of each member pair within a category. Participants performed a sorting task, an often applied technique to arrive at a similarity measure for large stimuli sets (e.g., Ameel & Storms, 2006; Van der Kloot & Van Herk, 1991). We will briefly describe the procedure.

For each category, 60 participants sorted the members into piles according to whatever principle they thought was fitting, the only restriction being that there had to be more than one pile and less than the number of members in a category. Following their initial sort, they were asked to either further divide the piles they made in subgroups (when the number of piles in the initial sort was smaller than five), or to join piles together (when the number of piles was larger than five). This procedure resulted in 120 exemplar-by-exemplar matrices (on for each separate sort) for each category, each cell reflecting whether the pair was in the same pile or not. We summed the 120 matrices, arriving at one matrix per category, the summed scores in the cells reflecting the similarity between two members.

Results

The similarity measures for all 21 categories were used as input for a SAS non-metric MDS analyses, resulting in spatial representations in Dimensionalities 2 to 8. Stress values, measuring the badness-of-fit for the resulting geometric representation, showed a monotonically decreasing pattern in each category, indicating that the algorithm did not get trapped in a local minimum. Overall, the stress values dropped below .1 from Dimensionality 4 onwards for the common taxonomic categories and from Dimensionality 3 onwards for the ad hoc categories. Taking into account stress and the number of members of the categories, we will present results for the common taxonomic categories in Dimensionalities 4 to 8 and for the ad hoc categories from Dimensionality 3 to 6 (following generally used rules of thumb regarding number of dimensions and stress).

Recently, increasing attention has been drawn to the importance of a model's flexibility and complexity in model evaluation, and the necessity to penalize models that are more complex (any data pattern can be accounted for perfectly by a sufficiently complex model). Comparing the best fit a model can provide ignores this complexity, while assessing the average fit of the model across all possible parameter values balances model complexity and data fit (e.g., Pitt, Kim & Myung, 2003). This average fit is measured by the marginal likelihood. Given the differences in functional form of the GCM and IDM, the model evaluation in terms of marginal likelihoods is preferable.

The results of the model analyses are reported through model weights. The model weight of a model reflects the relative evidence that the data provide in favor of that model, within the set of all models that are evaluated. The evidence for a model is the marginal likelihood of the model – calculated by sampling the parameter space. For each sampled parameter value, one can calculate the likelihood given the prior distributions of the parameters. After a number of samples, the average of all samples will converge into an estimate of the marginal likelihood of the model.

We relied on standard uninformative priors. For the IDM, this translates to a uniform prior over all points at a certain distance of the origin. For the GCM and the prototype model, a uniform prior over the range 0 to 1 was used for the dimensional weights, adding the restriction that the dimensional weights have to sum to 1. The prior for the sensitivity parameter followed a Gamma(.001,.001) distribution.

We will first present the results of the analyses of the common categories. Then we will present the results for the ad hoc categories.

Common taxonomic categories

Figure 1 presents the model weights for all three models for the common taxonomic categories. For 9 out of 11 categories, the results are highly consistent across dimensionalities. Results are not consistent for *musical instruments* and *vehicles*, consequently making inferences

regarding these categories rather difficult. We will consider the results of categories *fish* and *tools* to be consistent, since only in Dimensionality 4 they deviate from the other Dimensionalities. For *tools*, closer inspection of the underlying representation revealed that stress-values dropped below .1 from Dimensionality 5 onwards, possibly explaining the anomaly in the Dimensionality 4.

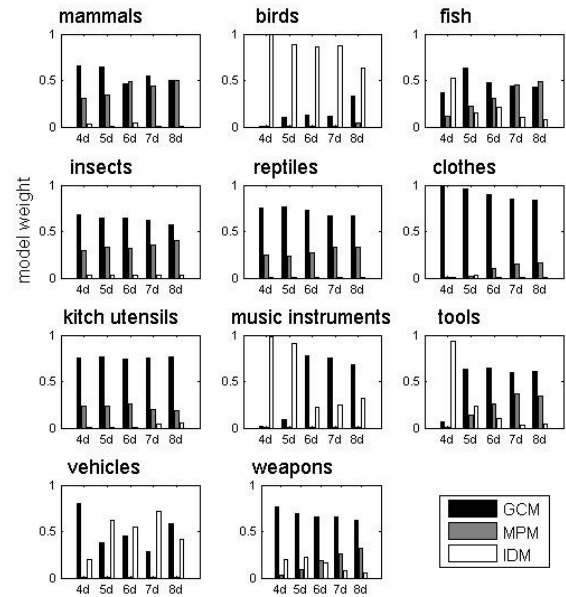

Figure 1. Model weights for the GCM, MPM and IDM for the common taxonomic categories.

It can be seen that for the 9 consistent categories, the GCM gives the better account of the typicality gradient for 8 out of 9 categories. For only 1 out of 9 categories, *birds*, the IDM clearly provides a better account. The MPM is not competitive in the present evaluation. Only for the category *fish*, it seems to provide a viable alternative in higher Dimensionalities (but even there, the MPM is not convincingly better).

In sum, the GCM seems to be the better model for the typicality gradient of the common taxonomic categories. The prototype model is never competitive, performing worse than the GCM in all categories and nearly all dimensionalities. This result confirms results of earlier comparisons between the exemplar view and the prototype view in common taxonomic concepts (e.g., Voorspoels et al. 2008) and artificial category learning (Nosofsky, 1992, Vanpaemel & Storms, 2010). The IDM possibly drives the typicality gradient of a small minority of common taxonomic categories (only *birds* in our set).

Ad hoc categories

Figure 2 presents the model weights of the three models for the ad hoc categories. For 9 out of 10 categories, the results are consistent across dimensionalities. Results are not consistent across dimensionalities for *things you take to a*

beach. Looking at the 9 consistent categories, the evidence is overwhelmingly in favor of the IDM in 7 categories. Only for the categories *hunting weapons* and *things you use when baking an apple pie* the GCM (in close competition with the MPM for the latter) is the best model. In sum, the ideal representation view indeed seems to provide a better account of the typicality gradient of ad hoc categories than the prototype and exemplar view, yet the evidence is not univocal.

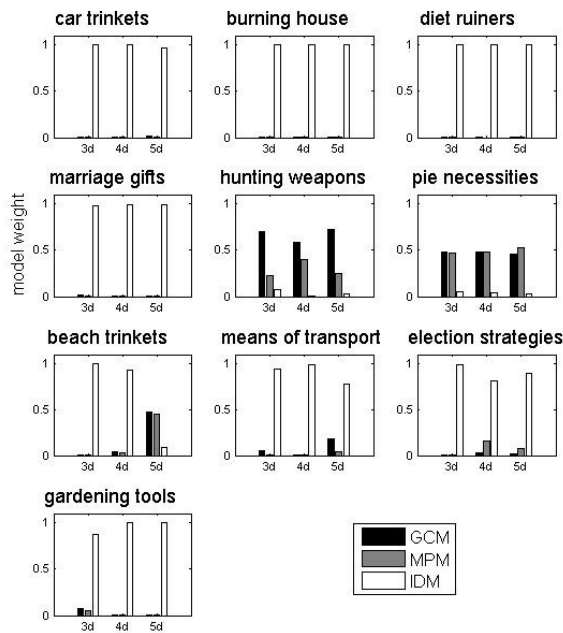

Figure 2. Model weights for the three models for the set of ad hoc categories.

The model weights reported are a relative measure of model performance, i.e., the model weight only reflects the performance of a model relative to a set of competitive models. To our knowledge however, the representational mode and the computational models used in the present study have not been applied to ad hoc categories. It is therefore informative to evaluate whether the models can give a sufficient account of the typicality gradient in absolute terms.

To this end we calculated correlations between observed and predicted typicality scores, using the optimal parameter values for each model. Results of these analyses are presented in Figure 3. It can be seen in Figure 3 that correlations rise above .6 for all categories in which the IDM is to be preferred based on the model weights, except for *properties and actions that make you win the election* and *means of transport between Brussels and London*. For the categories in which evidence based on the model weights was not in favor of the IDM, or the model weights were not consistent across dimensionalities, the optimal correlations are generally somewhat lower.

Discussion

The present study focused on the IDM, a model that provides a computational account of the notion of an ideal representation in the context of spatial similarity representations. The IDM was evaluated in its account of the typicality gradient both common taxonomic categories and ad hoc categories and compared to the GCM, arguably the most successful exemplar model, and the MPM. Following earlier findings by Barsalou (1985), we hypothesized that the IDM would have difficulty accounting for the typicality gradient of the common taxonomic categories, but that it would give a better account of the typicality gradient of ad hoc categories.

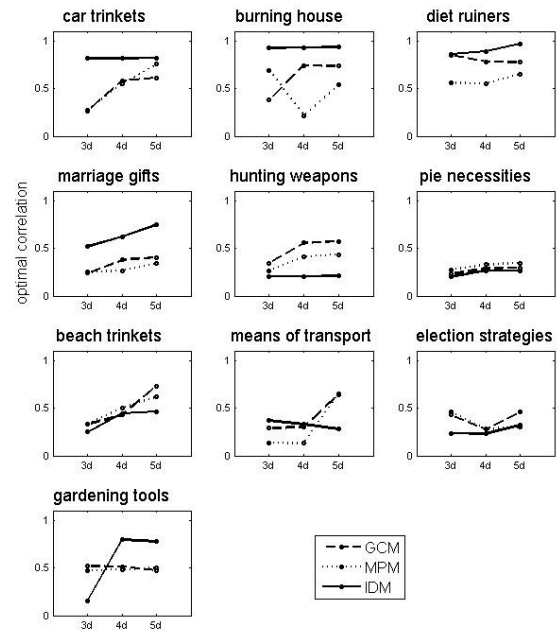

Figure 3. Optimal correlations between observed and predicted typicality ratings as a function of Dimensionality

The results supported the hypothesis. While evidence was not consistent across dimensionalities for 3 out of 21 categories, the overall pattern clearly showed the expected interaction: in the common taxonomic categories, the GCM was the better model – as can be expected based on earlier findings – and in the ad hoc categories the IDM was the better model. The evidence in any case strongly suggests that the typicality gradient of common taxonomic categories and of ad hoc categories is determined by a different representation. Moreover, the results support the reasonableness of the IDM as a formal implementation of Barsalou's (1985) notion of ideal representation.

It is unclear why this pattern broke down in 3 out of the 16 "consistent" categories. For *fish*, the IDM was the better model. In *hunting weapons* and *things you use to make an apple pie*, the GCM (MPM respectively) was the better model. Note however that for *things you use to make an*

apple pie, none of the models could give a good account of the typicality gradient in terms of optimal correlations (see Figure 3). This might suggest that the typicality gradient in this category is driven by yet another process, different from than the ones under consideration. For *hunting weapons*, the category might be considered a well-established category, rather than an ad hoc category.

To a certain extent, this study is a replication of Barsalou's work on ad hoc categories and ideal representations (Barsalou, 1985). There are, however, three crucial differences. First, we compared the ideal dimension approach to (advanced implementations of) both a prototype approach and an exemplar approach. This is important, since in this study, and in previous studies (e.g., Voorspoels et al., 2008) it is found that the exemplar approach is to be preferred over the prototype approach in concept representation.

Second, Barsalou (1985) used a priori ideals, which were generated intuitively by the researchers, for which all members of the relevant category were rated. No such instruction takes place with the IDM.

Third, Barsalou (1985) evaluated the relative contribution of different determinants of typicality, such as ideals and central tendencies, using regression analyses and a number of measures of these determinants. We tested and compared computational models of typicality that are derived from assumptions concerning concept representation. Importantly, we developed a computational model that introduces the notion of ideal representation to the context of underlying spatial representations in an intuitive way. An important finding of the present study is that the IDM indeed can be considered a computational model of ideal representations, which can be usefully applied in the further investigation of differences between concepts in terms of concept representation.

Learning Structured Generative Concepts

Andreas Stuhlmüller, Joshua B. Tenenbaum, Noah D. Goodman

Brain and Cognitive Sciences, MIT

Abstract

Many real world concepts, such as “car”, “house”, and “tree”, are more than simply a collection of features. These objects are richly structured, defined in terms of systems of relations, subparts, and recursive embeddings. We describe an approach to concept representation and learning that attempts to capture such structured objects. This approach builds on recent probabilistic approaches, viewing concepts as generative processes, and on recent rule-based approaches, constructing concepts inductively from a language of thought. Concepts are modeled as probabilistic programs that describe generative processes; these programs are described in a compositional language. In an exploratory concept learning experiment, we investigate human learning from sets of tree-like objects generated by processes that vary in their abstract structure, from simple prototypes to complex recursions. We compare human categorization judgements to predictions of the true generative process as well as a variety of exemplar-based heuristics.

Introduction

Concept learning has traditionally been studied in the context of relatively unstructured objects that can be described as collections of features. Learning and categorization can be understood formally as problems of statistical inference, and a number of successful accounts of concept learning can be viewed in terms of probabilistic models defined over different ways to represent structure in feature sets, such as prototypes, exemplars, or logical rules (Anderson, 1990; Shi, Feldman, & Griffiths, 2008; Goodman, Tenenbaum, Feldman, & Griffiths, 2008). Yet for many real world object concepts, such as “car”, “house”, “tree”, or “human body”, instances are more than simply a collection of features. These objects are richly structured, defined in terms of features connected in systems of relations, parts and subparts at multiple scales of abstraction, and even recursive embedding (Markman, 1999). A tree has branches coming out of a trunk, with roots in the ground; branches give rise to smaller branches, and there are leaves at the end of the branches. A human body has a head on top of a torso; arms and legs come out of the torso, with arms ending in hands, made of fingers. A house is composed of walls, roofs, doors, and other parts arranged in characteristic functional and spatial relations that are harder to verbalize but still easy to recognize and reason about. Besides objects, examples of structured concepts can be found in language (e.g. the mutually recursive system of phrase types in a grammar), in the representation of events (e.g. a soccer match with its fixed subparts), and processes (e.g. the recipe for making a pancake with steps at different levels of abstraction).

Such concepts have not been the focus of research in the probabilistic modeling tradition. Here we describe an approach to representing structured concepts—more typical of the complexity of real world categories—using probabilistic

generative processes. We test whether statistical inference with these generative processes can account for how people categorize novel instances of structured concepts and compare with more heuristic, exemplar-based approaches.

Because a structured concept like “house” has no single, simple perceptual prototype that is similar to all examples, learning such a concept might seem very difficult. However, each example of a structured concept itself has internal structure which makes it potentially very informative. Consider figure 1, where from only a few observations of a concept it is easy to see the underlying structural regularity that can be extended to new items. The regularities underlying structured concepts can often be expressed with instructions for *generating* the examples: “Draw a sequence of brown dots, choose a branch color, and for each brown dot draw two dots of this color branching from it.”

Figure 1: Three examples of a structured concept described by a simple generative process.

We build on the work of Goodman, Tenenbaum, et al. (2008), who introduced an approach to concept learning as Bayesian inference over a grammatically structured hypothesis space—a “language of thought.” Single concepts expressed in this language were simple propositional rules for classifying objects, but this approach naturally extends to richer representations, providing a concept learning theory for any representation language. Here we consider a language for generative processes based on *probabilistic programs*: instructions for constructing objects, which may include probabilistic choices, thus describing distributions on objects—in our case distributions on colored trees. Because this language describes generative processes as programs, it captures regularities as abstract as subparts and recursion.

The theory of concept representation that we describe here shares many aspects with previous approaches to concepts. Like prototype and mixture models (Anderson, 1990; Griffiths, Canini, & Sanborn, 2007), probabilistic programs describe distributions on observations. However, prototypes and mixtures generate observations as noisy copies of ideal prototypes for the concept and thus cannot capture more abstract structures such as recursion. Like rule-based models of concept learning, our approach supports compositionality: complex concepts are composed out of simple ones—but rather

than deterministic rules, our concepts denote distributions. Finally, the probabilistic program approach can be seen as a generalization of previous approaches to generative representations of concepts (Kemp, Bernstein, & Tenenbaum, 2005; Rehder & Kim, 2006; Feldman, 1997).

We investigate human learning for classes of generating processes that vary in their abstract structure, from simple prototypes to complex multiply recursive programs. We compare predictions for categorization judgments based on the true generative model to the predictions of exemplar models, which exploit the relational structure of the examples to varying degrees but cannot detect more abstract structure. We find two regimes: for concepts with simple prototype-like structures, human judgements are well described by a relational exemplar model, but humans can also easily learn more abstract regularities—such as sub-concepts and recursion—which are better captured by a model using more expressive generative descriptions based on probabilistic programs.

Formal Framework

In the following, we first explain the formal language we use to describe generative processes, then the different methods of categorization (or generalization) we compare to subjects' judgements.

Concept Representation

We analyze concepts as generative models, i.e. as formal descriptions of processes that generate observations. We do so within a simple domain where we can fully know and manipulate the actual generating processes behind complex objects. We use tree-structured graphs with colored nodes as observations in our experiments—these are a simple proxy for many real-world concepts, where the dependencies among parts are hierarchical or tree-like. Human bodies, buildings, and events all consist of parts that themselves contain parts, with each part standing in interesting relation to the others.

We represent these trees as nested lists: each list denotes a tree, with the first element in the list specifying the color of the root node and the remaining elements describing the children of this node, each child itself being a list (tree). For example, the second tree shown in figure 1 can be represented as `'(● (●) (● (●) (●)) (●))`.

We formalize the processes that generate these observations using a subset of Church, a Lisp-like stochastic programming language¹ (Goodman, Mansinghka, Roy, Bonawitz, & Tenenbaum, 2008). Programs in Church describe processes that produce values; running a program corresponds to generating a value from such a process. Because Church contains primitive functions that randomly choose from a distribution on values (e.g. the function `flip` that randomly chooses `true` or `false`), Church programs describe *stochastic* processes. The meaning of a Church program is

¹Church uses prefix notation, i.e. function application is written with the operator first, the operands following. For example, `(node x y)` means that the function `node` is called with the arguments `x` and `y`.

a distribution on return values—which may be complex values such as nested lists—and any given execution results in a sample from this distribution. In what follows we describe Church programs which sample colored trees.

We group generative models into classes by the abstract constructions they use. Table 1 illustrates each of these types using a single concept program and observations drawn from this program. The simplest tree-generating processes in our language use only the stochastic function `node`, which takes as its first argument a color symbol and as its remaining arguments subtrees. With high probability, `node` returns a tree that has the given color symbol at its root and the given subtrees as its children, but with some probability ϵ , it switches to a noise process that can return any tree, that is, `node` introduces a random noise process into the tree construction. Under the noise process, the number of children for a node is sampled from a geometric distribution with parameter ϵ and the node color is sampled uniformly.

Programs like `(node ● (node ●) (node ●))` denote stochastic *prototypes*. They are most likely to generate the tree that corresponds to the given colors, in this case `'(● (●) (●))`, but they can return any tree with a certain probability. The more a tree deviates from the prototype, the less likely this process is to generate it. For example, the simple program described above could switch at the third node to the noise process and produce `'(● (●) (● (●)))` instead of the prototype. By introducing the noise process, `node` turns a deterministic prototype into a stochastic process.

All of the more abstract ways of formalizing generative models in our tree domain compose these basic processes. *Nested prototypes* formalize the intuition that a concept or a part of a concept can be “either this or that”. Running the program `(if (flip .5) (node ●) (node ●))` will flip a fair coin and return a sample from `(node ●)` with probability .5, otherwise a sample from `(node ●)`.

One of the central reasons for analyzing concepts as represented in a language of thought is that they compose analogously to the components of natural and artificial languages—*parts* similarly allow composition through reuse in our domain. A part concept is defined first and can then be used in arbitrarily many places within other concepts. For example, the program `(define (part) (node ● (node ●)))` names a simple part consisting of only two nodes. This part can now be reused in other concepts. For example, the most likely return value for `(node ● (part) (part))` is `'(● (● (●)) (● (●)))`. When parts are defined, they are available to the noise process. This leads to some invariance to the position of parts and captures the idea that a generating process may give rise to observations that contain a part in a different place, although with lower probability compared to an observation with the part in the correct place.

Parameterized parts can capture both deterministic structure and random choices and reuse them in multiple places. When a part like `(define (part x) (node ● x x))` is used, for example in the program `(part (node ●))`, it evaluates

the body of the part—here `(node ● x x)`—with `x` assigned to its argument, here `(node ●)`. Evaluating the program `(part (node ●))` is therefore most likely to result in the observation `'(● (●) (●))`.

Allowing parts to call themselves introduces *recursion*, a means to capture a large amount of repetitive observed structure in a single short definition. For example, the part `(define (p) (if (flip) (node ●) (node ● (p))))` can generate arbitrarily deep lists of single blue nodes, with shorter ones being more likely.

The power of these program constructs is that they may be used compositionally to build more complex concepts, such as those shown in table 1.

Categorization

In order to model generalization and categorization behavior of human subjects, we need not only a way to represent concepts, but also a way to compute the probability of any given observation belonging to a known concept. We analyze our experimental results using four models that differ in how much they make use of representational structure.

On the unstructured end of the scale, we use a model that computes generalization judgements solely by comparing the fraction of nodes that have a given color. On the other end of the scale, a generative Bayesian model uses the likelihood under the true generative process to judge category membership. In between, an exemplar model makes use of tree structure in the observations, but not of the more abstract generative process that led to the observations.

Generative Model In modeling concept learning as Bayesian program induction, we follow the approach taken by Goodman, Tenenbaum, et al. (2008). Since we formalize concepts as probabilistic programs, the likelihood $P(O|C)$ of an observation O under a given concept C corresponds to the probability of the program making its random choices such that it returns the observation as its value (see Goodman, Mansinghka, et al. (2008)). The posterior probability of a concept C given observations O is proportional to this likelihood multiplied by the prior:

$$P(C|O) \propto P(O|C)P(C) \quad (1)$$

In the last section, we described a language for programs which generate trees; a prior $P(C)$ could be derived from this language, as in Goodman, Tenenbaum, et al. (2008). An ideal learner would then infer the posterior distribution $P(C|O)$ over concepts C given the observation O and make predictions about whether a new observation t belongs to the category of the observed objects using each concept $C \in \mathbf{C}$ in proportion to its posterior probability:

$$P(t|O) \propto \sum_C P(t|C)P(C|O) \quad (2)$$

In order to make computational modeling tractable, we make the simplifying assumptions that (1) subjects' reasoning is dominated by the maximum a posteriori (MAP) estimate of

this distribution, i.e. by the single concept that has the highest posterior probability and that (2) the true generating concept C_{true} is a good approximation to the MAP estimate. Thus, for each of the concept types we investigate, we model subjects' behavior using the program from which the training data was sampled. The likelihood of a new observation t belonging to this concept is simply $P(t|C_{true})$ which we compute using an adaptive importance sampling algorithm.

We do not claim that subjects necessarily identify the true generating concept from a few examples; this approximation is made for computational tractability. The full Bayesian model, which maintains uncertainty over generating concepts, can make different predictions in certain cases, but it is not clear whether this represents a bias for or against the approximation—to the extent that people remain uncertain of the concept after a few examples, the Bayesian model would capture human inferences better than our approximation.

Tree Exemplar Model This and the next two models are versions of the exemplar-based generalized context model (GCM) (Nosofsky, 1986). For observations O_1, \dots, O_n from category C and a new observation t for which we would like to estimate the likelihood under category C , we use $P(t \in C | O_1, \dots, O_n \in C) \propto \frac{1}{n} \sum_{i=1}^n e^{-d(O_i, t)}$ where d is a distance measure that is sensitive to the tree structure of the observations. Starting from the root node, this measure matches the trees as much as possible, incrementing by 1 for each node that differs in color between the two trees and for each node that must be generated because it exists in one tree but not in the other tree. This approach is similar to the structure mapping approach used by Tomlinson and Love (2006).

Frequency-based Exemplar Models As in the tree exemplar model, we use a distance measure d to estimate the likelihood of an observation belonging to a category for which we have only positive examples. In this version of the model, $d(t_1, t_2)$ is the RMSE between the transition count vectors of t_1 and t_2 . For each pair of node colors, the transition count vector contains the number of times this pair occurs adjacent (as parent-child) in the given tree. We call this model *Transition GCM*. We also investigate a simplified version that uses the distance between the color count vectors. The length of this vector corresponds to the number of possible node colors, with each entry in the vector denoting how often this node color appears in the tree of interest. We call this *Set GCM*.

Experiment

This experiment is an exploratory investigation into generalization from observations of structured objects. Since our main goal in this study is to investigate the representation of concepts and their use for categorization and generalization rather than the memory aspects of learning, we use a paradigm that minimizes memory demands. By doing so, we hope to focus on how people represent the commonalities between observed instances of a concept and how they use this knowledge to generalize to new instances. We chose a

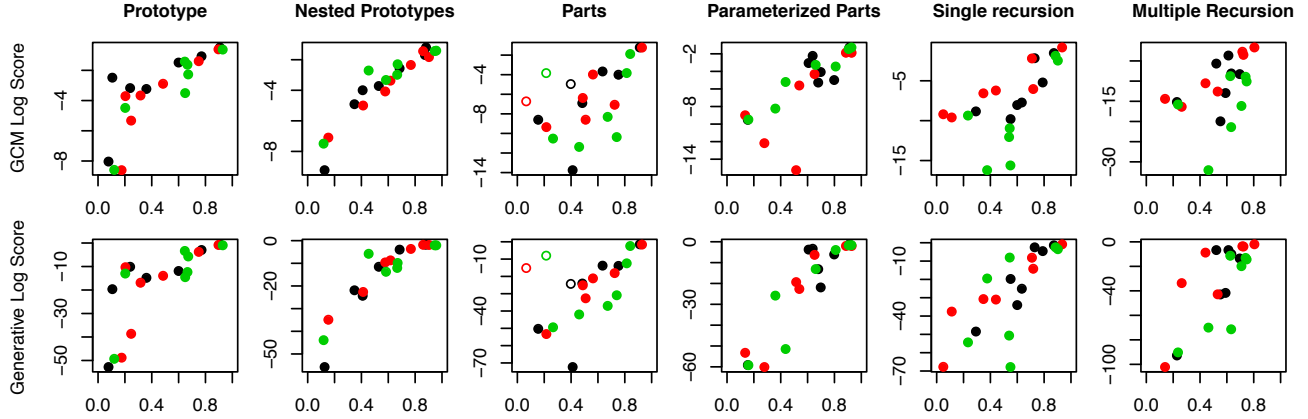

Figure 2: Comparison between human and model responses across concept types for tree exemplar and generative model. For each of the six concept types, three examples were shown; the color of the dots indicates to which example any given datapoint belongs. Empty circles denote isolated part cases that were excluded from the correlation analysis.

	Set GCM	Transition GCM	Tree GCM	Generative Model
Prototype	0.589	0.751	0.803	0.748
Nested Prototype	0.544	0.851	0.937	0.904
Parts*	0.320	0.617	0.705	0.835
Parameterized Parts	0.298	0.591	0.778	0.911
Single Recursion	0.284	0.499	0.637	0.773
Multiple Recursion	0.505	0.561	0.451	0.770

Table 2: Human-model correlations for the experiment. Each row shows how well the different models predicted subjects’ performance for a particular concept type. *Correlations excluding isolated part cases (see text).

tics was the best predictor for any of the concept types, with the transition-based exemplar model performing strictly better than the set-based model. An effect that is not accounted for by the less structural exemplar models is illustrated by the nested prototype example in table 3: Subjects generalize significantly more to examples with branches they have seen before than to examples that have a mixture of two known branches. Likewise, subjects seem to generalize significantly more to trees with known branches than to trees that have new branches with similar surface statistics. Both results are expected under the two models that make use of tree structure.

If we group prototype and nested prototype as “less structured” and subconcepts with and without arguments, single recursions, and multiple recursions as “more structured”, then the tree exemplar model best predicts human responses for the less structured stimuli whereas the true generative model best predicts performance for the more structured stimuli.

Our generative model makes the simplifying assumption that the learner infers a single generating concept from the examples whereas one interpretation of the tree exemplar model is that it uses each of the training examples as a hypothesis on what the true concept looks like. A fully Bayesian learner, which maintains a distribution over generative processes, may

predict human behavior in ways similar to the tree exemplar model for less structured examples and similar to the true generating process model for the more structured examples.

Having seen how different models predict human judgments for different concept types, we will now look at individual response patterns in order to determine ways in which both of the two structural models can be improved.

The part example in table 3 shows how changes to the location of a part can have significantly different effects depending on whether the overall concept is preserved (resulting in high generalization) or the part is moved into a completely different environment (resulting in low generalization). By analogy, a Picasso face, with eyes in odd places, is still more of a face than an eye alone. Parts seen out of context constitute a problem for all models (except for the simplest set-based one): subjects judged these isolated parts as unlikely to come from the concept that included them as subparts whereas the models did give a high score to these examples. Since including these outliers dramatically changed the scores and made the interpretation of the model comparison difficult, we excluded these data points from the analysis in table 2. Without correction, the model-human correlations for the part concepts are: 0.403 for the set-based exemplar model, 0.505 for the transition exemplar model, 0.512 for the tree-based exemplar model, and 0.543 for the generative model (note that rank-order among the models does not change as a result of excluding these data points).

For the parameterized part example in table 3, changing the argument uniformly, i.e. in all places where it occurs, leads to consistently higher scores than changing the argument differently in different places; however, this difference is not significant. This difference is expected if subjects inferred the true generative model, since changes to the argument require only one use of the noise process, whereas nonuniform changes require many different nodes to be generated by the noise process. Future research needs to determine whether this effect is real, perhaps by manipulating the diversity of

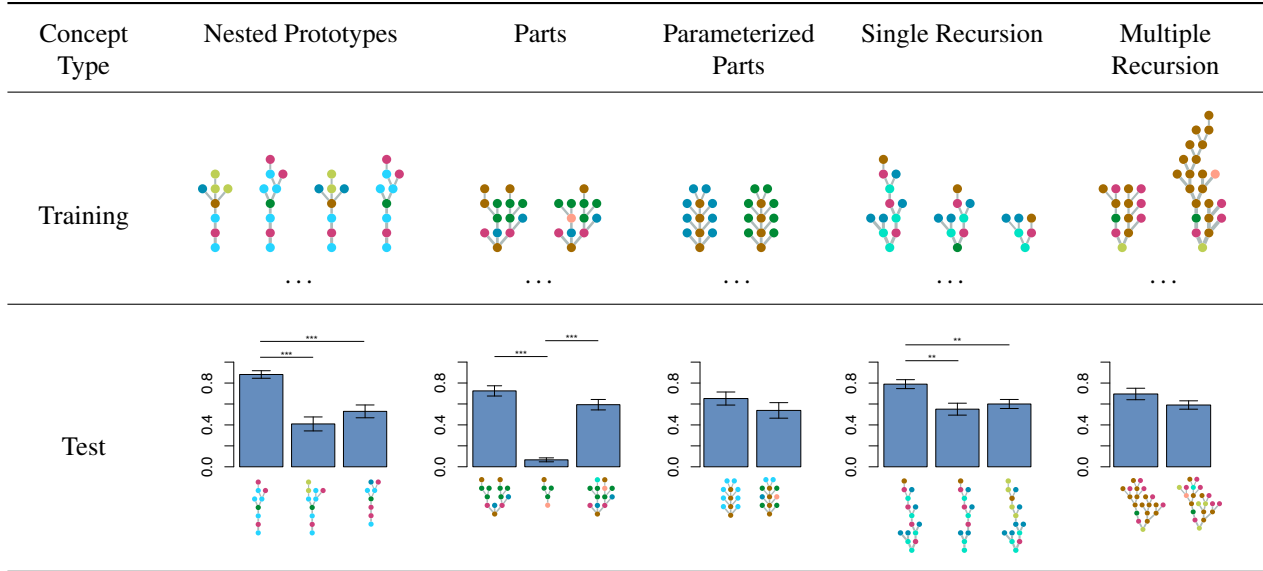

Table 3: This table illustrates a small selection of our experimental results. For five different concept types, training observations from a single concept of this type are shown together with subjects’ generalizations for particularly interesting test examples. The error bars are standard errors of the mean.

parameter arguments in the observations.

For the single recursion example in table 3, changing the color of a few nodes within the recursion results in a significantly lower generalization. At the same time, a very similar manipulation does not result in a significant change in the generalization rating for the multiple recursion example. Intuitively, we sometimes see a change as destroying a very obvious pattern structure whereas at other times, the change in structure is not assumed to be relevant. Future research needs to characterize when subjects infer that such a pattern exists, and when they instead assume coincidence.

The comparison between the frequency based exemplar models and the two models that rely on tree structure in the observations makes clear that subjects do make use of the fact that the observations are structured in their generalization judgements. Furthermore, comparing the tree exemplar model to the true generative model that makes use of more abstract structure hints at the possibility that subjects are relying on recursive structure in the observations. The individual response patterns in the results of our exploratory experiment highlight ways in which both the exemplar-based model and the generative model can be improved to more closely reflect human generalization patterns.

Conclusion

Most studies of concept learning have focused on relatively unstructured objects based on simple features. We have suggested viewing concepts as probabilistic programs that describe stochastic generative processes for more structured objects. In this view concepts denote distributions over objects, and these distributions are built compositionally. We explored this idea within a domain of tree-like objects, and carried out a study of human generalization using a broad variety of con-

cepts in this domain. Our results suggest that humans are able to extract abstract regularities, such as recursive structure, from examples, but also that there are many subtle effects to be discovered and accounted for in such domains.

Short-Term Word Priming Across Eye Movements

Stephen E. Denton (sedenton@umail.iu.edu) and Richard M. Shiffrin (shiffrin@indiana.edu)

Department of Psychological and Brain Sciences, and Cognitive Science Program, Indiana University

Abstract

The authors conducted a short-term repetition priming experiment (using a visual, forced-choice word identification task) that compared a standard priming condition, where prime and target words appeared in the same spatial location, with an experimental condition in which prime and target words were spatially separated enough to necessitate an eye movement. Prime presentation duration was manipulated and, within both eye movement conditions, it was found that short primes produced a preference to choose a primed alternative, whereas for longer duration primes this preference was absent. Based on the similarity between eye movement conditions, it is argued that prime and target features from separate fixations are still confusable and that evidence regarding prime feature must still be discounted. A computation model that includes these offsetting components of source confusion and discounting provides an excellent account of our results.

Keywords: short-term priming; immediate priming; repetition priming; perceptual identification

The term *priming* refers to a well-known information processing effect wherein one stimulus (a *prime*) influences a similar or related stimulus (a *target*) presented at a later time. The influence the prime has on the target is usually one of facilitation. In the typical priming task trial, the prime is presented first followed by a target that is briefly flashed and masked. This paradigm is referred to as *short-term* or *immediate* priming because primes are presented immediately prior to the targets, with inter-stimulus intervals generally less than a second. The first stimuli is called a prime because it is thought to “prime the pump” for a related target, yielding faster and more accurate responding. However, priming does not simply result in facilitation. Previous research has indicated that there is an intricate set priming effects that occur across various situations and experimental conditions (e.g., Huber, Shiffrin, Lyle, & Ruys, 2001; Weidemann, Huber, & Shiffrin, 2005). Some experiments find facilitation, while other fail to find facilitation or even find reliable deficits due to priming.

Huber et al. (2001) began to systematically examine the effects of priming using a two-alternative forced-choice (2-AFC) testing procedure with the goal of separating the perceptual and decisional components involved in priming. Observers were asked to correctly identify a previously flashed target word when given a choice between it and an incorrect foil word. This study indicated that priming largely arises from preferences to choose whatever has been primed. For example, in repetition priming (priming in which the prime can be the same word as either the target or foil), it was found that with short prime presentation durations, priming with the target increases accuracy and priming with the foil decreases accuracy, when both are compared to a control condition in which the prime is unrelated to either the target

or the foil. The corresponding prime conditions are termed *target-primed*, *foil-primed*, and *neither-primed*, respectively.

The preference effects revealed by Huber et al. (2001) proved to be readily manipulatable, changing in magnitude and direction as a function of prime saliency (e.g., Huber, Shiffrin, Quach, & Lyle, 2002; Weidemann et al., 2005; Weidemann, Huber, & Shiffrin, 2008). Thus, when the prime is made more salient, either through a longer presentation duration or through an active task that required responding to the prime, the conventional priming effect diminishes or in some cases reverses. Prime saliency manipulations result in reduced facilitation (or slight deficits) in target-primed conditions, while leading to increased accuracy in foil-primed conditions.

The ROUSE Model

To account for a range of findings within the 2-AFC identification paradigm, Huber et al. (2001) developed a feature-based Bayesian model of short-term priming. The *responding optimally to unknown sources of evidence* (ROUSE) model accounted for experimental priming data by incorporating the two offsetting components of feature source confusion and discounting. The source confusion portion of the model posits that features can be carried over from the prime to the target percept, without source information. Thus, when a choice word is presented, feature activations could be due to the prime presentation, the target presentation, and/or noise without the source of the activation being known to the system. This factor alone can produce the standard priming effect, as it causes a preference toward prime-related choice words. The discounting mechanism in the model can counteract this preference, because this component posits that perceived features are assigned evidence and feature evidence is discounted when known to have come from the prime. A Bayesian decision process then arrives at an optimal response given it is operating on this noisy and discounted evidence. The implication here is that making the prime more salient (e.g., long presentation duration) leads to increased discounting of prime feature evidence. Thus, discounting mechanisms can explain a lack of, or a reversal in, the typical priming preference.

In the ROUSE model, choice words are represented as a feature vector, typically consisting of 20 binary features (Huber et al., 2001). Features can be independently activated by the prime, with a probability α , by the target, with a probability β , or be activated due to noise, with a probability γ . The system is assumed to only have access to what features are active and not the source of their activation (i.e., source confusion), therefore the probabilistic effect of α , if

not counteracted, will result in a preference toward primed choice words. This preference is counteracted by a decision process that assigns lower levels of evidence to features that might have been activated by the prime word (i.e., discounting). To discount features optimally, the system needs to know the probabilities that features are active due to particular sources (i.e., α , β , and γ). However, it is assumed that the decisional system does not have access to the exact probabilities and therefore uses estimates, α' , β' , and γ' . These estimates, which reflect the amount of discounting applied to particular sources, are used to evaluate evidence. These estimates are theorized to be close to their true values, but the model's behavior depends critically on the magnitude and direction of the difference between α and its estimate. Under-discounting ($\alpha' < \alpha$) results in a preference for primed choice words and over-discounting ($\alpha' > \alpha$) produces a preference against primed choice words.

Given the estimated source probabilities, the optimal response among choice words can be computed by combining feature evidence. Feature evidence takes the form of a likelihood ratio that specifies the probability that a feature is from the target word over the probability the feature is part of the foil, given the feature's current activation state and whether or not the feature appeared in the prime. Assuming feature independence, these likelihood ratios can be multiplied together across all word features to produce an overall likelihood that the choice word is the target. The likelihoods of the two words can then be compared with the larger being identified as the target. In the case of ties, a random selection is made between the choice words.

The above description of the ROUSE model is only intended as a brief summary, which means a number of details, large and small, have been left out. For a more comprehensive presentation of the ROUSE model, the reader is referred to Huber et al. (2001) for the original stochastic version and Huber (2006) for a later analytic version.

Feature carry-over across eye movements

The ROUSE model has been useful in accounting for and predicting priming data, but there is still much uncertainty about how its key components, source confusion and discounting, actually perform their theorized functions. Many questions remain unanswered regarding what causes or allows both feature confusions and discounting. Source confusion could be the result of a number of candidate causes, e.g., spatial or temporal proximity between prime and target, or similarity between prime and target on any number of dimensions. Similarity relations (semantic, orthographic, etc.) between target and prime have received considerable attention elsewhere and will be set aside for present purposes. Temporal proximity does appear to be important as increasing the inter-stimulus intervals (ISIs) between prime and target to be greater than 250 ms has been shown to disrupt and diminish priming (Hochhaus & Marohn, 1991). In the following experiment, we chose ISIs to be less than 250 ms so that we can effectively ignore the temporal dynamics of priming for

the purposes of the present study.

The focus of this research is how spatial proximity effects priming. We are interested in knowing if feature confusions, discounting, or both are location dependent. In the present study, the location at which the prime and target were presented were sometimes spatially separated at a 10° visual angle. Visual acuity drops to roughly 25% (of central vision) at a visual eccentricity of 10° (Low, 1951). Given diminished visual acuity with this spatial separation, we are effectively enforcing an eye movement between viewing the prime word and the target word, if both are to be seen. Not only will the target appear in a different location than the prime, but it will also appear in a different eye fixation.

The goal of the present experiment is to see if features are carried over from a prime fixation to a target fixation when the fixation locations are relatively distant spatially. We would like to see if features from the prime join with the target percept at the new location (i.e., will there still be source confusion when an eye movement is made). Discounting could also be affected by our eye movement manipulation. If there is some source confusion across eye movements, it is conceivable that prime features could be discounted completely (i.e., little evidence from the prime would be used in making the target identification decision). Then again, given the presence of some source confusion, it is also possible that better estimates of feature activations due the prime can be made when the prime and target appear at separate and distinct locations. This would reduce or eliminate under-discounting and over-discounting of prime evidence. The ROUSE model will be used to provide an indication of the relative contribution of source confusion and discounting across eye movement conditions.

Priming Across Eye Movements Experiment

We designed the current experiment to investigate how spatial separation between prime and target affects priming. The experiment compared an eye movement condition to an appropriately matched control condition in which all words were presented in the center of the screen (i.e., the stereotypical short-term priming paradigm). For all trials, the prime word was presented in the center of the screen. As with our previous studies, prime salience was manipulated by adjusting the prime presentation duration, which was either short (50 ms) or long (1000 ms). On any particular trial, the prime word itself could be either the same as the target, the foil, or neither, corresponding to the prime conditions discussed earlier. The target word was flashed in the center of the display on half to the trials and on the other half it appeared equally often in one of four locations, directly above, below, left or right of the center. The participant's task was to identify the flashed target given a 2-AFC test at the end of each trial.

The experiment was a within-subject design that crossed the 2 levels of prime presentation duration (short and long) with 3 levels of prime condition (target, foil, or neither primed) and crossed both with 5 different target locations split

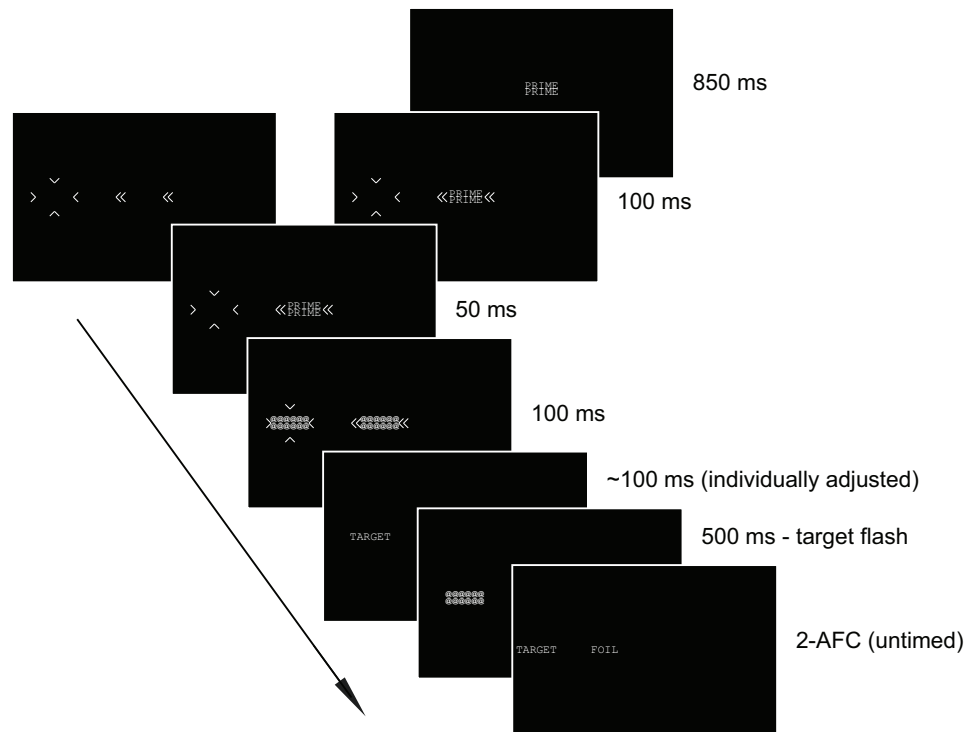

Figure 1: An example sequence of events in the present experiment. This figure shows both short and long prime duration conditions for one particular peripheral target location (left of center). The duration for each frame is presented on the right. The left sequence corresponds to a short prime duration condition, whereas the right sequence shows a long prime duration sequence where the total time the prime is presented is 1000 ms (850 ms+100 ms+50 ms). Both sequences were preceded by a 500 ms presentation of a fixation cross in the center of the screen (not shown). The positions of the target and foil word on the last frame were randomized.

into 2 general categories (center and peripheral [top, bottom, left, and right]). A schematic of two example trials is presented in Figure 1. A more detailed description of our exact experimental procedure is below.

Methods

Participants Fifty one undergraduate students volunteered to participate for partial credit in an introductory psychology course at Indiana University.

Materials and Apparatus We used two pools of 1,100 five-letter and 1,300 six-letter words with a written-language frequency of at least 4 per millions as defined by Kučera and Francis (1967). All words were presented in uppercase using the fixed-width “Courier Bold” 17-point font. Throughout the experiment, stimulus words were sampled randomly without replacement with the only constraint being that 5 and 6 letter word never appeared together in the same block of trials. All masking was done with two rows of six “@” signs presented in “Arial Narrow Bold” 13-point font. This ensured dense coverage of the prime and target. The stimulus words were presented in white against a black background.

All stimuli were displayed on 16-in. (40.6 cm) PC CRT monitors with vertical refresh rates of 120 Hz and a screen

resolution of 800×600 pixels. The experiment was programmed using the Vision Egg library for the python programming language (Straw, 2008). The display was synchronized to the vertical refresh of the monitor providing display increments of 8.33 ms.

Participants sat individually in a dimly lit, ventilated, sound-dampened booth. Participants were asked to sit up straight to keep the distance from their eyes to the monitor at approximately 50 cm., but no head restraint was used to enforce this viewing distance. This viewing distance ensured that peripheral targets would appear at least a 10° visual angle away from the center of the screen. Participant responses were collected using a standard computer keyboard. In a 2-AFC test, participants were asked to press the “F” key to choose the left alternative or the “J” key to choose the right.

Procedure The procedure used in the present experiment was carefully designed as to compare an experimental condition involving eye movements to an appropriate control that maintained important aspects of the experimental condition (namely timing and perceptual masking), while not requiring a eye movement. The experiment was designed based on some knowledge of the timing of eye movements or saccades. A 10° saccade would take less than 50 ms to complete

once initiated, but takes more than 150 ms to plan and initiate (Irwin, Brown, & Sun, 1988). As such, having the target flash appear in the periphery immediately after the prime would make it impossible to see. To remedy this, we preceded the target with a cue that indicated the correct location where the target would appear. This target indicator cue appeared 250 ms before the target flash. We left a 100 ms interval between the prime offset and the target onset. During this 100 ms interval the prime was post-masked while the target was pre-masked. This timing is reflected in the example sequences presented in Figure 1.

Each trial began with a fixation cross appearing in the center of the screen for 500 ms. In long prime duration conditions, the prime is presented (in duplicate) for 850 ms then the prime and target indicator appear together for 150 ms. In trials with short prime durations, the target indicator appears first by itself for 100 ms, then the prime and the target indicator appear together for 50 ms. Participants should not be able to plan and initiate a saccade in under 100 ms, therefore the prime will be viewed; the prime is ‘snuck-in’ before the eyes have a chance to move. After the prime and the 100 ms intervening mask, the target is flashed. The target is post-masked and then the 2-AFC options are presented to the immediate left and right of the location where the target appeared. A peripheral target word can appear at the top, bottom, left, or right of the screen. Center target location trials have the same timing as peripheral target trials. Besides the actual target location, the only differences between center and peripheral trials are that the target indicator appears in the center of the screen (surrounding the prime) and the prime post-mask and the target pre-mask are one in the same. On each trial, once a 2-AFC selection is made, feedback is provided.

Each participant went through 672 priming trials broken into 7 blocks of 96. The first 32 trials were neither-primed practice trials with long target durations (150 ms) to get participants used to the task. These practice trials were followed by 64 neither-primed calibration trials. Target word durations were individually adjusted for each subject such that accuracy was roughly 75% on neither primed conditions. This calibration was done separately for the center and peripheral target locations using a staircase method. As with previous studies (e.g., Huber et al., 2001; Weidemann et al., 2005), there were large individual differences. For center target trials, target flash times ranged from 25 ms to 91.7 ms with a median of 50 ms. For peripheral targets, flash times ranged from 33.3 ms to 200 ms (the maximum allowed) with a median of 91.7 ms. The increased variance in target flash times for peripheral locations is likely due to individual differences in saccade latency on top of individual differences in target processing time, i.e., some participants may have fixated on the target later and took longer to process the target.

Results

Data from all peripheral target locations were combined for the purposes of analysis, creating two target location conditions, central and peripheral, that initially had equal sample

sizes. Reaction times were collected and used to eliminate deviant trials in the data. Trials in which the participant responded in less than 100 ms or took more than 3-s to respond were eliminated. Approximately 1% of the data was thrown out by this criterion. The first block of trials, which included practice and calibration trials, were not included in the analysis. Remaining experimental data were analyzed with a $3 \times 2 \times 2$ (Priming Condition \times Prime Duration \times Target Location) repeated measures analysis of variance (ANOVA).

There were large main effects of prime condition, $F(2, 100) = 167.6, p < .001$, and prime duration, $F(1, 50) = 135.5, p < .001$. Also, these two variables interacted, $F(2, 100) = 121.37, p < .001$. The main effect of target location was not significant, however this variable had a significant interaction with both prime condition, $F(2, 100) = 20.43, p < .001$, and prime duration, $F(1, 50) = 8.637, p < .005$. Finally, there was a significant 3-way (Priming Condition \times Prime Duration \times Target Location) interaction, $F(2, 100) = 48.57, p < .001$.

Average accuracy across all conditions is shown graphically in Figure 2. The dots in the figure give ROUSE model predictions which will be discussed in the next section. As can be seen from Figure 2, the typical priming effect was found when the target and a short prime were both presented in the center of the screen. When the prime was presented for a longer duration this prime preference disappeared. When the target was presented in the periphery after a centrally presented prime, the trend remained largely the same, although the magnitude of the priming effect decreased.

Applying the ROUSE model

Fitting the ROUSE model to the current experiment involved estimating the following eight parameters:

1. the probability that a choice word feature is activated by the prime (α),
2. the estimated probability that a feature is activated by a short prime when the prime and target are located in the center ($\alpha'_{S,C}$),
3. the estimated probability that a feature is activated by a long prime located in the center ($\alpha'_{L,C}$),
4. the estimated probability that a feature is activated by a short prime from a previous fixation ($\alpha'_{S,P}$),
5. the estimated probability that a feature is activated by a long prime from a previous fixation ($\alpha'_{L,P}$),
6. the probability that a feature is activated due to the target flash (β),
7. the probability that a feature is activated due to noise given a short prime presentation (γ_S), and
8. the probability that a feature is activated due to noise given a long prime duration (γ_L)¹

¹Two separate noise parameters were included to account for trend in the data that performance is better on neither-primed trials when prime duration is long compared to when the prime duration is short. The γ values from the to-be-discussed model fit indicate there is higher noise in the short prime conditions when compared to long prime conditions. This is somewhat sensible given the erratic na-

Figure 2: Forced choice performance and corresponding ROUSE predictions (represented by the dots). The bar heights show the mean proportions of correct target identification choices (error bars show $\pm 95\%$ confidence intervals) within each condition. Panel A shows accuracy for centrally located targets and Panel B shows accuracy when the target was presented in a peripheral location. Each panel is further subdivided by prime duration and priming condition. The dashed horizontal line indicates 75% performance; the accuracy participants should roughly achieve on neither-primed trials due to the target duration calibration procedure.

As in previous work (e.g., Huber et al., 2001; Weidemann et al., 2005), it is assumed that estimates of feature activations due to targets and noise are equal to the actual values (i.e., $\beta' \equiv \beta$ and $\gamma' \equiv \gamma$).

The parameters listed above were estimated to generate the ROUSE model fit that appears in Figure 2. The parameter estimates used were: $\alpha = .12$, $\alpha'_{S,C} = .032$, $\alpha'_{L,C} = .65$, $\alpha'_{S,P} = .10$, $\alpha'_{L,P} = .20$, $\beta = .064$, $\gamma_S = .067$, and $\gamma_L = 0.011$. It is important to stress that exact values of these parameters are relatively immaterial, especially the exact values of the α and α' parameters, as it is their relative magnitudes that dictate the behavior of the model. Multiple model fits were done with both more and less parameters free to vary, but this fit provided the most satisfying account to the data. The large number of parameters (8 parameters for 12 data points) and possible over-fitting should be somewhat of a concern here, but since the model is largely descriptive, these complexity concerns are left unaddressed in the present context.

As can be seen in Figure 2, the ROUSE model provides a very good qualitative and quantitative description of the priming data we collected. Interpretation of the fit parameter values can be a tricky, because attending to the exact magnitude can be deceptive. For example, the same α value was used to fit all conditions. When the 2 target location conditions

ture of short duration priming trial (i.e., the target indicator, prime, mask, and target all appear in rapid succession) which could induce noise in the system. This seems especially true in neither-primed trials where all prime features presented are effectively noise. Increasing noise (γ) in the model decreases accuracy and uniformly translates all performance predictions down. Separate β parameters could be used similarly to selectively increase and decrease performance across short and long prime duration conditions, but saying that there is an increased probability of target features being activated for long prime durations provides a much less sensible explanation of the results.

were allowed to have separate freely estimated α parameters it produced virtually no fit improvement. This could be taken as evidence that source confusion was the same at peripheral locations as at the center. However, α' was fit separately for each condition and changes in these values can compensate for possible underlying differences in source confusion (α).

Given the relationship between the fit α' values, it does appear that the magnitude of discounting decreased when the target was moved to a novel location. The estimates of primed feature intrusion contracted closer to optimal in the peripheral conditions (i.e., $\alpha'_{S,C} < \alpha'_{S,P} < \alpha$ (optimal) $< \alpha'_{L,P} < \alpha'_{L,C}$), which means there was less under-discounting for short primes and less over-discounting for long primes when the prime and the target did not appear in the same spatial location.

Discussion

In the present research, we investigated whether spatial proximity of prime and target was necessary to find priming effects, particularly when there was a large spatial distance between the two requiring an eye movement. Our findings indicated that even after a relatively large eye movement (a 10° visual angle), participants showed similar priming preferences as when they viewed all stimuli in one location. More specifically, in both eye movement and control conditions, participants showed a preference to choose the prime word when the prime duration was short. Further, this prime preference was undetectable when the prime was made more salient by increasing its presentation duration.

The ROUSE model provided an excellent account of our experimental data. The model's success, the resulting best fitting parameters, and data themselves all provide evidence that across eye movements (a) source confusion is still present,

and (b) discounting of evidence regarding prime features persists. The evidence that source confusion endures after an eye movement to a novel location implies that prime features appearing in one eye fixation are carried over to the next and join with the target precept at the new location. Further, source confusion from two spatially distinct locations does not appear to be substantially different from what it is when all feature sources are in the same spatial location.

The presence of discounting across eye movements implies that the decisional system is, in some sense, aware that features are not tied to particular locations and therefore must continue to estimate the likelihood that feature activations in choice words are the result of the prime in an effort to produce optimal responses. Even when the prime was in a previous eye fixation, the estimation process evidently succumbs to the same biases that are present without an eye movement, i.e., short, difficult to detect primes are under-discounted and long, salient primes are over-discounted. Since evidence for the prime is only discounted to the extent that features are known to exist in the prime, it is conceivable that the distinct spatial location of the prime provides some additional information to the decisional system that helps it better estimate the actual probability that a feature activation is due to the prime. Consequently, spatially separating the prime and target would make discounting slightly more optimal. Our modeling results hint that this is the case as the model estimates of feature intrusions from the prime better match the actual intrusion probabilities in the peripheral condition.

Our study suggests that the offsetting mechanisms of source confusion and discounting operate on features that are in general not tied to specific locations. Eye saccades are thought to effectively erase iconic memory, which is a visual store with high capacity but with a very limited duration (Irwin, 1992). There are a few visual items (3 to 4) that are retained from one eye fixation to the next in what is termed trans-saccadic memory, which has a limited capacity compared to iconic memory but has a longer duration (at least 750 ms). Nevertheless, an enforced eye movement will eliminate most low-level visual features from the previous fixation. After a saccade, the features that remain are presumably more high-level and location-independent. If source confusion and discounting operate with such features then an eye movement would not eliminate priming effects. This conforms to the findings of the present study. It is possible that source confusion and discounting operate on low-level features as well, and this may provide some explanation as to why eye movements slightly degrade the effectiveness of priming. The extent to which priming involves low-level features, and if it is indeed their suppression during saccades that produce the minor differences across eye movement conditions, are topics for future research.

Toward a Large-Scale Characterization of the Learning Chain Reaction

Alexei V. Samsonovich (asamsono@gmu.edu)

Krasnow Institute for Advanced Study, George Mason University, 4400 University Drive MS 2A1
Fairfax, VA 22030-4444, USA

Abstract

Designing an agent that can grow cognitively from a child to an adult human level of intelligence is the key challenge on the roadmap to human-level artificial intelligence. To solve this challenge, it is important to understand general characteristics of the expected learning process at a level of mathematical models. The present work makes a step toward this goal with a simple abstract model of a long-term learning process. Results indicate that this process of learning is characterized by two distinct regimes: (1) limited learning and (2) global learning chain reaction. The transition is determined by the set of initially available learning skills and techniques. Therefore, the notion of a ‘critical mass’ for a human-level learner makes sense and can be determined experimentally.

Keywords: human-level artificial intelligence; self-regulated learning; teachable systems.

Introduction

Since the 1956 Dartmouth conference, researchers are taking seriously the challenge of creating machines capable of general human-level intelligence, human-like learning and self-improvement (McCarthy et al., 1955), yet the distance toward this goal has hardly decreased since 1955 (in fact, it is practically difficult to evaluate to make any judgment). Main progress made since the beginning is visible in reassessment of the difficulties, in emergence of new approaches, e.g., cognitive architectures (Newell, 1990; Gray, 2007), and in a new understanding of the goal. Yet, despite growing interest to the field, it is not clear what the final goal is and what would be the impact of achieving it.

Here four different views and associated with them schools of thought can be named: (1) computational neuroscience, that tries to understand how the brain works in terms of neurophysiological mechanisms and neuroarchitectures; (2) cognitive modeling, pursuing higher-level computational description of human cognition and behavior based on more abstract cognitive architectures; (3) human-level artificial intelligence, aiming at generally intelligent artifacts that can replace humans at work; and (4) a new emergent paradigm (that can be called “machine consciousness”, or “human-like learners”, etc.) aiming at artificial minds that can be understood by humans intuitively, that can learn like humans, from humans and for human needs. All these are fundamental scientific problems. While (1) and (2) are focused on understanding the roots of human cognition, and therefore allow for validation of their progress using brain-and-behavior data, (3) and (4) are oriented toward creation of an expected phenomenon that does not exist yet: a computational replica of the human mind capable of human-like learning and cognitive growth.

From this point of view, defining a success criterion for (3) and (4) is the key challenge on the roadmap to a human-level learner. Examples of practically inefficient guiding criteria include ambitious global challenges like the Turing test (Turing, 1950; Korukonda, 2003) and limited challenges like beating humans in chess or poker. As a result of the missing clear understanding of the overarching goal, the original high spirit appears to be lost in specific, incremental steps that together did not produce a quantum leap and seem to lead nowhere. On the other hand, both, computational neuroscience and microelectronics made tremendous progress in recent decades. Today there is no big mystery in functioning of the brain elements, in the sense that the generally accepted view of the brain is that of a natural information processing device. Capabilities of the modern computing hardware are approaching or have already exceed computational resources of the human brain, therefore, hardware is not a bottleneck on the road to human-level intelligence. Then, what are we missing?

Several recent conferences, e.g., the BICA symposia (Samsonovich, 2008, 2009, members.cox.net/bica2010) addressed this question. To summarize the situation: it becomes clear that biologically inspired cognitive architectures (BICA) provide the most promising approach to creating a functional replica of the human mind, and the key to solving this challenge is in replication of the human ability to learn. In other words, having a machine that can be taught virtually anything that a human child can be taught would imply the achievement of the grand overarching goal. Therefore, in order to successfully steer research toward this goal, it is necessary (a) to better understand principles and characteristics of human learning at a big scale: e.g., in educational practice, rather than in limited behavioral laboratory experiments, and (b) to match the same characteristics of learning in artifacts.

From this point of view, the overarching goal should be formulated as a challenge in terms of scalability laws characterizing the learning process over a long period of time, when previously learned knowledge and skills enable the acquisition of new knowledge and new learning techniques, and so on. This large-scale process of bootstrapped learning can be visualized as a chain reaction (e.g., as depicted in Figure 1). Understanding details of this bootstrapped learning process, such as principles of self-regulated learning (SRL: Zimmerman, 2002), is vital for achieving the goal. At the same time, description of the general laws and their mathematical understanding is possible at an abstract level. Indeed, this is a task of high priority on the roadmap toward general human-level artificial intelligence, or artificial human-like minds.

Similarly to the history of the study of the nuclear chain reaction, models and theories are needed to describe and understand the learning chain reaction in detail in order to make it achievable. The key task is to clarify the difference between solutions leading to small incremental steps and solutions leading to a big quantum leap, and to identify conditions (e.g., the ‘critical mass’ of the initially available capabilities, if it makes sense) that make the leap possible.

The present work presents an attempt to start developing the necessary theory by constructing and simulating a general model of large-scale learning of the above sort, using learning of an abstract curriculum as an example.

Methods

First, in this section a challenge scenario is outlined that can serve as a goal for designing a general-purpose human-like learner and at the same time as an example justifying abstract modeling. Then, based on this scenario, an abstract model is constructed that will be studied numerically in the next section.

An Example Challenge Scenario

The following challenge scenario for an artificial learner can be viewed as an operational definition of certain key aspects of the human learning ability that needs to be replicated in artifacts: in particular, scalability, robustness, cross-domain transferability, and most importantly, its metacognitive nature. This paradigm will also allow experimenters to measure the “critical mass” of initial knowledge and skills that enable human-level bootstrapped learning.

Settings: The agent is embedded in a virtual learning environment with the study material (the textbook and supplementary materials normally available to students) encoded electronically and made available to the agent. All interactions between human instructors and the agent are mediated by an interface implemented at a symbolic level. The agent is expected to make progress in study of the curriculum, being taught by human instructor(s) via the high-level symbolic interface. The domain of study can be limited, e.g., to high school algebra. The agent together with instructors will go through chapters of the textbook (e.g., Algebra 1 and Algebra 2: Larson et al., 2007a,b) in their electronic representation, will learn new concepts, will ask questions, will take quizzes, will do exercises, and will be able to explain the learned material.

Approach: The approach to implement an artificial student capable of learning how to solve high school algebra problems can be based on a biologically-inspired cognitive-metacognitive architecture implementing principles of SRL (e.g., Samsonovich, De Jong and Kitsantas, 2009; Samsonovich, 2010).

Metrics and Criteria: The challenge for the agent is (i) to demonstrate a long-term ability to learn the curriculum step-by-step, starting from basic concepts available initially

(examples: an integer number, a variable, a function) and gradually moving to their practical usage and to complex constructs based on them, and (ii) to demonstrate improvement of meta-learning skills over time, in particular, SRL skills (Zimmerman, 2002). The agent performance improvement over time at the task level will be measured using standard tests and metrics used for evaluation of student academic progress. The agent will be evaluated not only based on its task-level learning and problem solving performance, but also based on changes in the approach to problem solving, using general metrics for SRL (Winne & Perry, 2000). A particularly interesting question relates to the measure of initial intelligence (the “critical mass”) that enables learning of the curriculum.

Generalizations: This example of a challenge scenario entails a generalization. Taking a step to the abstract level, it makes sense to introduce elements of an abstract curriculum as a system of interrelated abstract units (skills, facts, etc.) that the agent may have the ability to learn, depending on its current knowledge and experience. This is done below.

Figure 1: A possible curriculum structure. Solid circles (black and blue) represent available techniques.

Designing an abstract Model

A simple abstract model of a learning process consistent with the above scenario can be defined as follows. Elements of the model are abstract problems P , abstract facts and techniques T applicable to the problems, and abstract solutions S understood as subsets of techniques associated with problems. It is assumed that the set of techniques $\{T\}$ is ordered based on their mutual dependence, excluding a possibility of circular dependence. This ordering can be understood as resulting from a process of adding new techniques one by one to the set, as follows. Given a set of available $i-1$ techniques, the new technique T_i is defined as an abstract function f_i of a subset of the available $i-1$ techniques:

$$T_i = f_i(\{T_j : 0 < j < i, W_{ij} = 1\}), \quad \sum_j W_{ij} = m, \quad (1)$$

where W is a randomly generated, sparse Boolean matrix with zero elements for all $i \leq j$. To simplify the modeling study, it is assumed that each row of W (except the first m rows) has exactly m nonzero elements that are uniformly sampled in the part of the row before the diagonal. Each of the first m rows has the maximal number of nonzero elements satisfying (1). Therefore, a typical matrix W looks like the example plotted in Figure 2 B.

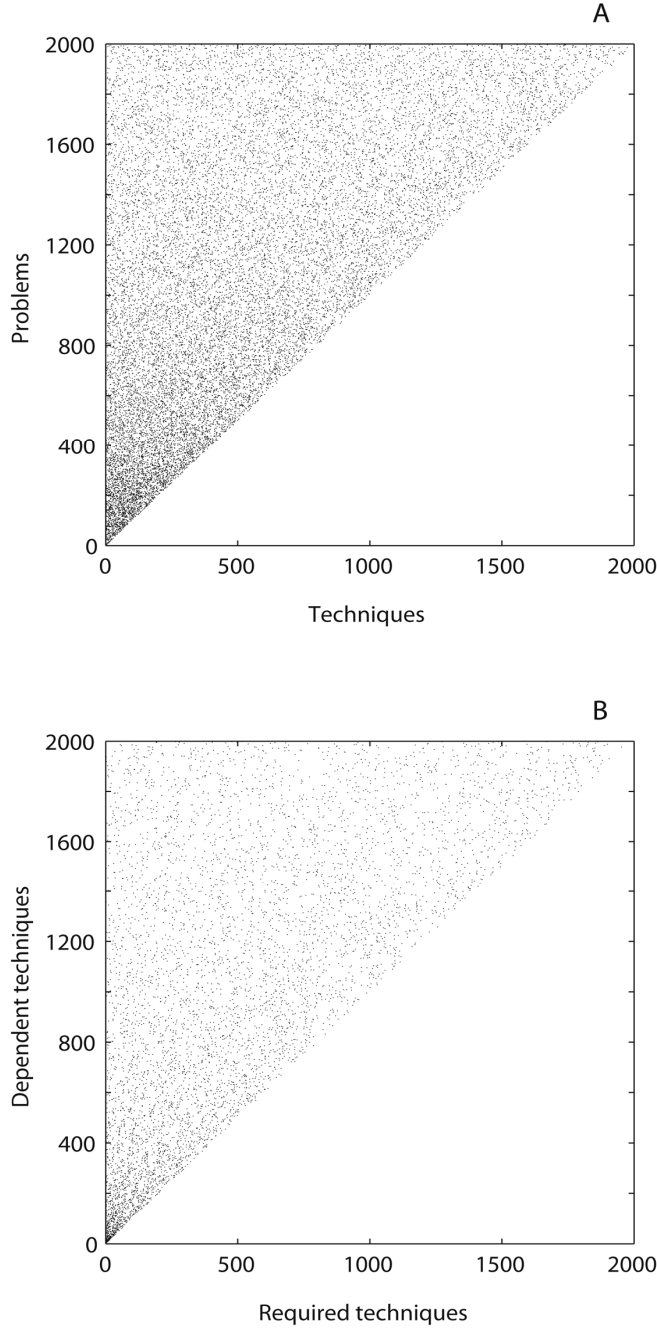

Figure 2: Examples of the abstract curriculum materials used in simulations. A: Example set of solutions for each of the 2,000 abstract problems. B: Example set of dependencies among the 2,000 abstract techniques.

Next, it is assumed that the set of problems $\{P\}$ is ordered similarly, and solutions S to problems are described by a matrix W' defined by a duplicate of (1), only with a different parameter m' :

$$S_i = \{T_j : 0 < j < i, W'_{ij} = 1\}, \quad \sum_j W'_{ij} = m', \quad (2)$$

To simplify the study, each problem is assumed to have exactly one solution, which is defined as a certain set of m' techniques. Of course, in real life, knowing a set of techniques that together are sufficient for solving a given problem does not imply the ability to solve the problem: one needs to know in what order and how to apply those techniques. For now, however, we assume that this part of solution is available automatically whenever each of the set of techniques that are necessary to solve the problem is mastered. Therefore, a typical matrix defining solutions of problems looks like the plot in Figure 2 A.

Naturally, there should be also an abstract notion of applicability of techniques to problems: each technique is either applicable to a given problem or not. In this sense, a solution must be a subset of techniques applicable to the given problem. The matrix of applicability $A = \{A_{ij}\}$ tells us whether T_i is applicable to P_j . The matrix A is again generated as a Boolean random matrix with given sparsity.

Model Dynamics

From the learner's perspective, each problem in this simplistic model is either solved or not. Similarly, each technique has three possible states: unavailable, available (yet not mastered), and mastered. The model dynamic rules of learning are defined as follows. A technique becomes (and forever remains) available when all techniques on which it depends are mastered. A technique becomes (and forever remains) mastered when it is successfully used to solve a problem. A technique can be used to solve a problem when it is available. A problem that is already solved is not considered again (indeed, with exactly one solution for each problem, its consideration would change nothing).

Experimental Paradigm

The abstract learning paradigm is the following. Given a set of n techniques and n problems (having the same n just simplifies the consideration), of which initially k techniques are available and zero problems are solved, the learner tries to solve as many problems as possible by randomly picking problems that are not solved yet and trying to apply available techniques to them. This is done in discrete steps. At each step, one problem is selected, and if the solution is contained within the set of available applicable techniques, then the problem is considered solved, and those techniques that constitute the solution become mastered. Simultaneously, states of all techniques are updated based on the above stated dynamic rules: this may result in the emergence of new available techniques. The process ends after a fixed number of steps N_{max} . The progress made in

learning is measured by the final numbers of solved problems, available and mastered techniques.

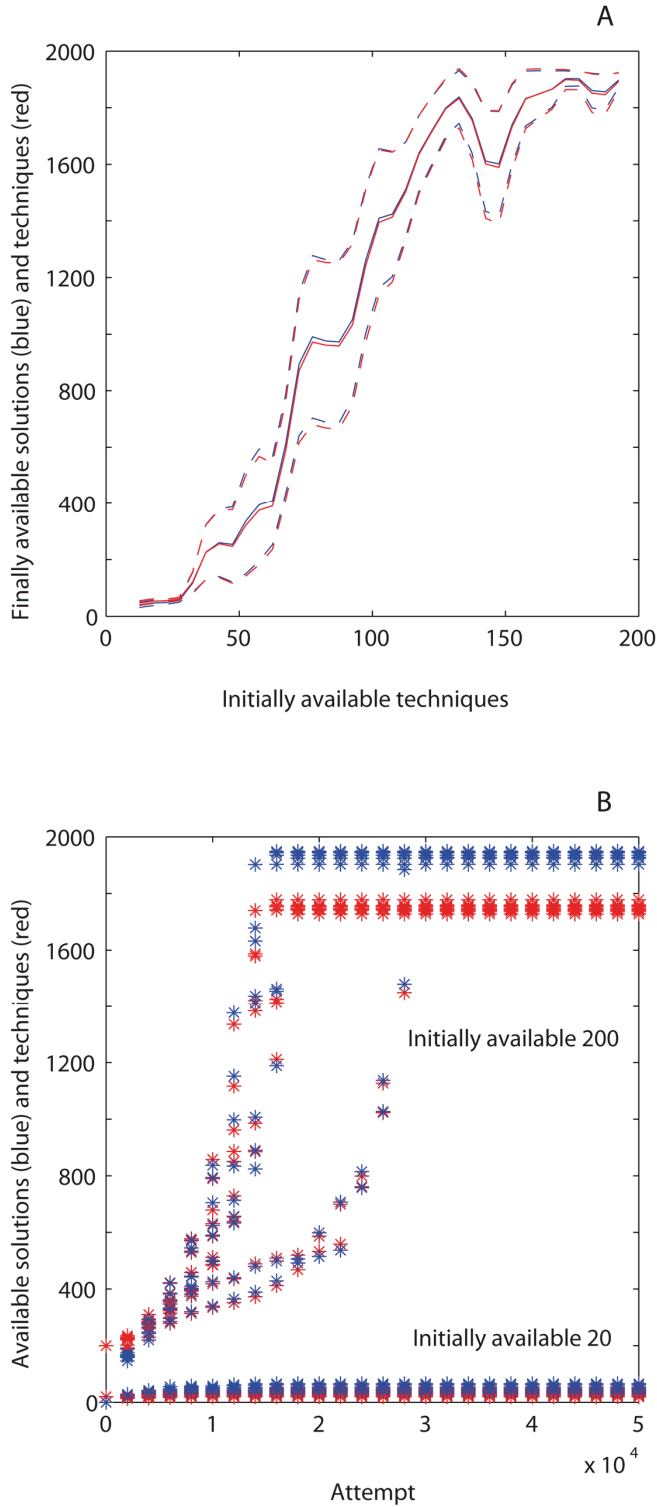

Figure 3: Simulation results. A: Results of learning as a function of initially available techniques. The dotted lines indicate the standard error. B: Learning curves for different numbers of initially available techniques.

Simulation Results and Analysis

The model described above was simulated on a computer with the following parameters. The number of techniques and problems was $n = 2,000$, the maximal number of dependencies for techniques $m = 3$, the maximal length of a solution = 10, the sparsity of the applicability matrix = 0.05, the number of steps $N_{max} = 50,000$, and the number of initially available techniques was $k = 200$ and $k = 20$ in two sets of trials. The results were averaged over 10+10 trials. Results of simulations are summarized in Figure 3.

Figure 3A shows the dependence of the number of finally available solutions (blue) and techniques (red) as functions of the number k of initially available techniques that was varied gradually from 20 to 200. Figure 3B shows multiple learning trajectories for two different values of k : 20 and 200. In this case, the numbers of available solutions (blue) and techniques (red) are plotted as functions of the number of learning attempts.

Results indicate two distinct regimes: “limited learning” ($k < 70$) and “global chain reaction” ($k > 100$). As Figure 3A shows, limited learning is characterized by the number of finally available solutions and techniques that is commensurate with the number of initially available techniques. By contrast, the chain reaction regime is characterized by the number of finally available solutions and techniques that is close to the maximal given number of solutions and techniques n . Figure 3B demonstrates clear clustering of the learning trajectories corresponding to the two regimes.

The qualitative observation of the two regimes is robust with respect to variation of parameters of the model. The transition is clearly visible in Figure 3 and shows a tendency to become sharper as the number of learning steps and the number of problems and techniques n are increased (not shown in Figure 3). The null hypothesis, that dynamics of learning produces results linearly increasing as a function of the amount of initial intelligence, can be ruled out based on the sigmoid appearance of the curve in Figure 3A: residuals of the linear fit exhibit the standard error several times along a substantial fraction of the curve (not shown in Figure 3A). A more rigorous validation of the result will be presented elsewhere.

Speaking generally, the observed chain reaction behavior resembles the phenomenon of percolation, which is characterized by threshold dynamics (a phase transition: see Ziman, 1979). The present limited study, however, does not allow for a detailed investigation of the phase transition characteristics.

Discussion

The presented study and its results are limited in many aspects. For example, from the cognitive psychological perspective, this approach may seem to be fundamentally lacking in an appreciation for the difficulty in understanding human cognition and learning and how they vary as a function of many variables (experience, context, personality differences, etc.). It is nevertheless always reasonable to

start with a simple general model, and then correct the findings by including missing details. This was the motivation behind the choice of the presented model and its simulation. In the present version, the model and its simulation results do not tell us precise details about how humans learn throughout their lifetimes, and this was not the intent. On the other hand, the present work opens a new topic in cross-disciplinary discussions: only through meaningful interactions between hardcore computer scientists and mathematicians and psychologists and cognitive neuroscientists we will be able to achieve the overarching goals described in the Introduction. Certainly, more formal analysis informed by all related disciplines will benefit artificial intelligence, psychology and neuroscience, as well as other disciplines.

The study and its analysis presented here constitute a first step of its kind, paving the way to finding general scalability criteria for intelligent learning systems intended to achieve the human level of performance. In this respect, it would be very interesting to compare results of this study with available data from educational studies and from machine learning: this will be done elsewhere. The questions to be addressed in future studies include: Do we see the same kinds of limited learning and global learning chain reaction regimes in human children? How this model might be made less abstract and more related to existing specific models of learning? How to include cross-discipline learning into the model? How to specifically describe the role of metacognition within the abstract formalism? And so on.

Returning to the topic of the Introduction, the present study outlined a new kind of scalability criteria that will be useful guiding the design of human-level learners. The knowledge that learning dynamics have a threshold nature allows in principle to identify the threshold (the “critical mass”) for a given learning system based on its abstract modeling and then to set the achievement of this “critical mass” as the goal of development.

Conclusions

Designing an agent that can master one specific cognitive skill in specific settings may be feasible today based on traditional approaches in artificial intelligence, regardless of the level of the selected cognitive skill. At the same time, designing an agent that can grow cognitively from a child to an adult human level of general intelligence is challenging. To solve the challenge, it is important to understand the different nature of the two tasks in terms of mathematical characteristics of the expected learning process. The present work addressed this goal with a simple abstract model of a long-term learning process. Results indicate that this process of learning is characterized by two distinct regimes: (1) limited learning and (2) a learning chain reaction that extends through the entire learning material.

The transition between the two regimes is determined by the ‘mass’ of initially available learning skills and techniques. Therefore, the notion of a ‘critical mass’ for a human-level learner makes sense and can be determined

experimentally. Therefore, this criterion can be used to guide research in human-level teachable systems.

Stated simply, while an intelligent learning agent may be successful in learning starting from any amount of initial knowledge, it needs to begin with a “critical mass” of knowledge and skills in order to successfully self-teach to learn much more than was conceived during its design – up to the human level of general knowledge.

The Effects of Communication Medium Upon Collaborative Orientation Task Performance

Laura M. D'Andrea (dandrea1@illinois.edu) & Wai-Tat Fu (wfu@illinois.edu)

Applied Cognitive Science Lab, Human Factors Division & Beckman Institute
405 N. Mathews Ave., Urbana, IL 61801

Abstract

Pairs of dispersed individuals are often forced to solve orientation tasks collaboratively. The present study examines how collaborative orientation tasks are solved when pairs of individuals complete the tasks using one of three computer-based communications (text, audio, and video). Both simple and complex tasks were presented. Pairs in the audio condition outperformed those in the text and video condition overall, and specifically on complex tasks, despite the fact that the video condition allows for the greatest amount of information to be communicated. Analysis of conversations between pairs indicates that those in the video condition had different conversational behavior. Results suggest that social effects of video communication may impair collaborative orientation task performance.

Keywords: Spatial Cognition; Interactive Behavior

Introduction

An understanding of spatial relationships is critical for successful interaction with the world around us, impacting our ability to complete tasks as simple as reaching for a pencil and complex as maneuvering an environment (Taylor & Tversky, 1996). The ability to orient oneself in an environment with the use of a navigational aid, such as a map, is a particularly interesting spatial task. This situation demands that the map-reader's personal perception/view of the environment be aligned with the map's view, a frame of the same environment from a perspective entirely independent of, and depicting locations external to, the reader (Gunzelmann, Anderson, & Douglass, 2004; Klatzky, 1998). These differing perspectives of the same environment are referred to, respectively, as egocentric and allocentric frames of reference (Klatzky, 1998). To orient oneself in an environment, one must recognize how the two frames of reference correspond and depict the same environment; in other words, the reference frames must be aligned. The act of aligning reference frames likely requires somewhat more complex processing than a mental rotation of the two perspectives, because the frames are two distinct formats of information (egocentric vs. allocentric) (Gunzelmann, Anderson & Douglass, 2004). Though various processing strategies are used to mentally coordinate the different perspectives of a scene, including array rotation and viewer rotation, all accomplish orientation within the environment through the same overall strategy - alignment of the differing reference frame types (Gunzelmann, Anderson & Douglass, 2004).

The current ubiquity of communication-oriented technologies has, in some ways, added complexity to the process of orienting oneself in an environment. The

forementioned work on orientation was done with regard to a single individual. However, a lost driver can now easily call a friend for directions rather than look at a map. An astronaut repairing a broken device in space can receive instruction from ground control on how to repair it if the instruction manual is outdated. In these and countless similar situations the orientation task is distributed across multiple geographically distributed individuals, each with information that is crucial to solving the task but insufficient on its own, and each with a different frame of reference.

Disparate, communicating individuals presumably must orient themselves in the same general manner as is done by an individual - by aligning the available egocentric and allocentric reference frames (Gunzelmann, Anderson, & Douglass, 2004). In distributed orientation tasks, however, reference frames cannot be aligned by examining the egocentric and allocentric frames and physically aligning them (as would be possible if an individual were lost and had a map in hand). Therefore, it seems that communicative partners can only overcome the disparity in their reference frames by actively discussing pertinent spatial relationships within the environment, until they are able to align each other's perspectives. The role of communication in distributed collaborative orientation tasks is critical, and the fact that the individuals are not co-located introduces challenges to their ability to effectively communicate. For instance, compared to face-to-face collaborators, dispersed collaborators have been found to often have different understandings of the information/task at hand and of the meaning of their partner's actions (e.g., silence during a conversation), and show a reduced ability to establish and maintain a common understanding of each others' knowledge of the situation or task at hand (Cramton, 2001; Diamant, Fussell, & Lo, 2008). A major contributing factor to these challenges is the inability of computer-mediated communication tools to allow for the same access to social and contextual cues that are visible during face-to-face interaction (Cramton, 2001; Diamant, Fussell, & Lo, 2008).

The type of communicative technology being used also introduces potential issues. By nature, different types of computer-mediated technologies (e.g., audio conference, video conference, text communication) convey different levels of cues about one's partner, and can differentially impact how an individual feels about his partner and their task performance (Diamant, Fussell, & Lo, 2008). Diamant, Fussell, & Lo (2008) evaluated the impact of three communication mediums - Text, Audio, and Video - to examine in relation to one another, and found that

technology type interacted with the culture of individuals to predict their attributions of performance (Diamant, Fussell, & Lo, 2008). Diamant, Fussell & Lo's (2008) findings indicate that the affordances of a technology determine the way in which it influences attributions of performance. Perhaps the affordances of those technologies also have differential impacts upon how individuals work together to complete collaborative orientation tasks, tasks in which communication is critical to solving the task. We expect the video condition to generate the best performance, the audio to allow the second best, and the text to result in the worst. This prediction is based upon the amount of information that each communication type provide (i.e., the video condition allowing individuals to not only speak but also use gesture to help describe spatial relationships within their view of an environment. We tested this possibility with an experiment studying the impact of different communication mediums upon collaborative orientation task performance.

Method

Overview

A collaborative orientation task is a type of spatial task that can only be solved when multiple individuals work together, combining their knowledge to deduce the solution. The impact of communication medium type upon collaborative orientation task performance was studied by requiring pairs of individuals to work together to solve spatial tasks while communicating through one of three communication mediums: text, audio, or video chat. Each of our collaborative orientation tasks included two unique displays of task-relevant information, one for either participant in the pair. Both displays contained solution-critical information, and the task demanded that pair members communicate their information in order to ultimately deduce the cardinal direction of the target.

Participants

Participants were 48 adults over the age of 18, recruited from Champaign, IL and paid for their participation. Participants were randomly assigned to a pair. One pair of participants (Audio condition) failed to perform the tasks, and their data was not included in the analysis. Of the remaining 46 adults (mean age=24.6; mean years of education=15.7), 29 were female and 17 were male. Participants were screened for normal or corrected-to-normal vision.

Measures

Spatial abilities were measured with two paper-pencil tasks. Participants' ability to mentally rotate objects was measured with the Mental Rotation Test (MRT) (Vandenberg and Kuse, 1978). Perspective taking ability (i.e., the ability to imagine how a scene looks from a different location in space) was assessed with the

Perspective Taking/Spatial Orientation Task (PTSOT) (Hegarty & Waller, 2004; Kozhevnikov & Hegarty 2001).

Collaborative Orientation Task Stimuli

Our stimuli were adapted from those used by Gunzelmann, Anderson, & Douglass (2004). In their study, a single task contained two separate displays of information that needed to be reconciled to solve the task; individuals completed the tasks alone. In our study, a single task contained the two separate displays of information. However, we gave only one display to either member of the pair (one for the Responder and one for the Instructor). We also slightly modified the appearance of the tasks. The Responder was presented with a 2D array of seven images and one target icon, all located in one of the eight cardinal directions (*North, South, East, West, Northeast, Northwest, Southeast, Southwest*). The Instructor was given a display showing two of the seven images seen by the Responder, as well as an arrow indicating North (relative to the center of their screen). In either pair members' display, the icons maintained identical spatial relationships with other icons. However, the entire array was rotated to some degree (rotations of 90° increments), so the Instructor and Responder's displays were not identical. See Figure 1 for examples of each display, as they would appear in an actual task.

For each task, pairs' goal was to deduce the cardinal direction in which the target was located, relative to the X in the center of the Responder's screen. The Responder was ultimately responsible for reporting the direction of the target. Because the Responder was given information regarding the target's location relative to other images, and the Instructor was given the cardinal directions of certain images, pairs needed to discuss their displays (e.g., images, directions of images, relationships between images, etc.) in order to align their perspectives of the displays and deduce the target's direction. Stimuli of two levels of complexity (simple, complex) were displayed. In simple tasks, each icon on the Responder's display was unique. In complex tasks, the Responder's display contained multiples of the two icons that were present in the Instructor's display.

Figure 1. Sample trial displays for a simple task. The left is a display seen by a Responder; the right is a display seen by an Instructor (correct response=Southwest).

Procedure

Within each pair, individuals were randomly assigned to their roles (Responder vs Instructor). Pairs were randomly assigned to one of the three communication conditions. 8

pairs participated in each condition; however, one pair in the Audio condition was not included in analysis due to a failure to perform the tasks. The orientation task portion of the experiment was conducted with both pair members present in the same room, but seated at computers separated by enough distance/barrier so that participants were out of each other's sight and hearing range during the task. Before beginning the collaborative orientation tasks, individuals completed demographic and spatial tasks. They were then shown to their computers and instructed as to what their communication medium would be. On each computer, an instruction screen was presented which explained the tasks and offered a sample display representative of what each individual would view, depending upon their role (Responder vs. Instructor). The pair then performed one practice task before beginning a set of 20 tasks, 10 complex and 10 simple. In each condition, the task workspace took up half of the computer screen; the other half contained the communication tool (*Text condition*: an IM chat box; *Video*: Skype video chat interface (see Figure 2); *Audio*: Skype audio chat interface). Accuracy of task performance and conversations between pair members were recorded.

Across all pairs, the practice trial was identical. However, each of the 20 actual trials was randomly generated for each pair. This randomization included: the 7 icons that appeared on the Responder's display (randomly selected from a master set of 18 icons); the target's location on the Responder's display; the direction of North on the Instructor's display; the relative locations of the two icons appearing on both the Instructor's and Responder's displays; the degree of disparity between the Instructor's and Responder's displays (90 increments); the distribution of complex/simple tasks throughout the 20 overall tasks.

Figure 2. Screenshot from Video condition (Responder's computer screen)

Equipment

Stimuli were presented on each participant's computer screen; responses were made using the mouse. Camtasia screen capture software was used to record audio and video feeds in the Audio and Video conditions.

In the Text condition, participants communicated by typing to each other using AOL Instant Messenger. In the Audio condition, participants wore Logitech ClearChat headphones (with microphone) when performing the

tasks. Auditory communication was enabled through the use of Skype's auditory calling feature. In the Video condition, participants wore Logitech ClearChat headphones (with microphone) when performing the task, as there is an auditory component to video chatting. Video chat communication was enabled through the use of Skype's video chat feature. Each computer was supplemented with Logitech Webcam Pro 9000 cameras in order to permit video chatting.

Results

Performance

We performed a two-way ANOVA examining the effect of communication media (video, audio, text) and task difficulty (simple, complex) on overall accuracies. There main effect of communication media was not significant ($p=0.11$), but the main effect of task complexity was significant ($F[1,21]=4.22$, $p<0.05$). There was also a significant communication by complexity interaction ($F[2,21]=3.55$, $p<0.05$). Simple effect analysis between media conditions in simple tasks showed no significant difference, but the difference was significant in complex tasks ($F(2,21)=5.86$, $p<0.05$). Posthoc tests (Fisher's LSD) showed that the audio condition was significantly better than the text condition ($t(6)=4.8$, $p<0.01$) and the video condition ($t(6)=3.1$, $p<0.01$), but the difference between text and video was not significant (see Figure 3). This demonstrated that pairs in the Audio condition performed the tasks better than pairs in either the Video or Text conditions only in the complex tasks.

Figure 3. Average proportion of trials correct by communication medium, as a function of trial complexity.

To assess whether these differences in task performance was linked to pairs' spatial aptitude, rather than the communication medium being used, spatial ability task scores were analyzed. Results indicate no significant difference in the abilities of individuals in the three communication conditions. A one-way ANOVA examining MRT scores of individuals in the different conditions (video, audio, text) revealed no significant difference in the MRT scores of individuals in the different communication conditions ($F[2,43]=0.70$, $p=0.50$). Similarly, a one-way ANOVA examining PTSOT scores across conditions (video, audio, text) revealed no significant difference in the PTSOT scores of

individuals in the different communication conditions ($F[2,41]=0.11, p=0.90$).

We also examined the relationship between a pair's average spatial ability score and their collaborative orientation task performance. For each pair, a single score was generated for both the MRT and PSOT by averaging the scores of the two individuals within the pair. This score (denoted with "-P") was then correlated with task performance. The MRT-P score was significantly correlated with task performance in the Text condition ($r=0.86, p<0.01, df=6$) and the Video condition ($r=0.77, p<0.05, df=6$). However, MRT-P was not correlated with performance in the Audio condition ($r=-0.38, p=0.40, df=5$). The same trend followed with regard to the PTSOT-P scores. PTSOT-P was significantly correlated with performance in the Text ($r=-0.87, p<0.01, df=6$) and was marginally correlated with performance in the Video condition ($r=-0.68, p=0.09, df=5$), but was not correlated with performance in the Audio condition ($r=-0.41, p=0.36, df=5$). The lack of correlation between spatial ability and performance within the Audio condition may be due to the restricted range of performance observed within this group. Additionally, averaging spatial ability scores is not an optimal approach to examining abilities across conditions, as an average score can obscure potentially interesting information (e.g., relative abilities of the Responder and Instructor in each pair).

The effect of practice on task performance was also assessed. Average scores for each trial were correlated with trial number. Overall performance on the collaborative orientation tasks, regardless of communication medium, was significantly correlated with trial number ($r=0.59, p<0.01$). Trial number was not significantly correlated with performance in the Text condition ($r=1.32, p=0.20$). It was marginally correlated with performance in the Audio condition ($r=1.98, p=0.06$). Performance of pairs in the Video condition, was significantly correlated with trial number ($r=2.46, p<0.05$). This finding suggests differential effects of practice depending upon the communication medium being used; thus, the communication mediums, rather than the task itself, are impacting whether practice improves performance.

Conversational Analysis

To investigate underlying factors as to why the Audio condition allowed for superior performance, the conversations between each pair were transcribed and coded. A coding scheme was developed post-hoc and addressed four main categories of Utterance Type: Object Description, Revision/Repair, Request for Confirmation, and Request for Expansion. These types are rooted in Clark and Wilkes-Gibbs's (1986) work regarding the ways in which pairs of individuals, during conversation, collaborate to reach agreement on the noun phrase being referred to (the noun phrase being crucial to understanding what each other is trying to communicate).

Within each of these main Utterance Type categories were sub-categories regarding the contents of the utterance. In turn, each of these Utterance Content categories contained more-specific Statement Type categories. Each utterance was coded with regard to the main Utterance Type (e.g., revision/repair, request for expansion), and with respect to the different specific Statement Types within utterance content categories A, B, and C. Each utterance could receive multiple categorizations.

We were interested in whether there were differences across communication conditions in their use of the main Utterance Types, as well as whether the use of different main Utterance Types related directly to task performance. Therefore, a 4 (utterances types) X 3 (communication media) X 2 (correctness of response) ANOVAs with average frequencies of occurrences of utterances as dependent variable was conducted. Occurrences of each utterance type were normalized, taking the frequency of utterance in proportion to the number of trials that had occurred. Results indicated a significant three-way interaction ($F(6,60)=4.33, p<0.001$), a significant two-way interaction between correctness and media ($F(2,20)=4.39, p<0.05$), and significant main effects of utterance types ($F(3,20)=43.24, p<0.001$) and correctness ($F(1,20)=20.42, p<0.001$). Given that we observed interactions between media and correctness, the significant 2-way interaction and main effects were likely caused by the different number of correct and incorrect trials in each medium. We therefore focus on the further analyzing the 3-way interaction.

We performed separate 3 (media) x 2 (correctness) ANOVAs on each type of utterances. Results showed significant main effect of media for requests for expansion ($F(2,20)=4.17, p<0.05$). Post-hoc comparisons showed that Video had significant more requests for expansion than audio ($t(7)=2.87, p<0.05$) and text ($t(7)=3.00, p<0.05$) conditions. We found significant main effects of correctness and media for requests for confirmation ($F(1,20)=16.15, p<0.05$) and $F(2,20)=3.67, p<0.05$ respectively). Posthoc comparisons showed that Video had significant more requests for confirmation than text ($t(7)=3.25, p<0.05$). We found significant main effects of correctness and significant interaction between correctness and media for object description ($F(1,20)=23.1, p<0.01$) and $F(2,20)=4.7, p<0.05$ respectively). Posthoc comparisons showed that *only in incorrect trials*, Video had significant more requests for confirmation than audio ($t(7)=2.47, p<0.05$). There was no significant difference in any of the variables for Revision/repair. [See Figure 4].

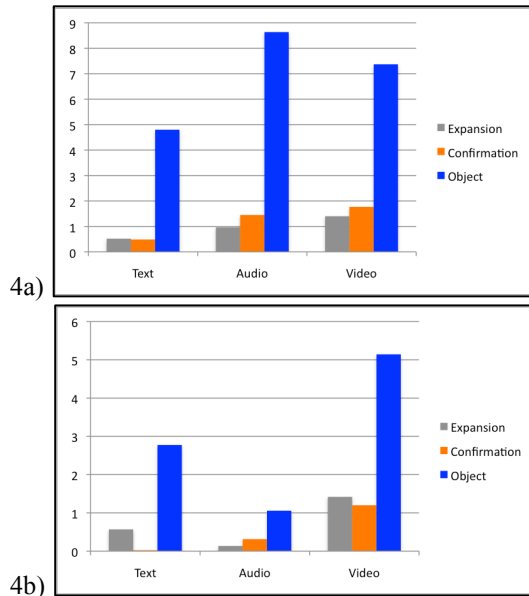

Figure 4. In each communication media, average utterance type per trial: 4a) Correct trials; 4b) Incorrect trials.

The Expansion and Confirmation request types are indicative of unsatisfactory or insufficient information communication between partners, indicating individuals' need/desire to gain more information from their communicative partner (Clark and Wilkes-Gibbs, 1986). Intuitively, one might think that the video condition would result in the fewest requests because it allows for greater amount of information to be communicated. However, participants in the video condition made more requests for expansion than individuals in text or audio, and more requests for confirmation than participants in text or audio (when incorrect performance resulted), indicating that the information communicated was more frequently deemed insufficient by pair members in the video condition than in either text or audio.

Discussion

This study's results were interesting in that, contrary to our predictions, the video condition did not induce the highest task performance level, but was in fact worse than audio and on the same level as text. The spatial abilities of individuals in each communication condition did not differ, indicating that our performance findings did not result from an overload in high or low ability individuals within specific conditions. Further research is needed to uncover the reasons behind observed performance trends, as our study was not geared to investigate several of the underlying factors that may have contributed to the performance differences. For instance, in the future we may match participants on spatial ability across conditions so as to better account for the abilities of pairs (rather than individuals) within conditions, and perhaps examine the impact of the relative ability of each pair member upon performance. However, current findings suggest an interesting social influence on cognition. The

remainder of this discussion focuses upon tying together our performance measure and conversational analysis results.

We found evidence that pairs' performance on collaborative orientation tasks is impacted by the type of communication medium used during task solving. Contrary to our expectation that the Video condition would result in the highest level of task performance, pairs in the Audio condition outperformed pairs in the Video and Text conditions both overall and on complex tasks, while performance of simple tasks was no different across communication mediums. So, it appears that all three communication mediums allowed for good performance on easier tasks, but some aspect of the auditory communication medium allows its users to sustain their performance level when tasks increase in complexity. In addition, the finding that the joint measure of pairs' spatial ability (MRT-P, PTSOT-P) was not correlated with task performance in the audio condition, but was in text and video, suggests that some factor inherent to the audio communication medium was at the root of its optimality for solving collaborative orientation tasks.

Our conversational analysis, aimed towards investigating why pairs in the other communication mediums did not show the same performance, revealed differences in how pairs in different communication conditions actually communicated information to each other. Two of the main utterance types – Requests for Expansion and for Confirmation – were used more by pairs in the Video condition than they were by pairs in both Audio or Text. Before moving forth with the discussion of our findings, it is important to reiterate the purpose of these types of utterances. Clark and Wilkes-Gibbs (1986) explain that when two people are speaking, over the course of the conversation one of them will utter a statement (specifically, a noun phrase) that their listening partner deems unacceptable or inadequate. The unacceptability could occur because the listener needs more of a description to understand what their partner is referring to (request for expansion), or because they want to clarify that what they heard is correct (request for confirmation) (Clark and Wilkes-Gibbs, 1986).

Although task performance overall and on complex tasks was significantly better in the audio condition, overall communicative behavior was essentially the same in the audio and text conditions. This suggests that there were factors inherent to the textual condition that impacted task performance without effecting how pairs actually worked together. Previous research indicates that textual communication is simply more difficult for pairs to work with, which could be the case here. Cramton (2001) discusses how various traits of text-based communication, including the slower rate of information exchange and the demand to communicate typically non-verbal cues with words (i.e., saying 'yes' instead of nodding), impede performance in text communication mediums. Text-based systems do not provide significant feedback, like verbalizing 'yeah' or 'mmhm' to indicate

understanding, and thereby imposes on pairs' ability to develop a shared knowledge of the situation (Cramton, 2001). Our text condition certainly presented these issues, which could have been the root of the resulting poorer performance. Another possibility is that the processing/resource demand of the text condition was higher than in audio, and while pairs could overcome the text condition's inherent difficulties in simpler tasks and they were unable to do so in more complex tasks. If this were the case it would follow predictions of theory on the impact of resources on multiple-task performance (Wickens, C. D., 1991). However, our study did not specifically examine any of these factors; therefore, a conclusion regarding the poorer performance in the text condition cannot be reached.

Performance in the video condition was also significantly poorer than that in the audio condition. The video condition *did* allow for some amount of Cramton's (2001) described non-verbal feedback so a lack of social and verbal cues cannot be entirely blamed for performance (though video communication is still deficient when compared to face-to-face; Cramton, 2001). It is possible that performance in the video and text conditions were both rooted in some cognitive/attentional load issue; however, the load induced by the video condition appears much higher than that of the text (as a large video feed of another individual was in close proximity to the task, compared to a text message box). If it were cognitive demand that decreased performance, one would expect the video condition to have experienced a more significant impact. And if the processing/resource demand had affected conversational behavior, one would expect text and video conditions to have communicated in the same manner. But, only the video condition incited pairs to use more requests for expansion and confirmation during their conversations. The difference in conversational behavior, and more specifically in the types that were differing (requests for confirmation/expansion, both statement types that indicate inadequacy of initial communication/a need to confirm what was said (Clark and Wilkes-Gibbs, 1986), suggesting that the video condition spurs a sub-optimal communicative behavior between partners. The video condition's poor performance levels indicate that this behavior was detrimental in some manner to task performance. The root of this behavior could lie in social effects imposed by the fact that video condition participants could see each other while communicating. For instance, perhaps individuals unfamiliar with each other restrict their display descriptions due to some discomfort felt by knowing that a stranger is watching them while they think. Additional research is needed to further examine the mechanism driving performance in different communication media, as we did not aim to examine such social influences. Follow-up work should include larger sample size and more trials, to better examine the effects of practice in varying conditions, and the aforementioned control of pairs' spatial abilities.

Conclusion

We found that audio communication allowed users to maintain a high level of performance on collaborative orientation tasks of varying complexities. Text and video communication mediums made the tasks more difficult to perform. In the case of video communication, this decrease in performance is likely tied to the style of conversational behavior incited by the communication medium. More research is needed regarding both the cause of decrease in performance observed in textual communication, and the reason behind the shift in conversational behavior observed in the video condition.

Semi-supervised learning is observed in a speeded but not an unspeeded 2D categorization task

Abstract

Recent empirical studies of semi-supervised category learning—where learners only occasionally receive information about a given item’s category membership—have yielded contradictory results, with some studies showing strong effects of unlabeled experience and others little or no effect. We report two experiments designed to help understand this heterogeneity. In both, participants performed a two-category classification task with novel stimuli varying along two psychologically separable dimensions. In semi-supervised conditions, participants categorized and received feedback on 32 “labeled” items intermixed with a large number of “unlabeled” items. In the supervised-only condition, participants viewed the same labeled trials intermixed with a large number of filler trials. Without time pressure participants learned the task equally well in both conditions. When required to respond very rapidly, however, participants performed substantially better in the semi-supervised condition. The discrepant results may indicate a role for selective attention in human semi-supervised learning.

Keywords: semantic interference, visual lexical decision, dual-task, single-system view

Introduction

Most theoretical and computational approaches to human category learning consider fully supervised learning: for every training experience, the learner has access to a representation of the stimulus and to the true category label (e.g. Nosofsky, 1986; Kruschke, 1992; Gluck and Bower, 1988; Anderson, 1991 and many others). Fully unsupervised approaches—where the learner never has access to the true category label but must learn to group items into categories on the basis of their similarity—are less common but have also appeared in the literature (e.g. Fried and Holyoak, 1984). Neither approach seems fully adequate, however, for explaining human categorization. Although a great deal of natural experience is unsupervised—we continually encounter objects in the world without a “teacher” telling us what kind of things they are—we also certainly get a nontrivial amount of “labeled” experience, where a recognized authority provides the true class label either directly in an explicit teaching scenario or indirectly through use of the label in communication. Human category learning may, therefore, involve combining both labeled and unlabeled sources of information—that is, human category learning may be semi-supervised.

The question of how best to combine labeled and

unlabeled data has been a topic of considerable investigation in machine learning, where it has been formally shown that, for some kinds of learning problems, a learner can converge much more quickly on an accurate representation of the category structure by combining labeled and unlabeled observations (Chapelle, Zien, and Scholkopf, 2006; Zhu and Goldberg, 2009). In cognitive psychology, the empirical question of how experience with both labeled and unlabeled items might influence category learning has rarely been studied. Some well-known computational approaches to category learning suggest ways in which labeled and unlabeled observations might combine to influence knowledge of category structure (e.g. Nosofsky, 1986; Schyns, 1991; Love et al. 2004), but these ideas have not been linked to the formal analyses offered by machine learning and have not been a focus of much empirical work.

We are aware of only two studies designed to assess whether category learning is influenced by unlabeled experiences, and these come to opposing conclusions. On the positive side, Zhu and colleagues (2007) studied performance in a 1-dimensional 2-category learning task. After learning a category boundary with a small amount of supervised training (ie training with corrective feedback), participants subsequently classified a large number of items with no feedback. These “unlabeled” items were sampled from a bimodal distribution with a trough that was displaced to one side or the other of the original learned category boundary. The authors found that, following the unlabeled experience, participants shifted their mental category boundary toward the trough of the unlabeled distribution. This finding suggests that people expect category boundaries to align with low-density regions in the unlabeled feature space, and use unlabeled observations to adjust their representations of category structure accordingly.

In contrast, Vandist and colleagues (2009) studied a binary classification task with stimuli that varied in two psychologically separable dimensions (the orientation and spatial frequency of Gabor patches). Participants viewed a number of labeled examples intermixed either with additional unlabeled examples or with unrelated filler items. Unlabeled items were sampled from a bimodal distribution in which the trough aligned with the true category boundary. The authors found no difference in the rate of learning or overall performance between these conditions—suggesting that the unlabeled items provided no overall benefit in learning the category structure, even though the distribution

of these items was consistent with the to-be-learned boundary.

In this paper we investigate some of the factors that might explain the different results obtained by these studies. Though both groups focused on semi-supervised learning, there were several key differences in their experiments: (i) Where Vandist et al. used stimuli varying in two psychologically separable dimensions, Zhu et al. employed visually complex shapes varying along a line in a multidimensional feature space. (ii) Where Vandist et al. provided participants with many labeled items, Zhu et al. trained participants with 10 repetitions each of just 2 individual tokens (ie one exemplar of each category). (iii) Vandist et al. employed a task requiring participants to integrate two separable dimensions (ie the category boundary was oblique in the 2D feature space) whereas Zhu et al. employed a simple 1D category learning task. (iv) Vandist et al. provided participants with ongoing labeled training experiences, whereas Zhu et al. performed a short block of supervised learning followed by a long block of unsupervised trials. (v) Vandist et al. compared performance in a semi-supervised condition to performance in a fully-supervised condition, whereas Zhu et al. compared two different semi-supervised conditions.

Thus there are several potential hypotheses as to why different results were obtained in the two studies. We report two experiments designed to narrow the range of possible hypotheses by capitalizing on the positive characteristics of both Zhu et al.'s (2007) and Vandist et al.'s (2009) original designs. Like Vandist and colleagues, our experiments (i) employ stimuli that vary along two obvious and psychologically separable dimensions, (ii) compare a semi-supervised condition to a matched supervised condition, and (iii) provide participants with ongoing exposure to labeled data. Like the experiment described by Zhu et al., (i) our stimuli were more object-like, (ii) participants in the semi-supervised condition received relatively few labeled trials (8%), and (iii) the boundary to be learned did not require integration of the two dimensions. In Experiment 1 we show that, under these conditions, people seem relatively insensitive to unlabeled learning experiences. Experiment 2 then tests a more explicit hypothesis about the conditions under which unlabeled experiences influence performance.

Experiment 1

Method

Participants. 50 undergraduate students from UW-Madison participated in Experiment 1 for course credit or monetary compensation. All had normal or corrected-to-normal vision.

Materials and Design. The stimuli were derived from classic work by Nosofsky (1986). They consisted of circles

bisected by an oblique line, and varied in radius (ie circle size) and in the precise angle of the bisecting line. Like the dimensions employed by Vandist et al. (2009), size and line orientation are two psychologically separable dimensions—that is, it is possible to attend selectively to one dimension without processing the other. In our stimuli, circle radius varied from 50 to 120 pixels while line orientation varied from 0 to 90 degrees (measured from the horizontal).

Figure 1. Example of the distribution of labeled (black) and unlabeled (red) items for one participant. Plus signs show labeled items from Category A, minus signs show labeled items from Category B.

Pilot testing with a fully-unsupervised procedure showed a general bias for classifying these stimuli according to the angle dimension—only 35% of participants made unsupervised categorization decisions based on size. Consequently our experiments involved learning to classify these items according to their size. Items larger than or equal to 85 pixels in radius were designated class A while those smaller than 85 pixels were designated class B.

The experiment included two between-subjects conditions. In the *semi-supervised* (SS) condition, participants viewed a total of 32 labeled items—items for which feedback was provided—sampled from a uniform distribution over the space. These were intermixed with 400 unlabeled examples sampled from a bimodal distribution that was uniform along the angle dimension but had a substantial gap along the size dimension (see Figure 1). Thus the gap in the unlabeled distribution provided a potential cue to orientation and location of the true category boundary. In the *supervised-only* (SO) condition, participants viewed the same 32 labeled items as in the semi-supervised condition. In this case, however, these items were intermixed with filler trials in which participants viewed the word “left” or “right” on the screen and pressed the corresponding mouse button. Labeled trials were ordered so that 8 appeared in each block of 100 unlabeled/filler trials. Subjects in the SS and SO

conditions were yoked so that each SO participant viewed exactly the same labeled items in exactly the same sequence and at exactly the same time as a participant in the SS condition. Thus the only difference between conditions was whether the trials interspersed among labeled examples consisted of unlabeled examples or of filler. After experience with the labeled and unlabeled/filler trials, both groups categorized, without feedback, 36 items forming an evenly-spaced “grid” in the stimulus space. Performance was assessed as the mean proportion correct in each successive block of 8 labeled items and on the unlabeled grid items.

If participants use the gap in the unlabeled distribution to form their mental category boundary, their accuracy on the labeled items should increase more rapidly, and their performance on the final grid should be better overall, than participants in the control condition.

Procedure The experiment was carried out on PCs running the DMDX software package under Windows XP. The 50 participants were randomly assigned to either the SS or SO condition with 25 participants in each. Participants in both groups were told that they would view a series of objects and that each belonged to one of two categories. Their job was to learn to classify the objects correctly by pressing one of two buttons on the mouse. Participants in both conditions were told that they would only occasionally get feedback indicating whether their choice was correct, but that they should do their best to categorize all of the items regardless. Participants in the SO condition were additionally told that categorization trials would be interspersed with button-pressing trials in which they would view the word “left” or “right” and must press the corresponding mouse button. The principal dependent measure was the mean proportion correct for each successive block of 8 labeled items and for the 36 unlabeled grid items.

Results

Figure 2 (top) shows means and standard errors of the accuracy for each block of 8 labeled items and for the final unlabeled grid in the two conditions. A repeated measures ANOVA treating time (each block of 8 labeled items plus final grid) as a within-subjects factor and learning condition (SS / SO) as a between-subjects factor revealed a significant main effect of time with performance improving overall ($F(5,192) = 5.36, p < 0.001$), but no effect of learning condition ($F(1,48) = 0.29, p = 0.59$) and no interaction between these ($F(4,192) = 0.51, p = 0.73$).

Performance overall was highly variable, with some participants learning fairly well and others not at all. In fact performance on the final grid was bimodal in both groups, with one subgroup choosing correctly on 67% or more of the grid trials and the other group at chance. We therefore classified each participant as a “learner” or a “nonlearner” based on grid performance, with learners showing accuracy

greater than 66%. The number of learners in each condition was comparable (13/25 in the semi-supervised group, 12 /25 in the control group), suggesting that the unlabeled items did not produce a greater likelihood of learning the correct boundary.

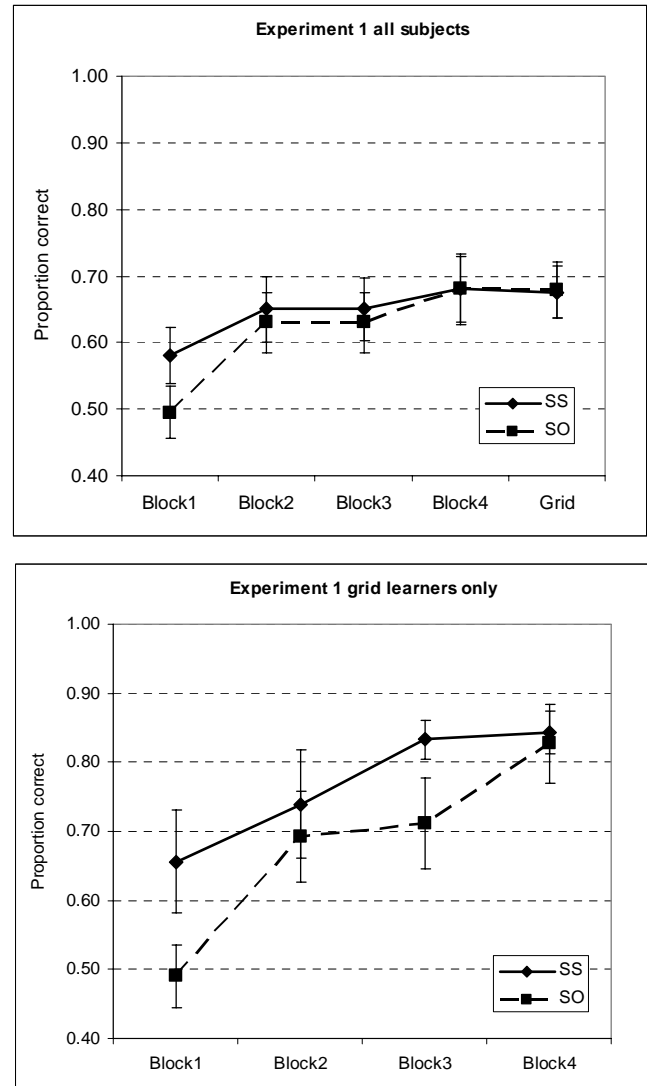

Figure 2. Top: Mean proportion correct for labeled items and grid for all participants in Experiment 1. Bottom: Mean proportion correct for labeled items in each block across participants who performed above criterion on the final grid. Error bars indicate the standard error of the mean.

Finally we investigated the effect of time and learning condition on accuracy for the 4 blocks of labeled items considering just those participants who performed to criterion on the grid items. These data are shown in Figure 2 (bottom). Though learners in the SS condition appeared to perform marginally better, this effect was not statistically reliable. A repeated-measures ANOVA showed a reliable main effect of time ($F(3,69) = 10.9, p < 0.001$) but no effect

of condition ($F(1,23) = 2.2, p = 0.15$) and no interaction ($F(3, 69) = 1.0, p = 0.40$).

In sum, we obtained no evidence for semi-supervised learning in this experiment: though unlabeled items were selected from a distribution with a prominent gap that aligned well with the true category boundary, experience with this distribution did not significantly impact the overall rate of learning, the mean accuracy, or the number of participants who learned successfully.

Experiment 2

Consistent with the observations of Vandist and colleagues (2009), Experiment 1 showed little effect of unlabeled experience on category learning. What then accounts for the strong effects of unlabeled experience previously observed by Zhu et al. (2007)? Experiment 2 tested one hypothesis: perhaps the difference is observed because, in both the current work and in Vandist et al.'s (2009) experiment, the stimuli were composed of two psychologically separable dimensions. A classic tradition of research in *concept attainment* has shown that, for such stimuli, people often adopt a “win-stay-lose-shift” strategy (Bruner, Goodnow and Austin, 1956). That is, they formulate a hypothesis about the relevant dimension for categorization, then make their decision based solely on that dimension until they receive evidence that their hypothesis is wrong, at which point they shift to a new hypothesis. If feedback is very sparse, participants may focus on the dimension they believe to be relevant to the exclusion of other dimensions. That is, participants may not attend to the competing dimension at all on many trials, and so may be exposed to very little information about the distribution on this dimension. Especially for our stimuli, where pilot studies suggest that participants are biased to attend to the irrelevant dimension (angle), such strategic/attentional effects might seriously attenuate any influence of unlabeled experience.

To test this hypothesis, we conducted a second study identical to Experiment 1 in all but one respect: in Experiment 2, participants were required to respond within a deadline of 600ms. With this requirement of a very rapid response, participants have little time to focus their attention on one dimension or the other. Consequently, we predicted that the distribution of unlabeled examples would have a more significant impact on category learning in this paradigm.

Method

Participants 50 undergraduate students who did not participate in Experiment 1 were recruited for this study in return for course credit. All participants had normal or corrected-to-normal vision.

Materials and Designs The materials and design were identical to Experiment 1, except that participants in both

groups were told that they would need to respond to each item as rapidly as possible.

Procedure Participants were randomly assigned to one of the 2 conditions, with 25 participants in each group. The procedure was identical to Experiment 1 with the following exceptions. First, each stimulus appeared onscreen for 125ms and was then replaced by a visual mask composed of hash marks. Participants were given 600ms from the onset of the mask to make their response. If the participant did not respond within this window, the computer indicated that the response was too slow. On labeled trials that did not meet deadline, the computer indicated that the response was too slow and also presented the correct category label. In both conditions, the deadline was imposed on both labeled trials and on unlabeled/filler trials.

Results

Trials that did not meet deadline were discarded from the analysis; these included just 5% of trials on average. Thus most participants were able to respond within the time-window on the majority of trials. For the remaining trials, we computed the mean accuracy on each successive block of 8 labeled trials and on the final unlabeled grid. Results are shown in Figure 3.

Figure 3. Mean proportion correct across all participants in Experiment 2 for labeled items in each block and grid. Error bars indicate the standard error of the mean.

In contrast to Experiment 1, participants in the semi-supervised condition showed greater accuracy across all blocks and on the final grid. A general linear model treating time (4 successive blocks of 8 labeled items + grid) as a within-subjects factor and learning condition (SS versus SO) as a between-subjects factor revealed reliable main effects of both factors (for time, $F(4,192) = 6.8, p < 0.001$; for learning condition, $F(1,48) = 4.32, p < 0.05$) and no

interaction between them ($F(4, 192) = 1.2, p = 0.32$).

As previously we also computed the number of participants who performed to a criterion of 67% or better on the final grid in each condition. In the SS condition, more than half the participants exceeded this criterion (13/25) whereas less than a third did in the SO condition (8/25). These odds are different with likelihood $p < 0.08$ according to a one-tailed test of the log odds ratio.

Figure 4. Mean proportion correct in Experiment 2 for participants who performed above criterion in the final grid. Error bars indicate the standard error of the mean.

Finally, we again considered mean accuracy over successive blocks of labeled items in just the participants who performed to criterion according to their grid accuracy. In these participants performance was much better in the SS than the SO group, with accuracy on labeled items improving from 50% to 73% for learners in the SS group but not exceeding chance on any block in the SO group. A general linear model of these data showed no reliable main effect of time or learning condition but these factors did interact significantly ($F(3,60) = 2.8, p < 0.05$). Inspection of Figure 4, which plots these data, explains the absence of any main effect and the interaction: performance did not improve significantly at all for the 8 participants in the SO group who performed above criterion on the final grid, but did improve substantially for those participants in the SS group. Consistent with these observations, oneway repeated-measures ANOVAS conducted separately for the two groups showed significantly different accuracy across blocks for learners in the SS condition ($F(3,36) = 4.6, p < 0.009$) but not in the SO condition ($F(3,24) = 0.3, p = 0.83$).

In sum, when responses were speeded, providing little time for strategic control of attention, participants in the SS condition performed more accurately overall, were marginally more likely to learn to criterion, and learned labeled items more rapidly than participants in the SO condition.

Discussion

In two experiments we assessed whether the ability to learn a simple 2D binary classification task is influenced by unlabeled experiences. In the first experiment, where participants responded with no time pressure, we observed little evidence that unlabeled data matter: participants performed equally well, were equally likely to learn, and learned equally rapidly regardless of whether they received unlabeled learning items. In the second experiment, which was identical in all respects except that participants were pressured to respond rapidly, we observed a very different pattern: in this case, experience with unlabeled items led to better overall performance, a greater likelihood of learning to criterion, and more rapid learning compared with supervised learning only. Like Vandist et al (2009), we found little evidence that unlabeled data influence category learning when response times were unconstrained. When responses were speeded, we replicated Zhu et al.'s (2007) finding that unlabeled data can produce substantial effects. What accounts for these different patterns?

One possibility concerns the extent to which participants can selectively attend to only some of the stimulus feature dimensions. Prior work has shown that, in categorization tasks where it is possible for participants to form an explicit categorization rule, learning depends importantly upon mechanisms of attention and cognitive control (Ashby and Maddox, 2005). In Zhu et al.'s (2007) work, stimuli varied along a line in a complex multidimensional feature space—therefore it was impossible for participants to selectively attend to information that was irrelevant to the category learning task. In contrast, in Vandist's et al.'s (2009) work and the current study, stimuli varied in two psychologically separable dimensions. If participants selectively attended to only one of these, so that distributional information about the unattended dimension was not available to the learning system, effects of unlabelled data might be attenuated or eliminated—producing the null result in Vandist's (2009) work and in Experiment 1.

On this hypothesis, the robust influence of unlabeled data in Experiment 2 was observed because participants lacked sufficient time to selectively attend to just one feature dimension. If, under speeded conditions, both stimulus dimensions are fully represented, then the unlabeled distribution should have a more robust impact on learning. On this view, it is not the speed of response that matters *per se*, but whether or not the learning system has access to all of the relevant distributional information. If this account is correct, it predicts that unlabeled data should have a stronger effect for multidimensional stimuli where the stimulus dimensions are not psychologically separable, even if response times are unconstrained. We leave this prediction to future work.

We further note that, because there are many factors that differentiate Zhu et al.'s (2007) study from that of Vandist and colleagues (2009), there remain several additional

hypotheses about the difference in their findings. The current study isolates speed of response as an important mitigating factor, but other potentially important factors—including the orientation of the category boundary in the stimulus space, the ratio of labeled to unlabeled examples, and the temporal distribution of labeled examples over the learning session—should be parametrically explored in future work.

More generally, the question of whether or not people make use of unlabeled observations when learning categories has strong implications for theories of human conceptual knowledge. Many researchers have noted that even young children are able, with just a handful of learning experiences, to infer the extension of many category labels (Hall and Waxman, 2004; Keil, 1979; Markman, 1989). Once they reach the right age, most children need hear the word “horse” only once or twice before being able to make a reasonable guess about which objects in the world are horses and which not. This rapid learning from sparse data is sometimes held to indicate that children bring strong inductive biases to bear on word-learning (Xu and Tenenbaum, 2007).

Semi-supervised learning suggests a different explanation: Maybe children can learn from just a few labeled examples because they are marrying these sparse episodes to knowledge gleaned from a vast amount of unsupervised experience. If children assume that category labels tend to span relatively dense clusters in a conceptual feature space, and that category boundaries follow the low-density valleys in this space, then—to the extent that this assumption holds—they only need a small number of labeled experiences to work out which labels “go with” which clusters. This explanation frees theories of word-learning from having to rely too heavily on strong inductive biases to explain rapid word-learning abilities in children.

Abstract

This study examines the facilitative effects of embodiment of a complex internal anatomical structure through three-dimensional (“3-D”) interactivity in a virtual reality (“VR”) program. Since Shepard and Metzler’s influential 1971 study, it has been known that 3-D objects (e.g., multiple-armed cube or external body parts) are visually and motorically embodied in our minds. Such findings confirm the theory that our mental images, and rotations of these images, are in fact confined by the laws of physics and biomechanics, because we perceive, think and reason in an embodied fashion. With the advancement of new technologies, virtual reality programs for medical education now enable users to interact directly in a 3-D environment with internal anatomical structures. Given that such structures are not readily viewable to users and thus not previously susceptible to embodiment, coupled with the VR environment affording all possible degrees of rotation, how people learn from these programs raises new questions. If we embody external anatomical parts we can see, such as our hands and feet, can we embody internal anatomical parts we cannot see? Does manipulating the anatomical part in virtual space facilitate the user’s embodiment of that structure and therefore the ability to visualize the structure mentally?

Medical students grouped in yoked-pairs were tasked with mastering the spatial configuration of an internal anatomical structure; only one group was allowed to manipulate the images of this anatomical structure in a 3-D VR environment, whereas the other group could only view the manipulation. The manipulation group outperformed the visual group, suggesting that the interactivity that took place among the manipulation group promoted visual and motoric embodiment, which in turn enhanced learning. Moreover, when accounting for spatial ability, it was found that manipulation benefits students with low spatial ability more than students with high spatial ability.

Keywords: Embodied cognition; Virtual reality; Visualization.

Introduction

Virtual reality programs have the potential to be the most dramatic change in the way anatomy is taught since Vesalius’s richly illustrated volumes of the human body based on careful and intricate cadaver dissections. Although computer technology has undoubtedly transformed the manner in which doctors evaluate and treat their patients (e.g., CT scans, robotic surgery), the methods used to teach medical students have been in place for centuries (e.g., lectures, anatomy textbooks, cadaver dissection). Some believe this is all about to change. Virtual reality (“VR”)

programs for medical education now enable users to interact directly with, as well as view, anatomical parts in three-dimensions, with the potential to change the way medical students learn anatomy, perform dissections and even practice surgical procedures.

The advent of these programs raises questions for cognitive psychologists, some of which this study aims to address. At the broadest level: how are complex, internal anatomical structures learned through 3-D viewing and interactivity? What factors, from both a cognitive and human-computer interaction perspective, contribute to the learning of anatomy through these VR programs?

This study considers the above-mentioned factors under the framework of embodied cognition: that cognition is inextricably linked to our physical interactions with our environment (Wilson, 2002). Using the embodied cognition framework, this study explores the following research questions: 1) Does the physical manipulation of, versus solely viewing, a complex internal anatomical structure in a virtual reality program facilitate a better visualization of the structure? 2) Does spatial ability affect participants’ visualizations in this particular study?

Theoretical Background

The theoretical framework underlying and informing the questions in this study bridges two distinct areas of cognitive psychology through the lens of embodied cognition: mental rotation and imagery and multimedia learning.

Studies in mental rotation and imagery provide some of the most compelling evidence of how cognition is rooted in our bodily interactions with the environment. Shepard & Metzler’s seminal research showed that people mentally manipulate objects similarly to the way they would with actual objects in physical space, and that the time it takes to rotate the image increases linearly with the degree of rotation (Shepard & Metzler, 1971; Shepard & Cooper, 1982). Subsequent research using the Shepard & Metzler paradigm has confirmed the proposition that motor processes are involved in mental rotation (Wexler et al., 1998) and that motor cortices (primary/M1 or premotor cortex) are activated when performing the task (Kosslyn et al., 1998).

Additional research in mental rotation and imagery has helped to clarify and refine the nature and extent to which motor processes are connected to mental rotation and

imagery. For example, it is known that there are differences in the way we conduct mental rotations of an object as compared with a body part. This difference arises because the trajectory imagined, for example, for the observer's hand or foot is strongly influenced by the biomechanical constraints specific to the actual movement of the hand and foot. For example, people are faster and more accurate at performing mental rotations of drawings of hands or identifying which hand is pictured when they are asked to imagine rotating the hand that does not require difficult bodily movements (Parsons, 1987a, b; Schwoebel et al., 2001). Given the details of the way the body actually works, the motor imagery system actively facilitates or constrains how quickly mental imagery is executed. Neuropsychological studies have proven that motor processes are recruited when we imagine and manipulate complex 3-D structures in our mind but also that the body's biomechanical constraints actually affect our ability to conduct mental rotations (Amorim et al., 2006).

Research in the area of multimedia learning endeavors to complement the research discussed above in embodied cognition and mental rotation and imagery by analyzing how multimedia programs may be designed to maximize learning and understanding. Recent theories and studies have focused on how the motor or haptic channel, through direct tactile manipulation and feedback can aid in deeper learning and understanding and the degree to which interactivity of any kind is productive (Meyer & Kieras, 1997; Chan & Black, 2006; Black, in press). For example, Chan & Black (2006) investigated how seventh graders are better at visualizing complex concepts such as Newtonian mechanics if they are able to interact with a technology-rich environment allowing for direct-manipulation animation ("DMA"). DMA allowed learners to interact directly with navigation controls, determine their viewing direction and to control the pace of the navigation of the content. Chan & Black found that DMA, which incorporated the haptic channel in the learning process, provided learners with a superior learning experience as compared with those who were in the non-haptic groups (narrative-only, narrative-and static visuals, narrative and animation) about causal interactions and functional relations in systems.

Despite the ubiquity of computer programs that exist for 3-D visualizations of anatomy, there are very few empirical investigations on what makes such programs effective. These studies have started to investigate, from a human-computer interaction and cognitive perspective, what factors contribute to developing successful visualizations of complex anatomy (or anatomy-like) structures from various 3-D visualization programs. From the corpus of these studies, the following variables have emerged as being significant: 1) manipulation (or interactivity) of the 3-D object versus just viewing, 2) the importance of having access to certain views and/or orientations of the structure, and 3) spatial ability of the learner. The most significant studies were conducted by Garg and his colleagues (Garg et al., 1999, 2001, 2002) and Keehner and her colleagues

(2008a, b), who concluded that developing accurate visualizations of an anatomical (or anatomical-like) structure has more to do with participants' access the critical views and orientations of the structure than being able to interact with it, and furthermore, that such programs should be used carefully with those with lower spatial ability were found to have had a harder time learning from such programs.

Yet, it is curious that the exact opposite findings have been found in some studies where active exploration appeared to benefit those participants with low spatial ability scores over those with higher spatial ability scores. In a study conducted by Luursema et al. (2006), participants were divided into groups viewing the same computer-generated 3-D images of anatomical parts of the abdomen, but with half of the group viewing the images stereoptically (using shutter-glasses), providing actual depth perception, and the other half of the group viewing the images binocularly (without shutter glasses). Luursema et al. found that a "combination of computer-implemented *stereopsis* (visual depth through seeing with both eyes) and *dynamic exploration* (being able to continuously change one's viewpoint with respect to objects studied in real-time) is beneficial to anatomical learning" (p. 455), and that participants with low visuo-spatial ability benefited more from this combination than participants with high visuo-spatial ability. In a more recent study, Meijer & van den Broek (2010) also found that active exploration actually improved low spatial participants' 3-D mental representations of complex 3-D objects (and had no effect on middle or high spatial participants' representations).

Research Design and Questions

This study builds from, as well as aims to overcome some of the potential confounds of the previous studies, in investigating the effects of interactivity and embodiment in a VR system when learning a complex, internal anatomical structure. First, the computer 3-D visualization program used in this study is more intuitive from a visual and motor processing standpoint. This VR system provides the user with stereoscopic vision with 3-D goggles, allowing for full depth perception of the object of study. In addition, this system has a joystick that allows the user to interact physically/motorically with the virtual object in a similar manner as one would outside of a virtual environment. Both these elements would, in theory, foster a stronger sense of embodiment because of the more realistic and natural aspects of visual and motor information in the VR system. Therefore, it is possible that if the interface of the VR program allows for a more intuitive mechanism for viewing and rotating the virtual object, and is compatible with the human body's natural movements, a participant might be able to develop a better internal 3-D visualization of a complex anatomical structure.

Second, the stimulus used in this study is an internal anatomical structure (as opposed to a fictitious structure or external body part) – the inner ear. In Garg et al.'s studies,

it is possible that the findings were confounded by the stimulus material – the carpal bones – because it is a part of the body that people are very familiar with both visually and motorically. That is, the wrist falls on two natural planes, and people are used to seeing as well as feeling their wrists in those two common positions. Therefore, it is not surprising that there are canonical views of the wrist that would naturally transfer to canonical views of the carpal bones within the wrist. Furthermore, using an internal anatomical structure free of any joint articulation or specific visual cues to orient the structure allows us to begin to investigate how (if at all) and which canonical views users develop of this structure during their study time. In essence, it is addressing the issue of whether the user literally embodies (or maps onto him/herself) the internal anatomical structure.

With these changes, this study addresses the following research questions:

- 1) Does the physical manipulation of, versus solely viewing, a complex internal anatomical structure in a virtual reality program facilitate a better visualization of the structure? If so, is there a difference in visualizing: a) different sub-structures within the larger structure that have different shapes, i.e., line (e.g., the path of a nerve) versus circles (e.g., semi-circular canals protruding off a surface); and b) the structure from different vantage points (i.e., anatomical planes)?
- 2) Does spatial ability affect participants' visualizations in this particular study? If so, does it have a different effect for: a) participants who manipulate versus view the structure; and/or b) participants with differing spatial abilities (i.e., low versus high)?

Method

Participants

Seventy-six medical students between the ages of 20-38 years at the University of Medicine and Dentistry of New Jersey, Newark, participated in this study. None of the participants had formal instruction of the inner ear or prior exposure to the VR machine.

Materials

The VR system and target anatomical structure

The VR machine is housed at the University of Medicine and Dentistry, Newark. It generates a stereoscopic 3-D environment that is viewed through stereoscopic 3-D goggles. It has a free-moving, non-mounted joystick, enabling the user to hold, control and manipulate the movement (by rotating on an x-, y-, and z- axis) of the 3-D representation of the anatomical structures in a similar manner as one would be able to with a tangible object outside of a virtual environment.

The target anatomical structure is the inner ear. The inner ear is a structurally complex system concentrated in a very small area in the human skull. The virtual ear model was developed by an otolaryngologist at UMDNJ in conjunction

with the engineers of the VR program to ensure accuracy of the model.

Pre-test measures

Participants took the following pre-tests prior to working on the VR machine: 1) a background questionnaire which includes questions on comfort level of using a joystick and playing video games, as well as any prior use of working with 3-D modeling programs; 2) an ear anatomy questionnaire; 3) Vandenberg & Kuse (1978) Mental Rotation Test ("MRT"). This is a standardized test of spatial ability that assesses one's ability to rotate and visualize a 3-D structure; and 4) Ekstrom et al.'s Building Memory Test. This standardized test was used to assess participants' ability to remember the location of an object within a map.

Post-test measure

A series of snapshots of the virtual ear model were taken in the following anatomical planes: lateral, superior, inferior, anterior and posterior. The purpose of using all these anatomical planes is to create a 3-D "voxel" of the area of study. For each plane, two snapshots were produced, one without the facial nerve and another without the semi-circular canals. Therefore, the post-test consisted of a total of 10 snapshots.

Procedure

Each participant was tested individually. First, each participant completed all four pre-test measures. Next, the participant was randomly assigned to one of the two conditions (*manipulation*, *visual*). The *manipulation* participant was given a brief training period with the joystick in the VR machine. Once the participant indicated that he/she felt comfortable using the joystick, the target anatomical structure (inner ear model) was presented. After providing a brief explanation of the inner ear and how it was positioned in a surgical position, the participant was asked to study the spatial configuration of two sub-structures within the inner ear: the facial nerve and the semi-circular canals. The *manipulation* participant was informed that he/she could use the joystick to rotate the ear model, and was given 5 minutes to study. Each *manipulation* participant's study of the inner ear, based on his/her own joystick movements, was recorded in the VR machine, which was then shown to the yoked, *visual* participant. After the study period, each participant was given the 10 post-test snapshots (randomized order by sub-structure) and asked to draw in, to the best of his/her ability, the missing sub-structure.

Coding

The drawings were assessed for accuracy of visual representation on the following criteria: parts, angle and placement and size. The various individual criteria were summed to derive the following TOTAL scores: 1) overall TOTAL; 2) TOTAL for each anatomical plane; 3) TOTAL for facial nerve; 4) TOTAL for semi-circular canal. The researcher and an independent coder coded the post-test.

Both coders were blind to the identity of the participants and condition assignment each coded all 760 drawings.

Analysis and Results

Participants in the *manipulation* condition scored higher than those in the *visual* condition on all the TOTAL scores (Table 1).

Table 1. Mean score analysis on all dependent measures

	Manipulation Mean (s.d.)	Visual Mean (s.d.)	t(37), p
TOTAL	72.47 (7.303)	60.76 (11.391)	6.437, <.001
TOTAL by sub-structure			
facial			
nerve	32.39 (5.900)	26.71 (6.375)	4.870, <.001
semi-circular			
canals	39.74 (3.020)	33.82 (6.673)	5.029, <.001
TOTAL by anatomical plane			
lateral	15.11 (2.051)	13.58 (2.937)	3.153, =.003
superior	13.92 (1.440)	11.63 (2.562)	5.663, <.001
inferior	13.79 (2.183)	10.74 (2.565)	6.481, <.001
anterior	14.18 (2.078)	12.13 (2.622)	4.830, <.001
posterior	15.03 (2.175)	12.45 (2.738)	4.700, <.001

A correlational analysis of all the pre-test measures with TOTAL score showed that only MRT was correlated ($r = .0325$). A one-way analysis of covariance (ANCOVA) was conducted using MRT as the covariate. A significant interaction effect was found between MRT and condition on TOTAL score, $F(1, 35) = 5.168$, $p < .029$. Simple group main effects tests were conducted to assess differences between those who scored lower on the MRT (1 *SD* below the mean = 11.274) and those who scored higher on the MRT (1 *SD* above the mean = 27.166) (Figure 1).

Figure 1. Differences on TOTAL score performance between the two conditions on two levels (high versus low) of the covariate (spatial ability).

Given that the statistical analysis revealed that those in the *manipulation* condition had more accurate 3-D visualizations of the inner ear over those in the *visual* condition, some ancillary questions arose with respect to

what the participants in the *manipulation* group were doing. For example, were there certain strategies used by the *manipulation* participants that enabled better embodiments of the inner ear? That is, were there common characteristics of the manner in which *manipulation* participants rotated the structure that led to highly successful performance on the post-test? Or, conversely, what were the common characteristics among *manipulation* participants who performed relatively poorly on the post-test?

A qualitative video profile of the top and bottom performing manipulation participants showed that common characteristics might exist on either end. First, among the top performing manipulation participants, they quickly oriented the structure into the posterior plane, which when put in context of the human body means positioned in an upright manner, standing up and looking forward. In addition to standing the model upright, the top manipulators often went back to this posterior view after exploring other views (as though it grounded them in some way), suggesting this view was the one they were most comfortable with. In contrast, the lowest scoring manipulators did not position the structure in an upright position as quickly as those in the top scoring group. There was no particular familiar or comfortable perspective that developed among the low scorers. Second, all the high scoring participants spent more time studying still positions as opposed to moving the object continuously. In contrast, the low scoring manipulators generally spent their time moving and rotating the object in various, haphazard directions and not holding it still.

Third, and perhaps most interestingly, when the high scoring manipulators moved between these still positions, they moved in a “wiggling” manner between these two planes. There were two kinds of wiggling among the top scoring *manipulation* participants. One type was a wiggling that constituted alternating between two still positions, in what appeared to be a comparison and analysis of the two positions. Another strategy demonstrated a different type of wiggling: choosing one “still” position and varying the view of that position by only a few degrees in either direction.

Discussion and Conclusions

The main finding of this study is that manipulating, rather than viewing, an internal anatomical structure in virtual space strengthens the embodiment of that structure and therefore the ability to visualize the structure. As demonstrated in the analysis (Table 1), the *manipulation* group outperformed the *visual* group regardless of whether the participants were visualizing different anatomical sub-structures or from different orientations (i.e., anatomical planes). Participants who are afforded the opportunity to manipulate in virtual space 3-D images of anatomical structures with which they are not familiar outperform participants who are only given the opportunity to watch the 3-D images being rotated. Such results support the general framework of embodied cognition, that there is an intimate connection between our motor and visual processes, and the more explicit the connection, the better the learning.

Beyond this main finding that the motor and visual processes are connected and provide stronger learning, it is posited that the participants may literally have tried to embody (to varying degrees) the inner ear model by mapping it onto their own bodies. Results of TOTAL scores by anatomical plane, combined with the video analysis, support the theory that the virtual inner ear was embodied by the participants in this study in a more literal sense of the term embodiment – that is, that they mapped the structure onto (or within) their own bodies. The results from the mean score analysis (Table 1) show that regardless of condition, participants performed better on the planes we are more familiar with seeing ourselves and others in (lateral, posterior and anterior) over less familiar planes (superior, inferior). As a general matter, we are much more comfortable and familiar with looking at others face-to-face rather than looking down a person's head (superior) or up a person's chin (inferior). This conclusion is similar to ones reached in studies by Parsons and others who have shown that the real world biomechanical constraints on our physical bodies do in fact constrain our mental abilities – specifically the ability to rotate and visualize a body part in our mind. Therefore, it is possible that participants in *both* the manipulation and visual conditions found that visualizing the ear from the superior and inferior planes was a somewhat physically awkward perspective to embody, as it is rare to look into the top of one's head or look up into one's chin. Even though the virtual ear was displayed in the absence of surrounding physical landmarks that would immediately cause the viewer to orient the image in an upright position, there was a way to orient the image (via embodiment) that made it the anatomical plane more familiar and more comfortable to the participants.

Further support for the embodiment theory is that the video analysis revealed that the top manipulators developed a *canonical viewpoint* (Palmer, Rosch & Chase, 1981) for this model. Palmer et al. coined the term canonical viewpoint to describe perspectives in which identification performance of 3-D objects is best. The canonical viewpoint for the ear model appears to be the posterior plane. The qualitative video analysis revealed that the top scoring manipulators started their study with the structure oriented in the posterior plane and often returned to this position as though it was the most stable position. Given that this is their canonical view, it strongly suggests that the manipulators literally embodied – that is, they mapped onto themselves the inner ear from the perspective of their own body schema, or rather that they projected their bodies onto the object in an embodied fashion, maintaining the body axes (head-feet, front-back, and left-right) when doing so (“bodily projection”, Lakoff & Johnson, 1999).

The results from this study also illustrate the facilitative effects of interactivity on embodiment and that the development of an internal visual representation of a 3-D structure depends on the spatial ability of the participant. Specifically, the benefits of embodiment in virtual reality appear to be greater for those participants with lower spatial

ability. As shown in Figure 1, those who score lower on tests of rotational spatial ability have more to gain from interacting with a 3-D virtual reality environment than those with high rotational spatial ability. There is a greater difference between the two regression lines at a low MRT score versus at a high MRT score, indicating that manipulation, which strengthens embodiment, may help those with lower spatial ability to perform as well as those who have higher spatial abilities (and may not need the manipulation experience).

It is important to note that the main effect of interactivity runs counter to some of the more relevant studies discussed in the literature review (Garg et al., Keehner et al.) who argue that interactivity, which allows for complete freedom of movement and exposure to views from varying perspectives, may overload the learner and prevent effective visualizations. Why is it then that in this study the participants in the *manipulation* condition outperformed the *visual* participants? Perhaps the answer is that this virtual reality program provided a stronger sense of embodiment or “presence” (Usuh et al., 1999) for the *manipulation* participants with the intuitive interface and stereoscopic depth perception of the target structure. Luursema et al. (2006) used a similar program and found that the combination of stereopsis and dynamic exploration to be beneficial for anatomy learning.

There are some limitations in this study. Regarding the dependent measure, the drawing test, it could be argued that assessing the accuracy of visualization by evaluating a participant's drawings may favor participants who have good drawing skills, while disadvantaging participants who may have successfully understood the visual features of the anatomical structures but were less skilled at transmitting their understanding onto several sheets of paper. One way that a future study might be able to address this limitation is to complement the drawing test with an interview of the participant in which the participant would describe his or her understanding of the anatomical structures and/or explain what he or she was trying to draw.

Another potential confound that exists in this study relates to the yoked-pairs design. Although this design is effective in terms of providing the participants in both conditions with the same visual information, it may be argued that certain strategies employed by the *manipulation* participant may make no difference, or may in fact actually hinder the *visual* participant when studying the model. For example, the wiggling that was used by many top performing *manipulators* may have introduced noise or confusion to the yoked, *visual* participant, which in turn made learning less effective. It is possible that a future study where the *visual* participant watches a recording of a high scoring *manipulation* participant without the wiggling could lead to results where learning is equalized.

The findings from this study present significant implications for the potential role of virtual reality in educational settings generally, as well as in field of medical education. Perhaps most significantly, this study suggests

that it is possible to embody internal anatomical structures that are not generally visible or familiar to people. While it has been known for some time that we embody wrists and hands, it has not previously been shown that we may be able to embody an internal structure we are not even aware of, such as components of the inner ear. It follows logically that if it is possible to embody the inner ear with its substructures (e.g., semi-circular canals and the facial nerve), perhaps it is also possible to embody the spleen or the liver or the heart. While further research in this area is warranted, if it is in fact the case that it is possible to embody other parts of our anatomy, then there may be benefits to approaching the teaching of anatomy with an understanding of embodied cognition in mind.

Abstract

Testing students as they study a set of facts is known to enhance their learning (Roediger & Karpicke, 2006). Testing also provides tutoring software with potentially valuable information regarding the extent to which a student has mastered study material. This information, consisting of recall accuracies and response latencies, can in principle be used by tutoring software to provide students with individualized instruction by allocating a student's time to the facts whose further study it predicts would provide greatest benefit. In this paper, we propose and evaluate several algorithms that tackle the benefit-prediction aspect of this goal. Each algorithm is tasked with calculating the likelihood a student will recall facts in the future given recall accuracy and response latencies observed in the past. The disparate algorithms we tried, which range from logistic regression to a Bayesian extension of the ACT-R declarative memory module, proved to all be roughly equivalent in their predictive power. Our modeling work demonstrates that, although response latency is predictive of future test performance, it yields no predictive power beyond that which is held in response accuracy.

Keywords: intelligent tutoring, ACT-R, Bayesian inference, fact learning

Introduction

An effective way to teach facts is to test students while they are studying (Roediger & Karpicke, 2006). For example, if a student is learning the meanings of foreign words, an appropriately designed tutoring system would display a foreign word, ask the student to guess the English translation, and then provide the correct answer. In this work, we consider the case where students undergo several rounds of this type of study. By convention, we refer to the group of rounds as a *study session*. At the end of a study session, students have had several encounters with each item being studied. In addition to promoting robust learning, testing students during study provides valuable information that can in principle be used to infer a student's current and future state of memory for the material. Through the use of a student's performance during study to predict recall at a subsequent test, informed decisions can be made about the degree to which individual facts would benefit from further study. In this paper, we explore

algorithms to predict a student's future recall performance on specific facts using both the accuracy of the student's responses during study, and their response latencies—the time it took to produce the responses. In principle, other information is available as well, such as the nature of errors made and the student's willingness to guess a response. However, we restrict ourselves to accuracy and latency data because such data are independent of the domain and the study question format. Thus, we expect that algorithms that base their predictions on accuracy and latency data will be applicable to many domains.

Predicting future recall accuracy from observations during study can be posed as a machine learning problem. Given a group of students for whom we have made observations, we divide the students into “training” and “test” groups. The training group is used to build predictive models whose performance is later evaluated using the test group. We developed several predictive models and describe them later in this paper. Of particular interest is a method we call Bayesian ACT-R (BACT-R). It is based on the declarative memory module of the ACT-R cognitive architecture (Anderson, Byrne, Douglass, Lebiere, & Qin, 2004). The module has equations that interrelate response latency during study, accuracy during study, the time periods separating study sessions from one another and from the test, and the probability of a correct answer at test. However, these equations have a large number of free parameters which makes it challenging to use the model in a truly predictive manner. BACT-R is a method for using Bayesian techniques to infer a distribution over the free parameters, which makes it possible to use the ACT-R equations to predict future recall.

This paper is organized as follows: first, we describe the experiment from which we obtained accuracy and latency data for a group of students studying paired associates. Next, we describe BACT-R and three other models we built to predict student recall in the experiment. Finally, we evaluate and discuss the performance of the algorithms.

Data

Our data are from an unpublished experiment by Pashler, Mozer, and Wixted (unpublished) in which 56 undergraduates tried to learn the disciplines of 60 relatively obscure Nobel prize winners. In an initial pass through the material, subjects were shown the names of the prize-winners paired with their disciplines. Each winner-discipline pair was displayed for five seconds. For each prize winner's name, subjects were given either three or six study opportunities during which they could guess the discipline. For each guess, they received auditory feedback that signaled whether or not the guess was correct. If it was incorrect, the correct answer was displayed on the screen. For these study trials, subjects responded by pressing one of four keys on a keyboard (the experiment involved only three disciplines, and a fourth key indicated "no guess"). During study, both the accuracies and latencies of the subjects' responses were recorded. Two weeks following study, subjects were evaluated in a cumulative test over all the material. The cumulative test was given in the same format as the study trials.

Approaches to Predicting Recall Performance

In our machine learning approach to predicting student recall at test, we split subjects into training and test groups. For both the training and test groups, we gave our algorithms access to response accuracies and latencies obtained during the study session. Additionally, we gave the algorithm access to the response accuracies at the cumulative test session for only the training group. In this section, we describe four increasingly complex algorithms designed to learn from the training group in order to make predictions about the test group.

We use the information from the training subjects to build a model that we apply to the test subjects to predict the probability that they will answer correctly when tested. The model is then evaluated on the test subjects: for each subject s in the test group and item i being learned, we use the model to predict the probability that s correctly recalled i , and compare this prediction to the observed accuracy. In the future, we will refer to s and i as a "subject-item pair."

Because all subjects learned the same set of items, it is possible to use the performance of the training group on a particular item to inform the predicted performance of the test group on this item. We chose to avoid methods that do this because they are restricted to situations where data are available for a large number of subjects learning the same set of items. In principle, the methods we explore here might work even if individuals learned different items chosen from the same domain.

Percentage Classifier

This was the simplest method we examined: given a subject-item pair, the predicted probability of a correct answer at test is simply the fraction of correct answers given during study. Unlike the other methods we describe in this section, the percentage classifier does not use data from the training

Figure 1: The grid used by the histogram classifier for subject-item pairs that had six study trials. Shading indicates the fraction of those subject-item pairs in the cell that had a correct answer at test. In this figure, the number of bins has been fixed. In practice, it is chosen by cross-validation and is unique to each test subject.

subjects — the only information came from the subject's own responses during study.

Histogram Classifier

For this method, we specified each subject-item pair by two numbers: the fraction of correct answers during study and the mean latency of the correct answers. We then formed two grids, one for the subject-item pairs that had three trials and another for the pairs that had six. The grids were formed in the following way: one axis had n numbers, such that each interval between two successive numbers contained an equal number of the mean latencies for the training set. n is a parameter of the model and was chosen by cross-validation. The other axis contained either four (for the three-session grid) or seven (for the six-session grid) numbers, such that each interval between two successive numbers contained exactly one of the possible fractions of correct answers. Each training example could then be placed in exactly one of the grid cells. For each cell, we found the number of training examples that fell within the cell and how many of these corresponded to a correct answer at evaluation. This enabled us to find, for each cell, a fraction correct. Given a test subject-item pair, we then found which cell it would fall into based on study performance and predicted that its probability of being correct at evaluation would be that cell's fraction correct. Figure 1 shows the grid for the six-trial case. Note that to display the figure, we had to fix the number of bins. In reality, since this number was chosen by cross-validation, it would be different for each test subject. In the grid shown in the figure, if a subject had a mean RT of 0.5 seconds for their correct answers and answered all study questions correctly, they would fall in the upper left hand cell, and have a predicted probability of future accuracy of about 0.6.

Logistic Regression

Logistic regression is a powerful prediction technique used in statistics and machine learning. In its simplest form, logistic regression takes the values of some number of predictor variables x_i (which may be either binary or continuous) corresponding to an input and then outputs a prediction of the probability that the input belongs to one of two classes. This probability of membership in one of the classes is given by:

$$f(x_1, \dots, x_n) = \left[1 + \exp(-\beta_0 - \sum_{i=1}^n \beta_i x_i) \right]^{-1}$$

The weights β_i are to be learned. β_0 is an offset term.

In this application, the predictor variables x_i are the latencies and accuracies obtained during study. More specifically, to predict the probability of a correct response at test for a subject-item pair with three study trials, we use six predictor variables. Three of these are binary and indicate whether each of the three answers given during study were correct or incorrect. The other three variables are the response latencies for the study answers and are therefore continuous. The predictor variables are constructed analogously for the six trial cases. The two classes are “correct answer at test” and “incorrect answer at test.”

BACT-R

ACT-R is an influential cognitive architecture whose declarative memory module is often used to model recall follow a series of study sessions (e.g., Pavlik and Anderson (2008)). ACT-R assumes a separate trace is laid down each time an item is studied. Each trace decays according to a power law, t^{-D} , where t is the age of the memory and D is the decay rate. Following N study episodes, the activation for an item combines the trace strength of individual study episodes. It is governed by the equation:

$$A(\mathbf{t}, D, B, c) = \log \left(\sum_{j=1}^N t_j^{-D} \right) + B + \epsilon, \quad \epsilon \sim f(x; c)$$

where A is activation, B is a base activation level, ϵ is a noise term drawn from a logistic distribution with mean zero. That is, ϵ has the density function $f(x; c) = \frac{1}{4c} \text{sech}^2 \frac{x}{2c}$, where c is a free parameter. Recall probability is related to activation by:

$$P(\text{correct recall} | A; \tau, c) = \left[1 + \exp \left(\frac{\tau - A}{c} \right) \right]^{-1}$$

where τ is a free parameter. According to the model, latency (RT) is related to activation by:

$$\text{RT}(A, F, f) = F e^{-fA}$$

where F and f are free parameters. In total, there are six free parameters whose values we must estimate from the data: D, B, c, τ, F, f . Of these, we assume that c, τ, F, f are to be chosen for each subject-item pair, while the trace decay D and base-level activation term B are fixed for each subject.

For each subject-item pair we have a set of study-trial accuracies and latencies, and we can compute the likelihood of these data for any parameter vector. To do this, we plug the parameters into the equations to generate predictions for study trials and then compare these predictions to actual results of the study trials. More explicitly, we do likelihood-weighted sampling. For a given test subject, we take n_S samples from prior distributions of the six parameters. For each item, we compute the likelihood L of each set of parameters that have been generated. The final prediction of the probability of a correct answer at test is then:

$$\hat{P} = \sum_{i=1}^{n_S} P([D, B, c, \tau, F, f]_i) \frac{L([D, B, c, \tau, F, f]_i)}{\sum_{j=1}^{n_S} L([D, B, c, \tau, F, f]_j)}$$

where \hat{P} is the prediction. The likelihood of a set of parameters with respect to a given subject-item pair is given by the product of its likelihood on each study trial:

$$L(D, B, c, \tau, F, f) = \prod_{i=1}^{n_{\text{trials}}} l_{\text{acc}}^i l_{\text{RT}}^i,$$

where i runs over study trials, and l_{acc} and l_{RT} denote the contribution to the likelihood of the accuracy and response latency. The l_{acc}

$$l_{\text{acc}}^i = \begin{cases} P(\text{correct recall} | \hat{A}; \tau, c) & \text{if response } i \text{ is accurate} \\ 1 - P(\text{correct recall} | \hat{A}; \tau, c) & \text{otherwise} \end{cases}$$

Here, $\hat{A} = A(\mathbf{t}, D, B, c)$.

$$l_{\text{RT}}^i = \begin{cases} \frac{1}{4c} \text{sech}^2 \frac{\hat{\epsilon}}{2c} & \text{if response } i \text{ is accurate} \\ 1 & \text{otherwise} \end{cases}$$

where $\hat{\epsilon} = \log \left(\frac{\text{RT}^i}{\text{RT}(\hat{A}, F, f)} \right)$ and RT^i is the observed latency on the i th study trial. The intuition is that for a given set of parameters, we calculate how much noise would be necessary for these parameters to produce the observed latency and then take the likelihood to be the probability of observing this noise level. We used 250 samples for likelihood-weighted sampling. We found that increasing this number did not noticeably improve performance. One implementation detail should be noted: since the interval between study and test is so much larger than the interval between study sessions, we followed Pavlik and Anderson (2008) and compressed the interval between study and test into what they call “psychological time” via a small multiplicative factor.

To define priors for the six parameters, we use the fact that the framework above allows us to find, for each subject, maximum likelihood estimates for the parameter values. We do this for a group of training subjects and compile the results in a histogram. We then fit the results for each parameter to a probability distribution which is then that parameter’s prior. In practice, the optimization routine we used to do the likelihood maximization did not converge for all subjects. The

Figure 2: A set priors used in BACT-R. To set these priors, we find the maximum likelihood parameter values for each of the subjects in the training group, compile these estimates into histograms, and then fit the data for each parameter to a continuous probability distribution.

subjects for which it failed to converge were left out of the calculation of the prior. A set of priors, together with the histograms used to define them, are shown in Figure 2. This figure shows that the histograms were generally sharply peaked.

Results

To evaluate the different methods we tried, we used leave-one-out cross-validation. Each subject in turn was held out as a test subject and a prediction for that subject was made by models trained on all the other subjects. This prediction takes the form of a probability between zero and one. Because the data with which we have to compare these predictions are binary — a subject’s response is either correct or incorrect — we thresholded the probability so that the predictions also become binary. After thresholding, the models’ predictions are either true positive, false positive, true negative, or false negative. Adjusting the threshold changes the number of predictions that fall into each of these categories. In Figures 3-8 (to be described shortly), we summarize the threshold manipulation with an ROC curve, which plots the false positive rate versus the true positive rate for various thresholds. If the ROC curve falls exactly on the dashed diagonal line in the figures, then the method achieves results equivalent to chance prediction. In general, the more bowed the ROC curve, the better the performance of the model.

Comparison of methods

The results obtained by the various methods we tried are shown in Figure 3. As this figure shows, all the methods performed almost equally well. In particular, BACT-R did not outperform other methods we tried. It is interesting to note that this implies that the *order* of correct and incorrect

Figure 3: ROC curves for the methods we tried. A comparison shows that all methods perform similarly.

responses, which is information to which BACT-R had access and the percentage classifier did not, seems not to have enabled BACT-R to outperform the percentage classifier. Of course, this does not necessarily mean that there is no useful information contained in the order data.

Relative Importance of Latency and Accuracy Information

We next examined how much information, if any, is contained in the latency data. Our findings are mixed. On the one hand, logistic regression and BACT-R performed just as well with the latency information removed as with it included (see Figures 4 and 5, respectively). On the other hand, when provided only with latency information, logistic regression yielded results significantly better than chance (Figure 4).

We also examined the weights given by logistic regression to latency and accuracy features. The inputs to logistic regression are normalized so that it is meaningful to compare the magnitudes of these weights. The mean magnitudes of the weights for accuracy and latency data are 0.3884 and 0.0751, respectively. The mean weight for the latencies is considerably smaller than the mean weight for the accuracies; it is not negligible. Thus, there is information in the latencies, but it is to a large extent redundant with the information from the accuracies.

The fact that latency information does not improve the performance of our methods may shed some light on our methods performing equivalently: no method took advantage of the latency information; all the information present in the accuracy information reduced to the percentage correct during study. Therefore, all methods did almost exactly as well as the percentage classifier.

Figure 4: ROC curves for logistic regression, when the model was trained with all available data (“log reg”), only accuracy data (“log reg acc”), and only latency data (“log reg RT”). Removing the latency information does not degrade logistic regression’s performance. However, using only the latency information gives results that are significantly better than random. We conclude that the latencies contain information, but that this information is redundant with the accuracy information, and does not help with classification.

Number of Study Trials

Figure 6 shows the performance of BACT-R when restricted to only the three- or the six-trial study conditions.

As expected, BACT-R performed better with six trials than with three, but the difference is not drastic. This is significant because it rules out the possibility that the BACT-R’s performance was being dragged down by the three-session cases.

Another experiment we did involved applying logistic regression to only the first study session. In general, we have data from either three or six study trials for each subject-item pair. For this experiment, we used only the first of these. Apart from this, logistic regression was applied in the same way as before. The motivation for this experiment was the hypothesis that even if the accuracy information dominated the latency information when we used all the trials available, perhaps it would contribute more if we used only one trial. In fact, this was what we observed, as is shown in Figure 7, which indicates that, in the one-trial case, adding the latency information to the accuracy information gives a substantial improvement in performance. In addition, we see that it is possible to get reasonably good predictive performance even when we use information from only one trial.

Effect of Priors on BACT-R

In order to examine how much information was contained in the priors we used for BACT-R, we tried replacing the priors chosen by maximum likelihood with uniform priors having mean zero and length four, values that were chosen heuristi-

Figure 5: ROC curves for BACT-R when the method uses all available data, only the accuracy data, and only latency data. As with logistic regression (Figure 4), removing latencies does not noticeably hurt the performance of BACT-R. Using only latencies with BACT-R gives worse performance than it does with logistic regression.

cally based on Figure 2. As Figure 8 shows, the results were noticeably worse than the results obtained with the maximum likelihood priors. This is a validation of the Bayesian approach, since it shows that the performance of the model was due, at least in part, to the knowledge contained in the prior distributions used for the parameters.

Variants

In addition to the methods described above, we tried several variants. For example, we tried replacing raw latencies with z-scores and including latencies from incorrect trials. We also tried assigning greater weight to information from later trials, since these were closer to the test time. No variant we tried significantly altered the performance of the models.

Discussion

Testing students as they study facts is known to be better than just having them reread the facts (Roediger & Karpicke, 2006). Testing has a side benefit: it produces feedback from the student which potentially could inform an intelligent tutoring system about how well the student has learned the facts. In this work, we described an experiment in which feedback was collected from students learning to identify the disciplines of 60 Nobel Prize winners. This feedback took the form of response accuracy and latency during a study session in which each fact was reviewed multiple times. Using data from the study session, we are able to predict memory for individual facts after a two-week retention interval.

We found that latency data alone was predictive. To the best of our knowledge, this finding has not been reported before in modeling literature. However, we also found that

Figure 6: A comparison of the performance of BACT-R on the three-trial and six-trial subject-item pairs. Since six study trials give more feedback than three study trials, we expected BACT-R to perform better for these cases. As the figure shows, this is what we observed. Also as expected, we see that the three-study trial cases gave worse performance. However, BACT-R's performance on the three-study trial cases was not sufficiently degraded to conclude that these trials are responsible for BACT-R's inability to outperform the other methods we studied.

adding latency data to accuracy data did not improve the performance of our models, suggesting that the latency information was redundant with the accuracy information.

We found that all the predictive models had similar performance, including a model based on ACT-R's declarative memory module, which is one of the best developed and evaluated high-level theories of human memory. Although BACT-R did not outperform other models, we believe that the addition of Bayesian uncertainty integration to the ACT-R framework is a promising idea that should be explored in other contexts. We also believe that the use of latency information for prediction of future recall warrants further study, especially when the feedback data are sparse (e.g., Figure 7, which shows the benefit of latencies when we have feedback from only one trial). Further, it would be interesting to see if the latency information from an experiment specially designed to elicit fast latencies would be more informative than the latencies from this experiment.

In one sense, our conclusions are not astonishing: accuracy of recall during study predicts accuracy of recall at a subsequent test. However, it is important that we have made this intuitively obvious relationship quantitative and that we have explored multiple computational approaches that can exploit the relationship to make concrete predictions of future recall performance.

Abstract

Theories of the development of analogical reasoning emphasize either the centrality of relational knowledge accretion or changes in information processing. Recent cross-cultural data collected from children in the United States and China (Richland, Chan, Morrison, & Au, 2010) provides a unique way to test these theories. Here we use simulations in LISA/DORA (Doumas, Hummel, & Sandhofer, 2008; Hummel & Holyoak, 1997, 2003), a neurally-plausible computer model of relational learning and analogical reasoning, to argue that the development of analogical reasoning in children may best be conceptualized as an equilibrium between knowledge accretion and progressive improvement in information processing capability. Thus, improvements in inhibitory control in working memory as children mature enable them to process more relationally complex analogies. At the same time, however, children produce more complex and more accurate analogies in domains in which they have learned richer and more refined representations of relational concepts.

Relational thinking—i.e., thinking based on the roles that objects play rather than the literal features of those things—is a cornerstone of human cognition. It underlies, among many other things, our ability to make analogies, or to appreciate correspondences between domains (e.g., Holyoak & Thagard, 1995).

As with many cognitive processes, our ability to make analogies changes with development. While there is considerable agreement that analogy is a very important process in cognitive development (e.g., Gentner, 2003), there is considerable disagreement as to how the ability to reason analogically develops.

Theories of the Development of Analogical Reasoning

Three primary hypotheses have been put forward to explain age-related differences in analogical reasoning: changes in domain knowledge, a relational shift from object similarity to relational similarity, and increased processing or working memory (WM) capacity.

Goswami and colleagues (Goswami, 1992, 2001; Goswami & Brown, 1989) proposed that the ability to make analogies is present even in early infancy. However, children can only evidence this ability with age and increased knowledge. In other words, the change in children's ability to make analogies is not a function of a developing mechanism, but rather knowledge accretion.

Alternately, Gentner and Rattermann (1991; Rattermann & Gentner, 1998) argued that a domain-specific “relational shift” is responsible for changes in children's analogical abilities. Gentner and Rattermann suggest that as children build knowledge in a particular domain they progress from reasoning about that domain in terms of the perceptual features of objects, to the relations between those objects. For example, 3 year-old children will categorize objects based on overall featural similarity (e.g., they will match apples to red balls rather than bananas), however by age 4 or 5, children will categorize objects based on relational similarity (e.g., matching apples to bananas even in the presence of featural distracters like red balls; Gentner & Namy, 1999). The ability to make analogies based on relational commonalities between domains, therefore, progresses on a domain-by-domain basis with more complex analogies produced in domains in which knowledge is richer.

In contrast to accounts of analogy development based on increases in knowledge, the relational complexity hypothesis of Halford (1993; Andrews & Halford, 2002; Halford et al., 2002) holds that limits in children's WM capacity affects their ability to process relations simultaneously, and therefore their ability to make analogies. According to Halford and colleagues, children can process only specific levels of relational complexity, defined as the number of sources of variation that are related and must be processed together. The simplest level of relational complexity is a binary relation, where only two arguments are sources of variation. The relation, *chase* (dog, cat), for instance, specifies a single relation (*chase*) between two objects (dog, cat). To reason about this relation, a one must keep only the two objects and their relation in mind. A ternary relation (e.g.,

gives-to (boy, girl, book) is more complex, requiring a reasoner to consider three objects and their respective roles. The more complex the relation, the more WM resources are required to process it. As children mature, neural developments leading to increased WM capacities (see, e.g., Diamond, 2002) allow processing situations with greater relational complexity, and, by extension, children are capable of drawing richer and more complex analogies.

Likewise, Richland, Morrison, and Holyoak (2006) proposed that inhibitory control might help to explain the relationship between maturation and the impact of relational complexity on analogical reasoning in young children. While inhibitory control has been a major topic in models of cognitive development (Bjorklund & Harnishbeger, 1990; Diamond, 2002) it has not previously been applied to understanding the development of analogy; however, the hypothesis that inhibitory control is important for the development of analogy is consistent with results from other cognitive tasks (e.g., Diamond, Kirkham & Amso, 2002; Lorschach & Reimer, 1997; Zelazo et al., 2003).

Multiple Sources in Analogical Development

Richland, Morrison and Holyoak (2006) developed a set of scene analogy problems to investigate relational complexity and featural distraction within a single analogical reasoning task. They found that children from age 3 to 14 steadily improved in their ability to solve more relationally complex problems and resist distraction.

In a follow-up study Richland, Chan, Morrison, and Au (2010) used these same problems with Cantonese speaking 3-4 year old children from Hong Kong. While US children of this age showed main effects of both relational complexity and featural distraction, Chinese children only showed an effect of featural distraction (see Figure 5).

There are several reasons to believe that the Chinese children would score differently on analogical reasoning problems than U.S. children based on their knowledge base and experience with reasoning about relations. Adult studies have shown cultural differences in normative patterns for drawing relational inferences (see Nisbett 2003) such that Chinese and Japanese reasoners may be more attuned to relational correspondences than U.S. participants. These differences also appear cross-culturally in children's socialization and linguistic routines. For example, Asian caregivers use more action oriented language and referential verbs than relatively object-focused U.S. caregivers (e.g., Chinese: (Mandarin) Tardif, 1996; Tardif, Gelman & Xi, 1999; Tardif, Shatz, Naigles, 1997; (Cantonese) Leung, 1998). Chinese children themselves may additionally show a higher relative rate of verb usage in Mandarin (Tardif, 1996; 2006; Tardif, Shatz, & Naigles, 1997; Tardif, Gelman, & Xu, 1999) than U.S. children of comparable ages who show a more pronounced noun bias. In contrast, there is

no theoretical reason to expect differences in information processing capacity between the US and Hong Kong (Hedden, et al., 2000).

Accordingly, Richland et al. (2010) reasoned that the US and HK 3-4 year old children each had decreased inhibitory control relative to older children resulting in their distractibility, but that HK children had more sophisticated relational representations than US children resulting in their superior ability to solve more relationally complex problems.

A Computational Account of the Multiple-Source Theory of Analogical Development

Previous Work

Traditionally, researchers have attempted to model the effects of knowledge accretion and increased working memory capacity on analogical development in isolation. For example, Gentner and colleagues (e.g., Gentner et al., 1995) used SME (Falkenhainer, Forbus, & Gentner, 1989) to model the relational shift data of Gentner and Rattermann (1991). Gentner et al. captured the differences in analogical reasoning in 4 and 5 year-old children by providing the model with more relational representations at age 5 than at age 4. That is, with limited knowledge of relations, the model behaved like the younger children in Gentner and Rattermann's experiments, making analogies based on over-all perceptual similarity. However, with increased relational knowledge, the model behaved more like the older children, making analogies based on shared relations. Importantly the representations provided to the model had to be hand-coded by the modeler.

More recently, Morrison, Dumas, and Richland (2006), used the LISA model (Hummel & Holyoak, 1997, 2003) in an attempt explain changes in children's analogy making in terms of changes in capacity limits. LISA is a model of analogy-making that relies on time as a signal to bind distributed (i.e., connectionist) representations of objects and relational roles into structured (i.e., symbolic) representations. LISA is powerful, in part, because it benefits from both the flexibility of connectionist approaches and the structure-sensitivity of symbolic approaches (an important property for demonstrating human like relational reasoning; see, e.g., Dumas & Hummel, 2005; Holyoak & Hummel, 2000; Penn, Holyoak, & Povinelli, 2008). In addition, as a consequence of using time to carry binding information, LISA suffers from capacity limitations that mirror those of human WM (Hummel & Holyoak, 2003; Morrison, Dumas, & Richland, 2006; Morrison et al., 2005). LISA relies on lateral inhibition between units to establish the temporal patterns that carry binding information. By decreasing lateral inhibition, LISA's WM is effectively reduced. Morrison et al. (2006), used this property of to capture the pattern of results from Richland et al. (2006).

Approaches using SME and LISA both suffer from limitations, though. First, each approach is based on a

single explanatory variable. As a result, the knowledge accretion approach seems insufficient to explain the results of the Scene Analogy task (see Richland et al., 2006), while the simply changing capacity limits cannot explain the cross-cultural findings of Richland et al. (2010). In addition, both approaches rely on hand-coded relational representations that must be added by the modeler. Neither model makes any claims where these representations, which both models require in order to reason relationally—and that provide the explanatory mechanism in the knowledge accretion case—come from in the first place.

Doumas, Hummel, and Sandhofer (2008) have developed an extension of the LISA model, called DORA (*Discovery of Relations by Analogy*) that learns structured representations of relations from unstructured (i.e., flat feature vector) representations of object properties. DORA provides a means by which the representations used by LISA are learned from examples, and, consequently, provides an opportunity to understand the interplay between the dual sources of knowledge accretion and increasing capacity limits as effectors of the changes in children's analogy making.

The LISA/DORA model

LISA (Hummel & Holyoak, 1997, 2003) is a symbolic-connectionist model of analogy and relational reasoning. DORA (Doumas et al., 2008) is an extension of LISA that learns structured (i.e., symbolic) representations of relations from unstructured inputs. That is, DORA provides an account of how the structured relational representations LISA uses to perform relational reasoning can be learned from examples.

DORA accounts for over 20 phenomena from the literature on relational learning, as well as its development (e.g., Doumas & Hummel, 2010; Doumas et al., 2008). In addition, as DORA learns relational representations, it comes to take LISA as a special case, and can simulate the additional 30+ phenomena in relational thinking simulated by LISA. The description of LISA/DORA that follows is a brief overview due to space constraints. For full details of the models and their operations see Doumas et al. (2008) and Hummel and Holyoak (1997, 2003).

LISAese Representations In LISA (and DORA *after* it has gone through learning) relational structures are represented by a hierarchy of distributed and localist codes (see Figure 1). At the bottom, “semantic” units represent the features of objects and roles in a distributed fashion. At the next level, these distributed representations are connected to localist units (POs) representing individual predicates (or roles) and objects. Localist role-binding units (RBs) link object and predicate units into role-filler binding pairs. At the top of the hierarchy, localist P units link RBs into whole relational propositions.

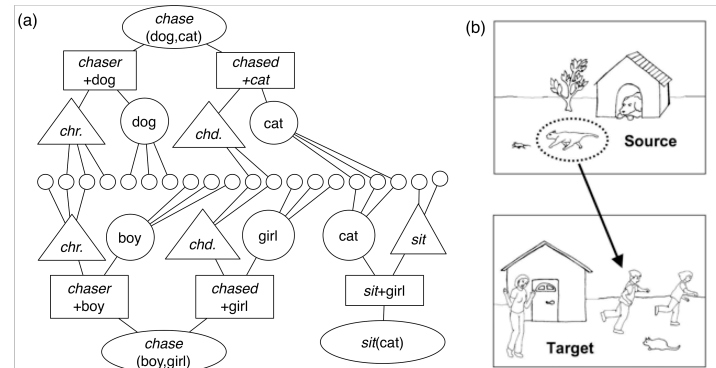

Figure 1. (a) Representation of a LISA/DORA representation like that used to simulate a Scene analogy problem like that in (b). The P (oval), RB (rectangle), and predicate (triangle) units were learned during Simulation Part One. Objects (circles) described the objects involved in the Scene Analogy problem. (b) Example of a scene analogy problem from Richland et al., 2006.

Propositions are divided into two mutually exclusive sets: a driver and one or more recipients. In LISA/DORA, the sequence of firing events is controlled by the driver. Specifically, one (or at most three) proposition(s) in the driver becomes active (i.e., enter working memory). When a proposition in the driver becomes active, role-filler bindings must be represented dynamically on the units that maintain role-filler independence (i.e., POs and semantic units; see Hummel & Holyoak, 1997). In LISA binding information is carried by synchrony of firing (with roles firing simultaneously with their fillers). In DORA, binding information is carried by systematic asynchrony of firing, with bound role-filler pairs firing in direct sequence (see Doumas et al., 2008 for details).¹ Activation flows from the driver units to their semantic units. Units in the driver and recipient share the same pool of semantic units. Thus, units in the recipient become active in response to the pattern of activation imposed on the semantic units by the active driver proposition.

Relational Learning Very simply, DORA uses comparison to isolate shared properties of objects and to represent them as explicit structures. DORA starts with simple feature-vector representations of objects (i.e., a node connected to set of features describing that object). When DORA compares one object to another, corresponding features of the two representations fire simultaneously. Any semantic features common to both objects receive twice as much input and thus become roughly twice as active as features connected to one but not the other. By recruiting a new PO unit and learning connections between that unit and active semantics via Hebbian learning (wherein the strength of connections is a function of the units' activation), DORA learns stronger connections between the new PO unit and more active

¹ Asynchrony-based binding allows role and filler to be coded by the same pool of semantic units, which allows DORA to learn representations of relations from representations of objects (Doumas et al., 2008).

semantic units. The new PO thus becomes an explicit representation of the featural overlap of the compared objects. Applied iteratively this process results in explicit and structured representations of object properties and relational roles (see Dumas et al., 2008). Comparison also allows DORA to learn representations of multi-place relations by linking sets of constituent role-filler pairs into relational structures (i.e., to learn the *chases* relation by linking together representations of the roles *chaser* and *chased*; see Dumas et al., 2008 for details).

Mapping For the purposes of analogical mapping, LISA/DORA learns *mapping connections* between units of the same type (e.g., PO, RB, etc.) in the driver and recipient (e.g., between PO units in the driver and PO units in the recipient). These connections grow whenever corresponding units in the driver and recipient are active simultaneously. They permit LISA to learn the correspondences (i.e., mappings) between corresponding structures in separate analogs. They also permit correspondences learned early in mapping to influence the correspondences learned later.

Simulations

Methods

We tested the hypothesis that differences in performance between U.S. and Chinese children were due to differences in relational knowledge. Specifically, we hypothesized that the relational representations of children from Hong Kong were more developed than those of children from the U.S. We used LISA/DORA to test this hypothesis by simulating the results of Richland et al. (2010). The simulation consisted of two complementary parts. In the first part we used DORA to develop representations of relational concepts from examples. We simulated the difference in U.S. and Chinese children by allowing DORA increased learning trials in order to simulate the Chinese children, reflecting the assumption that the experience of children in Hong Kong differs from children in the U.S. We then used the representations that DORA had learned during the first part of the simulation to simulate the Richland et al. (2010) task.

Simulation Part One We used DORA's relational learning algorithm (see Dumas et al., 2008 for details) to develop relational representations from unstructured examples. We started DORA with representations of 100 objects attached to random sets of features (chosen from a pool of 100). We then defined 4 relations (*chase*, *reach-for*, *angry-with*, and *hang-from*). Each relation consisted of two roles, each with three semantic features (e.g., for the *chase* relation, both the roles *chaser* and *chased* were each defined by three specific semantic units). Each of the 100 objects was attached to the features of between 1 and 3 relational roles chosen at random. For example, object1 might be attached to the features for *chaser* (one role of *chases*) and *reaching* (one role of *reach-for*). On each

iteration we presented DORA with sets of objects from similar relations, and allowed it to compare the objects and learn from the results (as per DORA's relation learning algorithm). As DORA learned new representations it would also use these representations to make subsequent comparisons. For instance, if DORA learned an explicit representation of the property *chases* (x, y) by comparing sets objects attached to the roles of *chase* (i.e., *chaser* and *chased*), it could use this new representation for future comparisons. On each trial we selected between 2 and 4 representations and let DORA compare them and learn from the results (i.e., perform predication, and relation learning routines).

We ran 25 sessions each consisting of 800 learning trials. During each session, the inhibition parameter was set to a value sampled from a random distribution with a mean of 0.7, and a standard distribution of 0.1. The value of the parameter reflected the reduced WM capacity evidenced in young children (see Morrison et al., 2006).. We measured the quality of the representations DORA had learned during the last 100 trials after each 100 trials. Quality was calculated as the mean of connection weights to relevant features (i.e., those defining a specific transformation or role of a transformation) divided by the mean of all other connection weights + 1 (1 was added to the mean of all other connection weights to normalize the quality measure to between 0 and 1). A higher quality denoted stronger connections to the semantics defining a specific relation relative to all other connections (i.e., a more pristine representation of the relation). Figure 2 shows the quality of the representations DORA learned for each set of 100 comparisons from 100 to 800. As expected, the quality of the representations DORA learns increase as a function of experience (see Dumas et al., 2008 for more details)

Figure 2. Quality of the representations DORA learned during Simulation Part One.

Simulation Part Two To model the Scene Analogy Problems we used representations of the four problem types (1-relation, no distracter; 1-relation, distracter; 2-relation, no distracter; 2-relation, distracter) composed from the representations DORA had learned during Simulation Part One. For example, to represent the problem from Figure 1, we used a representation of the *chase* relation DORA had learned during Simulation Part One (relational role, RB, and P units) along with object units (e.g. boy and girl) composed of 5 semantic features describing that object (see Figure 1). For 2-Relation problems both relations were represented in LISA's WM together (Hummel & Holyoak, 1997). Vitally, we simulated children from the U.S. by using the representations DORA had learned after only 400 comparisons, and those of the children from Hong Kong using the representations DORA had learned after 600 comparisons.

The lateral inhibition parameter was set exactly as in Simulation Part One. Each simulation run consisted of firing three phase sets in LISA/DORA's working memory, "randomly" assigned by LISA/DORA and allowing LISA/DORA to try to map the representation in the driver to the representation in the recipient. When LISA/DORA failed to determine a stable mapping after firing three phase sets, an answer was selected at random.

Results

The simulation results along with the experimental results from Richland et al. (2010) are presented in Figure 3. LISA/DORA's performance mirrored experimental results for the age groups from both the U.S. and China across conditions.

Figure 3: Experimental (Richland et al. 2010) and Simulation.,

General Discussion

In this paper we presented simulations in LISA/DORA that support the hypothesis that both maturation of inhibitory control in working memory and development of knowledge representations is critical for the development of adult-like analogical reasoning. Specifically, we demonstrated that simple changes in inhibition levels in LISA/DORA (i.e., inhibition between elements of competing relational representations in working memory) coupled with DORA's predicate learning routines could account for both relational complexity and featural distraction effects in young children's analogical reasoning performance across cultures. In contrast, approaches based on knowledge accretion and capacity changes in isolation seem unable to capture all of these results.

We conclude that both relational knowledge acquisition and inhibitory control in working memory shape an individual's analogical reasoning performance. We suggest that the development of analogical reasoning in children can be conceptualized as an interaction between these two factors. As children age their knowledge about relations advances while their working-memory capacity as modulated by inhibitory control also improves. At a given time during development, the child is able to perform an analogical task based on both their level of relational knowledge and their working-memory resources. Specifically, the equilibrium operates such that greater relational knowledge can impose fewer processing demands while less knowledge imposes higher demands. Thus, Hong Kong children given the same working-memory resources can better solve relational complex problems. Thus, as relational knowledge increases in a domain, the demands on working memory decline, allowing for more complex reasoning at any given age. This pattern in cognitive development builds on an understanding of working-memory effects in expertise (e.g., Chase & Simon, 1973) where advanced relational knowledge can decrease processing demands and thereby allow experts to accomplish cognitive tasks which novices cannot.

We believe that to truly understand the development of relational reasoning in children, future experimental and computational studies must take into account both advances in relational knowledge and changes in inhibitory control in working memory, and importantly, studying how these two aspects of development interact.

Discerning Affect in Student Discussions

Abstract

Students' emotions and attitudes are discernible in messages posted to online question and answer boards. Understanding student sentiment may help instructors identify students with potential course issues, optimize help-seeking, and potentially improve student achievement, as well as identify both positive and negative actions by instructors and provide them with valuable feedback. Towards this end, we present a set of context-independent emotion acts that were used by students in a university-level computer science course to express certainty and uncertainty, frustration, and politeness in an online Q&A board and develop viable classification approaches. To explore the potential of sentiment-based profiling, we present a heuristic-driven analysis of thread resolution and detail future research.

Keywords: student online discussions, discourse analysis.

Introduction

Online discussion boards are widely used in higher education, extending the availability of instructors, assistants, and materials to students beyond the traditional classroom. Students use discussion forums to collaborate, exchange information, and seek answers to problems from their instructors and classmates. Discussion board use is generally associated with improved academic performance and greater student satisfaction (Kumrow, 2005; Newman and Schwager, 1995).

Previous work on analyzing student discussions has been based on rhetorical speech acts, course topics, and problem tasks (Kim et al., 2007; McLaren et al., 2007). Classification systems for these features enable researchers to automatically identify student problems. Similarly, understanding student affect may help instructors identify students with potential course issues, optimize help-seeking, and potentially improve student achievement. In addition, by examining the results of different instructor-student interactions in terms of affect, instructors could potentially receive valuable feedback about their online interactions.

In this paper we present a set of dialogue features, or *emotion acts* (EAs), analogous to Speech Acts (Searle, 1969), that characterize student sentiment with respect to 1) frustration and tension, 2) high and low certainty (confidence) and 3) politeness. These sentiments were exhibited in student discourse within a question and answer (Q&A) board in an undergraduate Computer Science course. A discussion corpus consisting of 1,030 student posts was manually tagged with the emotion acts.

We describe the first stages of the development of practical classification for emotion acts and explore the potential of sentiment-based student profiling. Specifically, in this paper, we do the following:

1. Identify categories of affect exhibited in an online student discussion in an undergraduate CS course.
2. Examine the frequency of affect in the corpus by gender, role and types of participants.
3. Examine the influence of affect in instructor messages on student responses (discerned by affect).
4. Examine the correlation between affect and type of thread (resolved or unresolved).
5. Illustrate of how emotion acts can be used in assessing and predicting student discussion outcome.
6. Describe our approach to and initial results of automatically classifying three categories of affect.

Identifying Categories of Affect

It is extremely difficult to devise a category of affect labels given the gradations and subtlety of the way feelings and emotions are expressed in language. It is not surprising then that there is no general agreement on how to label affective content and that instead there exist a number of different labeling schemes for different domains (Ordelman and Heylen, 2005). However, previous work suggests that at least some affective content can be identified and selected for, independent of context. For example, acknowledgements are recognizable by the presence of common *politeness* phrases (Brown & Levinson, 1987), and may be used to indicate resolution in Q&A discussion; and *certainty* categorization was shown to assist in distinguishing between editorial and news writing (Rubin et al., 2006), and may be used to distinguish questions and answers by the presence and absence of student confidence.

Identifying a set of categories was an iterative process, and there were three criteria for selection: a) category examples had to be well represented in the corpus, b) researchers had to agree on the categories, and c) categories had to be relevant to student learning. Selection was originally motivated by the desire to identify students' self-efficacy and attitudes, although these categories were too abstract to be practical. We examined discourse that indicated confidence, interest and mastery, and also, urgency, understanding and technicality. Our final categories were *high and low certainty (confidence)*, *tension/frustration*, and *politeness*.

Tension (kappa: 0.74)	Examples
Instructor Judgments: Possible student issues with class attendance, judgment or choices	If you really want to do this; I stated in class on at least 2 occasions
Student Judgments: Possible student issues with questioner or target	Result of this sucks; Wow... That was..
Frustration (kappa: 0.92)	Examples
Repetitious Actions, Continual Actions: Descriptions of continuous actions without real progress	A lot (15+ times); Never seems to end; High rate of redundancy; Another can of worms
Large Quantities: Descriptions of overwhelming amounts of work and other material	Zillions of references; Super-huge; Simply gargantuan; Monstrous, super-verbose
Difficulty/Impassability, Material Denigration: Statements of explicit difficulty in either solution or understanding of issues, as well as frustration about the material itself	Serious disk quota problems; Severe annoyances; A pain to fix; Makes it really hard
Self-Denigration/Lack of Confidence: Declarations of a personal belief in a lack of ability on the part of the poster	I have spent FAR too long; ...I'm stumped; Longer than they should have
High Certainty (kappa: 0.80)	Examples
Specificity of Question/Answer: Specific phrasing that concisely explains through examples and pre-conditions	The only way; I found the answer; It only appears
Ease of Understanding/Completeness: Emphasis of the simplicity or completeness of a solution or question	The trick is; Just wait till; Will be simple; All you need to do is
Necessity: Specifically stating that the presented solution is required, or in the case of a question, its importance	Must be able to; Vitaly important task; Must have something; You will
Logical Presentation: A method of presenting a proposition, solution, or question that makes it a logical proposal	I assume that; Granted,; Likewise,; On the other hand,
Low Certainty (kappa: 0.95)	Examples
Vagueness in Question/Answer: Statements that imply only general or surface understanding of the material at hand by stating personal understandings over factual presentation	What is wrong?; If I understand; Seems to me; Read it somewhere
Lack of Understanding: Statements that clearly state a lack of understanding; differs from other Speech Acts as it implies a continuing lack, rather than an individual issue	I am still confused; Not sure if I understand; I follow most; I'm not sure
Optional Nature: Statements indicating a not strongly recommended or vital issue, solution, or question	Should be compiled from the network directory; You might try; ...maybe I'll try making; What is wrong?
Weakened Presentation: Phrases that weaken or justify logical proposal statements	Correct me if I am wrong; Apparently; I am guessing that is the way; As far I know
Politeness categories	Examples
Positive (kappa: 0.99): Language strategies used according to formal cultural rules to avoid losing face. Commonly identified as typical polite speech	Thanks; Okay thanks; Good luck with your project
Negative (kappa: 0.99): Dealing with a face-threatening act, by lightening the request or response into a less pressing, informal status.	I was wondering if; Thought I'd throw this out there; Get this cleared up early; Just a head's up,
Bald on record (kappa: 0.84): Dealing with a face-threatening situation by ignoring or emphasizing the consequences of the threat	I question the; don't bzero anything; Change it to this; Do we?
Off record (kappa: 0.82): Attempting to change the request or response into a non-face-threatening statement, i.e., by generalizing a query to a rather than asking for direct help	Has anyone else had this problem; What would do; Asking for answers directly is way easier

Table 1. Categories of affect – description and examples.

The final categories had high agreement among the research team, and thus had potential for use in an automatic classification system.

Annotation Methodology

Annotating affect involved identifying those speech fragments that reliably indicated an identified emotion act in a repeatable fashion throughout the corpus of student discussion board posts. This was complicated by the highly irregular nature of the message content, which was characterized by frequent misspellings and grammar and syntactical errors, stemming from common parlance, simple carelessness, and Computer Science student

subculture language use. This necessitated a high level of selectivity and repeatability in all annotations, as well as reliance on specific patterns of distinct phrases and grammar from within the corpus rather than whole statements.

Table 1 lists and describes the final EA categories. A dataset of 1,030 messages in 210 threads from an Operating Systems course was analyzed. Several iterations were performed until we minimized ambiguity among the categories and finalized clear EA definitions. For inter-annotator agreement, we compared two annotators' data on 322 messages in 30 discussion threads. For the current categories, the kappa values are

greater than 0.7. Some Politeness EAs show very high agreement ratios since the annotators consider them very clear and there are only small numbers of cases.

The labeling process consisted of EA classification as well as the marking up of contextual information within the message content. The markup included information about the type of response (question/query or answer/statement) and the role of the author (student, instructor, or TA).

Affect Frequency by Type of Participants

The final frequency distribution of emotion acts for messages posted by different participants within the dataset is shown in Table 2. Of interest are the high occurrences of low certainty and the relatively high frequency of frustration. Female students seemed to present less frustration than male students. Also, females present more positive politeness in their messages. As expected, the instructor's messages show high confidence. Among politeness categories, the instructor presents more bold-on-record politeness (BOR) than students.

We also looked at the presence of emotion acts among high and low frequency contributors. Figure 1 shows the distribution of different emotion acts for seven groups of contributors. As can be predicted from the distribution in Table 2, confidence and polite acts dominate. For the students who post many messages, the number of other emotion acts increases, especially confidence, but also frustration and negative politeness.

Influence of Instructor Affect on Students

The course instructor participated in discussions in many ways; he provided answers directly, gave alternative perspectives, supported student ideas, and elaborated on student answers. It is useful to analyze the influence of the instructor on student dialogue.

In Table 3, we consider what happens when an instructor exhibits emotion. It appears that students tend to express more emotion themselves (certainty, frustration, negative politeness) after an instructor shows emotion. Students appear to express high certainty when they respond to an instructor's high certainty. Similarly,

student frustration and low certainty can follow the instructor's expression of low certainty.

While these results show many interesting possible relationships between expressed emotion acts and topic success, the clear and immediate indication shows that emotion acts can show distinctions between different types of posts and threads, which prove their potential usefulness as a profiling mechanism.

Table 2. Distribution of Emotion Acts among participants.

Emotion Act	Percent Emotion Acts found in messages:			
	Total (N=1179)	Male Student (N=782)	Female Student (N=62)	Instructor (N=300)
Tension	2%	1%	0%	6%
Frustration	14%	19%	9%	2%
Certainty_High	32%	31%	36%	35%
Certainty_Low	20%	26%	27%	4%
Politeness_Pos	13%	15%	55%	0%
Politeness_Neg	13%	18%	3%	3%
Politeness_OFF	5%	6%	11%	0%
Politeness_BOR	10%	8%	11%	16%

Table 5. The distribution of relevant emotion acts in resolved vs. unresolved threads.

Affect Patterns in Threads

While sentiment-based discussion analysis is a significant development, emotion acts represent only the lowest level of potential analysis of student message content. With consistent and functional emotion acts, posters, posts, and entire threads can be analyzed in terms of repeatable EA profiles. As a proof of concept, we wished to develop an independent heuristic to classify threads with a hypothetically robust emotional distinction, and examine the resulting EA profile for such a distinction.

We chose the concept of resolved and unresolved discussion threads, where resolved threads contain a final solution or demonstrable ratification of issues, as well as a beneficial discussion, and open threads are those for which initial questions are not satisfied or which have unresolved issues. The ultimate goal is to identify patterns of affective states that help to discern students who may require further assistance, and topics that may require further clarification. Towards this goal, we experimented with several classification measures based upon observed trends in annotated threads. To fulfill the need for a conclusion, we focused on threads that concluded with an answer, or an acknowledgement of thanks for a provided solution. To ensure a basic level of back-and-forth pedagogic discourse we included only the subset of threads that also contained equal numbers of or more answer/statement posts. The generated results by these criteria were examined by the annotators and found to

closely conform to their intrinsic impressions of “resolved” threads. Those threads that were not considered resolved were classified as an “unresolved”. This revealed 180 resolved, and 30 unresolved threads.

After this classification, both resolved and unresolved threads were further broken-down into relevant subsets for EA analysis. The analysis was based upon a simple presence test for specific EAs, and the percentage of posts within the subset that contained that emotion act. Certainty, however, as the most common emotion act, was instead calculated as a level, defined by containing over 75% of a specific type of either high or low certainty emotion acts. If the ratio was less than 75%, it was designated as medium certainty. While rudimentary, this examines the potential for more rigorous profiling, by revealing any obvious difference among threads.

The results show a clear distinction between resolved and unresolved threads. Distinctions were noted when there existed at 10% or above difference from resolved vs. unresolved versions of the chosen subset.

Within the certainty measures, high certainty is shown to strongly influence the resolution of a thread with respect to answers, while having little effect on questions. However, in initial posts, high certainty seems to counter-indicate resolution. In contrast, low certainty seems to have minimal effect, except in the case of questions, in which it is strongly represented in unresolved questions. A lack of certainty (both high and low) also strongly differentiates resolved and unresolved questions and initial posts, while it shows the inverse in final posts.

In terms of frustration and politeness, frustration is unsurprisingly well-represented in unresolved posts, though most notably in initial posts. Bald-on-record politeness shows strongly in unresolved instructor answers, original posts, and final posts. Positive politeness is seen greatly in resolved questions and final posts, while negative politeness is greater in resolved final posts. Off-record politeness shows little effect overall.

Automatic Affect Classification

For automatic classification of emotion acts, we followed a similar approach that was previously applied to identify speech acts in student discussions (Kim et al., 2009). We focused on certainty and frustration because they are most relevant to student performance. The annotated discussion threads were first pre-processed: Because student discussions are informal and noisy with respect to grammar, syntax and punctuation, our model fixes common typos, transforms informal words to formal words, and converts apostrophes to their original forms. It replaces some typical words and phrases with fixed keywords; for instance, programming code fragments are replaced with by CODE, and contractions such as “I’m” and “You’re” were replaced with “I am” and “You are”. The features used include:

F1: Cue phrase and their position in the post

We used n-gram features including unigrams (1 word), bigrams (two word sequence), trigram (three word sequence) and two separate unigrams. We also use position in the post as in the first part, last part or elsewhere. Beginning sentences can have different meanings than those in subsequent sentences. For example, “Thank you” in the beginning sentence position may be an expression of gratitude for previous information, while “thank you” in the last sentence may indicate only politeness.

F2: Message position in the thread: Indicates if the post is the first post, last post or one of the other posts.

F3: The emotion acts of the previous message: EAs in the previous message that the current message is replying to.

F4: Poster class: Defined as either a student or instructor.

F5: Poster change: Checks if the current poster is the same as the previous.

F6: Post length: Categorizes the post as Short (1-5 words), Medium(6-30 words), or Long (>30 words).

Given all combination of features F1-F6, we used Information Gain (Yang and Pedersen, 1997) to prune the feature space and select features. For each Emotion Act, we sorted all features (lexical and non-lexical) by Information Gain and used the top N (=200) features.

We used the Support Vector Machine of Chang and Lin (2001). We did a 5-fold cross validation in the training. RBF (Radial Basis Function) was used as the kernel function. We performed a grid search to get the best parameter (C and gamma) in training and applied them to the test corpus. With the training data of 159 threads and the test data of 52 threads, the initial classification result is shown in Table 4.

The initial results indicate that the EA classification is feasible. Due to the relatively small set size of available

manually-annotated training data, the result is not yet at a level where it can be immediately applied in a functional setting. However, we strongly expect these results to improve as more training data becomes available.

Emotion Act	Test Data Results		
	Precision	Recall	F-Score
High Certainty	0.68	0.64	0.65
Low Certainty	0.80	0.83	0.81
Frustration	0.73	0.75	0.73

Table 4. Automatic classification test results for certainty and frustration.

Related Work

Our work builds on prior research on spoken dialogue analysis including dialogue acts (Searle 1969; Hirschberg and Litman 1993; Samuel 2000; Graesser et. al., 2001; Kim et al., 2009), rhetoric analysis (Mann and Thomson, 1988), and surface cue words analysis (Hirschberg and Litman 1993; Samuel 2000). There have also been Dialogue Acts modeling approaches for automatic tagging and recognition of conversational speech (Stolcke et al., 2000) and related work in corpus linguistics where machine learning techniques have been used to find conversational patterns in spoken transcripts of dialogue corpus (Shawar and Atwell, 2005). Although spoken dialogue is different from message-based conversation in online discussion boards, they are closely related to our thread analysis work, and we plan to investigate potential use of conversation patterns in spoken dialogue in threaded discussions.

Carvalho and Cohen (2005) present a dependency-network based collective classification method to classify email speech acts. However, estimated speech act labeling between messages is not sufficient for assessing contributor roles or identifying help needed by the participants. We included other features like participant profiles. Also our corpus consists of less informal student discussions rather than messages among project participants, which tend to be more technically coherent.

Requests and commitments of email exchange are analyzed in (Lampert et al., 2008). As in their analysis, we have a higher kappa value for questions than answers, and some sources of ambiguity in human annotations such as different forms of answers also appear in our data. However, student discussions tend to focus on problem solving rather than task request and commitment as in project management applications, and their data show different types of ambiguity due to the different nature of participant interests.

There has also been work on non-traditional, qualitative assessment of instructional discourse (Boyer et al., 2008; Graesser et al., 2005; McLaren et al., 2007), and results have been used to find features for critical thinking and level of understanding. Similar approaches for classifying speech acts were investigated in Ravi and Kim (2007). This work captures features that are relevant to analyzing

noisy student discussion threads and supports a full automatic analysis of student discussions instead of manual generation of thread analysis rules. Earlier work on annotating emotion in dialogue focused on polarity (positive or negative) and intensity (Craggs and Wood, 2004) but is less useful for analyzing student discussions.

Finally, there have been studies of student affective states in tutorial dialogue, including boredom, confusion, surprise and frustration. These were analyzed and captured using dialogue states with linguistic features such as cohesion measures (D'Mello et al., 2009). Our work focuses on 'threaded' discussions, and is potentially useful for analyzing student discussion outcome.

Summary and Future Work

As the distinctions between resolved and unresolved threads show that profiling and automatic identification by affect is fully possible, it is important to look forward toward methods and directions of higher-level interpretation. The procedure used in investigating closure is only for broad proof-of-concept, rather than developing specific profile criteria for automatic categorization. As such, future development in profiling will require specific categories, defined by interactions within posts between differing affect in a repeatable manner. This can reveal information about important qualities of posts, threads, and students.

We have described an important first step towards the identification and use of emotion acts for instructional analysis of student discussions: We have identified common acts used by students within a course discussion board, developed a promising classification approach, and have shown that these acts are significant within the corpus through an investigation of resolved/unresolved threads. There are many research avenues to explore. In combination with existing metrics based on rhetorical speech acts, contribution quantity and technical depth, the new measures will assist instructors and researchers in understanding how students learn. This study complements prior work on speech acts and discussion topics (Carvalho & Cohen 2005; Feng et al., 2006; Kim et al. 2007).

Abstract

It is hypothesized that creativity arises from the self-mending capacity of an internal model of the world, or worldview. The uniquely honed worldview of a creative individual results in a distinctive style that is recognizable within and across domains. It is further hypothesized that creativity is domain-general in the sense that there exist multiple avenues by which the distinctiveness of one's worldview can be expressed. These hypotheses were tested using art students and creative writing students. Art students guessed significantly above chance both which painting was done by which of five famous artists, and which artwork was done by which of their peers. Similarly, creative writing students guessed significantly above chance both which passage was written by which of five famous writers, and which passage was written by which of their peers. These findings support the hypothesis that creative style is recognizable. Moreover, creative writing students guessed significantly above chance which of their peers produced particular works of art, supporting the hypothesis that creative style is recognizable not just within but across domains.

Keywords: art; creative writing; creativity; Darwinian theory; expertise; heuristic search; honing; style; voice.

Introduction

The therapeutic nature of the creative process is well known. Eminent creators and laypeople alike often claim that through engagement in creative activities they gain a clearer sense of themselves as unique individuals. By making artistic choices, and observing how these choices guide subsequent thoughts about the work, eventually culminating in original, creative form, they acquire self-knowledge, and often, are left with a sense of completeness. The transformation that occurs on canvas or on the written page is said to be mirrored by a sense of personal transformation and self-discovery that occurs within.

Artists often find a style that feels as if it is 'theirs' only after periods of exploration with different media and established styles and art forms. Similarly, writers speak of transitioning from a stage in which they were merely imitating the styles of authors they admired to a stage in which they discovered their own authentic 'voice'. This sense of self-discovery may seem to the creator as real as anything he or she has ever experienced, and the transition from merely imitating others to finding one's own identifiable style is often evident to anyone exposed to an individual's creative works. But although the phenomenon of recognizable creative style seems obvious to artists

themselves, and to those who appreciate what they do, it is not predicted by well-known theories of creativity.

This paper presents the results of preliminary experiments designed to test the hypothesis that creative individuals possess a distinctly recognizable creative style, and that this creative style is recognizable not just within a domain but across domains. We begin by discussing well-known theories of creativity, and how the phenomena of individual style and 'voice' are not predicted by them. Three studies are then presented. The first two studies test the hypothesis that the phenomenon of creative style is real; that is, that creative individuals such as artists and writers genuinely exhibit a creative style that others come to associate with them. The third study tests the hypothesis that an individual's creative style is recognizable not just in one domain, but across different domains. Finally, we discuss how the findings are compatible with a new theory of creativity.

Theories of Creativity

This section very briefly summarizes some leading theories of how the creative process works, and then presents a new theory of creativity referred to as honing theory.

Creativity as Heuristic Search

Inspired by the metaphor of the mind as a computer (or computer program), it was proposed that creativity involves a process of heuristic search, in which rules of thumb guide the inspection of different states within a particular state space (set of possible solutions) until a satisfactory solution is found (Eysenck, 1993; Newell, Shaw & Simon 1957; Newell & Simon 1972). In heuristic search, the relevant variables are defined up front; thus the state space is generally fixed. Examples of heuristics include breaking the problem into sub-problems, hill-climbing (reiteratively modifying the current state to look more like the goal state), and working backward from the goal state to the initial state. A variation on this is the view that creativity involves heuristics that guide the search for, not a possibility within a given state space, but a new state space itself (e.g., Boden, 1990; Kaplan & Simon, 1990; Ohlsson, 1992). That is, it involves switching from one representation of the problem to another, sometimes referred to as *restructuring* (Weisberg, 1995).

The Expertise View of Creativity

Some posit that creativity involves everyday thought processes such as remembering, planning, reasoning, and restructuring; no special or unconscious thought processes need be postulated (Perkins, 1981; Weisberg, 2006). This is sometimes referred to as the *expertise view* of creativity because it stresses the extent to which creative acts draw upon familiarity with a particular domain of knowledge. Thus this view in particular is associated with the notion that creativity is highly domain-specific; expertise in one domain is not viewed as enhancing creativity in another domain. The expertise view is also associated with the notion that the creative process result in products that are largely derivative, or *reproductive* (as Weisberg puts it), as opposed to genuinely new, or *productive*.

The Darwinian Theory of Creativity

Another approach to modeling the creative process involves framing it in Darwinian terms. While some philosophers describe the growth of knowledge as Darwinian merely in the sense that conjectures must be refutable, *i.e.*, able to be selected against (Popper, 1963; Lorenz, 1971), Campbell (1960) goes further, arguing that a stream of creative thought is a Darwinian process. The basic idea is that we generate new ideas through ‘blind’ variation and selective retention (abbreviated BVSr): ‘mutate’ the current thought a multitude of different ways, select the fittest variant(s), and repeat this process until a satisfactory idea results. The variants are ‘blind’ in the sense that the creator has no subjective certainty about whether they are a step in the direction of the final creative product.

Currently the Darwinian view of creativity is most closely associated with Simonton (1998, 1999a,b, 2007a,b), who views creativity as essentially a trial-and-error process in which the most promising ‘blindly’ generated ideational variants are selected for development into a finished product. It should be noted that the endeavor to apply natural selection to creative thought is not without critics (Dasgupta, 2004; Eysenck, 1995; Gabora, 2005, 2007; Sternberg, 1998; Thagard, 1980; Weisberg, 2000). Nevertheless, the development of a creative idea can be said to be evolutionary in the very general sense that it exhibits descent with adaptive modification.

The Honing Theory of Creativity

Central to the *honing theory* of creativity is the notion of a *worldview*, by which we mean one’s internal model of the world, as well as one’s values, attitudes, predispositions, and habitual patterns of response (Gabora, 2000, 2004, 2008, Gabora & Aerts, 2009). Honing theory posits that creativity arises due to the *self-organizing, self-mending* nature of a worldview, and that it is by way of the creative process the individual hones (and re-hones) an integrated worldview. Honing theory places equal emphasis on the externally visible creative outcome and the internal cognitive restructuring brought about by the creative process. Indeed one factor that distinguishes it from other

theories of creativity is that it focuses on not just restructuring as it pertains to the conception of the task, but as it pertains to the worldview as a whole. When faced with a creatively demanding task, there is an interaction between the conception of the task and the worldview. The conception of the task changes through interaction with the worldview, and the worldview changes through interaction with the task. This interaction is reiterated until the task is complete, at which point not only is the task conceived of differently, but the worldview is subtly or drastically transformed. Thus one distinguishing feature of honing theory is that the creative process reflects the natural tendency of a worldview to seek integration or consistency amongst both its pre-existing and newly-added components, whether they be ideas, attitudes, or bits of knowledge; it mends itself as does a body when injured.

The Recognizability of Creative Style

Theories of creativity based on heuristic search, the acquisition of expertise, or chance, random processes, such as BVSr, give no reason to expect that the act of creation leads to a clearer or more integrated sense of self, or that the works of a particular creator should exhibit a unique and recognizable style. This is particularly so if, as is often claimed, creativity is strongly domain-specific (Baer, 1998; Sawyer, 2006; Weisberg, 2006). If creativity is limited to a particular domain then why should it result in a global sense of wellbeing or integration?

Claims about the domain-specificity of creativity are based largely on findings that correlations amongst alternative measures of creativity are small, and expertise or eminence with respect to one creative endeavor is rarely associated with expertise or eminence with respect to another (e.g. Getzels & Jackson, 1962). Thus, for example, creative scientists rarely become famous artists or dancers. The focus of these studies is squarely on expertise or eminence as evidence of creative achievement. But what if creative achievement is measured not by expertise or eminence but by having found a way to express *what is genuine and unique about us* through whatever media we have at a given time at our disposal? One might expect that an artist’s or scientist’s personal style comes through in how he or she prepares a meal or decorates a room, what creativity researchers refer to as little-c (Richards, Kinney, Benet, & Merzel, 1988) or mini-c (Beghetto & Kaufman, 2007) creative activities. Findings of domain-specificity in creativity may have more to do with the fact that we focus on creative achievement at a level that takes a decade or more to obtain (Simonton, 2007), as opposed to looking for evidence that creative potential and personal style transcends particular domains. In other words, looking for evidence of exceptional creativity in multiple domains is not the only or necessarily even the best way to address the question of whether creativity is domain-specific. Another way is to look for evidence that an individual exhibits a creative style in one domain that also ‘comes through’ when engaged in creative activities in other domains.

Although the phenomenon of recognizable style or voice is not predicted by the view that creativity is a matter of heuristic search, expertise, or Darwinian selection, it is predicted by the honing theory of creativity. We have seen that, according to honing theory, creativity is the process by which one hones a worldview, and each idea the creator comes up with is a different expression of the same underlying core network of understandings, beliefs, and attitudes. A worldview has a characteristic structure, and the creator's various outputs are reflections of that structure, and they are related to one another, and potentially pave the way for one another. Thus honing theory predicts that creative individuals have a recognizable style.

There is evidence that human creativity is more consistent with honing theory than with competing theories of creativity with respect to developmental antecedents of creativity, personality traits of creative individuals, and studies of lifespan creativity (Gabora, under revision). This paper reports on the results of creative style experiments that provide further support for the theory. The goal of the first two studies was to find empirical evidence for the common belief that there really *is* such a thing as recognizable style or voice. Although artists have no doubt this is true, it has not been studied by psychologists, and as we have seen, most theories of creativity do not predict it. The goal of the third study was to test a more controversial prediction of honing theory, the prediction that the structure of a worldview manifests in a unique and recognizable way, to varying degrees, through *different* creative outlets. Thus for example, you might recognize someone's art by knowing how they dress or decorate.

Study 1: Within-domain Recognizability of Artistic Style

The first study tested the hypothesis that individuals who are highly familiar with the art of a given artist will recognize other works by that artist that they have not encountered before.

Method

Participants The research was conducted with 10 University of British Columbia undergraduates majoring in art who were highly familiar with five well-known artists, and with each other's art.

Materials and Procedures Prior to the study, participants were instructed to bring from home a recently completed painting that they had never discussed with or shown to any of their classmates. They were asked to hide their signatures or any other identifying feature of the painting. Before the study, the paintings were examined to ensure that signatures and any other identifying features had been covered.

At the beginning of the study, the art students were shown three well-known paintings by each of five well-known artists as a refresher. The well-known artists were Picasso, Monet, Van Gogh, Dahli, and Andy Warhol. These artists were decided upon because previous discussion with the

class indicated that all students were highly familiar with them. The students were then shown ten unfamiliar (rare or newly completed) works that they had not studied in class. Signatures on all artworks were covered by black tape. The art students were given a questionnaire and asked to guess which famous artist did each painting. For each answer they were also asked to state how certain they were on a 3-point scale that they had not encountered the work before.

They were also shown the paintings by their fellow classmates that they had never seen before. The rationale for showing classmates' paintings was to control for the possibility that with the well-known artists, a participant who, though not recognizing the creative voice, might guess above chance levels to which era or country the artist belonged. The only sufficiently large number of artists from the same era and locale that the students were familiar with were their own classmates. As with the famous artists, they were asked to guess which classmate did each painting, and to state how certain they were on a 3-point scale that they had not encountered the work before.

The participants were debriefed, and the results were analyzed. If a participant had encountered a work before, or was uncertain about having encountered it before, the score for this question was not included in the analysis. Less than 5% of scores were not included in the analysis.

Analysis The data were analyzed to determine if the participants correctly identified the artists at above-chance levels. First, a proportion correct score for each participant was computed. For example, if a participant correctly identified seven out of 10 possible artists, the proportion correct score for that person was .70. Then, the proportion correct score that would have been obtained on the basis on random guesses for each question was computed. For example, for the well-known artists, since there were 5 of them, the proportion correct based on random guesses was .20. One-sample t-tests were then computed comparing the average proportion correct scores to the proportion correct values that would have been obtained had participants been randomly guessing. A one-sample randomization test (Manly, 2007) was used to compute the p-levels for these t-test values, given the small sample sizes, and .05 was used as the criterion for statistical significance.

Results

The results are divided into two sections: recognition of famous artists, and recognition of classmates' art.

Recognition of Famous Artists For the task in which art students were asked which famous artist painted each painting, the mean proportion correct was .78 (SD = .12). The proportion correct that would have been obtained on the basis of random guesses was .20. This difference is statistically significant, $t(9) = 15.3$, $p < .0001$, r (effect size) = .98. Thus art students were able to distinguish above chance which famous artists created pieces of art they had not seen before.

Recognition of Classmates' Art A similar result was obtained with works of art by the students themselves. The mean proportion correct was .74 (SD = .29). The proportion correct that would have been obtained on the basis of random guesses is .11. This difference is significant, $t(9) = 6.8$, $p < 0.0001$, $r = .92$. Thus art students also correctly identified their classmates' art above chance.

Study 2: Within-domain Recognizability of the Notion of a Writer's 'Voice'

This study tested the hypothesis that individuals who are highly familiar with the work of a given writer will recognize other works by that writer that they have not encountered before.

Method

Participants The research was conducted with seven University of British Columbia advanced undergraduate creative writing students who were highly familiar with five well-known writers, and with each other's writing.

Materials and Procedures The analogous procedure to that described above for art students was used for creative writing students. Prior to the study, they had been asked to write a passage about a kitchen and a poem about a month of the year. They were explicitly asked to include no immediately identifying content in their writing (e.g., no mention of surfing if it is known that they like surfing). These constituted their two pieces of writing. At the beginning of the study they were given three well-known written passages by each of ten well-known writers as a refresher. The well-known writers were Ernest Hemingway, Douglas Coupland, Emily Dickinson, Walt Whitman, Allen Ginsburg, Jack Kerouac, TS Eliot, Jane Austin, George Orwell, and Franz Kafka. These writers were chosen because previous discussion with the class indicated that all students were highly familiar with them. A sample of one of the written passages by well-known writers (in this case, Ernest Hemingway) that were provided to creative writing students as a refresher is provided in Table 1.

Table 1: Sample of written passage by well-known writer provided to creative writing students as a refresher.

"If the book is good, it is about something that you know, and is truly written, and reading it over you see that this is so, you can let the boys yip and the noise will have that pleasant sound coyotes make on a very cold night when they are out in the snow and you are in your own cabin that you have built or paid for with your work."

The creative writing students were then shown twenty rare passages that they had not studied in class. A sample of one of the passages by well-known writers (in this case, Jane Austin) is provided in Table 2.

Table 2: Sample of written passage by well-known writer provided to creative writing students as a test of their ability to recognize writer's style.

"However, here they are, safe and well, just like their own nice selves, Fanny looking as neat and white this morning as possible, and dear Charles all affectionate, placid, quiet, cheerful, good humour. They are both looking very well, but poor little Cassy is grown extremely thin, and looks poorly. I hope a week's country air and exercise may do her good. I am sorry to say it can be but a week. The baby does not appear so large in proportion as she was, nor quite so pretty, but I have seen very little of her. Cassy was too tired and bewildered just at first to seem to know anybody. We met them in the hall -- the women and girl part of us -- but before we reached the library she kissed me very affectionately, and has since seemed to recollect me in the same way."

The creative writing students were also given the two pieces of writing by each of their fellow classmates (the passage about a kitchen and the poem about a month of the year) that they had never seen before. They were given a questionnaire, and asked to guess which famous writer wrote each passage in the first set of passages, and which classmate wrote each passage in the second set. For each answer, they were also asked to state on a 3-point scale how certain they were that they had not encountered the work before.

Participants were debriefed, and the results were analyzed. As in the first study, if the participant had encountered the work before, or was uncertain about having encountered it before, the score for this question was not included in the analysis. Once again, less than 5% of scores were not included in the analysis.

Results

The results are divided into two sections: recognition of famous writers, and recognition of classmates' writing.

Recognition of Famous Writers For creative writing students exposed to passages by famous writers, the mean proportion correct was .34, (SD = .28). The proportion correct that would have been obtained on the basis of random guesses is .10. This difference is significant, $t(7) = 7.0$, $p < 0.0001$, $r = .94$. Thus creative writing students correctly identified above chance passages by famous writers that they had not encountered before.

Recognition of Classmates' Writing A similar but less pronounced result was obtained with passages written by the students themselves. The mean proportion correct was .27 (SD = .16). The proportion correct that would have been obtained on the basis of random guesses is .14. This difference is significant, $t(7) = 2.3$, $p < 0.05$, $r = .66$. Thus, creative writing students also correctly identified above chance passages written by classmates.

Study 3: Cross-domain Recognizability of Style

This experiment tested the hypothesis that familiarity with an individual's creative work in one domain facilitates recognition of that individual's creative work in another.

Method

Participants The same seven University of British Columbia advanced undergraduate creative writing students who participated in Study 2 also participated in Study 3. They were highly familiar with each other's writing, but unfamiliar with each other's art.

Materials Each creative writing student brought one piece of covered art to the professor's office. They were asked to hide their signature and any other identifying feature. Before the study, the paintings were examined to ensure that signatures and other identifying features had been hidden.

Procedure The students were shown unsigned art done by classmates. They were given a questionnaire and asked to guess which classmate did which piece of art. As above, for each answer they were also asked to state on a scale of 1-3 how certain they were that they had not encountered the work before. If they had seen the piece before, or thought they might have seen it before, their answer was not included in the analysis. Less than 5% of scores were discarded from the analysis.

Results

The mean proportion correct was .39 (SD = .27). The proportion correct that would have been obtained on the basis of random guesses is .17. This difference is significant, $t(6) = 2.2$, $p < 0.03$, $r = .67$. Thus creative writing students were able to identify above chance which of their classmates created a given work in a domain *other* than writing, specifically art.

Discussion and Conclusions

The experiments with artists and writers reported here provide support for the hypothesis that different works by the same creator exhibit a recognizable style or 'voice', and that this recognizable quality even comes through in different creative outlets. Art students were able to distinguish significantly above chance which famous artists created pieces of art they had not seen before. They also correctly identified their classmates' art significantly above chance. Similarly, creative writing students correctly identified significantly above chance passages by famous writers that they had not encountered before, and correctly identified their classmates' writing significantly above chance. Creative writing students additionally correctly identified significantly above chance works of art produced by classmates. (The opposite study, determining whether art students correctly identify written passages generated by their classmates, has not yet been carried out.)

The higher recognizability of artistic style (study 1) than writer's style (study 2) comes as a surprise. It cannot be entirely due to the famous artists coming from a wider range of eras and locales than the famous writers, for if that were the correct explanation, the recognizability of classmates' art in Study 1 and classmates' writing in Study 2 should have been comparable. Perhaps there are fewer constraints on artists, *i.e.* fewer demands that the work 'make sense', and it need not exhibit plot structure or character development. Thus there may be more acceptable ways of 'doing one's own thing'. The analysis takes into account that there were twice as many writers to choose from as artists, but in future studies the number of famous artists and writers will be the same, in order to make the studies as comparable as possible.

The results support the hypothesis that creators have a recognizable style. These findings are not predicted by theories of creativity that emphasize chance processes or the accumulation of expertise. If creative output is a matter of chance or the acquisition of expertise, then what is the source of this identifiable personal style? These findings are, however, predicted by honing theory, according to which personal style reflects the uniquely honed structure of an individual's worldview. The finding that creative writing students were able to identify above chance which of their classmates created a given work in a domain *other* than writing, specifically art, supports the prediction that creators hone a uniquely structured worldview that exhibits a style that is recognizable not just within a domain but across domains. Further experiments are underway to replicate these findings with larger groups of participants, and adapt the general procedure to study the recognizability of style within and across domains using trained jazz musicians.

It is worth pointing out how this approach, in particular the investigation of recognizable cross-domain style, differs from typical attempts to determine to what extent higher cognition is domain-general versus domain-specific. As mentioned in the introduction, it is commonly assumed that this issue can be resolved by determining to what extent ratings of expertise in one domain are correlated with ratings of expertise in another. An unspoken assumption here is that ratings of expertise are all that is needed to detect any quality that might characterize or unify an individual's creative or intellectual ventures, and indeed that outputs of higher cognitive processes are objectively comparable. In reality, while manifestations of higher cognition are *sometimes* comparable, even quantitatively, often there is little objective basis for comparison. The present results suggest that higher cognition is domain general not in the sense that expertise in one enterprise guarantees expertise in another, but in the sense that there are multiple interacting venues for creative exploration and self-expression open to an individual, and through which that individual's worldview may be gleaned. It may be that our potential for cross-domain learning is only just beginning to be exploited, through ventures such as the Learning through the Arts program in Canada, in which

students, for example, learn mathematics through dance, or learn about food chains through the creation of visual art. It seems reasonable that if knowledge is *presented* in compartmentalized chunks, students end up with a compartmentalized understanding of the world, while if knowledge were presented more holistically, a more integrated kind of understanding may be possible.

Computational Modeling of Emotional Content in Music

Abstract

We present a system designed to model characteristics which contribute to the emotional content of music. It creates n -gram models, Hidden Markov Models, and entropy-based models from corpora of musical selections representing various emotions. These models can be used both to identify emotional content and generate pieces representative of a target emotion. According to survey results, generated selections were able to communicate a desired emotion as effectively as human-generated compositions.

Keywords: Music cognition; computational modeling; learning; music composition.

Introduction

Music and emotion are intrinsically linked; music is able to express emotions that cannot adequately be expressed by words alone. Often, there is strong consensus among listeners as to what type of emotion is being expressed in a particular piece (Gabrielsson & Lindstrom, 2001; Juslin, 2001). There is even some evidence to suggest that some perceptions of emotion in music may be innate. For example, selections sharing some acoustical properties of fear vocalizations, such as sudden onset, high pitch, and strong energy in the high frequency range, often provoke physiological defense responses (Ohman, 1988). Researchers have demonstrated similar low-level detection mechanisms for both pleasantness and novelty (Scherer, 1984, 1988). There also appears to be some inborn preference for consonance over dissonance. In studies with infants, researchers found that their subjects looked significantly longer at the source of sound and were less likely to squirm and fret when presented with consonant as opposed to dissonant versions of a melody (Zentner & Kagan, 1996).

There are a variety of theories as to what aspects of music are most responsible for eliciting emotional responses. Meyer theorizes that meaning in music comes from following or deviating from an expected structure (Meyer, 1956). Sloboda emphasizes the importance of associations in the perception of emotion in music and gives particular emphasis to association with lyrics as a source for emotional meaning (Sloboda, 1985). Kivy argues for the importance of cultural factors in understanding emotion and music, proposing that the “emotive life” of a culture plays a major role in the emotions that members of that culture will detect in their music (Kivy, 1980). Tolbert proposes that children learn to associate emotion with music in much the same way that they learn to

associate emotions with various facial expressions (Tolbert, 2001). Scherer presents a framework for formally describing the emotional effects of music and then outlines factors that contribute to these emotions, including structural, performance, listener, and contextual features (Scherer, 2001).

In this paper, we focus on some of the structural aspects of music and the manner in which they contribute to emotions in music. We present a cognitive model of characteristics of music responsible for human perception of emotional content. Our model is both discriminative and generative; it is capable of detecting a variety of emotions in musical selections, and also of producing music targeted to a specific emotion.

Related Work

A number of researchers have addressed the task of modeling musical structure for the purposes of building a generative musical system. Conklin summarizes a number of statistical models which can be used for music generation, including random walk, Hidden Markov Models, stochastic sampling, and pattern-based sampling (Conklin, 2003). These approaches can be seen in a number of different studies. For example, Hidden Markov Models have been used to harmonize melodies, considering melodic notes as observed events and a chord progression as a series of hidden states (Allan & Williams, 2005). Similarly, Markov chains have been used to harmonize given melody lines, focusing on harmonization in a given style in addition to finding highly probable chords (Chuan & Chew, 2007).

Wiggins, Pearce, and Mullensiefen present a system designed to model factors such as pitch expectancy and melodic segmentation. They also demonstrate that their system can successfully generate music in a given style (Wiggins, Pearce, & Mullensiefen, 2009). Systems have also been developed to produce compositions with targeted emotional content. Delgado, Fajardo, and Molina-Solana use a rule-based system to generate compositions according to a specified mood (Delgado, Fajardo, & Molina-Solana, 2009). Rutherford and Wiggins analyze the features that contribute to the emotion of fear in a musical selection and present a system that allows for an input parameter that determines the level of “scariness” in the piece (Rutherford & Wiggins, 2003). Oliveira and Cardoso describe a wide array of features that contribute to emotional content in music and present a system that uses this

information to select and transform chunks of music in accordance with a target emotion (Oliveira & Cardoso, 2007). The authors have also developed a system that addresses the task of composing music with a specified emotional content (Monteith, Martinez, & Ventura, 2010). In this paper, we illustrate how our system can be interpreted as a cognitive model of human perception of emotional content in music.

Methodology

The proposed system constructs statistical and entropic models for various emotions based on corpora of human-labeled musical data. Analysis of these models provides insights as to why certain music evokes certain emotions. The models supply localized information about intervals and chords that are more common to music conveying a specific emotion. They also supply information about what overall melodic characteristics contribute to emotional content. To validate our findings, we generate a number of musical selections and ask research subjects to label the emotional content of the generated music. Similar experiments are conducted with human-generated music commissioned for the project. We then observe the correlations between subject responses and our predictions of emotional content.

Initial experiments focus on the six basic emotions outlined by Parrott (Parrott, 2001)—love, joy, surprise, anger, sadness, and fear—creating a data set representative of each. A separate set of musical selections is compiled for each of the emotions studied. Selections for the training corpora are taken from movie soundtracks due to the wide emotional range present in this genre of music. MIDI files used in the experiments can be found at the Free MIDI File Database.¹ These MIDI files were rated by a group of research subjects. Each selection was rated by at least six subjects, and selections rated by over 80% of subjects as representative of a given emotion were then selected for use in the training corpora. Selections used for these experiments are shown in Figure 1.

Next, the system analyzes the selections to create statistical models of the data in the six corpora. Selections are first transposed into the same key. Melodies are then analyzed and *n*-gram models are generated representing what notes are most likely to follow a given series of notes in a given corpus. Statistics describing the probability of a melody note given a chord, and the probability of a chord given the previous chord, are collected for each of the six corpora. Information is also gathered about the rhythms, the accompaniment patterns, and the instrumentation present in the songs.

The system also makes use of decision trees constructed to model the characteristics that contribute to emotional content. These trees are constructed using the C4.5 algorithm (Quinlan, 1993), an extension of the ID3 algorithm (Quinlan, 1986) that allows for real-valued attributes. The decision tree classifiers allow for a more global analysis of generated melodies. Inputs to these classifiers are the default features extracted by the “Phrase Analysis” component of the

freely available jMusic software.² This component returns a vector of twenty-one statistics describing a given melody, including factors such as number of consecutive identical pitches, number of distinct rhythmic values, tonal deviation, and key-centeredness. These statistics are calculated for both the major and minor scales.

A separate set of classifiers is developed to evaluate both generated rhythms and generated pitches. The first classifier in each set is trained using analyzed selections in the target corpus as positive training instances and analyzed selections from the other corpora as negative instances. This is intended to help the system distinguish selections containing the desired emotion. The second classifier in each set is trained with melodies from all corpora versus melodies previously generated by the algorithm, allowing the system to learn melodic characteristics of selections which have already been

²<http://jmusic.ci.qut.edu.au/>

accepted by human audiences.

For the generative portion of the model, the system employs four different components: a Rhythm Generator, a Pitch Generator, a Chord Generator, and an Accompaniment and Instrumentation Planner. The functions of these components are explained in more detail in the following sections.

Rhythm Generator

The rhythm for the selection with a desired emotional content is generated by selecting a phrase from a randomly chosen selection in the corresponding data set. The rhythmic phrase is then altered by selecting and modifying a random number of measures. The musical forms of all the selections in the corpus are analyzed, and a form for the new selection is drawn from a distribution representing these forms. For example, a very simple AAAA form, where each of four successive phrases contains notes with the same rhythm values, tends to be very common. Each new rhythmic phrase is analyzed by jMusic and then provided as input to the rhythm evaluators. Generated phrases are only accepted if they are classified positively by both classifiers.

Pitch Generator

Once the rhythm is determined, pitches are selected for the melodic line. These pitches are drawn according to the n -gram model constructed from melody lines of the corpus with the desired emotion. A melody is initialized with a series of random notes, selected from a distribution that models notes most likely to begin musical selections in the given corpus. Additional notes in the melodic sequence are randomly selected based on a probability distribution of note mosts likely to follow the given series of n notes.

For example, with the “joy” corpus, the note sequence (C4, D4, E4) has a 0.667 probability of being followed by an F4, a 0.167 probability of being followed by a D4, and a 0.167 probability of being followed by a C4. If these three notes were to appear in succession in a generated selection, the system would have a 0.167 probability of selecting a C4 as the next note.

The system generates several hundred possible series of pitches for each rhythmic phrase. As with the rhythmic component, features are then extracted from these melodies using jMusic and provided as inputs to the pitch evaluators. Generated melodies are only selected if they are classified positively by both classifiers.

Chord Generator

The underlying harmony is determined using a Hidden Markov Model, with pitches considered as observed events and the chord progression as the underlying state sequence (Rabiner, 1989). The Hidden Markov Model requires two conditional probability distributions: the probability of a melody note given a chord and the probability of a chord given the previous chord. The statistics for these probability distributions are gathered from the corpus of music representing the desired emotion.

For example, C4 is most likely to be accompanied by a C major chord, and F4 is most likely to be accompanied by a G7 chord in selections from the “love” corpus (probabilities of 0.099 and 0.061, respectively). In the “sadness” corpus, C4 is most likely to be accompanied by a C minor chord (probability of 0.060). As examples from the second set of distributions, the G7 chord is most likely to be followed by the G7 or the C major chord in selections from the “love” corpus (both have a probability of 0.105). In selections from the “sadness” corpus, the G7 chord is most likely to be followed by the G7 or the C minor chord (probabilities of 0.274 and 0.094 respectively).

The system then calculates which set of chords is most likely given the melody notes and the two conditional probability distributions. Since many of the songs in the training corpora had only one chord present per measure, initial attempts at harmonization also make this assumption, considering only downbeats as observed events in the model.

Accompaniment and Instrumentation Planner

The accompaniment patterns for each of the selections in the various corpora are categorized, and the accompaniment pattern for a generated selection is probabilistically selected from the patterns of the target corpus. Common accompaniment patterns included arpeggios, block chords sounding on repeated rhythmic patterns, and a low base note followed by chords on non-downbeats.

For example, arpeggios are a common accompaniment pattern in the corpus of selections expressing the emotion of “love.” Two of the selections in the corpus feature simple, arpeggiated chords as the predominant theme in their accompaniments, and two more selections have an accompaniment pattern that feature arpeggiated chords played by one instrument and block chords played by a different instrument. The remaining two selections in the corpus feature an accompaniment pattern of a low base note followed by chords on non-downbeats. When a new selection is generated by the system, one of these three patterns is selected with equal likelihood to be the accompaniment for the new selection.

Instruments for the melody and harmonic accompaniment are also probabilistically selected based on the frequency of various melody and harmony instruments in the corpus. For example, melody instruments for selections in the “surprise” corpus include acoustic grand piano, electric piano, and piccolo. Harmony instruments include trumpet, trombone, acoustic grand piano, and acoustic bass.

Evaluation

In order to verify that our system was accurately modeling characteristics contributing to emotional content, we presented our generated selections to research subjects and asked them to identify the emotions present. Forty-eight subjects, ages 18 to 55, participated in this study. Six selections were generated in each category, and each selection was played for four subjects. Subjects were given the list of emotions and asked to circle all emotions that were represented in each

song. Each selection was also played for four subjects who had not seen the list of emotions. These subjects were asked to write down any emotions they thought were present in the music without any suggestions of emotional categories on the part of the researchers. Reported results represent percentages of the twenty-four responses in each category. To provide a baseline, two members of the campus songwriting club were also asked to perform the same task: compose a musical selection representative of one of six given emotions. Each composer provided selections for three of the emotional categories. These selections were evaluated in the same manner as the computer-generated selections, with four subjects listening to each selection for each type of requested response. Reported results represent percentages of the four responses in each category.

Results

Figure 2 outlines the characteristics identified by the decision trees as being responsible for emotional content. For example, if a piece had a Dissonance measure over 0.107 and a Repeated Pitch Density measure over 0.188, it was classified in the “anger” category. Informally, angry selections tend to be dissonant and have many repeated notes. Similar information was collected for each of the different emotions. Selections expressing “love” tend to have lower repeated pitch density and fewer repeated patterns of three, indicating these selections tend to be more “flowing.” Joyful selections have some stepwise movement in a major scale and tend to have a strong climax at the end. The category of “surprise” appears to be the least cohesive; it requires the most complex set of rules for determining membership in the category. However, repeated pitch patterns of four are present in all the surprising selections, as is a lack of stepwise movement in the major scale. Not surprisingly, selections expressing “sadness” adhere to a minor scale and tend to have a downward trend in pitch. Fearful selections deviate from the major scale, do not always compensate for leaps, and have an upward pitch direction. Downward melodic trends do not deviate as much from the major scale. Our model appears to be learning to detect the melodic minor scale; melodies moving downward in this scale will have a raised sixth and seventh tone, so they differ in only one tone from a major scale.

Tables 1 and 2 report results for the constrained response surveys. Row labels indicate the corpus used to generate a given selection, and column labels indicate the emotion identified by survey respondents. Based on the results in Table 1, our system is successful at modeling and generating music with targeted emotional content. For all of the emotional categories but “surprise,” a majority of people identified the emotion when presented with a list of six emotions. In all cases, the target emotion ranked highest or second highest in terms of the percentage of survey respondents identifying that emotion as present in the computer-generated songs. As a general rule, people were more likely to select the categories of “joy” or “sadness” than some of the other emotions, perhaps

Figure 2: Decision tree models of characteristics contributing to emotional content in music.

because music in western culture is traditionally divided up into categories of major and minor. A higher percentage of people identified “joy” in songs designed to express “love” or “surprise” than identified the target emotion. “Fear” was also a commonly selected category. More people identified angry songs as fearful, perhaps due to the sheer amount of scary-movie soundtracks in existence. Themes from “Jaws,” “Twilight Zone,” or “Beethoven’s Fifth Symphony” readily come to mind as appropriate music to accompany frightening situations; thinking of an iconic song in the “anger” category is more of a challenging task. Averaging over all categories, 57.67% of respondents correctly identified the target emotion in computer-generated songs, while only 33.33% of respondents did so for the human-generated songs.

For the open-ended questions, responses were evaluated by similarity to Parrott’s expanded hierarchy of emotions. Each of the six emotions can be broken down into a number of secondary emotions, which can in turn be subdivided into tertiary emotions. If a word in the subject’s response matched any form of one of these primary, secondary, or tertiary emotions, it was categorized as the primary emotion of the set. Results are reported in Tables 3 and 4. Again, row labels indicate the corpus used to generate a given selection, and column labels indicate the emotion identified by survey respondents.

The target emotion also ranked highest or second highest in terms of the percentage of survey respondents identifying that emotion as present in the computer-generated songs for the open-ended response surveys. Without being prompted or limited to specific categories, and with a rather conservative method of classifying subject response, listeners were still often able to detect the original intended emotion. Once again, the computer-generated songs appear to be slightly more emotionally communicative. 21.67% of respondents correctly identified the target emotion in computer-generated songs in these open-ended surveys, while only 16.67% of respondents did so for human-generated songs.

Listeners cited “fondness,” “amorousness,” and in one rather specific case, “unrequited love,” as emotions present in selections from the “love” category. One listener said it sounded like “I just beat the game.” Another mentioned “talking to Grandpa” as a situation the selection called to mind. Reported descriptions of selections in the “joy” category most closely matched Parrott’s terms. These included words such as “happiness,” “triumph,” “excitement,” and “joviality.” Selections were also described as “adventurous” and “playful.”

None of the songs in the category of “surprise” were described using Parrott’s terms. However, this is not entirely unexpected considering the fact that Parrott lists a single secondary emotion and three tertiary emotions for this category. By comparison, the category of joy has six secondary emotions and 34 tertiary emotions. The general sentiment of “surprise” still appears to be present in the responses. One listener reported that the selection sounded like an ice cream truck. Another said it sounded like being literally drunken with happiness. “Playfulness,” “childishness,” and “curios-

ity” were also used to describe the selections.

Angry songs were often described using Parrott’s terms of “annoyance” and “agitation.” Other words used to describe angry songs included “uneasy,” “insistent,” and “grim.” Descriptions for songs in the “sad” category ranged from “pensive” and “antsy” to “deep abiding sorrow.” A few listeners described a possible situation instead of an emotion: “being somewhere I should not be” or “watching a dog get hit by a car.” Fearful songs were described with words such as “tension,” “angst,” and “foreboding.” “Hopelessness” and even “homesickness” were also mentioned.

Conclusion

Pearce, Meredith, and Wiggins (Pearce, Meredith, & Wiggins, 2002) suggest that music generation systems concerned with the computational modeling of music cognition be evaluated both by their behavior during the composition process and by the music they produce. Our system is able to successfully develop cognitive models and use these models to effectively generate music. Just as humans listen to and study the works of previous composers before creating their own compositions, our system learns from its exposure to emotion-labeled musical data. Without being given a set of preprogrammed rules, the system is able to develop internal mod-

els of musical structure and characteristics that contribute to emotional content. These models are used both to generate musical selections and to evaluate them before they are output to the listener. The quality of these models is evidenced by the system's ability to produce songs with recognizable emotional content. Results from both constrained and unconstrained surveys demonstrate that the system can accomplish this task as effectively as human composers.

Cross-Situational Statistical Learning: Implicit or Intentional?

George Kachergis, Chen Yu, and Richard M. Shiffrin

{gkacherg, chenyu, shiffrin}@indiana.edu

Department of Psychological & Brain Science / Cognitive Science Program
Bloomington, IN 47405 USA

Abstract

For decades, implicit learning researchers have examined a variety of cognitive tasks in which humans seem to automatically extract structure from the environment. Similarly, statistical learning studies have shown that humans can use repeated co-occurrence of words and referents to build lexicons from individually ambiguous experiences (Yu & Smith, 2007). In light of this, the goal of the present paper is to investigate whether adult cross-situational learners require an explicit effort to learn word-object mappings, or if it may take place incidentally, requiring merely attention to the audiovisual stimuli. In two implicit learning experiments with incidental tasks that direct participants' attention to different aspects of the stimuli, we found evidence of learning, suggesting that cross-situational learning mechanisms can be incidental without explicit intention. However, learning was superior under explicit study instructions, indicating that strategic inference may also play a role.

Keywords: implicit learning; language acquisition; cross-situational statistical learning; automaticity

Introduction

Humans have a remarkable capacity to adapt to the regularities in our environment, and our everyday actions—from navigating a room to navigating a conversation—are evidence of our learned skills. Often, we adapt without overt effort or even awareness of the regularity or of our changing behavior. Dubbed *implicit learning* (Reber, 1967), this automatic adjustment to the world is typically studied in cognitive experiments using grammaticality judgments or reaction times to stimuli generated by finite state grammars (see Shanks, 2005 for a review).

The burgeoning statistical learning literature has motivations and predictions that significantly overlap with those of the implicit learning literature, as discussed by Perruchet and Pacton (2006). The seminal work on statistical learning (Saffran, Aslin, & Newport, 1996) demonstrated that infants are sensitive to statistical regularities in a continuous stream of an audible artificial language, enabling them to distinguish probable syllable sequences (i.e., words) from improbable syllable sequences. Newport and Aslin (2004) found that infants are also sensitive to temporally distal regularities, which weighs in favor of a more general statistical learning mechanism, rather than a simple mechanism for associating adjacent sounds. Other studies have found that infants can acquire nouns via the repeated co-occurrence of words and their referents across situations containing multiple words and objects, which are thus separately ambiguous (e.g., Smith & Yu, 2008).

As in adult studies of implicit learning, infant statistical learning studies present participants with structured training data but no explicit learning instructions, and find behavioral differences due to the statistical regularities in the training data. Inspired by this, our aim here is to empirically investigate the automaticity of cross-situational statistical word learning in adults, who are typically given explicit instructions to learn the meaning of the words (e.g., Yu & Smith, 2007). In Experiment 1, we presented participants with a set of spoken words and visual objects with one-to-one mappings between them, but framed the task as one of recognition memory for individual stimuli, and not as one of learning word-object mappings. We then gave participants a surprise test: for each of 54 word-object pairings, they were asked to indicate how often the word and object co-occurred. With their attention focused on memorizing individual words or visual objects, would participants unintentionally learn which words and objects co-occurred more frequently? In Experiment 2, we used a signal detection task as another incidental task to direct participants' attention to both auditory and visual streams, but again with no explicit instructions to learn word-object mappings. After that, we gave them a surprise test to assess their knowledge of word-object mappings. In both experiments, after the initial implicit learning blocks, as a measure of their statistical learning capability (to compare with implicit learning), participants also completed blocks in which they were explicitly instructed to either count word-object co-occurrences, or simply to learn the meaning of the words.

The organization of the paper is as follows: we first introduce the cross-situational learning paradigm, and then discuss the possible learning mechanisms and potential contributions of the present implicit learning studies to advance our understanding of statistical learning. We then present two implicit learning experiments and their results. Finally, we conclude by summarizing the results from the two studies and discussing the connection between statistical and implicit learning.

Cross-Situational Statistical Learning

In a typical version of cross-situational learning, adults are asked to learn which word goes with each object, and are then shown a series of training trials, each of which contains four objects (e.g., a sculpture) and four spoken pseudowords (e.g., “manu”). Because correct word-referent pairings are not indicated, learners can utilize only the repeated co-occurrence of words with their intended referents to learn across many trials. In a typical learning scenario (e.g., in Yu & Smith, 2007), participants attempted

to learn 18 pseudoword-object pairings from 27 12-second trials. This design allowed each stimulus (and hence each correct word-referent pairing) to be presented six times. In one form or another, the learning of a pairing involves the accumulation of word-object co-occurrence statistics across the training trials. Participants acquired, on average, nine of the 18 pairs, as measured by a 4-alternative forced choice (4AFC) referent test for each word.

When each trial contains 16 possible word-referent associations, how might learning proceed? There are at least two distinct approaches that learners may apply. First, an ideal associative learner may maintain a word \times object co-occurrence matrix M , incrementing the count in cell $M_{w,o}$ whenever word w and object o appear together in a trial. Table 1 shows such a matrix, which represents the training statistics used in the present study. At test, such a learner may choose the most frequently co-occurring referent for each word. Associative models typically approximate this co-occurrence matrix by strengthening a randomly sampled (perhaps according to current association strengths) subset of pairings on each trial. The association of spatiotemporally proximal stimuli could be carried out by automatic processes that require neither strategy nor intent to learn. Modern memory models such as REM (Shiffrin & Steyvers, 1997) even predict such associations by allowing feature values of nearby items to accidentally be recorded in an item's trace.

Another plausible learning approach is implemented in rule- and inference-based models (e.g., Siskind, 1996), which propose and store a number of hypothesized word-object pairings on each trial. Proposals may be made with respect to constraints such as mutual exclusivity, and hypothesized pairings may be confirmed if consistent evidence is presented later or removed from the lexicon if contradictory evidence is observed. This type of learning is more in accord with a deliberative, strategic learning process. If cross-situational learning is largely automatic, one may expect participants to have some knowledge of which words and objects frequently co-occurred during training, even when they were not explicitly trying to learn these relations. On the other hand, if cross-situational learning relies on more strategic, intentional inferences, then participants may perform much worse in such an incidental learning condition. Thus, the results from incidental learning tasks may shed light on the underlying learning mechanisms that learners use.

In particular, the present study will test participants' knowledge not only of the correct pairings (i.e., the diagonal cells of Table 1) as is typically done, but also of the spurious word-object co-occurrences (non-diagonal cells) that appear during training—the sort of detailed and partial information that is stored by associative models (or an ideal learner), but typically not by rule-based models. We do this by asking participants to rate the strengths of co-occurring word-object pairings for both correct and incorrect pairings.

Table 1: Word \times Referent matrix with the co-occurrences of each word and object accumulated across the 27 training trials used in each condition in both present experiments.

The testing paradigm allows us to both access participants' knowledge of spurious pairs and to compare that with what they know about correct pairs. Previous work has found evidence that people are sensitive to how often words and objects have co-occurred—even when a single object appears with a few words with differing frequency (Vouloumanos, 2008). However, Vouloumanos presented only a single word-object pair per trial, giving participants no choice as to which pairings to attend. In contrast, our paradigm offers 16 possible pairings per trial. Thus, the presence of four concurrent objects and four successive words per trial demands that participants modulate their attention, possibly forming stronger associations between particular words and objects, or perhaps attending only a subset of possible pairings. Thus, it is unclear how well participants' co-occurrence ratings will be correlated with actual stimuli co-occurrences in the explicit conditions, since inference-based learners may only track a lexicon of the most likely pairs (i.e., high co-occurrence stimuli), rather than a full matrix of associations.

Experiment 1

Every participant went through four blocks of training and testing in a fixed order. Training and testing in block 0 was structured differently than the remaining three. Participants were told that they would see multiple objects and hear multiple words on each trial, and that they should remember each object and word because their memory will be tested at the end. After the brief training period in block 0, they were given a recognition memory test: a single stimulus (word or object) was presented, and they were asked to label it *old* or *new*. In block 1, participants were told again that they should remember each object and word for a subsequent memory test. However, after this training period, participants were given a surprise test of their knowledge of stimuli co-occurrences. In block 2, participants were explicitly asked to remember how many times each word and object appeared together during training. They were not

told what type of test to expect, but the co-occurrence rating test given was exactly the same as in block 1. In block 3, participants were simply asked to learn the meanings of the words—explicit learning instructions like those given in previous cross-situational word learning studies.

Subjects

Participants were 35 undergraduates at Indiana University who received course credit for participating. None had participated in other cross-situational experiments.

Stimuli

Verbal stimuli were 72 computer-generated pseudowords that are phonotactically-probable in English (e.g., “bosa”), and were spoken by a monotone, synthetic female voice. Objects were 72 photos of uncommon, difficult-to-name objects (e.g., strange sculptures). Of these sets of objects and words, 54 were randomly assigned to three sets of 18 word-object pairings; one set for each study condition. The remaining 18 words and 18 objects were used for an initial recognition memory test.

In block 0, each trial presented three unusual objects concurrently and three pseudowords heard in succession. Block 0’s training consisted of only three 11-second trials, displaying in total nine unique words and objects. After these trials, participants were given a recognition test for each trained word and object, as well as nine new words and objects. On each test trial, a single stimulus (word *or* object) was presented, and participants were asked to indicate if it was *old* or *new*.

In blocks 1-3, each training trial consisted of a display of four objects and four pseudowords were played in succession, and 27 such trials were in each block. Each training trial began with the appearance of four objects, which remained visible for the entire trial. After 2 seconds of initial silence, each word was heard (randomly ordered, duration of one second) followed by two additional seconds of silence, for a total duration of 14 s per trial.

After each training period, participants were tested for knowledge of stimuli co-occurrences. One word and one object were presented on each trial, and participants were asked to indicate how many times [0-6] the given word-object pairing had appeared during training. Each of the 18 words and objects appeared in three test trials, for a total of 54 randomly-ordered trials. The correct (6-co-occurrence) pairings comprised 18 of the test trials (Table 1’s diagonal). The remaining 32 trials tested cells in the matrix with 0 (14 trials), 1 (14), 2 (12), 3 (8), and 4 (6) co-occurrences.

Procedure

Condition order was fixed, and each participant took part in all four blocks. Block 0 was a three trial training period with three words and objects per trial, followed by a recognition test of every individual stimulus presented, and nine new words and objects. In block 1, participants were instructed to study individual stimuli for a memory test. However, following the 27 training trials, participants were instead asked to indicate how many times [0-6] each of 54 specific word-object pairings appeared during training. In block 2,

participants were asked to track how often each word co-occurred with each object. After the 27 training trials—which had the same co-occurrence statistics as in block 1, albeit different stimuli—participants were again given test trials asking them to rate the same 54 pairings. Finally, in block 3 participants were simply instructed to learn the meanings of the words, given cross-situational training (statistically identical to blocks 1 and 2), and again tested on the same 54 pairings.

Results & Discussion

In block 0, participants recognized a mean of 96% of the objects and 90% of the words, with a low false alarm rate (8%). In both word and object recognition, every participant was at least 77% accurate. It is notable that memory is imperfect for the stimuli, since many models of cross-situational learning assume that learners can absolutely identify each stimulus, which is evidently not the case.

To determine how related participants’ co-occurrence ratings were to the actual number of times the tested word-object pairings actually appeared together during training, Kendall’s rank correlation coefficient (tau) was calculated for each participant’s 54 test trials in each condition. The mean tau values for each condition are shown in Figure 1. In block 1, when participants were studying individual words and objects (but not attending to co-occurrences), their responses in the surprise rating task showed a small but significant positive correlation with the actual number of times the presented pairings co-occurred during training ($M = .04$, one-sided $t(34) = 1.90$, $p < .05$). In comparison, in the explicit learning conditions in blocks 2 and 3, when participants were respectively told to track all word-object co-occurrences and to learn the meaning of the words, their ratings were significantly more positively correlated than in block 1 (block 2 $M = .15$, paired $t(34) = 3.82$, $p < .001$; block 3 $M = .17$, paired $t(34) = 3.86$, $p < .001$). Moreover, the strength of correlations in the two explicit conditions is not significantly different (paired $t(34) = 0.66$, $p > .05$).

Correlation of Ratings with Pair Co-occurrences

Figure 1: Mean correlation of participants’ responses with the actual pair co-occurrences in Exp. 1. Error bars: +/-SE.

Positive correlations between ratings and a broad sample of the actual co-occurrence statistics from training indicate that participants are sensitive to arbitrary stimuli co-occurrences when explicitly told to attend to such correspondences. However, one could imagine that the positive correlations could be due largely to knowledge of some particular subsets of the co-occurrences: e.g., perhaps learners are sensitive to words and objects that never co-occurred, and thus rated these pairings very low, and all others high. To examine performance in more detail, we calculated each participant's d' ¹ for the most extreme pairings tested in each condition: stimuli that co-occurred 0 or 6 times. Positive d' shows sensitivity resulting from a high hit rate and low false alarm rate. As shown in Figure 2, participants only had significant sensitivity for 6-co-occurrence ('correct') pairings in the explicit learning conditions (count co-occurrences $M = 0.64$, one-sided $t(34) = 4.92$, $p < .001$; word meanings $M = 0.81$, one-sided $t(34) = 5.08$, $p < .001$).

Two patterns from this study are noteworthy. First, based on both d' analysis and correlation measures, the learning that results from the counting co-occurrences condition and the word learning condition were similar. Although not conclusive, this may suggest that participants in the word learning condition may have used an associative learning strategy based on counting word-object co-occurrences.

Figure 2: Mean d' for 0- and 6-co-occurrence word-object pairings in Experiment 1, by condition. Error bars are \pm SE.

Second, despite having good recognition memory for individual words and objects that were presented during training, word learning was very poor in the implicit learning condition, as measured both by correlation of their responses with actual pair co-occurrences, and by d' for

correct pairings and stimuli pairings that never co-occurred. Nonetheless, the positive correlations found in every condition—although smaller in the implicit condition—show that participants do, on average, absorb some of the stimulus co-occurrences in all conditions. However, this sensitivity is not enough to support implicit word learning in our study, as much stronger correlations are shown when learners are instructed to count co-occurrences or learn word meanings. Under these instructions, participants become sensitive to words and objects that frequently co-occur.

Experiment 2 investigates whether a different incidental task, which may direct attention to word-object co-occurrences, rather than the stimuli themselves, may yield automatic word learning.

Experiment 2

Experiment 1 showed that an incidental memory task results in some implicit knowledge of word-referent co-occurrences, but that explicit instructions to learn word-object co-occurrence or to learn word meanings resulted in much greater knowledge. In Experiment 2, we use a different task in the implicit learning condition: instead of asking participants to remember individual stimuli for a later memory task, we give participants a signal detection task to carry out during training. This task—detecting visual noise added to visual objects, and louder auditory stimuli (words)—directed participants to pay attention to both visual and auditory stimuli simultaneously, but gave no directions to engage in learning of word-object pairings.

Subjects

37 undergraduates at Indiana University received course credit for participating. None had participated in previous cross-situational experiments.

Stimuli

The sets of pseudowords and referents for Experiment 2 were identical to those used in Experiment 1. Training trials were the same as those used in Experiment 1, and had the same co-occurrence statistics (shown in Table 1). However, on each training trial in blocks 1 and 2, a random number [0-4] of the words were louder than others, and Gaussian pixel noise was momentarily added to a single object *during a word presentation* a random number of times [0-4] each trial. Thus, for 6.3% of audio stimulus presentations during training, that word would be loud and *one* of the objects would simultaneously have noise added, highlighting a pairing—but only the correct pairing in 25% of these cases.

Procedure

In block 1, participants were told that they would be presented with artificial words and objects on a series of slides, on which some words would be louder than the others and some objects would have multicolored speckles (noise). Their task was to quickly press the mouse button each time a loud word or noisy object was presented. However, after the 27 training trials, participants were given a surprise test, and asked to indicate how many times [0-6]

¹ For example, hits for 0-co-occurrence pairings are responses of 0, and false alarms are responses of 0 for pairings that co-occurred more than never. $d' = Z(p(\text{hit})) - Z(p(\text{false alarm}))$, where Z is the inverse of the cumulative Gaussian distribution.

each of 54 specific word-object pairings appeared during training. In block 2, participants were asked to track how often each word co-occurred with each object, and were also told to do the same signal detection task during training. Instructions for block 3 asked participants to track word-object co-occurrences without doing the signal detection task, and in block 4 participants were simply told to learn the meanings of the words. The same 54 rating test trials of specific pairings followed the training periods of blocks 2, 3, and 4, though with different stimuli for each block.

Results & Discussion

Experiment 2 used a signal detection (SD) task that required participants to attend to both auditory and visual stimuli, but did not mention that they would need to remember the stimuli later. However, as in Experiment 1, after this first training block participants were given a surprise test for incidental learning. In successive learning conditions, participants were instructed to do both the SD task and to count word-object co-occurrences (SD+CC), to count co-occurrences (with no other task; CC), and finally, to simply learn the meanings of the words (Word Meanings). As in Experiment 1, Kendall's tau was calculated for each participant's 54 test trials in each condition to measure how related their ratings were to the actual number of word-object co-occurrences. As shown in Figure 3, although the SD task resulted in significantly positive correlations ($M = .10$, one-sided $t(36) = 3.75$, $p < .001$), the explicit learning conditions showed significantly more correlated responses (CC $M = .21$, paired $t(36) = 3.57$, $p < .01$; SD+CC $M = .25$, paired $t(36) = 5.12$, $p < .001$; Word Meanings $M = .29$, paired $t(36) = 4.97$, $p < .001$). Thus, as found in Experiment 1, participants show sensitivity to stimuli co-occurrences in every condition, but greater sensitivity in the explicit learning conditions than in the implicit learning condition.

Figure 3: Mean rank correlation of each participant's responses with the actual number of pairing co-occurrences in Experiment 2. Error bars show \pm SE.

As in Experiment 1, we calculated d' for maximal and minimal co-occurrence pairings by condition to gain insight into the kind of pairings to which participants in Experiment 2 were sensitive. As shown in Figure 4, participants had significant sensitivity for 6-co-occurrence pairings in the implicit learning condition (SD $M = .19$, one-sided $t(36) = 1.81$, $p < .05$) as well as the explicit conditions, but showed significantly greater sensitivity in the explicit conditions (CC $M = .61$, paired $t(36) = 2.97$, $p < .01$; SD+CC $M = .61$, paired $t(36) = 3.44$, $p = .001$; word meanings $M = .81$, paired $t(36) = 3.58$, $p < .001$). In the explicit conditions, d' for 0-co-occurrence pairings was significantly positive (CC $M = .49$, one-sided $t(36) = 1.50$, $p = .07$ (marginal); SD+CC $M = .32$, one-sided $t(36) = 2.66$, $p < .01$; word meanings $M = .30$, one-sided $t(36) = 2.20$, $p < .05$), but not in the implicit condition (SD $M = .07$, one-sided $t(36) = .87$, $p = .19$). Thus, although participants given SD instructions did show some implicit learning of 6-co-occurrence pairings, they were more sensitive to these pairings under explicit instruction.

There are a few intriguing results from this experiment. First, performance in the SD+CC condition was at least as good as CC alone. Thus, participants could handle the two tasks concurrently without hindering performance. We suspected that the signal detection task might encourage participants to attend to both auditory and visual streams simultaneously, perhaps increasing storage of cross-modal associations. Possibly as a result of this focus, in contrast to Exp. 1, participants in Exp. 2 showed significant sensitivity to 0-co-occurrence pairings in the explicit conditions.

Second, word-learning instructions yielded performance as high as found in other explicit instructions (SD+CC and CC). This confirmed our finding from Experiment 1: both counting co-occurrences—as an ideal associative learner might do—and attempting to learn words result in similar performance in humans, both for correct pairs and for spurious co-occurrences.

Figure 4: Mean d' for 0- and 6-co-occurrence word-object pairings in Experiment 2, by condition. Error bars are \pm SE.

General Discussion

Implicit learning and statistical learning both describe an agent's adaptation to regularities in its environment. We set out to determine whether cross-situational word learning can be accomplished by mere exposure to the same type of training used in intentional settings. In Experiment 1's implicit learning condition, participants attempted to remember individual stimuli. In a surprise test of knowledge for word-object co-occurrences, participants' ratings were correlated with the actual number of co-occurrences, meaning that learners had acquired a rough approximation of the real-world statistics, much like associative models predict. However, a signal detection analysis showed no sensitivity to correct word pairings. Moreover, in subsequent explicit conditions, participants showed stronger correlations, as well as sensitivity to correct pairings. Using a signal detection task rather than a memory task in the first block, thus encouraging concurrent attention to both words and objects, Exp. 2 asked again whether participants acquire cross-situational co-occurrence statistics automatically. Participants demonstrated some implicit knowledge as in Exp. 1, but also showed some sensitivity for correct word-referent pairs. However, in explicit conditions participants showed greater sensitivity to such frequently co-occurring stimuli, as well as significant knowledge of spurious co-occurrences. Furthermore, we found that participants' learning when instructed to count co-occurrences looks similar to learning under instructions to merely learn words, which we speculate may mean that participants utilize a similar strategy in both conditions. By asking participants to perform slightly different tasks with the same input and then comparing their resulting learning, it will be possible to determine which regularities are automatically acquired and which must be explicitly attended or inferred.

What do the present results tell us about cross-situational statistical learning? They seem to contradict simple hypothesis-testing mechanisms, which would typically not maintain information about spurious co-occurrences, and which may not operate automatically. However, the results also contradict a strong associative account: learning was greater in explicit conditions than in implicit conditions, suggesting that learning may be in part strategic, or at least modulated by attention. Thus, we may say that cross-situational statistical word learning is neither wholly implicit, nor wholly explicit: some statistics are acquired automatically, and the learning system indubitably uses this information during explicit study, as well. Moreover, the fact that the explicit conditions always produced greater sensitivity for the correct pairings than for pairings that never co-occurred suggests that some mechanism for highlighting stimuli that frequently co-occur is at work.

In summary, although the implicit learning we observed was inferior to the explicit learning, its presence indicates that knowledge of co-occurrence statistics can be acquired incidentally. Since implicit learning requires few resources, it can be carried out minute-by-minute, hour-by-hour and day-by-day. Hence, in the long run, cumulative implicit

learning may still play an important role in human language acquisition. Overall, our work suggests that neither simple associative models that approximate ideal observers, nor hypothesis-testing models relying on explicit inferences capture both the implicit and intentional aspects of cross-situational word learning. We hope that this work will motivate researchers to consider hybrid models that include both strategic, inference-based mechanisms as well as automatic, associative ones. Finally, we believe this work represents an early step in linking the implicit learning and statistical learning literatures.

An Interactive Environment for Explanatory Biological Modeling

Pat Langley (langley@asu.edu)

Computing Science and Engineering

Arizona State University, Tempe, AZ 85287 USA

Abstract

In this paper, we describe an interactive environment for the representation, interpretation, and revision of explanatory biological models. We illustrate our approach on the systems biology of aging, a complex topic that involves many interacting components. We also report initial experiences with using this environment to codify an informal model of aging. We close by discussing related efforts and directions for future research.

Keywords: scientific models, qualitative reasoning, applied cognitive science

Introduction and Overview

There is general agreement that the explosive growth in biological data offers great opportunities but also poses major challenges. Although less widely recognized, the growing complexity of biological models that aim to account for these observations raises a host of other issues. Computational techniques hold promise for mitigating this complexity, but most responses have been driven by algorithmic concerns rather than the cognitive needs of scientists who must develop, interpret, and understand complex models. Biologists would benefit from new computational tools designed with scientific users in mind.

Many efforts in modern science aim to understand complex phenomena from a systems perspective. One important example comes from research on aging, with recent studies suggesting that senescence results from the interaction of many distinct but interconnected processes (Vijg & Campisi, 2008). Individual laboratories report experiments and propose hypotheses to explain them, but there has been little work on how they fit together. The systems biology movement has championed integrative science, but it has emphasized topics like gene regulation and left phenomena like aging understudied.

In this paper, we report an interactive computational framework designed to support modeling of this variety. Our approach relies on three distinct but mutually supportive ideas:

- formal representations of scientific knowledge that make contact with specific fields' terms and concepts;
- methods for reasoning over models cast in these formalisms that provide the same flexibility and draw the same conclusions as scientists;
- techniques that let researchers analyze and update these models in an incremental, cumulative manner.

In the next section, we discuss three computational challenges that these capabilities raise, after which we describe an interactive software environment that embod-

ies our responses. We illustrate the system's abilities with examples from the domain of aging, then report initial experiences with the environment. We conclude with a discussion of related work on scientific modeling, along with directions for additional research.

Some readers may question the relevance of our work to cognitive science. Of course, scientific reasoning has long been a topic of study within this community, but we will not claim our system reasons in precisely the same way as biologists. However, our approach is informed by results from cognitive science that constrain it in important ways. In particular, it borrows from research on qualitative mental models, which has proposed representations and reasoning methods that are consistent with knowledge about human cognition. A good analog comes from work on intelligent tutoring systems (e.g., VanLehn, 2006), which does not model the details of human tutors but takes lessons from them. We view our work on computational aids for biological modeling as another important instance of applied cognitive science.

Challenges in Scientific Modeling

As we have noted, the construction of complex scientific models raises three separate but interrelated challenges. Here we expand upon each of them in turn, placing constraints on the form our responses should take in developing an environment for biological modeling.

The overall aim of science is to produce knowledge, but the social nature of science requires the use of *communicable* formalisms that researchers can exchange and understand (Džeroski, Langley, & Todorovski, 2007). Thus, our first computational challenge involves selecting a communicable formalism for biological models. Over the past decade, computational researchers have proposed many notations for such models, but most utilize notations borrowed from other fields that have questionable relevance to traditional biological thinking. Research in biology generally, and on aging in particular, imposes two constraints on modeling formalism. One is that most accounts of phenomena are qualitative, not because researchers prefer them intrinsically, but because they enable useful claims even when lacking more precise information. A second feature is that biologists often move beyond simple predictive models to posit causal hypotheses or processes that underlie known phenomena.

Science also differs from some areas of inquiry by its concern with observations. However, biologists typically

desire more from their models than simple predictions; they prefer *explanations* that account for observations in terms of concepts and mechanisms they find familiar and plausible. Such explanatory reasoning is common in biology (Darden, 2006), but the growing complexity of models suggests that, without assistance, researchers will otherwise overlook important implications. Thus, a second computational challenge involves supporting reasoning over the communicable scientific formalisms just described. Methods for calculating results from numeric equations are well established, but automated reasoning over the qualitative models that dominate biology requires a different approach. One complication that arises in qualitative models is that two or more causal pathways can predict different relationships between variables. Another is that it can be difficult to reason qualitatively about how a system changes over time.

A third important feature of science is its cumulative character. Historians often focus on conceptual breakthroughs by individuals like Darwin, Pasteur, and Morgan, but the great majority of research involves filling in technical details rather than changing paradigms. This is especially true for biology and medicine, in which scientists devote considerable effort to piecing together complicated models with many interacting parts. Thus, our final computational challenge involves supporting the cumulative improvement of system-level models by biological researchers. A common response is to develop curated knowledge bases (e.g., Karp et al., 2000; Vastrik et al., 2007) that rely on centralized control by a few experts, but the field has also explored community-based approaches. Both require ways to update models incrementally as new knowledge becomes available.

An Interactive Modeling Environment

We have incorporated our responses to the above issues into an interactive software environment for biological modeling. We have implemented the initial system in Lisp and we have used it to formalize four compartments of Furber's (2009) network diagram of aging, which depicts in a graphical but informal way some well-supported hypotheses and phenomena from biogerontology. In this section, we report the environment's response to each of the challenges just described, using examples from aging to clarify its operation.

Representing Biological Models

Recall that our first computational challenge involves encoding explanatory models and presenting them in ways that biologists will understand. Let us review some key features of aging that hold implications for modeling these phenomena:

- Different effects of aging and age-related disease are localized in different portions of body. For instance, some age-linked changes occur in specific parts of the cell, such as the lysosome or the mitochondria.

- Some hypotheses about aging involve transient substances, such as enzymes and reactive oxygen species (ROS), whereas others involve far more stable entities like lipofuscin and mitochondrial mutations that accumulate over time.
- Empirical results generally take the form of qualitative relations between continuous variables. For instance, one robust finding involves a negative influence of caloric intake on lifespan in model organisms.
- Aging takes place over time, but its effects are primarily monotonic in character, with the values of variables increasing or decreasing consistently. For example, lipofuscin in the lysosome is generally observed to increase with chronological age.
- Empirical findings about aging come in two distinct varieties: uncontrolled observations about changes over time and results of controlled experiments that measure the effect of one variable on another.

Taken together, these observations provide both constraints on our approach to modeling aging processes and avenues for making the task more tractable.

Table 1 presents our reformulation of the lysosome compartment of Furber's network diagram. The initial 12 statements in (a) and (b) reflect the first two points above. They declare specific locations – the lysosome, the cytoplasm, and the cell that contains them – along with quantities that are measurable (at least in principle) in those locations. Some quantities refer to stable substances, such as junk protein, oxidized protein, and lipofuscin, which accumulate over time unless actively broken down, whereas others denote transient substances, like Fe, ROS, and lytic enzyme, which are reactive enough to be very short lived.

The table also includes a set of hypotheses (c) about how these quantities influence each other. One claim is that transient ROS increases with transient Fe within the lysosome, whereas another is that stable oxidized protein increases with transient ROS in the same location. Hypotheses may also relate quantities in distinct locations (e.g., that lipofuscin in the cytoplasm increases with damaged membrane in the lysosome). These hypotheses have a clear causal interpretation, in that they state how one variable will change when one alters another. However, although they link continuous quantities, the relations themselves are qualitative in character.

Of course, we should remember the purpose of hypotheses like those in Table 1 (c), which is to explain known empirical results and predict new ones. This in turn requires not only that we represent these empirical findings formally, but also that we distinguish them clearly from the hypotheses themselves. Table 1 (d) shows four facts about aging in the lysosome that illustrate our earlier point about two forms of empirical findings. The first two items clarify both the observational, nonexperimental character of many facts about

Table 1: Formalization of Furber’s (2009) lysosome model, including (a) locations, (b) stable and transient quantities in these locations, (c) hypothetical claims about causal influences between these quantities, and (d) empirical facts about relations between quantities.

(a) location cell location lysosome in the cell location cytoplasm in the cell
(b) stable junk protein in the lysosome and cytoplasm transient degradation rate in the lysosome transient Fe in the lysosome transient ROS in the lysosome stable oxidized protein in the lysosome stable lipofuscin in the lysosome and cytoplasm transient lytic enzyme in the lysosome stable damaged membrane in the lysosome transient H2O2 in the lysosome and cytoplasm
(c) hypothesis junk protein decreases with degradation rate in the lysosome hypothesis junk protein in the lysosome increases with junk protein in the cytoplasm hypothesis Fe increases with junk protein in the lysosome hypothesis ROS increases with Fe in the lysosome hypothesis oxidized protein increases with ROS in the lysosome hypothesis lipofuscin increases with oxidized protein in the lysosome hypothesis degradation rate decreases with lipofuscin in the lysosome hypothesis lytic enzyme decreases with lipofuscin in the lysosome hypothesis ROS increases with lipofuscin in the lysosome hypothesis damaged membrane increases with ROS in the lysosome hypothesis lipofuscin in the cytoplasm increases with damaged membrane in the lysosome hypothesis H2O2 in the lysosome increases with H2O2 in the cytoplasm
(d) fact lipofuscin in the lysosome increases with time fact membrane damage in the lysosome increases with time fact lytic enzyme decreases with ROS in the lysosome fact H2O2 does not change with ROS in the lysosome

aging and also their monotonic nature. These explicitly mention time as a variable, which the model hypotheses do not. The other two facts reflect (plausible) results of experimental studies that measure the effect of one quantity’s variation on another. The first states that lytic enzyme decreases with ROS in the lysosome. The second states that H2O2 does not vary with of ROS. Such negative results place constraints on models, although hypotheses may contain only positive causal relations.

This notation meets two of the criteria given earlier. It supports qualitative models that nevertheless relate quantitative variables of the type that biologists typically measure, and the hypotheses that make up models

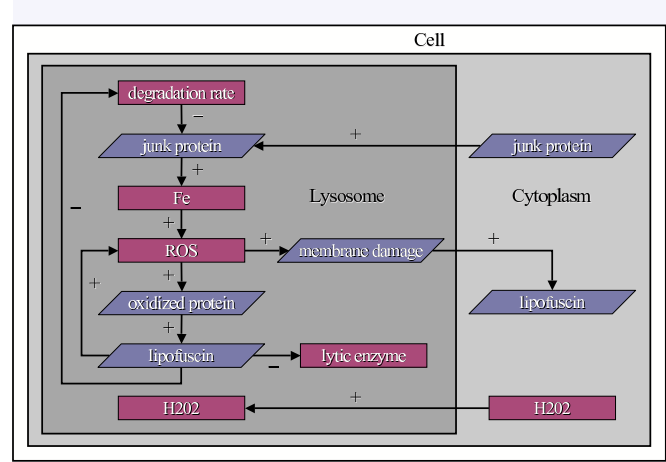

Figure 1: A graphical visualization of the qualitative lysosome model from Table 1, with plus (+) on an arrow denoting that one quantity increases with another and with minus (−) denoting a decreasing relationship.

have a clear causal interpretation. The formalism also lends itself to graphical display, with quantities shown in locations where they occur and with arrows depicting direct causal influences between these variables. Figure 1 shows a graphical version of the lysosome model from Table 1, with the empirical facts omitted. Our implemented system does not yet generate such graphs automatically, but adding this ability should not be difficult.

In addition, our notation lets users specify places, quantities, hypotheses, and empirical facts in constrained English, which we believe will make it more accessible to biologists who are uncomfortable with traditional computer languages. Yet models stated in this notation are well defined and unambiguous about their claims, making them just as formal as ones stated in the more arcane languages typically proposed in computational biology. This also distinguishes our approach from work on qualitative reasoning in cognitive science and AI (e.g., Bredeweg et al., 2007; Forbus, 1984), which has influenced our approach to biological modeling.

Reasoning over Biological Models

Our second computational challenge involves interpreting a given model to account for known phenomena. Scientists regularly engage in such reasoning, but with complex models they can easily overlook some conclusions and incorrectly infer others (e.g., Feldman et al., 1989). Thus, automatically determining a model’s implications should be a key part of our scientific modeling environment. Good models should explain known phenomena and predict new ones accurately, while phenomena place constraints on model content. Our framework’s formal statement of hypotheses and empirical results has another advantage: it lets one answer questions about how one quantity should affect another and predict the outcomes of thought experiments.

We can clarify this ability by introducing the notion of a *query* about how two quantities are related. This takes the same form as an empirical finding except that it does not state the direction in which one variable influences another or indeed whether an influence occurs at all. Thus, given the hypotheses in Table 1, we might ask “Does lipofuscin in the cytoplasm vary with Fe in the lysosome?” or “Does ROS in the lysosome vary with time?” The first asks a question about how changes to one quantity in a controlled experiment affect another; the second asks how a given quantity changes over time. The reasoning task is simplified by our assumption that effects are monotonic in character, giving behavior that one can describe in terms of a single qualitative state. This differs from much work on qualitative reasoning, which deals with trajectories of such states over time (e.g., Bredeweg et al., 2007; Forbus, 1984).

Because hypotheses take a form similar to facts, we can utilize a relatively straightforward chaining procedure to answer queries. To handle a question about how dependent variable Y varies with independent variable X, other things being equal, one simply finds a causal pathway, typically through other quantities, that starts with Y and ends with X. If no such path exists, then one can conclude that changes to X do not produce changes in Y. If there is such path, then one must still predict the direction of the effect. Briefly, if the path contains an even number of ‘decreases’ links, then one predicts that Y increases with X; otherwise one predicts that it decreases. For example, the model in Figure 1 lets one conclude that lytic enzyme will decrease with ROS. The justification for this strategy is simple: each ‘decreases’ link reverses the direction or sign of the path’s overall influence, so that an even number of them cancel out.

One complication arises when multiple paths from Y to X make different predictions. Without knowing the functional forms and parameters that produce each causal link, one cannot determine the exact effects of alternative pathways. Given the modeling framework as we have described it, in such cases one can only state that the hypotheses make contradictory predictions. However, we can extend the formalism in a simple way that lets it express another type of hypothesis that biologists regularly make: that the effect of one causal pathway dominates that of another. This requires a way to specify paths between two quantities and note which has the greater or dominating effect. Once included, such dominance relations let a qualitative causal model make unambiguous predictions about how one quantity varies with another, despite its abstract character.

Reasoning about how quantities change over time requires a slightly different approach. We assume that any exogenous variables not influenced by other quantities take on constant positive values. One can then infer the effect of such an exogenous quantity on another variable

downstream by finding pathways that connect them and combining the influences on their causal links. One can conclude that ‘stable’ quantities occurring downstream will increase or decrease over time, depending on their relation to the exogenous term. We can treat causal loops between two variables as special cases of conflicting paths in which a variable influences itself, again provided we specify which path is dominant.

Taken together, these computational mechanisms respond to a number of the issues raised above. They let our biological models move beyond inert structures to become interpretable ‘programs’ one can use to answer directed queries and make predictions about empirical relations. They also support reasoning about the effects of both controlled manipulation and the passage of time. As we will see shortly, the system can also explain the reasons for its conclusions. Computational aids of this sort should let biologists derive the implications of system-level models of aging that are more complex than ones they can handle without assistance.

Interactive Aids for Model Improvement

Our third computational challenge involves the incremental revision of models to bring them into closer alignment with known phenomena. This depends on the ability to represent such models and reason over them, but it must go beyond to identify portions of models that are problematic and modify them in response. Although there has been some research on automated model revision (e.g., Mahidadia & Compton, 2001), we have chosen to rely on interactive revision under user control. To this end, the system includes a number of commands through which users can update the knowledge base. These are currently available only through a textual interface, but we also plan to embed them in a graphical environment.

Naturally, the most basic commands includes ones for adding new model elements. The user can introduce new locations, quantities, hypotheses, and empirical facts by entering this content in the same format as shown in Table 1. The modularity of the modeling formalism, and its constrained English syntax, make these steps simple to carry out. The environment also includes a display command that presents the user with all elements in the current model or only those of a specified type. These commands provide the basic functionality needed for the cumulative improvement of causal biological models.

However, the system also provides users with additional details about the model’s behavior that can inform their revisions. In addition to answering specific queries like “Does ROS in the lysosome vary with time?”, users can also ask the environment to compare the current model’s predictions to known phenomena. When these predictions disagree with the empirical facts, the user can also ask the system to explain its reasoning. For each explanation, it presents the causal chain between two quantities that, taken together, predicted a partic-

ular outcome. Exceptions occur when the model incorrectly predicts no effect because no causal chain exists or makes an ambiguous prediction when two paths conflict and the user has not specified one as dominant.

The ability to inspect not only predictions but the reasoning behind them provides important insights about a model's strengths and weaknesses. If the model fails to match one or more empirical facts, explanations may reveal the source of the problem and ways to fix it. The user can remedy such situations in two basic ways – by adding new hypotheses, as described above, and by removing existing hypotheses. However, because the impact of deleting an element may be unclear in advance, the environment also lets users disable a model element without removing it entirely, as well as enable it later if that seems desirable. Taken together, these commands provide basic support for the incremental improvement of models, which will continue to be needed as new phenomena become available and demand explanation.

Initial Experiences with the Environment

We selected the systems biology of aging as our initial application domain because it was gaining increased attention within biology and because John Furber (2009) had already developed a network diagram that summarized many hypotheses and phenomena in this complex field. Repeated discussions with Furber let us convert his informal statements into our modeling notation.

We have focused our efforts on four compartments of Furber's diagram. These involve the dysfunction of lysosomes due to the accumulation of indigestible aggregates known as lipofuscin, the degeneration of mitochondrial energy production in the cell as the result of mutations, the shortening of telomeres and decline in Lon protease mRNA over time in the cell nucleus, and the crosslinking of proteins in the extracellular matrix. The lysosomal model, already seen in Table 1 and Figure 1, incorporated three places, nine quantities, and 12 hypotheses. The mitochondrial model included three places, nine quantities, and ten hypotheses, while the nuclear and extracellular models have similar complexities.

Naturally, translation of content from the informal diagram into our logical notation required some care and effort, with certain representational issues becoming apparent only along the way. Interactions with Furber clarified his intentions and usually determined how to proceed. Once we had the initial translation complete, we used the environment to detect and correct problems with these models, much as we intend its use by scientists. Running the reasoning mechanism over these models revealed a number of errors, some in our encoding of Furber's chart but also a few ambiguities in the original aging diagram itself. Formalization of the aging model, combined with the environment's reasoning methods, led to repair of these problems.

Related Work on Scientific Modeling

Our approach to interactive biological modeling borrows ideas from three distinct traditions, but combines them in new ways to produce novel capabilities. The computational biology community has pursued a number of projects that support Web-based access to biological knowledge. For instance, KEGG (Kanehisa, 1997), Reactome (Vastrik et al., 2007), and Metacyc (Karp et al., 2000) let their users explore biological content that curators have extracted from the literature, but they have only limited abilities to reason over their knowledge.

Some other biological modeling efforts come closer to our framework. For example, Genepath (Zupan et al., 2003) offers a Web-based environment that lets users enter qualitative results from genetics experiments and knowledge about gene regulation, but the model construction process is entirely automated. JustAid (Mahidadia & Compton, 2001) supports iterative revision of qualitative causal models, with the system proposing changes but the user selecting which to implement. Racunas et al.'s (2004) HyBrow supports interactive creation of qualitative models and checks their consistency with logical reasoning, but our system provides a more general treatment of explanatory biological models.

Of course, we have also been strongly influenced by research on mental models in cognitive science, especially work on qualitative reasoning and simulation (e.g., Forbus, 1984). Our approach shares some key ideas, especially that models involve qualitative causal relations among continuous variables. One difference is our assumption that behavior is monotonic over time, which simplifies reasoning considerably. Another distinction is our willingness to resolve ambiguity by specifying that one path dominates another. A third lies in our emphasis on predicting relations between pairs of quantities, rather than on model simulation. Our incorporation of qualitative models into an interactive modeling environment is not new. Bredeweg et al.'s (2007) GARP lets users construct qualitative models manually and simulate their behavior, although it focuses on ecology rather than biology, it uses a more complex process ontology, and it does not emphasize incremental revision.

Directions for Future Research

Although our modeling environment shows considerable promise, we need to extend the framework along a number of fronts. Clearly, our first step should be to embed the existing abilities in a graphical interface. This would let users visualize models in a manner similar to Figure 1, but it would also use this display to support query answering, prediction, and explanation, each of which have natural visual analogs. The environment would include templates for creating new locations, quantities, hypotheses, and empirical facts, for disabling and enabling model elements, and for copying and editing entire

models. These features would not change the environment's basic functionality, but they would make it more accessible to many biologists.

We should also expand the representational abilities of the modeling framework. One extension would enable grouping a set of causal links into a process, much as in Forbus' (1984) qualitative process theory. This would let a graphical interface hide model details until a user asks to see individual connections. Another augmentation would allow contextual conditions on causal links that specify the tissues and organisms in which they occur. If queries included similar conditions, then the reasoning system would collect relevant connections to create query-specific models for use in drawing conclusions. Finally, we should explore ways to move beyond the framework's strict assumption of monotonic behavior. One response would involve adding quantitative conditions to causal links and dominance relations that specify when they hold, with the reasoner collecting relevant model elements to make predictions for a specific situation.

Concluding Remarks

In this paper, we reported an interactive approach to the representation, interpretation, and revision of scientific models. Our environment encodes models as sets of qualitative causal influences that relates quantities in particular location, and its reasoning methods answer queries, make predictions, and explain its conclusions. Users can interactively invoke these abilities, which should help them understand a model's behavior and improve it over time. We have carried out initial tests on cellular models of aging, using the environment's interactive character to identify problems in these models and repair them.

Although our approach draws on ideas developed in earlier work, it combines them in novel ways to support three key facets of the scientific enterprise: the formal representation of knowledge and hypotheses, relating that knowledge to observations through explicit reasoning, and the incremental development of knowledge over time. Many projects that formalize biological knowledge have focused on inert structures, rather than offering aids for reasoning over complex models, and most techniques for codifying knowledge rely on curators, rather than giving scientists tools to make their own changes. We believe our interactive environment offers a promising approach that addresses these issues in ways that biologists will find accessible and useful.

Abstract

To mentally extrapolate the trajectory of a moving object which disappears from sight, it is possible to exploit two different sources of information. One source is the memory of the last visible movement of the object, and the other is its inferred movement through time. It is often assumed that these cues are integrated into dynamical analog mental representations. To investigate the nature of the mental representation of imagined movements, we used a new experimental paradigm for which a causality attribution task was combined with motion prediction task. Participants were instructed to imagine the trajectory of a moving object disappearing behind a screen while estimating the degree to which the movement was caused by another moving object.

We show that the predicted movement departs from a correct extrapolation based on accurate memory for velocity. Furthermore the mental representation of the physical and causal structure of the dynamical events did not appear to be as detailed as a theory of mental simulation would predict.

Keywords: mental imagery, prediction of motion, perception of causality.

Introduction

Correctly performing actions on moving objects typically requires a high level of accuracy. Tasks, such as hitting or catching a ball show that humans can accurately and consistently represent the timing of a visible moving object and anticipate its future positions (Regan, 1982).

However, when the stimulus is not visible, such as when it is temporarily occluded, it is not clear how precisely we can time a non visible movement and whether we possess an extrapolation mechanism that can time non visible displacements. Interception tasks are mostly driven by kinematic properties, whereas mental extrapolation may be more influenced by cognitive factors, particularly by how we represent the causal interactions of the objects within a scene.

In studies of mental imagery, it is putatively assumed that the mind builds analog representations that can be used to estimate possible outcomes of dynamical events (Johnson-Laird, 1983) or to reveal spatial properties of objects (Kosslyn, 1994). Similarly, dynamical analog representations may subserve the ability to represent the timing structure of an invisible dynamical event (Shepard & Cooper, 1982; Schwartz, 1999).

Additionally, dynamical analog representations could integrate variables related to the physical structure of the

environment. Results suggesting that humans are capable of recognizing physically correct object movements (Kaiser et al., 1992), along with findings showing that we can perceive high-level properties of these stimuli, such as their causal relations (Leslie, 1994), or agency status (Premack, 1990), support this possibility. Indeed, it has been claimed that internalizing invariant properties of the environment is evolutionarily adaptive (Hubbard, 1995; Shepard, 2001).

Thus, it is plausible to conjecture that information regarding the dynamic properties of a scene that we are capable of representing (for example, their causal relations, or the amount of physical forces acting upon an object) is integrated in a unique mental simulation. This being the case, such a dynamical representation may allow for accurate prediction of future states of invisible events. Alternatively, the prediction of motion and the representation of other forms of physical information may be independent, and hence not merged into a single optimal simulation of dynamical events. In the present article, we aim to determine the ability to accurately estimate motions of invisible objects and to clarify how participants integrate an intuitive causal understanding of the represented events into a mental representation of motion.

Experiment 1

Experiment one determined the accuracy for predicting the position of a moving object that is no longer visible. Participants were required to predict the time-to-arrival of an animated ball at different positions after its disappearance.

We also tested how the representation of causal relations influenced participants' accuracy for predicting invisible dynamical events. If the information used to compute the velocity of an object is integrated with the information used to compute the causal structure of the scene, we would expect that events considered as causally correct are predicted more precisely than events considered as causally anomalous. However, if the two kinds of information are processed separately, we should observe a dissociation between the accuracy of online predictions of imagined position and the perception of causal correctness.

In every experimental condition, there were two moving objects, a launcher and a target, the movement of the target behind the occluder was to be predicted, while the causal relation between the launcher and the target, which could vary both in spatial and temporal contiguity, was to be estimated.

Method

Participants. Nineteen randomly chosen participants completed the experiment (mean age = 24,4; range from 20 to 31 years).

Stimuli. We created video stimuli with the animation software Cinema4D. The animation clips used were created with some intent of realism. For example, objects' shadows cast on the ground, had slight grooves, offering some depth cues. In each clip, a white and a green ball moved onto an earth-ground, below a blue, cloudy sky. A red screen partially covered the movement of the green ball (see Figure 1).

After 1 s, a white ball with a 3° diameter appeared from one side of the scene, and travelled horizontally at a constant speed of either 25,8°/s, 19,3°/s or 12,9°/s toward a green ball, which was stationary at the centre of the scene.

The white ball (the launcher) either did or did not contact the green ball (the target), but the target always started its movement as fast as the launcher and in the same direction.

A red rectangular screen was positioned such that its border contacted the edge of the target and its length covered the entire trajectory of the target. After initiating its movement, the target continued its trajectory behind the screen, until the end of the animation segment. Three vertical black lines were drawn on the red screen, placed at six different positions, yielding two configurations (see Tables 1 and 2). The direction of the balls (movement to the right, or left) was balanced across trials.

Three different spatio-temporal conditions were implemented by either varying the spatial interval between the launcher and the target at the end of the launcher's movement, or by varying the delay between the end of the launchers' movement and the beginning of the target's movement.

Table 1: Angular speed and hypothetical arrival time (s) in bar configuration 1 (in parentheses, distance from the origin of each bar).

Bar Number	12.9°/s	19.3°/s	25.8°/s
1 (44.2°)	0.44	0.28	0.24
4 (60.8°)	1.72	1.16	0.88
6 (71.8°)	2.6	1.72	1.32

Table 2: Angular speed and hypothetical arrival time (s) in bar configuration 2 (in parentheses, distance from the origin of each bar).

Bar Number	12.9°/s	19.3°/s	25.8°/s
2 (49.7°)	0.88	0.56	0.44
3 (55.3°)	1.28	0.84	0.68
5 (66.3°)	2.16	1.4	1.12

In the **Contact** condition, the motion of the launcher immediately ceased after having contacted the target, and the target began to move immediately after contact with the

launcher. Neither the launcher nor the target exhibited deformation as a result of contact.

In the **Delay** condition, an interval was introduced at the moment the two balls made contact. The interval was 480 ms for the first condition and 640 ms for the second condition.

In the **Space** condition, although the end of the movement of the launcher and the beginning of the movement of the target were simultaneous, the launcher stopped its trajectory before contacting the target. The space between the endpoint of the launcher's path and the target's starting position was determined according to the delays previously specified: the distance between the two balls was equal to the distance the launcher would have covered during the interval specified in the Delay condition had it continued its movement (a distance of 100 pixels for the first condition and 130 pixels for the second condition).

Figure 1. Overall sequence of events in a trial and causal conditions (Contact, Space, Delay).

To reveal the impact of occlusion on the time-to-arrival estimation, we designed another set of video sequences for which the target remained visible. However, in these clips the bars remained in the same positions as in the above described segments, and had the same spatio-temporal properties described previously. Also, the velocity of the target was constant and equal to the velocity of the launcher. Finally, in order to break the monotony resulting from the horizontal movements of the launcher, we intermixed the experimental animations with distractor segments in which the launcher fell from above, landing in the same position that the launcher stopped in the experimental sequences. Finally, for all the animations, the launcher appeared either from the left of the screen and moved right, or vice versa. Thus, in total, 120 experimental animations were created (5 conditions of interest crossed with the other experimental factors: Contact/Delay (x2)/Space (x2), target visibility (x2), bar configuration 1/2, speed (x3), direction of movement (x2) and 40 distractor animations).

A graded scale (from 0 to 9) was employed to collect participants' causal judgments for each clip.

Apparatus. Stimulus animations were displayed and the data were collected using a PowerMac G4 running the GNU software package PsyScope X (<http://psy.cns.sissa.it>). The animations were projected on a 200x135 cm screen with an Epson EMP 8100 projector. Reaction times were recorded using a Newmicros Button Box. This response box, together with a mouse and a numerical keypad were placed on a table positioned in front of participants.

Procedure. Participants sat in a darkened room, 2.5 meters from the screen. From their position, they could easily press the button box.

Each session began with a practice trial (Contact condition), with the velocity of the balls always set to 19.3°/s. Participants were instructed to visually track the launcher and, after the target disappeared behind the occluder, to press the key on the button box each time they felt the target would reach a bar on the red screen. They were encouraged not to press the key only three times. They were also informed that the balls would move at constant velocity and that they had identical speed. This information could be used to predict the position of the second ball on the basis of the speed of the first ball. Participants were able to move their head freely as they tracked the balls.

Participants were also informed that at the end of each segment a 1-to-9 scale would be projected on the screen. They were instructed to evaluate the perceived strength of the causal relation between the two balls by moving the mouse on the scale and clicking on the appropriate magnitude (1= not at all causal; 9 = completely causal). No explicit relation was drawn between the first online prediction and the second causal judgment tasks.

Each trial was initiated by pressing a button on the response box. The movement of the launcher started one second after the beginning of the scene. According to the velocity of the balls, the trial could last either 10, 11 or 12 seconds. At the end of the trial, a black screen, in which the causality scale appeared, filled the scene. After participants punched a number on a numerical keyboard, the next trial started. The beginning of the novel segment was controlled by participants. No feedback about response accuracy was given. Animation segments were presented in blocks of 80 (60 experimental, 20 distractors), arranged in a semi-random order, with the constraint that the same spatio-temporal condition could not be presented more than three times in a row. The first block contained only animations with occluded targets, and the second block contained the sequences with visible targets. The overall duration of the experiment was one hour, with a pause between the two blocks after thirty minutes.

Results

The mean timing error was computed as the difference between the total response time to a tested position from the beginning of the sequence and the total arrival time of the target, from the beginning of the sequence to the moment the target crossed a bar. The frame in which the invisible target ball reached each bar was determined offline, as the first frame where the target made contact with the bar. Thus, a positive error value indicates that participants entered their

response after the target crossed the bar, while a negative error value indicates the response was given before the arrival time.

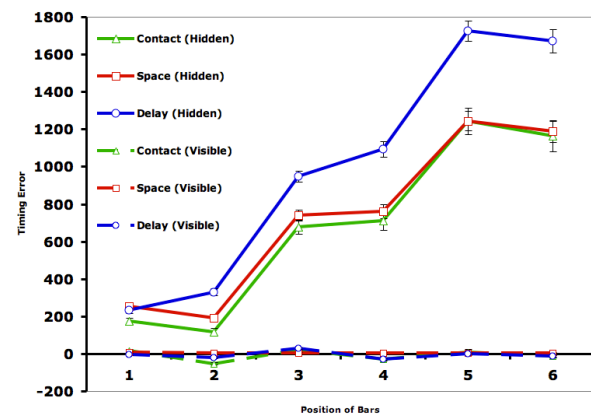

Figure 2: Mean timing error (in ms) for the main experimental conditions (Contact/Space/Delay), separated by target visibility. The horizontal axis indicates the position of the bars on the trajectory of the target.

Trials were excluded from analysis if participants did not press the button exactly three times, if they pressed the button before the disappearance of the target, or if reaction times exceeded 2.5 SD from the mean response time in the relevant conditions.

We initially analyzed how the visible and invisible conditions differ for each tested position. Figure 2 shows the time differences between participants' responses and arrival time of the target ball, plotting together the three tested positions of each experimental animation sequence (1,4,6 and 2,3,5). When the target was visible, participants were accurate at determining the exact moment of arrival. Not only does the result show participants' accuracy at predicting contacts with direct visual feedback, but it also reveals that the task of tracking three successive positions with the spatio-temporal parameters we tested is perfectly feasible. However, when the target was not visible, clearly the average prediction systematically overestimated the time of arrival of the target. A two-way repeated measures ANOVA with individual means of timing error as a dependent variable and object occlusion as independent variable (visible/non visible) reveals an effect of occlusion on timing error ($F_{1,18} = 78.28, p < 0.0001$). The error was positive at every tested position, indicating an overestimation of the time needed for the target to cover the distance between the different bars. This response delay increased with occlusion time, but neither linearly nor continuously, as a simulation hypothesis would predict. In fact, the timing error did not differ between any two close bar pairs tested in the two bar position conditions. In other words, participants could not distinguish between any two close positions (as confirmed by post-hoc t-tests with Bonferroni alpha adjustment) when tested separately, but only in the invisible target condition, suggesting that the ability to predict the position of an invisible target is, if at all present, rather coarse.

In successive analyses, we thus collapsed the two bar position conditions, which did not differ. A two-way repeated measures ANOVA, restricted to the invisible target condition, with the sequence of response as independent variable (R1/R2/R3) revealed an effect of response order ($F_{2,18} = 109.04, p < 0.0001$). For each response, the timing delay increased as confirmed by a post-hoc t-tests (Bonferroni alpha adjustment) on the differences between timing errors in the third, second, and first response (**R2 – R1** = 631.02, $p < 0.0001$; **R3 – R1** = 1348.62, $p < 0.0001$).

Effect of causal conditions on timing accuracy. Figure 2 shows the timing error at each tested bar for the main conditions of the experiment. Timing was not accurate in any of the three tested conditions compared with the error values obtained in the visible movement conditions. There were also differences observed within the three conditions in the target-occluded animations. A two-way repeated measures ANOVA performed on individual error means for the invisible target conditions, with the type of interaction between the balls as the independent variable, indicated a significant effect of the three causal conditions ($F_{2,18} = 84.43, p < 0.0001$). This main effect depended on the difference between the Contact and the Delay conditions (post-hoc, Bonferroni adjusted t-tests : **Delay - Contact** = 337.84, $p < 0.0001$) and between the Space and Delay conditions (post-hoc, Bonferroni adjusted t-tests : **Delay – Space** = 293.14, $p < 0.0001$), while there was no difference between the Contact and Space condition (post-hoc, Bonferroni adjusted t-tests : **Space – Contact** = 44.7, $p = 0.53$).

Thus, the Delay condition reveals a timing error that is not only greater than the (almost null) error in the corresponding visible condition, but also greater than both non-visible conditions. Instead, timing errors in the Contact and Space conditions remained relatively similar across the trajectory of the target.

The effect of the spatio-temporal conditions did not depend on the size of the temporal or spatial intervals, as indicated by the lack of interaction between the two factors in a two-way ANOVA restricted to the responses in the Space and Delay conditions ($F_{1,18} = 0.02, p = 0.89$).

Effect of causal conditions on causal attribution. We analyzed participants' estimates of the causal strength of the scenes. A two-way repeated measures ANOVA with causal attributions as the dependent variable and interval size and causal conditions as independent variables revealed no effect of interval size ($F_{1,18} = 3.39, p = 0.08$) and no interaction between size and conditions ($F_{1,18} = 0.66, p = 0.43$). Thus, we collapsed the data across the interval dimension in further analyses.

A two-way repeated measures ANOVA yielded a significant effect of the type of interval introduced ($F_{2,18} = 66.99, p < 0.0001$). The effect was mainly carried by the difference between the Contact condition and Space conditions, but all conditions were different (post-hoc, Bonferroni adjusted t-tests : **Contact - Space** = 6.23, $p < 0.0001$; **Contact - Delay** = 4.52, $p = 0.03$; **Delay - Space** = 2.18, $p < 0.01$).

As expected, in the Contact condition the relation between the launcher and target was considered to be the causally strongest. Instead in the Space condition causality was considered non existent. Noticeably, causal interaction in the Delay condition was judged higher than in the Space condition. Combining such results with the prediction task, and comparing the two conditions in which causal violations were introduced, one can see that participants were better at predicting the position of an invisible target in the condition (Space) that was judged causally weaker than the other (Time). That is, prediction abilities and perception of causality do not align.

Effect of expertise on timing accuracy. Because many of our participants were highly skilled in physics and had a thorough understanding of real kinematics, we also checked whether expertise had any effect on accuracy. We divided the total number of participants in three groups based on the number of years they received physics education (naive: up to middle school; intermediate: up to high school; high: Masters and Ph.D in Physics).

Overall, expertise had no effect on prediction accuracy, as revealed by a two-way repeated measures ANOVA with individual means of timing error as a dependent variable and levels of expertise as independent variable (naive/intermediate/high) ($F_{2,18} = 0.35, p = 0.71$). Nor did any effect appear when causal attributions were the dependent variable ($F_{2,18} = 1.35, p = 0.29$). Expertise did not interact with spatio-temporal conditions in either predictive accuracy or causal attributions.

Discussion

Experiment one revealed that participants were highly accurate when predicting the time of contact of a moving target when the target was continuously visible, regardless of the type of interaction with the launcher. Yet, they were highly inaccurate when the target moved behind an occluder, making errors as high as 70% of the duration of the full scene. Furthermore, the amount of overestimation did not appear to increase continuously as the distance of the arrival point increased, revealing a sort of quantization of the error that is difficult to reconcile with a simulation theory of imagined movement.

This overestimation is difficult to explain by the violations of causal interactions in the events presented, as a large overestimation error was also present when the events were causally correct (Contact condition). Although we cannot be certain that, at a perceptive level, the computation of causal interactions does not interfere with the prediction, we found that the attributions of causality were dissociated from prediction accuracy: participants were better at predicting the position of an unseen object in conditions that they judged causally worse.

It is thus more likely that the variations in the amplitude of timing error have a source in the time necessary to integrate the two successive movements at a purely kinematic level. As such, this experimental situation might reveal particularly interesting in the exploration of movements integration.

Overall, these results suggest that our ability to predict future states in a partially occluded dynamical event is severely limited and probably does not integrate our knowledge about causal interactions.

Experiment 2

An alternative explanation for the large delays observed in experiment one, which maintains the tenet that humans simulate physical events, could be that participants do simulate physical events, but they do it even better than required. We showed animation sequences in which balls rolled over flat terrain. If participants integrate real physical constraints they may not avoid considering friction in their simulation, thus 'mentally slowing down' the speed of an unseen object. This integration of a physical variable might explain why participants delayed their reactions in imagination. Although the size of the delays we found is not easily reconciled with a simple integration of real friction parameters given the terrain in our videos, the point remains valid. Indeed Hubbard (1995) suggested mental analogs of gravity and friction are directly integrated in our simulations of object motion, systematically biasing certain position estimations. So the time-to-arrival overestimation in our experiment could reflect the fact that participants are simulating a deceleration instead of using their memory of a constant velocity.

We tested this possibility by modifying the context of the previous sequences, so as to prime certain physical representations. Specifically, we tilted the slope of the track such that the balls would either roll downwards or upwards. A previous study has shown that such a transformation can bias memory for position in a representational momentum paradigm (Bertamini, 1993).

If the prediction is indeed driven by inferred dynamical properties, we expect the timing error to be modified according to the orientation of the slope. If, instead, the prediction is not affected by the integration of physical variables and the error we found in Experiment one was due to limits in how we can simulate physical events (if we have such an ability), then we expect the timing error to persist unaffected by the conditions of Experiment two.

Method

Participants. Thirteen randomly chosen participants were recruited for the experiment. Their ages ranged from 19 to 30 years (mean age = 22,9).

Stimuli. We used the animations with occluded target movement from Experiment one, but modified such that the slope of the track was altered by rotating the images 20° either clockwise or counterclockwise. Thus, in experiment two there were three groups of animation stimuli: two containing balls rolling on an inclined plane, and a third group containing the same sequences used in Experiment one, with the balls rolling on a horizontal plane. This configuration allowed us to determine how gravity modifies the results of Experiment one. No vertical movement distractor was present in this experiment.

Apparatus and Procedure. The same set-up and procedure used in Experiment one were used for Experiment two, with the exception that we did not run the visible target condition, as performance in this condition was previously shown to be accurate.

Results

Data exclusion criteria and error calculations were as in Experiment one.

Effect of the orientation of the slope on timing accuracy.

Figure 3 represents the variation of timing error as a function of slope. As in Experiment one, an overestimation of the time-to-arrival, increasing with response order, was observed. There was no obvious difference in timing accuracy between the different slope conditions, although a slight decrease in timing error appeared in the slope downward condition.

A two-ways repeated measures ANOVA performed on the timing error, with speed and slope as independent variables, revealed a main effect of slope ($F_{2, 12} = 4.61$, $p = 0.02$). Post-hoc t-tests with Bonferroni adjustment revealed that the effect was carried by the difference between the Slope up and Slope down conditions (**Slope up - Slope down** = 175.34, $p = 0.02$), whereas no difference was found between the two tilted conditions and the horizontal condition. Furthermore, the difference between these conditions only occurred at one speed. Indeed, speed and slope interacted ($F_{4, 12} = 2.87$, $p = 0.03$); post hoc analyses showed that the difference between Slope up and Slope down was significant only when the balls moved at 19°/s (post-hoc Bonferroni-adjusted t-tests: 19°/s **Slope up - Slope down** = 300,86, $p < 0.01$; 13°/s **Slope up - Slope down** = 102,38, $p = 0.99$; 26°/s **Slope up - Slope down** = 122,78, $p = 0.94$).

Figure 3. Mean timing error (ms) for the three plane rotations (Slope up, Slope Down, Horizontal). The horizontal axis indicates the position of the bars on the trajectory of the target.

Discussion

In this experiment, we tested whether the prediction of the position of an unseen object was influenced by the

integration of physical variables in a mental simulation of the dynamic of the action.

We observed a slight effect of slope on participants' predictions, but only at one velocity. While the effect is compatible with the mental simulation of physical parameters, it remains mysterious as to why it should occur only in the 19°/s velocity condition. Thus, overall, it is difficult to entirely reconcile the results with the assumption that our mental models faithfully simulate the dynamics of object movements.

General Discussion

How does the cognitive system deal with incomplete information about the trajectory of a moving object? Research on mental imagery and on the prediction of motion frequently appeals to mental analog representations as a potential substrate for spatial computations and dynamics understanding. Here we provided evidence that this conception may not offer an adequate account of how we represent dynamic stimuli.

We devised a task for motion prediction that directly probed participants' ability to estimate the position of a moving object online, as opposed to other known paradigms of motion prediction which test memory for past positions rather than fast prediction of future positions (e.g., Hubbard, 1995). With this task, we demonstrated that estimations of time-to-arrival are inaccurate, with a large overestimation of the time necessary for the target to reach a position (confirming and expanding upon previous results obtained with different paradigms; e.g., Gilden Blake & Hurst, 1995). This result supports the claim that there is no predictive mechanism to estimate an object's position when it is occluded, when a direct visual evidence is lacking (Keane & Pylyshyn, 2006).

Furthermore, by coupling this task with causal strength judgment task, we showed that intuitive perceptions of causality do not integrate with online prediction of imagined object movements, casting further doubts on the existence of a representation that integrates physical variables into an analog simulation of objects and physical forces in the world. Finally, we showed that the system responsible for the overestimation error we revealed, takes into account very obvious physical properties, such as gravity, only haphazardly. This aspect of our results is difficult to reconcile with evolutionary accounts of cognition, according to which integration of gravity should be a prime candidate for a variable that evolutionary history may have embodied into a mental simulator.

How then can we account for the overestimation error we observed? Some studies suggest that when we track a moving object, our time perception for rapidly moving stimuli is lengthened as compared to static stationary stimuli (Brown, 1995; Kanai et al., 2006). Such a phenomenon could account in part for the present results, and as a consequence it could indicate that rather than extrapolating object position by means of an analog mental simulation of real physical forces, we use an internal clock to make an only coarse estimate of when an invisible object should be at a given location.

As a general conclusion, our results point toward the existence of several independent systems, one of which may compute object velocity, and another that may compute causal relations in the world. Although it may be tempting to unite the two kinds of systems, our results cast doubt on the existence of a common substrate for the extrapolation of trajectories in dynamical sequences of movements. These results also cast doubts on the existence of richly detailed analog representations that could assist us in knowing and understanding the physical world.

(Category) Learning by Doing: How Goal Directed Tasks Constrain Conceptual Acquisition

Seth Chin-Parker (chinparkers@denison.edu)
Department of Psychology, Denison University
Granville, OH 43023 USA

Abstract

The current study explores conceptual acquisition that occurs as the result of completing a task in a novel domain. The items encountered in the domain were complex in that there were multiple sources of information that might be used to organize conceptual knowledge related to the domain. I test the hypothesis that goal-directed interactions will constrain the acquisition of knowledge such that functional categories of the items, organized around goal-relevant features, are learned. Converging evidence from two measures provided strong support for the idea that participants organized their knowledge of the domain in terms of goal-relevant features, and the conceptual organization was able to support both the completion of the task and subsequent categorization tasks.

Keywords: category learning, goals, similarity.

Prior experience underlies intelligent behavior – people learn through interactions with the environment what behaviors lead to successful outcomes and what ones do not. An important component of this is recognizing categories of events and items among those experiences, a process that leads to the acquisition of conceptual knowledge, knowledge of those categories. That knowledge can be used to categorize, communicate, reason, and problem solve at later points. A fundamental question then is how coherent categories of items are identified so that the conceptual knowledge can be appropriately applied. Theories of categorization address what ties together items within a category and subsequently coheres the conceptual organization that reflects those categories, and most theories rely on a notion of similarity for at least a component of that cohesion (Hahn & Ramscar, 2001). Thus, the question shifts to how this similarity is determined.

There have been two basic approaches to answering this question (Malt, 1995). The first assumes that the environment constrains the similarity. Rosch et al. (1976) nicely capture this idea by positing that features of items in the world occur in reliable clusters and the conceptual system learns to recognize that structure. They go so far as to illustrate in one “experiment” (1976, Exp. 3) how overlaying tracings of the members of various basic level categories (e.g. cat, shoe, truck) results in greater perceptual overlap within-category than across categories. Similarly, others (e.g. Anderson, 1991) have stressed the role of the environment in determining conceptual structure. That view can be contrasted with one that places much of the emphasis on the individual to constrain the similarity. Murphy and Medin (1985) argued information from the environment has to be situated within the knowledge structures (e.g. inter-

category relations and theories) that the individual brings to any interaction with the environment. In this way, the structure of conceptual knowledge is constructed as the individual interprets what is to be considered feature information and how those features relate to one another.

Although most researchers interested in concepts and categories stake out some middle ground in this debate, much of the work in human category learning assumes that the environment provides structure. This assumption has seemingly created a disconnect between work exploring more naturalistic concepts and the basic experimental work examining conceptual acquisition (Murphy, 2005). I identify two critical differences between basic experimental studies and more naturalistic ones and explore them in the current study. First, in most experimental work, the categories are well defined in terms of their features and structure. Second, participants interact with members of those categories with the goal of differentiating the items they encounter based on that structure. In more naturalistic studies, the presence of the categorical structure is less clear and people interact with the items not with the goal of classifying items, but with the goal of accomplishing some other task. I present a study that incorporates a more complex, arguably more naturalistic, structure and vary the interactions that participants have with the items. In this manner, I examine how goal-directed behaviors within a domain affect the structure of the conceptual knowledge acquired about items within that domain.

I begin this research with the assumption that the environment is not a source of simple, unambiguous information about the categories that exist. For instance, people are able to recognize and use information about the taxonomic categories of food items, e.g. breads and vegetables, but they also recognize and use goal-related categories, e.g. snack foods and breakfast foods, to guide inferences and determine appropriate groupings of foods (Ross & Murphy, 1999). Similarly, people can identify and use ad-hoc categories (Barsalou, 1991) to guide behaviors. A study by Medin, Lynch, Coley, and Atran (1997) illustrates how this complexity can be reflected in conceptual knowledge. The experimenters asked various tree experts to sort cards labeled with tree names into groups. Those experts concerned with research and teaching tended to create groups that were highly correlated with the biological taxonomy, but landscapers tended to create groups that reflected the way the trees would be incorporated into landscaping decisions (e.g. a shade tree versus a weed tree). These cross-classifications and the development of ad-hoc categories of items are problematic

for an account that posits that the environment alone provides structure to our conceptual knowledge (although see Anderson, 1991, for a rebuttal). Although we have evidence of the complexity of naturalistic categories, the structure of the categories used in basic experimental work does not reflect this complexity (Murphy, 2005). Most items that comprise the categories are defined by specific feature lists or simple visual features, and the relation of the features to the categories is also carefully controlled. This typically results in a structure with only one “correct” organization for the items. Instead of operating in a situation with multiple possible configurations, participants in experimental studies are placed into a situation that is much more constrained by the information available.

Within these experimental studies, the interactions that people have with the categories are also different from what occurs in more naturalistic situations. In a typical category learning study, an item is presented, the participant predicts the category membership of the item, and feedback is given on the classification judgment. This approach has produced a great deal of information about how people learn to classify items, but may not capture important aspects of how people learn about categories in more naturalistic situations (Ross, Chin-Parker, & Diaz, 2005). Numerous studies have shown that classification learning promotes a near exclusive focus on diagnostic information, the features that distinguish the categories (Chin-parker & Ross, 2004; Rehder & Hoffman, 2005), but it is not apparent whether other means of category learning share this restricted focus (e.g. Minda & Ross, 2004). Arguably, the interactions we have within more naturalistic contexts are more varied and richer than the classification decisions made in a typical experimental setting. Importantly, I note that these interactions occur not with the primary intention to learn about the categories but rather to accomplish some other goal. The importance of goal-directed interactions has been explored by a range of cognitive scientists (e.g. Ram & Leake, 1995), and goals are implicated to some extent in how we come to recognize structure in the environment (Love, 2005). For instance, the naturalistic studies mentioned prior (e.g. Medin, Lynch, Coley, & Atran, 1997) suggest goal-directed interactions give rise to conceptual organizations that are able to support those interactions.

So, it seems that we can begin to bridge the chasm between experimental and naturalistic study of concept acquisition by adopting more complex categorical structures and varying the goals of the participants as they interact with the items that comprise those categories. Recently, Jee and Wiley (2007) did just that. They had participants learn about creatures that could be distinguished in terms of their perceptual features, shown through simple line drawings, or the nutritional value and ability to avoid predators (information about these features was conveyed through a list of features located beneath the picture). In their study, participants initially organized items in terms of similarity of the simple perceptual features, but as they learned about the domain and interacted with items, they either learned to

identify the nutritional value or how the creature avoided predators, the goal-relevant information came to be important within the conceptual organization. Subsequent transfer tasks showed that a participant adopted a conceptual organization that reflected the information that was critical to their interactions within the domain, and the participants’ similarity judgments were shaped by the presence of that information. Their study provides more clear evidence that the goal-directed interactions caused the shift in the conceptual structure.

In the current study, I examine category learning that occurs as the result of goal-directed interactions with items. Like Jee and Wiley (2007), I have a complex structure and participants interact with the items in accordance with different goals. In our study, the items are Flux Capacitor Boards, actual physical boards with various electrical components (non-functioning) affixed to them. As is described below, I created the boards so that there were two types of the boards that the participant would encounter during their initial task. However, only the classification participants were informed that these categories existed; the other participants were simply asked to complete their assigned task with the boards. Our primary hypothesis is that the conceptual organization adopted by the participants will be organized around the features of the boards that are relevant to the attainment of their goal.

As is described below, the *goal-relevant features* of the boards varied across the conditions. In one condition, the goal-relevant features are the configuration of specific components of the boards. In another condition, the goal-relevant features are relationships that exist between the components of the boards. For the classification condition, there were several possible sources of information that would be considered goal-relevant, or diagnostic. As noted in Jee and Wiley (2007), working towards a specific goal can often lead to information that is not goal-relevant to be left out of the conceptual organization. In this study, I expect that the two conditions with specific goal-relevant information will focus exclusively on that information, like classification learners in previous studies (e.g. Chin-Parker & Ross, 2004). Interestingly, since the classification condition will have multiple sources of information relevant to differentiating the categories, I predict that they will show a more general knowledge of the boards. I have no strong prediction as to whether the difference in the kind of goal-relevant information available to the two non-classification task conditions will affect the participants’ acquisition of useful conceptual knowledge.

Experiment

Methods

Participants and Design Fifty-seven participants were randomly assigned to three experimental conditions: 18 participants were assigned to the *flexible condition*, 19 to the *solid condition*, and 20 to the *classification condition*. Two participants in the classification condition failed to show evidence of learning during their initial task, so their data

were removed from all analyses. All participants interacted with the same set of items during the initial task and completed the same two transfer tasks¹. The presentation order of items during the initial and transfer tasks was randomized for each participant.

Materials and Procedure The primary materials for the study consisted of the Flux Capacitor boards and the connectors used to complete the boards. Each board had a series of nine terminal posts and various electrical components affixed to the board (see Figure 1). The posts were organized into three sets: One set in the upper, left-hand region of the board, one in the middle region, and one in the lower, right-hand region. The other components were placed around these posts according to the parameters described below. The boards were designed so that there were two types of boards that the participants encountered during the initial task, and variations of these two types of boards were created for the transfer tasks. During the initial task, participants in the flexible and solid conditions were given connectors that they placed onto the terminal posts to complete each board. The participants in the classification condition did not use connectors during their initial task

In the flexible condition, the connectors were made of wire and varied in terms of how they fit onto the terminal posts: The connector either fit over an open post or was inserted into a hole drilled into the “capped and drilled” post. As can be seen in Figure 1, each set of terminal posts in the Type A boards featured one post that has been capped and drilled and two posts that were open. In contrast, the Type B boards featured sets consisting of two capped and drilled posts and one open post. The configuration of the posts is considered to be the goal-relevant feature for the flexible condition because they constrain how the flexible connectors can be placed onto the board.

In the solid condition, the connectors were made of inflexible aluminum pieces, and the placement of these connectors was constrained by the presence of components situated near the terminal posts. For the Type A boards, the connectors had to go between components. For the Type B boards, the connectors had to go around the components. Thus, the relationship of the components to the posts is considered the goal-relevant feature for the solid condition because it constrained how the solid connectors could be placed onto the board.

The electrical components were unique to each board. However, each of the boards featured a perceptually salient *correlated component*. The correlated component for the Type A boards was a two-inch section of a computer memory module placed in the near left corner, and the correlated component for the Type B boards was a stack of silver clips with copper wire loops placed in the far right

corner. These components were not implicated in how the connectors in either condition could be placed onto the board but were perfectly diagnostic of the two board types. During the initial task, participants in the solid and flexible conditions were asked to complete the boards by placing three of the six connectors onto the terminal posts. The participants in the classification condition were told that the boards were incomplete and before they could be completed they needed to be identified as “positive flux” or “negative flux” boards. The classification participants were instructed to learn how to identify the two types of boards. There were eight boards used in the initial task phase, half were Type A and half were Type B. Each participant encountered each board twice during this phase.

In the classification condition, a board was placed into the holder, and after the participant responded with either “positive flux” (correct for the Type A boards) or “negative flux” (correct for the Type B boards), the experimenter provided feedback about the classification and allowed the participant to study the board. In the solid and flexible conditions, the experimenter placed a board into the holder, and the participant determined which connectors to place

Figure 1: Example problem boards from Experiment 1

Notes: The boards on the left are Type A boards, and the boards on the right are Type B boards. The top images show boards with no operators present. The center images show boards completed with the flexible connectors. The bottom images show boards completed with the solid connectors.

¹ Participants also completed a sorting task following the same-different task. However, the classification condition was inadvertently given different instructions for the task, so we are unable to compare performance across the groups. The results of the task very closely tracked those of the same-different task.

onto the board. After each trial, the board was removed from sight and a new board was placed into the holder.

After the initial task, all participants completed the same two transfer tasks. The materials for the transfer tasks consisted of photographs of flux capacitor boards the participants had not encountered during the initial task. The boards in the images were designed so that they varied in terms of how they related to the Type A/Type B board distinction that had been present during the initial task. No feedback was given to participants as they completed the transfer tasks.

First, the participants completed the *same-different task*. During each trial, the participant was presented with images of two boards affixed to a piece of paper. She was asked to indicate whether she would consider the two boards pictured to be the same type or different types. Across the sixteen items in the same-different task, I balanced whether the boards matched or mismatched in terms of the goal-relevant features. Eight of the pairs of boards maintained the same structure as the initial tasks boards; four of those pairs matched and four mismatched. All participants regardless of condition should identify the matches as the same and the mismatches as different if they picked up on any of the sources of information that differentiated the Type A and Type B boards during the initial task. The other eight boards were designed so that the goal-relevant features from the solid and flexible conditions were placed into opposition. For instance, if the goal-relevant features for the flexible condition matched what had been seen on the Type A board, the goal-relevant features for the solid condition would match what had been seen on the Type B board. Four of these board pairs were designed so that flexible condition goal-relevant features matched while the solid condition goal-relevant features mismatched. The other four board pairs were designed so the flexible condition goal-relevant features mismatched while the solid condition goal-relevant features matched.

The *category goodness-rating task* was the final task. I balanced whether the Type A or Type B boards were rated first. The participant was first shown a target board, one of the boards solved during the initial task phase, and was told that the board was either an “X-12” (Type A) or “G-59” (Type B) board. She was asked to rate each subsequent board shown in terms of the category indicated by the target board on a scale from one (“excellent example of this board type”) to nine (“not this type of board”); also anchored at three (“good example of this board type”), five (“ok example of this board type”), and seven (“poor example of this board type”). After the participant studied the target board for a minute, it was removed, and the items for the goodness-rating task were shown to the participant one at a time. There were five types of boards pictured in the stimuli for this task, and the participant rated two of each type for each of the categories. The *category consistent* boards were structurally identical to the target board. The *category inconsistent* boards were structured like the other type of board; so if the target board was a Type A board, the

category inconsistent board was a Type B board. The *correlation violation* boards were the same type of board as the target board, but the correlated feature was replaced by a small, perceptually dissimilar component. The *flexible violation* boards were of the same type as the target board, but were altered so the flexible connectors would not fit onto the posts. The *solid violation* boards were also of the same type as the target board, but they were altered so the solid connectors would not fit. Once the participant completed rating the ten boards for the first type, the target board for the second type was shown to the participant, and the task repeated for the second type.

Results

In the same-different task (Table 1), I found strong evidence that the participants in the flexible and solid conditions organized their knowledge of the domain in terms of the goal-relevant features. Across all items in the task, both the flexible condition, $M = 0.95$, $SD = 0.13$, $t(17) = 14.72$, $p < 0.001$, and the solid condition, $M = 0.87$, $SD = 0.18$, $t(18) = 8.64$, $p < 0.001$, were above chance performance in terms of assigning the pairs as the same or different in terms of the goal-relevant features for their conditions. The difference between the flexible and solid conditions was not significant, $t(35) = 1.57$, $p = 0.12$. A similar summarization of the results for the classification condition is not possible because there was no a priori prediction of how the classification participants would handle the items when the two goal-relevant features were placed in opposition. However, as can be seen in Table 1, when both of the goal-relevant features matched, they considered the boards as the same, and when both did not match, they considered the boards as different. When the goal-relevant features for the flexible and solid conditions were put into opposition (as in the “Flex + / Solid -” and “Flex - / Solid +” items), the participants in the classification condition did not show a preference for one source of information over the other as a group. Within the

Table 1: Proportion of Items (standard deviation) Identified as “the Same” in the Same-Different Task

Condition	Relation of Boards in the Pair			
	Flex + Solid +	Flex - Solid -	Flex + Solid -	Flex - Solid +
Flexible	0.94 (0.24)	0.01 (0.06)	0.90 (0.26)	0.04 (0.18)
Solid	0.86 (0.21)	0.11 (0.23)	0.15 (0.29)	0.86 (0.21)
Classification	0.83 (0.33)	0.19 (0.24)	0.46 (0.39)	0.36 (0.36)

Notes: For each item, the boards pictured either matched in terms of the goal-relevant features of the flexible (Flex +) or solid (Solid +) conditions or mismatched in terms of those features of the flexible (Flex -) or solid (Solid -) conditions.

classification condition, five participants had a pattern of response that indicated that they were using information about the goal-relevant features for the flexible condition, four participants appeared to be using information about the goal-relevant features for the solid condition, and nine participants had a pattern of responding that did not clearly indicate a preference for either source of information.

The category-goodness rating task provided a more specific indication of what information from the domain was being used by the participants in each condition. The data from the task (Figure 2) were analyzed using a series of ANOVAs. I report the results of five one-way ANOVAs that compared the ratings for each items type across the experimental conditions. I also include relevant within-condition comparisons where appropriate (full analyses are not included due to space restrictions).

There were no differences as to how participants in the three conditions rated the category consistent items, $F(2, 54) = 0.01$, $MSE = 0.02$, $p = 0.99$, but there were significant differences within all the other item types. Participants in all conditions rated the category inconsistent items as less good category members compared to all other items. Also, within the ratings for the category inconsistent items, there were some differences between the conditions, $F(2, 54) = 3.41$, $MSE = 1.27$, $p = 0.04$, primarily between the classification and flexible conditions. The ratings of the correlation violation items also varied by condition, $F(2, 54) = 3.72$, $MSE = 3.45$, $p = 0.03$. The classification condition rated these items as significantly worse category members than the category consistent items ($p < 0.01$) but the other two conditions did not. There were significant differences in the ratings of both the flexible violation items, $F(2, 54) = 21.62$,

$MSE = 3.69$, $p < 0.01$, and the solid violation items, $F(2, 54) = 40.51$, $MSE = 3.04$, $p < 0.01$. As predicted, the participants in the solid condition rated the solid violation items as significantly worse than the category consistent items ($p < 0.01$), but did not rate the flexible violation items differently than the category consistent items ($p = 0.54$). The participants in the flexible condition rated the flexible violation items as significantly worse category members than the category consistent items ($p < 0.01$), but not the solid violation items ($p = 0.83$). The classification condition did not rate the solid violation items as significantly worse than the category consistent items ($p = 0.13$), but did rate the flexible violation items as worse category members ($p = 0.02$).

Discussion

I return to the question regarding what constrains the similarity underlying conceptual organization. The results of the participants in the flexible and solid conditions clearly show that the goal-relevant features are central to their notion of similarity for the items and thus critical for the organization of categories of boards within the domain. They identify novel boards as the “same” when they match in terms of the goal-relevant features and “different” when those features do not match. They also show a pattern of category goodness ratings that indicates that violating those goal-relevant features makes the boards less good members of the category while violating other sources of information have little or no effect on those judgments. The participants in the classification condition seem to maintain a more diffuse attentional focus during the initial task. This is interesting given earlier studies that show a very narrow focus for classification learners. However, these results fit well together when we consider that the goal of classification learning is to predict the category membership of items. Typically only a subset of the information available within the experimental materials allows those judgments to be accurately made, so the classification learner attends most to that subset of information. In this study, multiple sources of diagnostic information existed, so the classification learners maintained a correspondingly wide attentional focus. It was the participants in the solid and flexible conditions that had a narrow focus in this experiment, and this was due to the fact that only a subset of the information available within the domain was goal-relevant for each condition.

In one sense the results of this study are not surprising – there are numerous models of learning that incorporate an attentional mechanism (as discussed in Kruschke, 2003) to account for shifts across the information available during learning. Although attention obviously plays a critical role in the learning, it is not a sufficient determinant of learning; we need to understand what drives the attention. I propose that attention is guided by comparisons between the boards as the participants interact with them in terms of the goal they have (how to place the connectors or classify the board), and those features that are relevant to the person’s

Figure 2: Mean Category-Goodness Ratings by Condition and Item Type

Figure Note: The category-goodness rating scale ranged from one (“excellent example of this board type”) to nine (“not this type of board”).

goal are picked out during the comparison process (e.g. Medin, Goldstone, & Gentner, 1993). It is important to note that this approach helps to explain how “simple” perceptual features (e.g. the capped and drilled posts) and relational information (e.g. how components were positioned with regard to the posts) can both be picked up and used in grounding similarity.

One critical question is whether the participants in this study were *really* engaged in category learning, or to put it another way, did they *really* recognize categories of boards during the initial task? In the typical classification learning paradigm, this question is deflected because the participants explicitly know of the presence of the categories and their responses are made in response to those categories. However, as has been noted prior, there are questions as to whether even that *really* constitutes learning a category (Ross, Chin-Parker, & Diaz, 2005). For this study, I would argue that the participants acquire knowledge that is sufficient to support their task (identifying the “type” of board facilitates the placement of the connectors, and there was ample evidence of this facilitation occurring during the learning) and to guide later, more explicitly category-based tasks. It is at least the foundation of category learning.

The current study was not designed to address all facets of this process. For instance, additional study within this paradigm will be able to determine whether the participants came to adopt different representations of the features (e.g. Schyns, Goldstone, & Thibault, 1998) or whether they learned to ignore certain information (e.g. Denton & Kruschke, 2006) as they better discriminated the features during the learning. This paradigm provides a unique way to approach these types of questions and to situate the study of them within a larger framework intended to guide our understanding of the acquisition of conceptual knowledge.

Conducting this type of study within a more complex, and arguably more naturalistic, domain, we can begin to see the interaction between the individual and the environment that helps to shape the acquisition of conceptual knowledge. We can extend our understanding of the ways in which goals are implicated in category learning and how we might bridge the chasm that has separated naturalistic studies of concepts from more experimental studies.

Different Kinds of Pragmatic Factors Explain Failures of Default-to-Stereotype Inferences

Matthias Unterhuber

University of Düsseldorf

Gerhard Schurz

University of Düsseldorf

Abstract: Connolly, Fodor, Gleitman, and Gleitman (2007) present theoretical and empirical evidence against the Default-to-Stereotype (in short: DS) inference and argue that prototype theories of concepts predict (DS)-inferences. Hence, they conclude that prototype theories are inadequate. Jönsson and Hampton (2008) and Hampton, Jönsson, and Passanisi (2009) argue that (1) prototype theories do in general not predict (DS)-inferences, and that (2) Gricean pragmatic effects can largely account for Connolly et al.'s empirical results. They, however, interpret a minor but still substantial part of the findings as a genuine deviation from the (DS)-inference rule. In this paper we first argue that the results of Connolly et al. (2007) pose a greater threat to prototype theories of concepts than Jönsson and Hampton (2008) suggest. Second, we present an experiment which implies that Connolly et al.'s findings can be solely explained by following Gricean pragmatic factors: (a) non-redundancy preferences and (b) informativeness suppositions.

The Effect of Graph Design Type on Word Preferences In the Description of Trend and Cyclic Events

Ozge Alacam

Middle East Technical University

Annette Hohenberger

Middle East Technical University

Kursat Cagiltay

Middle East Technical University

Abstract: This study was conducted as a part of larger study on the effect of graph type on trend and cyclic event comprehension. It aims to present the analysis of subjects' word preferences in the verbal description of trend and cyclic events, given different graph types (linear, round). For this purpose, a novel round graph type was designed. For instance, while in the linear graph timeline for a year, January is located on the left and December on the right side, in the round graph, January and December are located adjacently. As a data collection tool, verbal description task and evaluation forms were used. 40 university students participated in this study.

The results revealed that, although the graph type has no significant effect, the event type conveyed by them modulates word preferences (ex. usage of trend, discrete, and conceptual words) in the description of relations among elements depicted in the graph.

When to Switch? Understanding How Performance Tradeoffs Shape Dual-Task Strategy

Duncan Brumby

University College London

Nina del Rosario

University College London

Christian Janssen

University College London

Abstract: We use a novel dual-task paradigm to investigate how people adapt their strategy for interleaving attention between tasks to meet varying performance objectives. The study required participants to encode and enter a series of route instructions from a secondary display while driving a simulated vehicle. Experimental instructions were given to encourage participants to either prioritize safe driving or the secondary navigation task. Results show that participants met the required task objective by varying the frequency that they interleaved tasks and by varying the amount of time they spent in between visits to the secondary display. We explain these data using a framework for modeling driver distraction effects. The model explained the observed change in performance measures between the two priority conditions and also the observed change in strategy. Taken together these results support the idea that people can strategically allocate attention in multitask settings to meet specific performance criteria.

When More Load Leads to Less Distraction in Multimedia Learning: An Event-Related Potential Approach

Krista DeLeeuw

Knowledge Media Research Center

Richard Mayer

University of California, Santa Barbara

Barry Giesbrecht

University of California, Santa Barbara

Abstract: In multimedia learning, the modality effect occurs when students learn better from a lesson containing graphics accompanied by narration than one accompanied by on-screen text. The redundancy effect occurs when students learn better from a lesson containing graphics accompanied by narration than one accompanied by narration and on-screen text. In order to determine the information-processing mechanisms responsible for these effects, 36 students viewed three multimedia lessons in which the words were presented as narration, on-screen text, or both. During the lessons, brief visual distractors were presented and event-related potentials (ERPs) in response were measured. Learners showed a more positive early (P1) ERP response during the graphics+text lesson than during the graphics+narration+text lesson, indicating that more perceptual processing was required for the latter condition. In general, results suggested that perceptual load plays an important role in the modality and redundancy effects, a useful clarification of the cognitive theory of multimedia learning.

Information Search in Decisions from Experience: Do Our Patterns of Sampling Influence Our Decisions?

Thomas Hills
University of Basel

Ralph Hertwig
University of Basel

Abstract: Does the way we sample information from the environment influence the decisions we make, even when the information we obtain would otherwise be equivalent? In past research, this question has been difficult to answer because the information we obtain is often confounded with its consequences. We investigate this question by analyzing data in a paradigm where exploration comes prior to consequential decision-making, in the binary choice paradigm of decisions from experience. By investigating the relationship between patterns of information sampling and subsequent decisions, we find that individuals who switch more between options are less sensitive to the sample means and more likely to make decisions based on the outcome of pairwise comparisons, especially recent outcomes—choosing options that win most of the time. We further show that such pairwise strategies are associated with the underweighting of rare events.

The sensory nature of knowledge

Lionel Brunel

Benoit Riou

University lyon 2

Mathieu Lesourd

University lyon 2

Elodie Labeye

University lyon 2

Rémy Versace

University lyon 2

Abstract: The aim of the present studies are to assess the sensory nature hypothesis of knowledge through a series of experimental results. Especially, we investigated the links between memory and perception using a short-term priming paradigm based on a previous learning phase consisting of the association between a geometrical shape and a white noise. The priming phase examined the effect of a geometrical shape, seen in the learning phase, on the processing of a target (tones or picture). Our main results demonstrate that memory and perception share some mechanisms and components. These ones are relevant for the processing of each form of knowledge (episodic and semantic). At last, reflections about the implication of this work to study perceptual learning and memory are presented.

Wrong prediction by experts provide more support than that by novices

Kuninori Nakamura

Tokyo Institute of Technology

Abstract: The current research explored whether lay people have a tendency to provide higher support for "wrong" predictions made by experts than those made by novices. Three empirical studies consistently revealed that there indeed exists a preference for wrong predictions even when predictions are made by experts. In addition, the current research also formulates preferences for wrong predictions made by experts in terms of a Bayesian inference and expresses the processes by which one may believe the wrong prediction in the form of two factors—prior odds and likelihood ratio. Finally, I argue that this preference is logical when treated as a result of the comparison between the two competing hypotheses.

Change in Encoding Facilitates Principle Acquisition

Richard Prather

Indiana University

Abstract: This study addresses the interaction between stimulus encoding and learning. Specifically I address the acquisition of arithmetic principle knowledge and its relation to learners arithmetic equation encoding. Arithmetic principle knowledge has been shown to be a key aspect of early mathematical development. Behavioral results suggest that children with experience encoding relevant characteristics show a change in their principle knowledge. Computational results mirror this finding. Model instantiations in which the same equation encoding is used show similar behavior. I take this as preliminary evidence of a direct connection between the encoding of arithmetic equations and knowledge in the arithmetic domain. This has clear applications to both developmental theory and educational practice.

Complementary processing systems: A PDP model of the simultaneous perception of multiple objects

Cynthia Henderson
Stanford University

James McClelland
Stanford University

Abstract: Illusory conjunctions in normal and simultanagnosic subjects are instances where the binding of visual information fails to function correctly. When presented with multiple objects simultaneously, simultanagnosic patients and normal subjects under conditions of attentional loads or brief presentation times often erroneously report miscombinations of features of the objects. A connectionist model of multi-object perception examines how the concurrent perception of more than one object could occur in normal subjects and become deficient with shortened processing times. In this model, the correct identification of two objects is accomplished through lateral connections between the ventral and dorsal pathways. Lesioning of the dorsal pathway produces failures in multi-object recognition characteristic of the effect of parietal damage in simultanagnosia. It is hoped that the functioning of this model might help elucidate possible processes underlying the correct solution of the binding problem in normal subjects.

Ascribing Causality and Intention to 2D Animations

David Pautler

A*STAR Singapore

Bryan Koenig

A*STAR Singapore

Boon-Kiat Quek

A*STAR Singapore

Andrew Ortony

A*STAR Singapore, Northwestern University

Abstract: People routinely ascribe intentions and other mental states to others (partly) on the basis of observed behavior, and research shows that they tend to do this spontaneously, even with simple geometric objects moving in a 2D plane. We believe that 2D animations isolate a critical kind of information — object movement — that avatars and social robots could use when making attributions in social interaction. Our approach uses spatiotemporal, contoured constraints about objects and their movements to identify candidate causes and intentions, and then, based on evidence from background knowledge, infers which is most likely. This approach could eventually be integrated with perceptual information, such as appearance or gaze, as well as richer models of the world and other agents' minds, in order to augment the social intelligence of artificial agents.

Limits in Monitoring and Recall with Constant and Changing Memory Sets

Daniel Cassenti

U.S. Army Research Laboratory

Richard Carlson

The Pennsylvania State University

Troy Kelley

U.S. Army Research Laboratory

Abstract: Monitoring of the environment for consistency with working memory is a common aspect of human performance, as is updating working memory to reflect changes in the environment. In two experiments, we examined limits in monitoring performance and working memory retention as the number of items to be held and monitored varied from one to eight. In Experiment 1, participants monitored a display on the basis of a static memory load. In Experiment 2, participants sometimes updated the memory load by substituting new information in the display. Both monitoring and retention were quite good in Experiment 1. In Experiment 2, monitoring performance was compromised even with a single-item load, and retention was poor for loads greater than 4 or 5 items. We discuss both theoretical and applied implications of these results.

Hick's Law in the Random-Dot Motion Task

Leendert van Maanen

University of Amsterdam

Eric-Jan Wagenmakers

University of Amsterdam

Abstract: In a series of experiments we studied whether Hick's law is present in the random-dot motion task (RDM). Hick's law is the very strong experimental finding in multiple-choice research that mean response time increases with the logarithm of the number of response options. In the RDM task participants have to indicate from a group of moving dots what the dominant direction of movement is. We studied how response times in this task increased as a function of the number of alternative directions of movement presented to the participants. Using a computational model, we show that Hick's law is present, but only if the relative distance between the alternative directions of movement is taken into account.

Are Place Names Merely Referencing Expressions?

Paula Engelbrecht

Ordnance Survey

Michael Tull

University of Portsmouth

Abstract: Previous research found cross-modality priming for the names of well-known people and landmarks, but not for nouns or country names (Hollis & Valentine, 2001). Hollis and Valentine argue that country names were processed like nouns because they have sense (i.e. they can act as adjectives) and are therefore not pure referencing expressions. However, it could be argued that the participants processed country names like nouns because they possessed richer knowledge about countries (e.g. culture, climate, political structure) than about landmarks. The current study used locality names that cannot act as adjectives to test this interpretation. No cross-modality priming was found for locality names, indicating that they are processed like nouns. One possible interpretation of these findings is that the richness of the mental representation associated with a given place name determines whether it will be processed as a noun. © Crown Copyright 2010 Reproduced by permission of Ordnance Survey.

Sociocultural history of the machine metaphor

Vladimir Glebkin

Gymnasium 1514, Moscow

Abstract: Most theories of metaphor in modern cognitive linguistics either highlight the metaphorical system of human beings in general or describe differences in metaphorical systems of various cultures as a fact and do not explain the reason for these differences. When does some metaphor appear in the language? Why does it appear in this period of time but not earlier or later? Such questions sound weird in the context of this discourse, but prove to be important for understanding of sociocultural nature of some basic metaphors. The most obvious answer to these questions is: metaphor appears in language when its source domain begins to play an important role in social life. However, the history of metaphor of machine shows that this answer is not always correct. The metaphor of machine was not known in antiquity, but it had appeared in the Middle Ages long before the machines became widely used.

Agile Software Development Process: A Case Of Collaborative Cognition In Flux

Nik Nailah Binti Abdullah

GRACE Center, National Institute of Informatics

Robert G.M Hausmann

Carnegie Learning Incorporation

Shinichi Honiden

GRACE Center, National Institute of Informatics

Helen Sharp

Centre for Research in Computing, The Open University

Abstract: What role do physical artifacts play in decreasing the flux of an individual's and a group's representation during collaboration? This question was addressed in the case of Agile software development, which emphasizes collaboration. Evidence suggests that the keys to success in Agile are two physical artifacts: the "story card" and the "wall." These artifacts are particularly useful when supported by appropriate social interactions. Thus, we conducted an ethnography study of an Agile team and used situated cognition to study their communication process. We found that members perform a categorization process both at the perceptual and conceptual level, which is akin to structural coupling. The physical artifacts play a mediation role to help members form and sustain the structural coupling process, both together as well as individually. This, in turn, helped them to sustain common ground and decrease the flux of the individual's and group's representation of system design.

The Influence of Prior Knowledge on Recall for Height

Pernille Hemmer

University of California, Irvine

Jenny Shi

University of California, Irvine

Mark Steyvers

University of California, Irvine

Abstract: Many aspects of our experiences do not have to be explicitly remembered, but can be inferred based on our knowledge of the regularities in our environment. Such knowledge can operate at multiple levels of abstractions. For example, this could lead to recall for the height of a particular person to be influenced not only by general knowledge about heights of people, but also by specific knowledge about the height of men and women. We assess the relative contribution of this type of prior knowledge on reconstructive memory. In a series of behavioral studies we first assessed people's a priori expectations of the heights of men and women. We show that people's a priori expectations are in line with the true distribution of heights in the population. We then tested memory performance in a continuous recall task in which subjects had to reconstruct from memory the height of people shown earlier in a sequence. The stimuli were either naturalistic images of males and females or gender-ambiguous silhouettes. Our results suggest not only that prior knowledge can improve average recall, but also that knowledge can come from multiple levels of abstraction such as gender and the overall height of people.

Harry Potter and the Sorcerer's Scope: Scope Biases in Explanatory Reasoning

Sangeet Khemlani

Princeton University

Abigail Sussman

Princeton University

Daniel Oppenheimer

Princeton University

Abstract: What makes a good explanation? We show that individuals prefer explanations with a more narrow scope – those that account for fewer unobserved effects – to broader explanations. In Experiments 1 and 2, participants evaluated a narrow scope and a broad scope explanation of an observed symptom and preferred the former to the latter. In Experiment 3, participants evaluated more natural explanations of unexpected observations, and again displayed a bias for narrow scope explanations. We conclude by considering what this novel bias tells us about how humans evaluate explanations and engage in causal reasoning.

Cognitive Load Measurement through Multimodal Behaviour Patterns

Natalie Ruiz
NICTA, UNSW

Ronnie Taib
NICTA, UNSW

Fang Chen
NICTA, UNSW

Abstract: Our research focuses on extending the accepted benefits of multimodal computer interaction by using the paradigm to detect fluctuations in cognitive load. The advantage of this approach is that cognitive load can be determined implicitly by monitoring variations in specific multimodal input features executed during day to day tasks using a computer interface. Such unobtrusive measures may help determine the user's cognitive load in real-time, and achieve the ultimate goal of adapting information selection and presentation in a dynamic computer interface with reference to load. We identified some correlations between the communicative structure of combined speech and manual gesture input and high levels of cognitive load. The results suggest that semantic multimodal communicative structures are sensitive to cognitive load variations, with multimodal communication becoming half as redundant in high load than in low load. The feasibility of using rates of redundant constructions or complementary constructions in multimodal input as an index of cognitive load is supported by the results of our study.

Conceptual understanding of the relationship between consciousness, memory, and attention

Eunsook Kim

Interdisciplinary Research Program of Cognitive Science, Pusan National University, South Korea

Hyunjung Shin

Department of Psychology, Pusan National University, South Korea

Abstract: Consciousness is regarded as too ambiguous a concept to be understood and accepted as a mental construct without the inclusion of memory and attention in any conceptualization. We need one criterion to count satisfactorily as an explanation of consciousness in information processing. An operational working definition of consciousness could be made in comparison of memory and attention: Consciousness would be a subjective awareness of momentary experience and also have the characteristics of an operating system performing control and consolidation information processing, even though those are not equivalent concepts. This could be called a cognitive consciousness. If cognitive consciousness is postulated as a mental construct characterizing awareness, control and consolidation, the phenomena like word superiority effect, auditory continuity and object categorization, could be understood clearly, which was not the case in the past.

To Be Subtle or To Be Clear?: Comparing Strategies for Changing People's Attitudes Towards Social Groups

M. Afzal Upal

Influence & Effects Research Group Adversarial Intent Section Defence Research & Development
Canada Toronto

Abstract: The problem of deciding which strategy to use to influence a target audience's social identity beliefs is of interest to social influence practitioners as well as social cognition researchers. This paper compares the effectiveness of three social influence strategies in terms of their ability to lessen their reader's affiliation for a targeted social group. We designed three messages that vary in terms of (a) how well they hide their persuasive intent and (b) clarity of the message. Our results indicate that message clarity had a stronger impact on people's group affiliation than the persuasive intent of the message. The most rhetorical and blunt Message 1 was more effective in reducing people's affiliation for the targeted group than the more subtle narrative Messages 2 & 3. The most subtle Message 3 was least effective in terms of being able to reduce subject's affiliation for the targeted group.

Category directedness

Steven Verheyen

University of Leuven

Gert Storms

University of Leuven

Abstract: The answer to the question of what constitutes a category generally comes in two guises. The first refers to the set of characteristic features associated with the category (category intension). The second refers to the set of items in the world that is delineated by the category (category extension). Although intension and extension are two complementary depictions of what a category is, little is known about their interrelation. We will present a theory of semantic categories that assumes both exemplars and features to vary along a common latent scale. Evidence for this theory will be provided through an analysis of feature by exemplar applicability matrices with the two parameter logistic model. This item response model for unidimensional data not only fits the applicability matrices, its parameters naturally account for the varying representativeness of the constituting features and exemplars.

'Meryem (reportedly) missed her flight': Cognitive Implications of the Turkish Evidential

Sumeyra Tosun
Texas A&M University

Jyotsna Vaid
Texas A&M University

Lisa Geraci
Texas A&M University

Abstract: Two experiments with adult native users of Turkish and English speaking controls examined cognitive repercussions of obligatory grammatical marking in Turkish of directly vs. indirectly experienced events. Exp. 1 examined recall accuracy of Turkish sentences containing direct vs. indirect past tense suffix markers; equivalent sentences in English contained lexical marking of indirectness (e.g., "reportedly"). Exp. 2 examined incidental recognition memory for sentences containing direct vs. indirect experience markers. Performance in Exp. 1 was uniformly low, indicating a floor effect in sentence information recall. Exp. 2 showed significantly better recognition memory for sentences containing the direct marker vs. the indirect marker in Turkish; no such advantage was observed in English. The findings suggest that obligatory marking of directly experienced events has a privileged status in mental representation.

Abstract Perceptual Learning of Hidden Patterns

Everett Mettler

University of California at Los Angeles

Hongjing Lu

University of California at Los Angeles

Philip Kellman

University of California at Los Angeles

Abstract: 'Perceptual learning' (PL) refers to experience induced improvements in the extraction of information from the environment. Although early work emphasized that PL often involved discovery of abstract invariants from stimulation (Gibson, 1969), most recent work has focused on concrete, low level stimulus properties. We describe research to understand abstract perceptual learning (APL), which requires discovery of structural relations between features, and compare it to concrete PL. Learners discovered hidden targets – 10 squares of the same luminance embedded in 12x12 'grids' of varying luminance noise. Concrete targets maintained pixel position and luminance across trials. Abstract targets changed either position or luminance across trials. In a discovery task, humans were able to discover both concrete and abstract patterns. We show that existing computational models can describe concrete but not abstract learning and we suggest models that can account for abstraction in PL.

Metathesis in English and Hebrew: A Computational Account of Usaged-Based Phonology

Paul De Palma

Gonzaga University University of New Mexico

George Luger

University of New Mexico

Abstract: It is now well understood that language use shapes the acoustic delivery of phonological patterns. One common example of this type of language change-under-use is metathesis, which is the reversal of the expected linear ordering of sounds. The gradual transformation of the Spanish word chipotle to chipolte in the United States is an example of metathetic change. The Genetic Algorithm (GA) is an optimization technique loosely based on the idea of natural selection. This paper shows that the GA can provide a computational model of a usage-based account of examples of metathesis. In the process, it argues that computer models can bring precision to linguistic theory. As an example we create a GA that is able to characterize metathesis in English and then is able to achieve even better results for related expressions in modern Hebrew.

Explaining the Minimal Counterintuitiveness Effect Without Assuming A Strongly Modular Mind

M. Afzal Upal

Influence & Effects Research Group Adversarial Intent Section Defence Research & Development
Canada Toronto

Abstract: This paper outlines two approaches to account for the finding that concepts that are minimally counter-intuitive are better remembered than intuitive or maximally counterintuitive concepts. The first approach considers such memory advantages to be a property of the concepts themselves while the second approach emphasizes the role played by the context in which such concepts appear in allowing a reader to make sense of them. The context-based view also suggests that counterintuitive concepts lose their advantages as they become widely accepted and embedded in a cultural milieu. In the new context, ideas with enhanced counterintuitiveness obtain transmission advantages. This helps explain cultural innovation and dynamism. It also allows us to account for the development and spread of complex cultural ideas such as the overly counterintuitive religious concepts including the Judeo-Christian-Islamic conceptions of God.

Interpretate Novel Conceptual Combinations: Age-Related Impact of Memory Availability

Sandra Jhean-Larose

Université Paris Sorbonne /I.U.F.M. de Paris Equipe CHArt (Cognitions Humaine et Artificielle)-
E.P.H.E 41, Rue Gay-Lussac.75005 Paris. FRANCE

Fabiola Martinez

Equipe CHArt (Cognitions Humaine et Artificielle)- E.P.H.E 41, Rue Gay-Lussac.75005 Paris.
FRANCE

Abstract: This study looks at how combinations of two French nouns ("Incendie Brûlure" /"Fire Burn" ; "Voiture Tortue"/"Turtle Car") are interpreted. The order of occurrence of the constituents of two types of conceptual combinations, Relation and Property, was manipulated in view of determining how property-based and relation-based interpretations evolve with age. Three groups of French-speaking children (ages 6, 8, and 10) and a group of adults performed an interpretation-selection task. The results for the children indicated that while property-based interpretations increased with age, relation-based interpretations were in the majority for both combination types, whereas for the adults, relation-based interpretations were in the minority for property combinations. For the children and adults alike, the most frequent interpretations were ones in which the head noun came first and was followed by the modifier (the opposite of the order observed for English).

Interactive Representation in the Motor Control

Daniel Hsi-wen Liu

Providence University

Abstract: Within the approach to embodied representation, Bickhard's (1993, 2000) account of interactive representation, like Rosenberg & Anderson's (2004) guidance theory of representation, employs a notion of representation that is not grounded on the standing-in-for relation. However, Bickhard's accounts of interactive representation remains in need of explanation as to why the interactive representation is genuine representation. The present paper aims at this explanation, with the focus of anticipatory motor activities, by employing Merleau-Ponty's notion of 'motor intentionality' (Merleau-Ponty, 2006). For this, the present paper explains how the interactive representation relates to motor performance in its immediate environment, in other words, how the interactive representation gains its intentional content. In addition, the present paper argues that the interactive representation of motor activities provides the guidance of motor actions, and vice versa, hence Bickhard's notion of interactive representation and Rosenberg & Anderson's guidance theory of representation are two versions of the same theory.

The network properties of episodic graphs

Yuwen Zhuang

Department of Computer Science and Engineering, Ohio State University (OSU)

Vishnu Sreekumar

Department of Psychology, Ohio State University (OSU)

Mikhail Belkin

Department of Computer Science and Engineering, Ohio State University (OSU)

Simon Dennis

Department of Psychology, Ohio State University (OSU)

Abstract: We present statistical analyses of the small world properties for two particular types of episodic graphs. One is from the paragraph space of the Internet Movie Database (IMDb) and the other is from images collected as subjects engaged in their activities of daily living. We show that they have a small-world structure which is characterized by sparse connectivity, short average path lengths between nodes, and high global clustering coefficient. However, the degree distribution analyses show that they are not scale-free graphs. For the analyses, we selected edges from different proportions to construct the networks, hence, a series of analyses reveal the growth style of these two episodic graphs.

Keywords: Small World; Episodic Graphs; Scale-Free Graphs; Internet Movie Database (IMDb);

Weakly Supervised Learning: What Could It Do and What Could Not?

Jinhui Yuan

Tsinghua University

Bo Zhang

Tsinghua University

Abstract: Weakly supervised learning is not only a typical way of human concept learning, but also has wide real-world applications. Of particular interest to this paper is the theoretical aspect of weakly supervised learning: (a) Could weakly supervised learning learn the target concept the same as that of fully supervised learning? (b) If yes, under what conditions it will and how to achieve it? In other words, this paper will investigate what weakly supervised learning could do and what could not. The basic idea is, weakly supervised learning could be transformed into an equivalent supervised learning problem, in which way, it could be understood with the tools of supervised learning. The major results of the paper include: (a) the hardness of weakly supervised learning depends on the properties of training data and the adopted feature representation; (b) though there is no theoretical guarantee for a unique identification of the relevant variables, incorporating minimum description length principle may help infer target concept; (c) weakly supervised learning could be solved by EM-style algorithm, which is not a novel idea, however, the theoretical analysis suggests that the E-step and M-step should adopt feature representations with distinct properties rather than using the same feature.

Models of Information Integration in Perceptual Decision Making

Jared Hotaling

Indiana University

Andrew Cohen

University of Massachusetts

Jerome Busemeyer

Indiana University

Richard Shiffrin

Indiana University

Abstract: In cognitive science there is a seeming paradox: On the one hand researchers studying judgment and decision making (JDM) have repeatedly shown that people employ simple and often sub-optimal strategies when integrating information from multiple sources. On the other hand another set of researchers has had great success using Bayesian optimal models to explain information integration in fields such as categorization, perception, and memory. One impediment to reconciling this paradox lies in the different experimental methods each group has used. Recently, Hotaling, Cohen, Busemeyer, & Shiffrin (submitted) conducted a perceptual decision making study designed to bridge this methodological divide and test whether the sub-optimal integration found in verbal problems stated in terms of probabilities may also appear in perceptual tasks. Their results indicate that a classic JDM finding, the dilution effect, does arise in perceptual decision making. Observers were given strong evidence X favoring A over B, and weak evidence Y also favoring A over B. According to Bayesian analysis, the odds in favor of A should be multiplied, resulting in an increased likelihood of A. Instead, Hotaling et al. found that the weak evidence diluted the strong evidence, producing decreased judgments and choice probabilities favoring A, given X & Y, than given X alone. I review these empirical findings and test both rational and cognitive models of the integration process.

The Influence of Integration and Counterintuitiveness on Memory for Text

M. Afzal Upal

Influence & Effects Research Group Adversarial Intent Section Defence Research & Development
Canada Toronto

Mary Harmon-Vukic

Psychology Department Providence College

Abstract: Recent studies suggest that counterintuitive ideas embedded in stories facilitate their subsequent recall, thus increasing the likelihood that such stories survive time and space. However, it could be that structure of counterintuitive stories affects memory rather than the distinctiveness of their contents. Indeed, Harmon-Vukic and Slone (2009) demonstrated that integration of story information eliminated the counterintuitiveness effect. The purpose of the present experiment was to further explore the influence of integration on memory for counterintuitive concepts. Participants were presented with a story containing elements that were either intuitive, minimally counterintuitive, or maximally counterintuitive. In addition, the stories were either integrated or not integrated. Participants were asked to recall the material either immediately, or one week later. Consistent with the results of Harmon-Vukic and Slone recall performance was best for integrated stories, regardless of level of intuitiveness. The same effect occurred on week later, although overall memory performance was lower.

An Attention Based Theory to Explore Affordances of Textual and Diagrammatic Proofs

Peter Coppin

University of Toronto

James Burton

University of Brighton

Abstract: Shimojima and Katagiri have demonstrated that diagrams reduce "inferential load" during reasoning by scaffolding visual-spatial aspects of memory. In response, we wondered why, if this is true, that proofs are usually text based? The purpose of this paper is to explore ergonomic affordances of text that may encourage its use in the communication of proofs by building on prior work in attention. We claim that textual notations may focus a reasoner's "spotlight" of attention through serialized sequential chunks, whereas many diagrams may "diffuse" attention and that a diagrammatic notation system that serialized information in chunks amenable to focused attention could leverage the power of textual notations. We present such an example through a case study focused on generalized constraint diagrams, a visual logic with attributes that may support focused attention and extract ergonomic principles that may transcend each notation system.

Socially Facilitated Alignment and Novelty in Separate Channels of Communication

Monica Riordan
University of Memphis

Rick Dale
University of Memphis

Roger Kreuz
University of Memphis

Abstract: We discuss two viewpoints of potential interactive alignment, socially facilitated priming and socially facilitated novelty, and test them by using simulated online conversation. In a computer-based pseudo-interactive environment, participants were led to believe they were interacting with another person or that they were seeing examples from a database and must supply 12 responses. The exchange consisted of a modified game of "I never." In both conditions, nine prompt sets were presented in which the verb, tense, topic, and presence of emoticons varied. Recall was also tested. Results show that those who believed they were conversing with another person aligned less than those who believed they were seeing examples, but recalled more of the prompts. In addition, those who believed they were talking to another person used more emoticons than those who believed they were seeing examples. We suggest that a more complex theory of alignment is necessary in which different levels of alignment, including but not limited to topical and emotional, are modulated differentially to account for the flow and drive of conversation.

The Influence of Causal Information on Memory for Misinformation

Jessecae Marsh

Texas Tech University

Sarah Kulkofsky

Texas Tech University

Abstract: Causal information has been characterized as a "mental glue" that binds ideas together in the mind. This experiment tests the influence of such causal binding in a traditional memory misinformation paradigm. Participants studied information that either appeared as individual traits or as traits connected by causal links. Participants then rated a series of traits that contained both true and "misinformation items." Misinformation items were created to be causally plausible or implausible alternatives to previously learned information. Our question was whether the presentation of causal links in the study phase would affect the reporting of misinformation in later phases. Participants in the causal version of the study phase were more influenced by misinformation items that were causally plausible than items that were causally implausible. Participants in the noncausal version of the study phase were not differentially influenced by the plausibility of misinformation lures. Explanations for these results are discussed.

The Interaction of Age and Skill for Recognition of Chess Positions

Jerad H. Moxley

Florida State University

K. Anders Ericsson

Florida State University

Tyler J. Towne

Florida State University

Ryan Best

Florida State University

Abstract: Even young chess players display superior recall for chess positions (Chi, 1978; Horgan & Morgan, 1990; Schneider, Gruber, Gold, & Opwis, 1993), which has been attributed to their greater chess knowledge and available patterns and chunks (Chase & Simon, 1973). Controlling for skill no effect of age has generally been found in youth chess players on chess tasks. This study demonstrates, a strong effect of age, where older children are better able to recognize chess positions. Additionally this study uncovered an interaction between age and skill whereby older children who are better at chess do much better than other groups. We propose that older children use deeper processing techniques to scaffold the complex memory structures that support chess playing, which may not be automatically applied to an unfamiliar task.

Thinking Ahead: How Children Reason About the Future

Janani Prabhakar

Rutgers University, New Brunswick

Judith Hudson

Rutgers University, New Brunswick

Abstract: Episodic future thinking relies heavily on self-projection, i.e., projecting oneself into the future. It involves the use of episodic and semantic memory in order to plan and anticipate future need. In our study, we focused on understanding the role of self in episodic future thinking in 3- and 4-year old children. Children were asked to make choices either for their own future need (self group) or for another individual's future need (other group). Including these groups allowed us to directly manipulate the role of self. Participants were shown a 3-D model of a neighborhood with several locations (houses and stores) and were asked to navigate around the neighborhood to achieve a future goal requiring a two-step action (go to toy store to buy present and then go to friend's house to give present). In one version of the study, children were given only a few choices of locations in the neighborhood in order to achieve their goal. Preliminary results suggest that both 3- and 4-year-old children demonstrate episodic future thinking by accurately following the actions to achieve the future goal. In the second version of the study, 2 additional choices of location were added to the neighborhood, while keeping the goal the same. These additional items served as distracters in the environment. Results show that while 4-year-old children still demonstrate episodic future thinking skills, 3-year-old children are no longer able to accurately follow the actions necessary to achieve the future goal. Further research on optimal performance by 3-year-old in such visual working memory and episodic future thinking tasks is necessary.

When Distance Relationship Contradicts Similarity in SUSTAIN

Chung-Yu Wang

National Cheng-Kung University

Lee-Xieng Yang

National Chengchi University

Abstract: SUSTAIN is an influential multiple clusters (i.e., prototypes) model for categorization, in which the cluster nearer to the stimulus is activated for categorization. Due to that the cluster activation is the average of the dimensional similarity weighted by attention, the choice between clusters is little influenced by the dimension on which the similarity difference to the stimulus between clusters is negligible, even with equivalent dimensional attention weights and the clusters having the same distance difference on dimensions (e.g., 1 vs.2 on dimension 1 and 4 vs.5 on dimension 2). This is evident in modeling Experiment 1 in Erickson and Kruschke (1998) that SUSTAIN activates the rule-category cluster, which is actually farther to the critical item than the exception-category cluster. The computer simulation results suggest that the larger the learning rate, the more likely this similarity-distance contradiction occurs. With the SUSTAIN using the ALCOVE's similarity computation equation, this contradiction disappears.

Adaptive Information Indexing in Re-finding Information

J. Michelle Moon

Carnegie Mellon University

Wai-Tat Fu

University of Illinois at Urbana-Champaign

Abstract: We studied how the human cognitive system adaptively performs information indexing (i.e. knowing where to re-find information without necessarily knowing the information content). Participants searched for information using computer icons with or without locations or luminance cues. The cues represented the history of use of icons and were calculated using the ACT-R memory equation. Results suggest that participants adaptively used the location/luminance cues to offload information indexing from internal memory to external cues. Availability of location cues led to more frequent icon accesses and worse recall of icon titles. Availability of luminance cues led to worse recall of icon titles and locations. Participants adapted to the cost-benefit structure of the environment by strategically shifting the use of different kinds of external cues based on their relative access costs. Results highlight the dynamic interplay between external representations and human information processes in shaping adaptive interactive behavior in information search and indexing.

Variability Helps Children Balance a Beam

David Pfeiffer

University of Cincinnati

Daniel Bullard

University of Cincinnati

Heidi Kloos

University of Cincinnati

Abstract: Basic-level research suggests that learning about an event is a function of what is being attended to and what is being ignored rather than amount of time spent exploring the event. However, what about learning to overcome a misconception, such as the task of balancing an asymmetrically weighted beam away from center? This research investigated the effects of training variability for children trying to balance visually symmetrical yet proprioceptively asymmetrical beams on a fulcrum. Results indicate that (i) older children's judgments of a beam's weight distribution improved with experience, (ii) younger children had particular difficulty distinguishing between the heavier and lighter side when the weight difference was smallest, and (iii) children in the mixed-experience condition scored fewer errors than children who received more extensive experience but in just one type. The findings of a significant quadratic trend for effect of learning underscore the importance of variability in children's experience.

Mutual Alignment Analogy Facilitates Abstraction and Transfer of a Complex Scientific Principle

Judy Orton

Georgia State University

Florencia Anggoro

College of the Holy Cross

Benjamin Jee

College of the Holy Cross

Abstract: Learning about a scientific principle often occurs in the context of unfamiliar examples. Mutual alignment analogy—a type of analogical comparison in which the analogs are only partially understood—has been shown to facilitate learning from unfamiliar examples (Kurtz, Miao, & Gentner, 2001; Loewenstein, Thompson, & Gentner, 1999, 2003). The present study examined the role of mutual alignment analogy in the abstraction and transfer of a complex scientific principle from examples presented in expository texts. The results provide evidence that promoting comparison between two examples and orienting the learner toward the relational commonality between the examples result in greater abstraction and transfer of the principle "convergent evolution". These findings suggest that mutual alignment analogy can promote learning complex scientific principles from texts. Mutual alignment analogy is therefore likely to be a helpful learning aid and pedagogical technique in science education.

A Lexical Gap in the Humor Domain of Japanese and Its Possible Implications for Theories of Conceptual Language

Whitney Vandiver
Purdue University

Abstract: Interviews with native speakers of Japanese reveal that, within the humor domain, Japanese experiences a lexical gap, lacking terms for ethnic, political, and religious humor and their corresponding preference terms. However, Japanese terms do exist for the same concepts in non-humorous domains but yet, they do not cross into the humor domain, thus pointing to a specific phenomenon within the language. These limited data may indicate a variation in the mind's conceptual structure or, perhaps more likely, of the concepts' realizations as lexical items depending on one's native language. Not to fall into Whorf's overgeneralization, this may still suggest that the acceptable application of a concept's expression in a language is more than simply a linguistic variation and but may still be the consequence of a language's influence on conceptual structure, resulting in its deliberate and possibly societal and ethically conventionalized deviation from the organization of the language-independent ontology.

Reactive Task-Set Switching Ability, Not Working Memory Capacity, Predicts Change Blindness Sensitivity

Robert Youmans

California State University, Northridge

Abstract: Individual differences in working memory capacity (WMC) have long been shown to predict how well people perform tasks that require directed attention, but other individual differences responsible for task-set switching and noticing behaviors are less well understood. In this study, students from California State University, Northridge completed a measure of WMC, a measure of cognitive flexibility, and attempted to identify disappearing objects in change blindness slides. WMC had no relationship with the other measures, but measures of cognitive flexibility were directly correlated with the ability to notice change, and no relationships were established. The author argues that these findings support: 1) new ways of thinking about task-set switching behaviors, and 2) the existence of individual differences in the ability to notice changes in an environment that are independent of WMC.

Perception of Visual Similarity: Modeling Feature-Based Effects

Michael Romano

University of California, Merced

Michael Spivey

University of California, Merced

Abstract: Similarity is central to human cognition. Its relevance is apparent in nearly all theories of cognitive science. Concept acquisition, metaphor, pattern recognition, priming, predictions, inferences; all these processes rely on similarity. Despite its relevance, relatively little is understood about how similarity is processed. In particular, there is a need to better understand the scope in which our perceptual systems constrain our judgments of similarity. The current study investigates this question in the area of visual cognition. By attempting to control for the influence of categorical knowledge, the goal was to understand how different types of feature-dimensions and category boundaries influence the perception of similarity. A connectionist model was developed to explain these findings.

Preschooler's Performance in Three Visual Perspective Taking Tasks

Yue Yu

Department of Psychology and Yuanpei College, Peking University

Yanjie Su

Department of Psychology and Yuanpei College, Peking University

Raymond Chan

Neuropsychology and Applied Cognitive Neuroscience Laboratory, Key Laboratory of Mental Health, Institute of Psychology, Chinese Academy of Sciences

Abstract: Previous studies suggested that visual perspective taking (VPT) requires spatial computation (transformation) and solving conflict between reality and imagination (interference). The current study examined how these two processes may influence preschoolers' performance in different VPT tasks. Eighty-four 3-5-year-old children and 8 adult controls completed three VPT tasks, where different conditions were set to manipulate the requirement to perform transformation and to solve interference. The result showed that 4-year-olds could solve the interference between reality and imagination, but the immature spatial computation ability remained a confining factor throughout preschool years and prevented children from passing more complex VPT tasks.

Implicit Learning of Spatial Context by School-Age Children

Hanako Yoshida

University of Houston

Kevin Darby

University of Houston

Joseph Burling

University of Houston

Abstract: The contextual cuing effect refers to a robust phenomenon in which a repeated context guides attention to relevant information by constraining search. The effect is measured by an object search task in which a target is located within repeated or nonrepeated visual contexts. Shorter response times with repeated configurations indicate that contextual information has facilitated search. Though the effect is robust among adult participants, recent tests of the effect with children yielded mixed results. Because contextual cuing could play a critical role in cognitive development, resolving this issue is important. The present study used child-friendly paradigms to investigate whether children show the effect. The study suggests that adult participants show the effect regardless of stimulus type; 9- to 12-year-old children's contextual cuing effect was limited to certain stimuli types. The results are discussed in terms of the relation between visual complexity of stimuli and the recognition of search items.

Studies of the Effects on Creativity of Having Very Different Parents

Brian O'Connor

University of British Columbia

Liane Gabora

University of British Columbia

Abstract: We tested the hypothesis that having parents who are very different from one another is associated with heightened creativity. In the first study, scores for 591 participants on the five factor model of personality were used to compute the personality vector known to be associated with creativity. Higher scores were significantly correlated with parental difference scores. In the second study, 114 participants were given questionnaires that included a measure of creativity (the Remote Associates Test), and a measure of creative personality (the Creative Personality Scale), as well as measures of parental behavior and personality, and parental conflict. Creativity scores and creative personality scores were significantly correlated with parental differences, but not with measures of parental conflict. We posit that the greater the parental differences, the greater the extent to which the child's worldview contains inconsistencies that invite contemplation, and thereby accustom the child to thinking for him/herself.

A Dynamic Memory Model

Eva Cadez

School of Social Sciences, Humanities, and Arts, University of California, Merced, 5200 North
Lake Road Merced, CA 95343 USA

Evan Heit

School of Social Sciences, Humanities, and Arts, University of California, Merced, 5200 North
Lake Road Merced, CA 95343 USA

Vladimir Cadez

Astronomical Observatory of Belgrade, Volgina 7 Belgrade, 11060 Serbia

Abstract: We introduce a mathematical model of evolution of a memory trace. The model generalizes similar dynamical systems models used in other research areas of cognitive science as well as physics and other sciences (e.g. transport processes of radiation). We then simulate an experimental data set and argue that the model may well simulate complexity of serial recall reported in Anderson, J. R., Bothell, D., Lebiere, C. Matessa, M. (1998). An integrated theory of list memory. *Journal of Memory and Language*, 38, 341-380. Finally, we argue that in the future our model may be used to simulate seemingly broad spectrum of memory research data: familiarity effects and rate of presentation effects in list memory, attention, false memory, instructions in memory tasks, and noise and phase transitions in neural networks and other dynamic systems. Our hope is that this kind of work may help integrate data while showing constraints useful for directing future research in cognitive science.

Effects of the Target Distribution on Numerical Prediction

Jason Jones

University of California, San Diego

Abstract: Human subjects repeatedly attempted to predict a four-digit number. The distribution producing the target numbers was varied within subjects. Target distribution had a large effect on prediction performance. The target distribution standard deviation was a good predictor of the slope of the learning curve across trials.

Cognitive leaps and multiple epistemological resources: an agent-based modeling approach

Paulo Blikstein

Stanford University

Abstract: Agent-based modeling (ABM) has been increasingly used by scientists to study a wide range of phenomena in physics, chemistry, and biology. In these models, each element ('agent') follows local, simple rules, and the overall macroscopic pattern emerges from these multiple local behaviors. Despite its roots in the natural sciences, ABM is highly relevant to research in the social sciences. The recent decades have seen a surge in social-science studies employing ABM, and more recently it has also been used to illustrate aspects of cognitive development, collaboration, and group work. In this paper, we describe a model to explain sudden leaps in cognition observed in a science classroom when students switch between the use of two types of epistemological resources. The model confirms that reliance on brute-force search is very sensitive to increased complexity of the content, whereas selective search is initially less efficient but more accurate for complex content.

Representing Conceptual Knowledge: A Network Analysis

Takashi Yamauchi

Texas A&M University

Ricardo Gutierrez-Osuna

Texas A&M University

James Caverlee

Texas A&M University

Abstract: We adopted social network analysis and investigated how concepts related to living things (e.g., organic objects such as dogs, cats, and trees) and artifacts (e.g., desks, tables, and cars) are organized. Our analysis shows that there is a basic division between the two types of concepts (living things and artifacts), and that the division emerges partly from the fact that living things are highly interconnected as compared to artifact concepts in their attributes. Three network measures, density, clustering coefficients, and complete triplets, indicate that organic concepts are heavily clustered by their attributes as compared to non-organic artifacts.

Development of the Semantic Network: From a random to a complex network

Shohei Hidaka

Japan Advanced Institute of Science and Technology

Abstract: In the present study, we investigate semantic knowledge of both adults and children for early learned words. Previous studies have suggested that semantic knowledge forms a network with particular properties, called a complex network. Since, in theory, a particular kind of network structure may be generated by a particular process, the structure of the semantic knowledge network found in semantic tasks has been supposed to reflect the developmental process of semantic knowledge acquisition. However, at this point, no empirical description is available for the development of children's knowledge –adult substitutes are used. We investigate children's semantic knowledge using an alternative-forced-choice association task. The result suggests that the children's semantic network is closely approximated by a random network which is different from adults' network. However, it is not truly random but contains a reliable structure. We discuss a possible developmental trajectory from a children's random-like network to an adult's complex network.

Predicting Coreference: the role of alternative constructions

Peter Baumann

University of Freiburg

Lars Konieczny

University of Freiburg

Barbara Hemforth

CNRS, Universite Paris Descartes

Abstract: Expectations about alternative constructions play a crucial role in anaphora resolution.

In a self-paced reading experiment, we presented Portuguese sentences, consisting of a main clause with two referents, followed by a subclause with a pronoun referring unambiguously to one of the referents. The sentences varied in the kind of subordinating conjunction: 'antes que' (before) vs. 'quando' (when).

On the pronoun and the spill-over, there is a clear decrease in reading times for the conjunction 'antes que' in the object coreference condition, whereas no difference was not found for 'quando'.

These results can be explained by comprehenders using an expectation-based strategy: in Portuguese, for sentences with 'antes que' there is a frequent alternative infinitive construction (antes de abrir: before opening), which allows coreference only with the subject of the preceding clause. Upon seeing the subordinate construction, comprehenders may assume that the speaker intended coreference with an antecedent other than the subject.

The Effects of Transcranial Magnetic Stimulation over Premotor Cortex on the Perception of Biological Motion

Abstract: We investigated the roles of posterior superior temporal sulcus (STS) and premotor cortex in biological motion perception using transcranial magnetic stimulation (TMS). Subjects viewed noise masked point light displays (PLDs) of humans and scrambled figures and determined whether a person was present in each trial. Non-biologically moving PLDs (polygons) served as control stimuli. Theta burst TMS was delivered over left premotor cortex, left STS, or vertex (Saygin, 2007, Brain). Sensitivity and response bias were both affected after premotor TMS (but not STS) which was due to an increase in false alarms. This effect was not found in the control task. These data suggest that the STS and premotor areas play dissociable roles in biological motion perception. The increased false alarms after premotor TMS suggests that this region may normally help refine the computations of posterior areas during biological motion perception.

Questioning the Free Will Comprehension Question

Abstract

Understanding the folk notion of free will and moral responsibility is important for a host of applied and theoretical issues in psychology, philosophy, and ethics. The bulk of experimental research has focused on folk intuitions concerning determinism's relation to free will and moral responsibility. However, determinism is a difficult term for many folk to understand. Accordingly researchers often use comprehension questions to identify and exclude large proportions of participants who seem to struggle with relevant concepts. Here, we document some of the cognitive mechanisms involved in folk judgments related to comprehension of determinism, and its relations to free will and moral responsibility. Results provide prescriptions for experimental designs that can increase comprehension, potentially decreasing sampling biases. Theoretical and methodological implications are discussed.

Keywords: Free will, moral responsibility, experimental philosophy, judgment, decision making, cognitive control, methodology.

Free Will and Moral Responsibility

One of the most persistent philosophical problems deals with difficult issues surrounding free will and moral responsibility. When grappling with these issues, some philosophers take what ordinary people think about free will and moral responsibility to be important theoretical considerations for a variety of reasons. For example, beliefs in free will and moral responsibility form essential cornerstones of many people's relationships to themselves and others. Some philosophers even go so far as to say that if we find that humans in fact do not have free will and moral responsibility, we should continue to let people indulge in the myth that they can be free and moral responsibility (Smilansky, 2002). But typically, philosophers have not conducted systematic or controlled scientific studies to uncover what ordinary people think about free will and moral responsibility. Over the past decade, empirically minded theorists have begun filling in this lacuna.

Most of the debate about free will and moral responsibility concerns determinism's relation to free will and moral responsibility. The empirical investigation of folk intuitions about free will and moral responsibility has reflected this tradition. Most empirical studies so far have focused on ordinary people's

intuitions about determinism's relation to free will and moral responsibility.¹ But "determinism" is a "term of art". Because determinism is a term of art, some have worried that some folk may not be fully internalizing or understand determinism when making judgments about free will or moral responsibility. We agree that this is a problem for any measure of folk intuitions about determinism's relation to free will and moral responsibility. In this paper, we present evidence from two studies suggesting that one can make the deterministic nature of some scenario more transparent to participants with a simple manipulation. We argue that these results provide some important insights into judgments of free will and moral responsibility, the processes responsible for those judgments, and the philosophical importance of those judgments.

Free Will Comprehension Question

In recent years, researchers have attempted to help shed light on folk notions of freedom and moral responsibility. For example, Nahmias, Morris, Nadelhoffer, and Turner (2005; 2006) found that most people judge that people in some deterministic universes are free and morally responsible—a result that has been widely replicated (Feltz & Cokely, 2009; Nahmias, Coates, & Kvaran, 2007; Nichols & Knobe, 2007). These results indicated that many people have *compatibilist* intuitions that free will and moral responsibility are compatible with the truth of determinism. Relatively few people have *incompatibilist* intuitions that free will and moral responsibility are not compatible with the truth of determinism.

However, many theorists have worried that participants do not fully understand the deterministic nature of the commonly used scenario. If participants do not appropriately appreciate the deterministic nature of the scenario, then their responses do little to help illuminate folk intuitions about determinism's relation to free will and moral responsibility. The worry is

¹ There are, of course, some exceptions. For examples, Vohs and Schooler (2008) explore the effects of increasing anti-free will beliefs, Woolfolk, Doris, and Darley (2006) explore intuitions about moral responsibility as a function of constraint, and Miller and Feltz (2009) discuss Frankfurt-style cases. These studies do not obviously gauge people's intuitions about determinism's relation to free will and moral responsibility.

especially problematic because the philosophical sense of determinism is highly technical and nuanced. To illustrate, Alfred Mele (2006) describes determinism as the thesis that “at any instant exactly one future is compatible with the state of the universe at that instant and the laws of nature” (p. 3). This notion is conceptually distinct from other, yet related, notions such as fatalism. Fatalism is “the thesis that whatever happens must happen; every event or state of affairs that occurs, must occur, while the nonoccurrence of every event and state of affairs is likewise necessitated” (Bernstein, 2002, p. 65). One reason why fatalism and determinism are distinct concepts is that fatalism is consistent with determinism being true or false (Bernstein, 2002). That is, all things may happen necessarily even if some things are indeterministically caused (e.g., God may have foreknowledge of all events). Many compatibilists believe that fatalism rules out free will and moral responsibility. Hence, it is difficult but essentially important to convey to non-philosophers an accurate notion of determinism that does not imply something too strong (e.g., fatalism) or something that is too weak (e.g., indeterminism).

To help ensure that participants understand the deterministic nature of the scenarios, many authors include comprehension questions. It is common practice to exclude those who fail the comprehension checks (Nahmias, Morris, Nadelhoffer, & Turner, 2005, 2006). However, one shortcoming of previous research is that often the number of participants who fail the comprehension question is not reported and no empirically tested explanation is offered why participants fail the checks. Feltz, Cokely, and Nadelhoffer (2009) suggest that “many participants often fail the manipulation checks in these kinds of studies” (p. 16).² But why do so many people fail the manipulation checks and how can we get more people to pass them? We explore this question in a series of two experiments.

Experiment 1

One possible explanation of why participants do not give the “correct” answer to the comprehension question is that they may not spend the time necessary to internalize the description of determinism.

² In one of the few studies that report the percentage of participants who were excluded, Nahmias, Coates, and Kvaran (2007) reported that they excluded 22 percent of their participants because of comprehension failures. However, in their study, participants first answered the comprehension question. Anecdotal evidence suggests that in other experiments, rates of failure were much higher. These data provide some evidence suggesting that placement of the comprehension question is a key factor in correct responses (see Experiments and Discussion)

Typically, participants are volunteers or are given for partial course credit for participating. In these situations, there may be some reason for the participants to complete the survey, but there is little reason for them to spend a great deal of time or effort completing the surveys. In these conditions, participants may fail the comprehension question because of a relative lack of concentration, effort, or time needed to understand the deterministic nature of the scenarios. Hence, one hypothesis is that increasing incentives for participants to understand the deterministic nature of the scenarios would increase correct answers to the comprehension question.

An alternative hypothesis is that the order of presentation of questions biases responses to the comprehension question. On a standard “two systems” conception of cognition, System 2 (controlled, deliberative processing) works to override and correct System 1 processing (effortless, quick, effortless processing) (Stanovich & West, 2000; but see Cokely, 2009 or Gigerenzer & Regier, 1996; Osman, 2004 for critical discussion of “dual systems”). Hence, once impressions are formed (e.g., after making other judgments about crimes that have high emotional valence), one can only attempt to correct previous, perhaps erroneous intuitions. Unfortunately, theory suggests that many people do not have the requisite cognitive control capacities that would allow such an intervention. Fortunately, evidence suggests biases can also be overcome or entirely avoided by shaping the initial interpretation and representation of tasks before alternative intuitions are issued. This shaping requires early intervention (e.g., early selection cognitive control or changes in task orders) and can circumvent the need to correct biased processing (Cokely & Kelly, 2009; Cokely, Parpart, & Schooler, 2009; for related mechanistic accounts see also *Query Theory* by E. Weber, E.J. Johnson, & colleagues).

To be clear, cognitive processes associated with philosophical intuitions (e.g., long term memory activation and retrieval dynamics) may be shaped by participants’ representation of the content of the previously viewed scenarios. Such influence is especially likely when the task involves a strong affective component. Evidence already suggests that a scenario’s affective strength can alter people’s judgments concerning freedom and moral responsibility (Nichols & Knobe, 2007). Those given especially strong affective scenarios tend to give more compatibilist-friendly responses than those given a relatively less affectively charged scenario. Nichols and Knobe (2007) even go so far as to say that these results indicate the existence of an “affective bias” for judgments of freedom and moral responsibility.

We hypothesized that a similar phenomenon might occur with respect to the comprehension question. When affective components are presented before the comprehension question, they may alter the interpre-

tation of the task making it difficult to give the normatively correct answer to the comprehension question (e.g., as this answer could contradict the previous answer that participants feel very strongly about). However, when the comprehension question is presented first and in the absence of affective information, many people may find it relatively easier to answer the comprehension question according to the supplied definition. Hence, this possibility generates the hypothesis that if the comprehension question is presented first and before affective material, then there should be more correct answers to the comprehension question than if the comprehension question is presented after affective material.

Methods and Materials

There were three conditions in Experiment 1. In the Control and Paid condition, participants read the following scenario from Nahmias, Coates, and Kvaran (2007):

“Most respected psychologists are convinced that eventually we will figure out exactly how all of our decisions and actions are entirely caused. For instance, they think that whenever we are trying to decide what to do, the decision we end up making is completely caused by the specific thoughts, desires, and plans occurring in our minds.

The psychologists are also convinced that these thoughts, desires, and plans are completely caused by our current situation and the earlier events in our lives, and that these earlier events were also completely caused by even earlier events, eventually going all the way back to events that occurred before we were born.

So, once specific earlier events have occurred in a person's life, these events will definitely cause specific later events to occur. For example, one day a person named John decides to kill his wife so that he can marry his lover, and he does it. Once the specific thoughts, desires, and plans occur in John's mind, they will definitely cause his decision to kill his wife.

Assume the psychologists are right that events that occurred before John was born definitely caused his decision to kill his wife. Please rate to what degree you agree with the following statements.”

After reading this scenario, participants were asked to rate their level of agreement with the following two sentences (1 = strongly disagree, 4 = neutral, 7 = strongly agree): (1) John decided to kill his wife of his own free will; (2) John is morally responsible for killing his wife. Immediately following those two questions, participants were asked two 'yes' or 'no' questions: (3) Do you personally think the psycholo-

gists are right that all of our decisions are ultimately caused by events occurring before our birth? and (4) Regardless of how you answered question 3, if the psychologists are right, is it accurate to say that if the universe were re-created, people would make all the same decisions?

In the Early Selection condition, participants only read the first paragraph and then answers questions (3) and (4) (with appropriate substitution). After answering questions (3) and (4), they went to a separate page where the entire scenario was present and they were asked to answer questions (1) and (2). They were instructed not to go back and change their answers to (3) and (4) after they submitted their answers.

Participants

In the Control and Early Selection conditions, participants completed the surveys at the Philosophical-Personality website. In the Paid condition, participants completed surveys at Schreiner's Behavioral Philosophy Lab. Participants were tested in 6 groups of no larger than 12 and no smaller than 4 participants. They received exactly the same materials as those in the Control condition. Participants completed the survey at computer terminals and were told that they would be paid \$2.00 for getting at least 80% of the questions correct.

Following standard practice, we eliminated all those with extensive philosophical training (all those reporting having a B.A. or greater in philosophy), those whose first language was not English, and those who reported themselves to be age 18 or under.

Results and Discussion

Question (3) is one typical comprehension question. Table 1 represents the numbers of those who passed and failed the question for each condition:

Table 1: Comprehension Failures.

	Fail	Pass
Early Selection (N = 71)	23, 32%	48, 68%
Control (N = 115)	54, 47%	61, 53%
Paid (N = 40)	24, 60%	16, 40%

The difference between Early Selection and Control was significant $\chi^2 (1, N = 186) = 3.837, p = .05$. The difference between Early Selection and Paid was significant, $\chi^2 (1, N = 111) = 7.99, p = .005$. However, the difference between Control and Paid was not significant $\chi^2 (1, N = 155) = 2.02, p = .16$, but showed a very small, potential non-significant trend.

These results suggest that a substantial number of participants can pass the comprehension question. In addition, giving participants incentive to answer the comprehension question correct did not have a reliable effect. Rather, the position of the question seemed to be the most relevant factor determining participants judgment accuracy. However, one possible alternative explanation might be that the rather lengthy scenarios complicates interpretation and is the primarily reason participants did not make the correct inference concerning the deterministic nature of the scenarios. Participants may be more likely to lose track of the deterministic nature of the scenarios because they are so long and the comprehension questions late in the series of questions (Nichols and Knobe, 2007). To rule out this possible explanation, we performed a second experiment to replicate and extend the results of Experiment 1.

Experiment 2

Experiment 2 was designed to address two different issues. First, the length of the scenarios was drastically reduced. If we still find an effect with respect to the placement of the comprehension question, then it is not likely that the length of the scenario is what was responsible for differences observed in Experiment 1. Second, we wanted to make perfectly clear what the correct answer to the comprehension question was. So, in one version of the scenario we provided a sentence that clearly states what the correct answer to the comprehension question was. This provides the strongest test of whether the placement of the comprehension question is responsible for correct to that question in comparison to the ‘too lengthy’ hypothesis. Those who received the extra sentence should get the comprehension question correct more frequently than those who did not receive the extra sentence. In addition, those who receive the extra sentence and the comprehension question first should give the correct response to the comprehension question more often than those who receive the extra sentence with the comprehension question second.

Experiment 2a

Participants Participants completed the short survey on the Philosophical Personality website. We excluded those who reported that their first language was not English, had at least a bachelors degree in philosophy, and who were under 18. After excluding these people, there were 109 participants remaining.

Methods and Materials Participants were randomly divided into two conditions. One group was in the No Sentence condition where they read the following passage: “Most respected psychologists are convinced that our thoughts, desires, and plans are completely caused by our current situation, the earlier events in our lives, and events that occurred before we were born.” The other group of participants were

in the Extra Sentence condition. Participants in this condition read the following passage in addition to the passage read by those in No Sentence: “That means that if the psychologists are right and the world was exactly re-created, people would make all the same decisions.” They were then asked two questions: (a) According to the psychologists, is it accurate to say that if the universe was exactly re-created people would make all the same decisions? and (b) Regardless of how you answered question 1, do you personally think the psychologists are right that all of our decisions are completely caused by our current situation, earlier events in our lives, and events occurring before our birth? They could only respond ‘yes’ or ‘no’. On a separate page, both groups were given an addition sentence: Please imagine that one day a person named John decides to kill his wife so that he can marry his lover, and he does it. Following this sentence, they were asked to rate their level of agreement with two sentences (1 = strongly disagree, 4 = neutral, 7 = strongly agree): (c) John decided to kill his wife of his own free will, (d) John is morally responsible for killing his wife. After submitting their answers to (a) and (b), participants could not go back and change their answers.

Results and Discussion Results for each condition are reported in Table 2.

Table 2: Comprehension Failures.

	Fail	Pass
“No Sentence” (N = 60)	36, 60%	24, 40%
“Extra sentence” (N = 49)	16, 33%	33, 67%

The difference between the two conditions was statistically significant, $\chi^2 = (1, N = 109) = 8.09, p = .004$. To test whether order made a difference in these judgments, an additional experiment was conducted.

Experiment 2b

Participants Participants completed the survey on the Philosophical Personality website. The same exclusion criteria that applied in Experiment 2a applied in Experiment 2b. After excluding these participants, 187 participants remained.

Methods and Materials Participants received the exact same materials as those in Experiment 2a except that the order of the questions was reversed. Participants received questions in the following order: (c), (d), (a), (b). Importantly, participants received the sentence concerning John killing his wife before they answered all questions. Questions (c) and (d) appeared on one page. Once participants answered (c) and (d), they then answered on a separate page (a) and (b) and were not able to go back to change their answers to (c) and (d).

Results and Discussion Results for Experiment 2b are reported in Table 3.

Table 3: Comprehension Failures

	Fail	Pass
“No Sentence” (N = 89)	54, 61%	35, 39%
“Extra sentence” (N = 98)	56, 57%	42, 43%

The difference between the two conditions was not statistically significant, $\chi^2 = (1, N = 187) = .24, p = .62$. Importantly, across experiment 2a and 2b, the order had an effect on whether those who received the extra sentence version gave the correct answer, $\chi^2 = (1, N = 147) = 7.84, p = .005$.³

General Discussion

Our experiments suggest that the placement of the comprehension question was an important factor in whether participants give the correct answer. Experiment 1 suggested that those who received the comprehension question first and in the absence of affective material were more likely to give the correct answer than those who received it later and after the presence of affective material. Moreover, Experiment 1 suggested that motivation to understand the scenarios was not a reliable, primary factor in whether people were able to make the correct inferences about the deterministic nature of the scenarios (although it is possible, but by no means certain, it could become more influential with higher levels of incentive). Experiment 2 suggested that the length of the scenario was not responsible for comprehension failures. In addition, Experiment 2 suggested that the order of presentation was a factor even when it was very clear what the correct answer to the comprehension question was.

These results lead to some clear prescriptions regarding how to go about measuring comprehension in these scenarios. If one desires to maximize the usable sample (i.e., those who pass the comprehension question) and avoid potential sample bias one should present the comprehension question first and before any potentially biasing, affective content. These results also indicate that people may interpret scenarios and questions differently than intended by the experimenters (Feltz & Cokely, in press; see also Cokely

& Feltz, 2009a; 2009b) or at least that the ability to infer correctly the deterministic nature of these scenarios is plastic. A common explanation of failures to the comprehension questions is that the participant did not “care” enough or could not correctly apply or understand the deterministic nature of the scenarios. However, our data suggest something different. Perhaps those who fail the comprehension question simply interpret and represent the question differently. Perhaps they understand the question in a fundamentally different way. Perhaps they are biased by affect. Given their understanding of the task, they may not be giving an incorrect answers at all (Feltz, Cokely, & Nadelhoffer, 2009; but for more general examples from the judgment and decision making see Gigerenzer, 1991, and Gigerenzer & colleagues). In such cases, these responses reveal something important about how plastic our intuitions about freedom and moral responsibility can be. The understanding of determinism appears to bi-directional—correctly understanding determinism could influence judgments about free will and moral responsibility. But importantly, it could be that beliefs about free will and moral responsibility can influence judgments about determinism. If all of this is true, it provides a more plausible description of the rich and nuanced ways people go about making a host of important judgments about themselves, their place in the world, and their relationships with others. Critically, results such as these (and others) necessitate that experimental philosophers and cognitive scientists adopt psychologically sensitive multimethod approaches to the investigation of folk intuitions.

Abstract

Comprehenders can rapidly use both their linguistic knowledge and different kinds of information in visual context during language comprehension. Little is known, however, about the relative time courses and mechanisms by which different kinds of visual information influence language comprehension. We recorded event-related brain potentials (ERPs) as participants read a subject-verb-object sentence and verified whether or not it matched different (verb-action versus role relations) aspects of a recently viewed picture. When the verb-action did not match the depicted action, we replicated larger N400s (300-500ms) over centro-parietal scalp to the verb (300-500 ms) relative to the responses for matches. In contrast, ERP effects to role-relation mismatches (a person depicted as undergoing an action but described as performing it) qualitatively differed from and occurred prior to the verb-action congruence N400. Our findings implicate at least two temporally distinct mechanisms governing picture-sentence verification processes.

Keywords: sentence-picture verification; visual context effects; event-related brain potentials;

Introduction

Information in visual context can rapidly influence online language comprehension and ambiguity resolution (e.g., Altmann, 2004; Knoeferle, Habets, Crocker, & Münte, 2008; Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995). Recently, researchers also have begun to examine picture-sentence congruence processes even when sentences are structurally unambiguous and do not necessarily globally match visual context (e.g., Knoeferle, Urbach, & Kutas, 2009; Vissers, Kolk, van de Meerendonk, & Chwilla, 2008; Wassenaar & Hagoort, 2007). The motivation for these studies is that determining the correspondence between what is said and how things are, appears to play a central part in natural language processing: Positive verification may be readily inferred from, e.g., expressions of agreement (*So I heard*) while failures to verify may be inferred from corrections and expressions of disbelief, requests for clarification and the like (e.g., *Well no, actually what happened was ..., Are you sure?*).

Psycholinguistic research on verification processes is by no means a recent endeavour: Just and Carpenter (1971) found that participants' verification latencies were shorter when the color of the dots on an image (red vs. black) matched than

mismatched the color adjective in a corresponding sentence (henceforth "congruence effects", see also, e.g., Clark & Chase, 1972). To account for these findings and a range of others, Carpenter and Just (1975) developed the Constituent Comparison Model (CCM) of sentence-picture comparison processes. The model operates via a serial mechanism that incrementally compares representations of sentence ([AFF, (RED, DOTS)]) and picture ("black dots") constituents. The comparison proceeds from inner to outer representations (in this case right to left). When a mismatch is found (here for the inner representations), it is indexed "-"; the truth value is changed to "false", and the comparison process is reinitialized, resulting in one extra comparison step (and hence longer response times) relative to a match (e.g., "red dots"). The output of that comparator process is the truth value of the comparison and response time values.

This verification model does not specify the time course of constructing the representations of verbal information as the sentences are read, and it is unclear to which extent the constituent-wise comparator mechanism implies incremental comprehension processes. Recent event-related brain potential (ERP) research, however, suggests that congruence processing is incremental, i.e., ongoing during (not merely after) word-by-word sentence processing, and furthermore can be systematically related to end-of-sentence verification times (Knoeferle et al., 2009). This was evidenced by finding (a) reliable congruence effects in ERPs as soon as a word (e.g., the verb) that mismatched aspects of a preceding visual context (e.g., a depicted action) was encountered; (b) reliable congruence effects in verification time response latencies; and (c) reliable correlations between a participant's ERP and verification time congruence effects.

The incremental ERP congruence effects at the verb are, in principle, compatible with the CCM comparator mechanism. One may question, however, to what extent the CCM can account for verification processes during (rather than after) the sentence. Specifically, it is unclear whether all aspects of picture-sentence mismatch processing are adequately accounted for by a single comparator mechanism as suggested by the CCM.

Findings from two recent studies can be viewed as supporting a single mechanism account: highly similar ERP congruence effects were observed in response to different picture-sentence mismatches (Vissers et al., 2008; Wassenaar & Hagoort, 2007). In Wassenaar and Hagoort (2007), healthy older adults inspected a line drawing of an agent-action-patient event (e.g., man pushing woman vs. a woman pushing a man), and then listened to a spoken utterance in Dutch (e.g., 'The tall man on [sic] this picture pushes the young woman'). Participants indicated whether the thematic relations of the utterance were congruent with the depicted role relations or not. There was no reliable response time congruence effect¹. In the ERPs, however, healthy adults exhibited congruence effects. For active sentences as in the above example, there was a larger posterior negativity (with a non-reliable late positivity) to mismatching than matching conditions in the verb region (centro-posterior from 50-450 ms; for anterior sites from ca. 50-300 ms). Irreversible active and reversible passive sentences showed an early negativity for incongruous relative to congruous trials and a subsequent (reliable) late positivity. These effects were interpreted as reflecting thematic role assignment.

In a different study, participants inspected a line drawing containing two objects (e.g., a square followed by a circle, Vissers et al., 2008). They then read a sentence via rapid serial visual presentation (e.g., *De cirkel staat achter het vierkant*, 'The circle stands in front of the square'), and verified whether or not the object arrangement described in the sentence matched the depiction. For a first condition the location mismatch occurred within the same (horizontal) dimension (e.g., the sentence would state that the circle was in front of the square while it was in fact behind it). For a second, mismatch, the incongruence occurred between the horizontal and vertical dimensions: The sentence stated that the circle is below the square while it was in fact behind it. The authors observed an N400-P600 ERP pattern as in Wassenaar and Hagoort (2007) despite differences in the mismatches (object location rather than role relations) and language modality (written versus spoken). They interpreted the mismatch effects as reflecting monitoring of potential processing errors. Crucially, mean amplitudes of the ERPs in Vissers et al. did not differ in response to the two kinds of picture-sentence mismatches (200-400 ms; 500-700 ms time-locked to the critical preposition).

Based on these findings, it appears that some picture-sentence mismatches (e.g., role relations versus object location mismatches) elicit similar ERP patterns, providing - at least tentative - support for a single functional brain mechanism dealing with these incongruences (though note the different interpretations of the ERP pattern in these two studies).

In contrast with the Vissers et al. and Wassenaar and Hagoort findings, tentative support for the alternative - multi-

ple mechanism - view comes from Knoeferle et al. (2009) in which participants read a subject-verb-object sentence and verified whether or not the verb matched a previously viewed (depicted) action. When verbs mismatched a depicted action, speeded verification response latencies were reliably longer, N400s over centro-parietal scalp to the verb were larger, and post-verbal potentials up to the time of the response (including an anterior negativity to the object) were more negative relative to the responses for matches. These different negativities across the sentence differ from the ERP congruence effects in response to role relations and object location mismatches per the absence of an ensuing P600-like congruence effect. In either case, however, our knowledge of the *relative* time course and nature of different visual context effects during sentence comprehension is relatively limited and only few studies have directly compared different visual context effects.

The present research further investigates the nature and time course of picture-sentence verification processes by directly comparing visual context effects that require interpreting a written verb in relation to an action with effects that involve interpretation of sentential role relations in relation to depicted role relations. In two Experiments, we analyzed ERPs as participants read a subject-verb-object sentence and verified whether or not the sentence matched a recently viewed visual scene. The verb either matched the previously depicted action or not; and who-does-what-to-whom in the sentence was either congruous with the depicted role relations or not, resulting in 4 (fully counterbalanced) conditions (see Table 1).

If there is a single mechanism for congruence processing we would expect to see similar ERP patterns to role relations and verb-action mismatches. Alternatively, the action and role-relation mismatches involve different mechanisms. Processing a role-relations mismatch involves comparing depicted agents and patients with a compositional interpretation, perhaps requiring more time and processing effort than relating an action to a verb interpretation. Recall, that prior research observed a verb-action congruence N400 effect (Knoeferle et al., 2009). Assuming a larger negativity reflects greater processing difficulty (see Monetta, Tremblay, & Joannette, 2003), and given that Wassenaar and Hagoort (2007) observe their first congruence effects at the verb, such an account predicts greater negative mean ERP amplitudes during the N400 region at the verb for the role relations than verb-action mismatches (and most negative for the combined mismatches), and also later ERP and verification time congruence effects.

Alternatively, role-relation effects would precede verb-action congruence effects: People likely expect the first noun phrase of a sentence to be the agent. When they read the first noun and realize that it does not refer to the character depicted as the agent, they may begin to anticipate incongruence between picture and sentence even though there is no overt mismatch at the first noun phrase; the moment the verb confirms

¹The failure to replicate the verification time congruence effect could be due to the fact that the verification response occurred well after sentence end (but essentially this requires further investigation.)

this expectancy (specifying agent-action relationships), role (in)congruence could be confirmed and thus might elicit earlier ERP congruence effects than verb-action mismatches. To better delineate any role relations and verb-action congruence effects, we varied stimulus onset asynchrony between Experiment 1 (500 ms) and Experiment 2 (300 ms). The timing of those congruence effects that depend solely on processing associated with the first noun phrase is not expected to change substantially as a function of SOA. Alternatively, the timing of congruence effects related to information provided by the verb, is expected to vary with the interval between the noun and verb.

Experiments 1 and 2

Methods

Participants Thirty-two students of UCSD took part in Experiment 1, and a further thirty-two participated in Experiment 2. All participants were native English speakers, right-handed (Edinburgh Handedness Inventory), and had normal or corrected-to-normal vision. All gave informed consent; the experiment protocol was approved by the UCSD IRB.

Materials, design, and procedure We derived materials for both experiments from a previous study (Knoeferle et al., 2009). The present two experiments had a 2-factor *role-relation congruence* (congruent, Picture 1a/b vs. incongruent, Picture 1c/d) \times *action congruence* (congruent, Picture 1a/c vs. incongruent, Picture 1b/d) within-subjects design (Table 1).

Table 1: Example of the four experimental conditions

Condition	Picture	Sentence
full match	1a 	<i>The gymnast punches the journalist</i>
action mismatch	1b 	<i>The gymnast punches the journalist</i>
role mismatch	1c 	<i>The gymnast punches the journalist</i>
combined mismatch	1d 	<i>The gymnast punches the journalist</i>

The sentence, *The gymnast punches the journalist*, in Table 1 is congruent on both action and role dimensions with Picture 1a, (full match); it is incongruent on the action but congruent on the role-relation dimension with Picture 1b (action mismatch); it is congruent on the action but incongruent on the role relations dimension with Picture 1c (role mismatch); and it is incongruent on both of these dimension following Picture 1d (combined mismatch). The materials were counterbalanced to ensure that any congruency-based ERP differences were not spuriously due to stimuli or to their pre-

sentation. There were 80 item sets which, combined with the conditions and further counterbalancing, yielded 16 experimental lists. Each list contained one occurrence of an item sentence/picture, and an equal number of left-to-right and right-to-left action depictions. Each list also contained 160 filler items, of which half were mismatches. These filler sentences had different syntactic structures including negation, clause-level and noun phrase coordination, as well as locally ambiguous reduced relative clause constructions.

Participants inspected the picture on a CRT monitor for a minimum of 3000 ms terminated via a right thumb button press. Next, a fixation dot was presented for a random duration between 500 and 1000 ms, followed by the sentence, one word at a time. Word onset asynchrony was 500 ms in Experiment 1 and 300 ms in Experiment 2; word duration was 200 ms in both. Participants were instructed to examine the picture and then to read the sentence in the context of the preceding picture. Participants indicated via a button press as quickly and accurately as possible after each sentence whether it matched or did not match the preceding picture. After that button press, there was a randomly varying pause between 500 and 1000 ms prior to the next trial.

Analysis We report analyses of variance (ANOVA) on response latencies and mean amplitude ERPs. Time regions for the ERP analyses were: the first noun; the verb, and the post-verbal object noun. We performed omnibus repeated measures ANOVAs on mean ERP amplitudes (averaged by participants for each condition at each electrode site) with role congruence (mismatch vs. match), action congruence (mismatch vs. match), hemisphere (left vs. right electrodes), laterality (lateral vs. medial), and anteriority (5 levels) as factors. The pre-stimulus baseline for all analyses was 200 ms. Time windows (0-100, 100-300, 300-500) were chosen based on prior studies and visual inspection of waveforms.

Results Experiment 1 (500 ms SOA)

Behavioural results Repeated measures ANOVAs for the verification latencies showed that response times were marginally faster for the action match than mismatch conditions (1115 ms vs. 1163 ms, $p = 0.06$), while there was no reliable effect for the role relations factor ($p > 0.2$); the interaction between these two factors was reliable ($p < 0.01$).

The response latency data replicate findings of a verb-action congruence effect (Knoeferle et al., 2009) as well as the absence of verification time congruence effects for role relations mismatches (Wassenaar & Hagoort, 2007).

ERP results We present grand average ERPs at prefrontal, parietal, temporal, and occipital sites for all four conditions (Fig. 2) and for mean amplitude role mismatches versus matches (Fig. 3).

For the role relations factor, differences emerged early, during the first noun phrase. ERPs for role mismatches were more negative beginning about 200 ms after noun onset (Figure 3), with the effect more pronounced at lateral electrodes over right anterior scalp (100-300 ms, $p < 0.05$). In line

with early (200-400ms) mismatch effects observed by Visers et al., we also measured ERPs from 200-400 ms at the first noun. Analyses revealed more negative going ERPs to role mismatches than matches ($p < 0.01$). Following the anterior negativity, a relative positivity for mismatches was observed, largest over posterior scalp, beginning around 400ms after noun onset and continuing beyond the onset of the subsequent verb. This effect was reliable from 0-100 ms and 100-300 ms following the verb ($p < 0.01$). These role congruence effects were also reliable when analyzed relative to a pre-noun baseline. They did, however, not last into the later portion of the verb (300-500 ms).

Figure 1: Experiment 1 verification response times (error bars indicate 95% confidence interval)

Figure 2: Grand average ERPs (mean amplitude) for all four conditions across the sentence at prefrontal, parietal, temporal, and occipital sites (Experiment 1)

For action mismatches, the first reliable effects occurred at the verb, where we replicated larger mean amplitude ERPs to action mismatches than matches with a a centro-parietal maximum (300-500 ms, $p < 0.001$, see Fig. 2 Knoeferle et al., 2009). The reliable verb-action congruence effect in this window (300-500 ms at the verb and the absence of a

Figure 3: Grand average mean amplitude ERPs for role mismatching conditions versus role matching conditions across the sentence at prefrontal, parietal, temporal, and occipital sites (Experiment 1)

role-relation effect a lead to an interaction between these two factors ($p < 0.05$). During the second noun (300-500 ms), the role mismatches were more negative-going than the role matches ($p < 0.05$).

Results Experiment 2 (300 ms SOA)

Analyses of verification time latencies revealed no reliable effects of the manipulated factors (see Fig. 4).

Figure 4: Response latencies in ms for Experiment 2

For the ERPs, the earliest effect of a role mismatch appears to be a broadly distributed relative negativity that reached a maximum between about 300 and 400ms, i.e., shortly after the verb onset (Figure 5). These role congruence effects and occurred from 0-100 and 100-300 ms after verb onset (i.e., 300-600 ms after noun onset).

In these early verb time windows (0-100, 100-300 ms) role mismatches were more negative than role matches ($p < 0.001$, see Fig. 5). That negativity is confirmed when analysing the data re-baselined relative to the first noun (300-500 ms and 200-400 ms ($p < 0.01$). Analysis of the time

window 300-500 ms post-verb found no role mismatch effects ($F < 0.2$). There were no further reliable role relations congruence effects except for more negative ERPs for mismatching than matching trials during the post-verbal object noun (second noun: 400-600 ms, $p < 0.05$).

For the action mismatches, the effects in Experiment 2 appeared after the verb (300-500 ms, $p < 0.001$, see Fig. 6) just as in Experiment 1, leading to a reliable interaction of role and action congruence ($ps < 0.01$). Post-verbally, the verb-action congruence negativity continued into the determiner and object noun (see Fig. 6).

Figure 5: Grand average mean amplitude ERPs scores for role relations mismatches versus matches across the sentence at prefrontal, parietal, temporal, and occipital sites (Experiment 2)

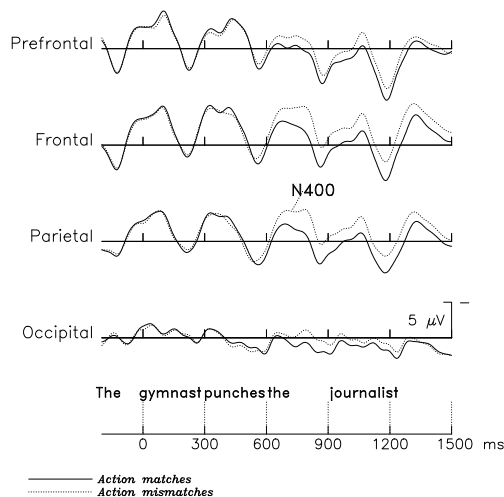

Figure 6: Experiment 2: Grand average mean amplitude ERPs scores for action mismatches versus matches across the sentence at prefrontal, parietal, temporal, and occipital sites (Experiment 2)

In Experiment 2, role mismatch effects again clearly preceded verb-action mismatch effects. Although the role mis-

match effect was more broadly distributed and laterally symmetric than the early role congruence negativity in Experiment 1, both effects had the same polarity and a similar time course and neither exhibited the posterior, right lateralized maximum frequently observed for N400 effects.

General Discussion

The present ERP experiments compared role-relation and verb-action congruence processing in a picture-sentence verification task, and examined whether they differed in their natures and/or time courses. Verification time congruence effects for verb-action mismatches (longer response times for action mismatches relative to matches) were replicated (marginal effect) at the longer SOA (Exp 1) and were not reliable at the shorter SOA (Exp 2). By contrast, role match and mismatch response times did not differ at either SOA. ERPs, however, revealed reliable but different effects for both role and action mismatches (vs matches)

The earliest role mismatch effects were seen within a few hundred milliseconds of the first noun onset at both SOAs. By contrast, reliable effects of action mismatches were observed only later, a few hundred milliseconds after verb onset. Although the action mismatch effect also was a broadly distributed relative negativity to the mismatches, it tended to be larger over posterior scalp (as is characteristic of visual N400) whereas the role relation mismatch effect was not. At the longer SOA (only) the role relation congruence negativity was followed by a reliable positivity over posterior scalp that continued past the onset of the next word (verb).

As in Knoeferle et al. (2009) we find ongoing ERP congruence effects across the sentence suggest that verification-related processes are part of ongoing incremental sentence interpretation. We observe effects of the action-verb mismatch at the verb, continuing into the second determiner and object noun (see also Ferretti, Singer, & Patterson, 2008; Singer, 2006, for related evidence on text verification). The overall morphology, latency, and centro-parietal distribution of the N400 is similar to that for lexico-semantic anomalies or low cloze probability words in sentences read for comprehension (e.g., Kutas, 1993; Kutas, Van Petten, & Kluender, 2006; Berkum, Hagoort, & Brown, 1999).

Conclusions Our findings are consistent with verification models on which depicted information modulates processing of verbal information as sentences unfold word by word. In the context of a just-viewed depicted action in which a journalist is punching a gymnast, there is nothing incongruous or anomalous about a sentence that begins with *The gymnast* People could have waited until they read the verb before assigning a thematic role to the first noun phrase. It seems, however, that when they read the first noun and realized that it referred to a character that had not been depicted as the agent of an action, their expectations of thematic role assignment (i.e., that the first noun in a sentence often refers to the thematic agent) conflicted with their visual context representation (of that character as a patient). Such incongruence may

have led to the larger negativity for role relations mismatches at the first noun. The subsequent centro-parietal positivity elicited by role relations mismatches may be a P600, related to the revision of thematic role assignments though, if so, it is unclear why it did not replicate in Experiment 2.

Furthermore, although action and role relations mismatches were both evident at the verb (mismatching the action; identifying the first noun phrase as a role filler that mismatches its role in the picture, respectively), critically, the time course of their effects differed, as did - at least for the positivity during the early verb in Experiment 1 - polarity. Role mismatch effects were further absent in the later time window at the verb for which we found the verb-action congruence N400 effect. The reliable interaction of role and action congruence suggests these two effects are dissociable. To the extent that a single mechanism account does not straightforwardly predict this dissociation, our findings appear to accord better with the view that multiple functional brain mechanisms govern visual context effects during online language comprehension.

Neither the ERP nor verification time data confirmed the complexity account which predicted substantially longer verification latencies for role than action mismatches. In both studies, verification times to the role relations conditions were no longer than those to action mismatches. A complexity account also predicts larger (and possibly delayed) negative mean ERP amplitudes for role mismatches (combined mismatch and role mismatch) relative to action mismatches (action mismatch and combined mismatch, 300-500 ms at the verb, e.g., Fig. 2). This also was not what we observed.

Why then did we find a difference in ERP effects for a role relations mismatch relative to verb-action mismatch effects, while prior research has failed to find differences between ERP congruence effects in response to such - at first blush - different mismatches as object locations versus role relations (Vissers et al., 2008; Wassenaar & Hagoort, 2007)? First, prior studies did not compare object location with role relations mismatches directly. A theoretically more interesting possibility is that for both the role relations and object location mismatches, re-processing involves restructuring of mental representations (spatially and/or in terms of thematic role relations) whereas for our verb-action mismatches, re-processing concerned lexico-semantic content (rather than the structure) of mental representations.

In sum, we find that the time course of visual context influences on language comprehension can vary as a function of which aspects of a picture (role relations versus actions) mismatch corresponding aspects of a sentence. The findings best align with an incremental account of comprehension in picture-sentence verification.

Abstract

It has been suggested that children learn the meanings of words by observing the regularities across different situations in which a word is used. However, experimental studies show that children are also sensitive to the syntactic properties of words and their context at a young age, and can use this information to find the correct referent for novel words. We present a unified computational model of word learning which integrates cross-situational evidence with the accumulated semantic properties of the lexical categories of words. Our experimental results show that using lexical categories can improve performance in learning, particularly for novel or low-frequency words in ambiguous situations.

Learning the Meaning of Words

In the course of learning a language, children need to learn mappings between words and their meanings, mostly from noisy and ambiguous contexts. It has been suggested that children learn the meanings of words by observing the regularities across different situations in which a word is used, or the *cross-situational evidence* (Quine, 1960; Pinker, 1989). Experimental studies on children and adult learners have shown that both groups are sensitive to cross-situational evidence, and can efficiently use it to deduce the correct meanings of novel words in ambiguous situations (Smith & Yu, 2007; Monaghan & Mattock, 2009). Moreover, many computational models have demonstrated that cross-situational learning is a powerful and efficient mechanism for learning the correct mappings between words and meanings, and can explain several behavioural patterns observed in children (Siskind, 1996; Yu, 2005; Fazly et al., 2008).

Another valuable source of information for mapping words to meanings is the syntactic structure of the sentence that a word appears in. There is substantial evidence that children are sensitive to the structural regularities of language from a very young age, and that they use these structural cues to find the referent of a novel word (e.g. Naigles & Hoff-Ginsberg, 1995; Gertner et al., 2006), a hypothesis known as syntactic bootstrapping (Gleitman, 1990). The syntactic bootstrapping account is in accordance with children’s early sensitivity to distributional properties of language: one-year-old infants can recognize sentences from an artificial grammar after a short period of exposure (Gomez & Gerken, 1999), and 2 to 3-year-olds demonstrate robust knowledge of some of the abstract lexical categories such as nouns and verbs (e.g., Gelman & Taylor, 1984; Kemp et al., 2005).

Therefore, it is likely that they draw on their knowledge of the structural regularities of language (and of lexical categories in particular) to facilitate word learning, especially in cases where cross-situational evidence is not reliable. However, a coherent account of word learning that explains the interaction between these two information sources is lacking. Also, despite the extensive body of experimental research on the role of syntactic knowledge in semantics acquisition, few computational models have been developed to explore the usefulness of lexical categories in learning word meanings (but see Yu, 2006).

We present a probabilistic model of word learning which integrates cross-situational evidence and the knowledge of lexical categories into a single learning mechanism. We use an existing computational model of cross-situational learning proposed by Fazly et al. (2008), and augment it with the syntactic categories of words. Our computational simulations show that such information can improve the model’s performance in learning words. Especially, the results suggest that the syntactic category of a word and the context the word appears in provide complementary information for the acquisition of word–meaning mappings.

Related Computational Models

A number of computational word learning models have used cross-situational learning as their core mechanism for mapping words to meanings. The rule-based model of Siskind (1996) and the probabilistic models of Yu (2005) and Fazly et al. (2008) all rely on the regularities of the co-occurrences of words and meaning elements, successfully learning word meanings from noisy and ambiguous data. Moreover, these models simulate several behavioural patterns observed in children, such as vocabulary spurt, fast mapping, and learning synonymy and homonymy. However, all these models ignore the syntactic properties of the utterances and treat them as unstructured bags of words.

There are only a few existing computational models that explore the role of syntax in word learning. Maurits et al. (2009) has investigated the joint acquisition of word meaning and word order using a batch model. This model is tested on an artificial language with a simple relational structure of word meaning, and limited built-in possibilities for word order. The Bayesian model of Niyogi (2002) simulates the bootstrapping effects of syntactic and semantic knowledge in verb learning, i.e., the

use of syntax to aid in inducing the semantics of a verb, and the use of semantics to narrow down possible syntactic forms in which a verb can be expressed. However, this model relies on extensive prior knowledge about the associations between syntactic and semantic features, and is tested on a toy language with very limited vocabulary and a constrained syntax. Yu (2006) integrates information about syntactic categories of words into his model of cross-situational word learning, showing that this type of information can improve the model’s performance. Yu’s model also processes input utterances in a batch mode, and its evaluation is limited to situations in which only a coarse distinction between referring words (words that could potentially refer to objects in a scene, e.g., concrete nouns) and non-referring words (words that cannot possibly refer to objects, e.g., function words) is sufficient. It is thus not clear whether information about finer-grained categories (e.g., verbs and nouns) can indeed help word learning in a more naturalistic incremental setting.

An Overview of Our Integrated Model

Consider a young language learner hearing the sentence *the kittie is playing with the yarn*, and trying to find out the meaning of *yarn*. Usually there are many possible interpretations for *yarn* based on the surrounding scene, and the child has to narrow them down using some learning strategy. One such method is to register the potential meanings in the current scene, and compare them to those inferred from the previous usages of the same word (i.e., cross-situational learning). Another way to make an informed guess about the meaning of *yarn* is to pay attention to its syntactic properties. For example, if the child has already heard some familiar words in a similar syntactic context (e.g., *daddy is playing with the ball*, *the kittie is sniffing the slipper*), she can conclude that a group of words which can appear in the context “*is Xing the -*” usually refer to physical objects. Therefore *yarn* must refer to one of the objects present in the scene, and not for example to an action or a property.

We present a computational model that combines these two complementary approaches into a single mechanism of word learning. Our goal is to examine whether using the knowledge of word categories in addition to cross-situational observations can improve the performance in word learning. We use the computational model of Fazly et al. (2008) as the base model of cross-situational learning: the model learns word meanings as probabilistic associations between words and semantic elements, using an incremental and probabilistic learning mechanism, and drawing only on the word–meaning co-occurrence statistics gradually collected from naturally-occurring child-directed input. This model has been shown to accurately learn the meaning of a large set of words from noisy and ambiguous input data, and to exhibit patterns similar to those observed in children in

a variety of tasks (see Fazly et al., n.d., for a full set of experiments on this model).

In order to augment the base model with category knowledge, we assume that an independent categorization module can process each sentence and determine the lexical category for each word, e.g., based on its surrounding context. That is, we make the simplifying assumption that prior to the onset of word learning, the categorization module has already formed a relatively robust set of lexical categories from an earlier set of child-directed data. This assumption is on the basis of previous empirical findings that young children gradually form a knowledge of abstract categories, such as verbs and nouns (e.g., Gelman & Taylor, 1984). In addition, several computational models have been proposed for inducing reliable categories of words by drawing on distributional properties of their context (see, e.g. Parisien et al., 2008). However, children’s acquisition of categories is most probably interleaved with the acquisition of word meaning, and these two processes must be studied simultaneously. As a first step, we investigate whether the word learning process can benefit from the knowledge of lexical categories, assuming that such knowledge exists.

In the next sections we sketch the base model of cross-situational learning, and explain how we extend it to integrate lexical categories as an alternative source of guidance. During the course of learning in both models, we use the feedback from the categorization model to detect different senses of the same word. That is, the same word types which belong to different categories are represented as separate lexical items. For example, the verb sense and the noun sense of the word *cry* are mapped to two independent meaning representations.

Cross-situational Learning

This section explains the details of the cross-situational word learning model of Fazly et al. (2008), which we use as our base model.

Representation of Input

The input to our word learning model consists of a set of utterance–scene pairs that link an observed scene (what the child perceives) to the utterance that describes it (what the child hears). We represent each utterance as a sequence of words, and the corresponding scene as a set of semantic features, for example:

He hit the rabbit { ANIMATE, MALE PERSON, ACT, MOTION, CONTACT, FORCE, ANIMAL, MAMMAL, RABBIT }

In the Evaluation section, we explain how the utterances and the corresponding semantic features are selected.

Given a corpus of such utterance–scene pairs, our model learns the meaning of each word w as a probability distribution $p(\cdot|w)$ over the semantic features appearing in the corpus. In this representation, $p(f|w)$ is the probability of feature f being part of the meaning of word w .

In the absence of any prior knowledge, all features can potentially be part of the meaning of all words. Hence, prior to receiving any usages of a given word, the model assumes a uniform distribution over semantic features as its meaning.

The Learning Algorithm

The model proposes a probabilistic interpretation of cross-situational learning (Quine, 1960) through an interaction between two types of probabilistic knowledge acquired and refined over time. Given an utterance–scene pair $(U^{(t)}, S^{(t)})$ received at time t , the model first calculates an alignment probability a for each $w \in U^{(t)}$ and each $f \in S^{(t)}$, using the meaning $p(\cdot|w)$ of all the words in the utterance prior to this time. It then revises the meaning of the words in $U^{(t)}$ by incorporating the alignment probabilities for the current input pair. This process is repeated for all the input pairs, one at a time.

Step 1: Calculating the alignment probabilities.

For a feature $f \in S^{(t)}$ and a word $w \in U^{(t)}$, the higher the probability of f being part of the meaning of w (according to $p(f|w)$), the more likely it is that f is aligned with w in the current input. In other words, $a(w|f, U^{(t)}, S^{(t)})$ is proportional to $p^{(t-1)}(f|w)$. In addition, if there is strong evidence that f is part of the meaning of another word in $U^{(t)}$ —i.e., if $p^{(t-1)}(f|w_k)$ is high for some $w_k \in U^{(t)}$ other than w —the likelihood of aligning f to w should decrease. Combining these two requirements:

$$a(w|f, U^{(t)}, S^{(t)}) = \frac{p^{(t-1)}(f|w)}{\sum_{w_k \in U^{(t)}} p^{(t-1)}(f|w_k)} \quad (1)$$

Note that a feature can have a non-zero alignment with more than one word in an utterance. For example, if two concrete nouns occur in a sentence, they both need to be aligned with the single feature ARTIFACT.

Step 2: Updating the word meanings. We need to update the probabilities $p(\cdot|w)$ for all words $w \in U^{(t)}$, based on the evidence from the current input pair reflected in the alignment probabilities. We thus add the current alignment probabilities for w and the features $f \in S^{(t)}$ to the accumulated evidence from prior co-occurrences of w and f . We summarize this cross-situational evidence in the form of an association score, which is updated incrementally:

$$\text{assoc}^{(t)}(w, f) = \text{assoc}^{(t-1)}(w, f) + a(w|f, U^{(t)}, S^{(t)})$$

where $\text{assoc}^{(t-1)}(w, f)$ is zero if w and f have not co-occurred before. The model then uses these association scores to update the meaning of the words in the current input, as in:

$$p^{(t)}(f|w) = \frac{\text{assoc}^{(t)}(f, w)}{\sum_{f_j \in \mathcal{F}} \text{assoc}^{(t)}(f_j, w)} \quad (2)$$

where \mathcal{F} is the set of all features seen so far. We use a smoothed version of this formula to accommodate noisy or rare input, as explained in Fazly et al. (n.d.).

Word Acquisition Score

To evaluate our model, we need to verify how accurately the model learns the meaning of words. We thus define the *acquisition score* of a word w at time t as an estimation of how closely the meaning probability $p^{(t)}(\cdot|w)$ resembles the *correct* meaning of w , or \mathcal{T}_w . The correct meaning of a word is a set of semantic features according to an input-generation lexicon.¹ Ideally, a word is accurately learned when its relevant semantic features (those in \mathcal{T}_w) are ranked at the very top of the distribution $p^{(t)}(\cdot|w)$. We use average precision² to measure how well $p^{(t)}(\cdot|w)$ separates the relevant features of w from irrelevant ones.

Adding Lexical Categories to the Model

As mentioned before, we assume that prior to the onset of word learning, the child has formed a number of lexical categories, each containing a set of word forms. More formally, we assume that the word learning model has access to a categorization function $\text{cat}(w, U^{(t)})$ which at any time t during the course of learning can determine the category of a word w in utterance $U^{(t)}$. We do not make any assumptions about the details of the categorization process, except that it does not rely on the meaning of words in order to find their appropriate category.

As the model learns meanings for words, the categories that these words belong to are implicitly assigned a meaning as well. Once the word learning process begins, we assign a meaning distribution to each category on the basis of the meanings learned for its members. Formally, we define the meaning of a category C as the average of the meaning distributions of its members, as in:

$$p^{(t)}(f|C) = \frac{1}{|C|} \sum_{w \in C} p^{(t)}(f|w) \quad (3)$$

where $|C|$ is the number of word forms in category C , and $p^{(t)}(f|w)$ is the meaning probability of word w for feature f at time t . Prior to observing any instances of the members of a category in the cross-situational input, we assume a uniform distribution over all the possible meaning elements for each category.

¹The model does not have access to this lexicon for learning; it is used only for input generation and evaluation.

²Precision is calculated as the proportion of the number of features from \mathcal{T}_w to the total number of features at each cut-off point in the ranked list $p^{(t)}(\cdot|w)$. The acquisition score is the average over the precisions for all the cut-off points up to the point where all the features in \mathcal{T}_w are included in the ranked list. Note that this score is 1 when the probabilities assigned to all of the relevant features of w are higher than those assigned to the irrelevant features.

Using Categories in Alignment

Knowledge of word categories is integrated into the base model in the alignment phase (i.e. **Step 1** of the learning algorithm), where we decide which semantic feature in an observed scene must be aligned with which word(s) in the accompanying utterance. Given a new utterance–scene pair, we can align words in the utterance with the semantic features in the observed scene based on the cross-situational evidence that we have accumulated so far. Alternatively, we can find the category for each word and use the meaning associated with the word category as a guide to align it with the best matching semantic features from the scene. We can merge these two pieces of information into an extended version of Eqn. (1):

$$a(w|f, U^{(t)}, S^{(t)}) = \text{weight}(w) \cdot a_w(w|f, U^{(t)}, S^{(t)}) + (1 - \text{weight}(w)) \cdot a_c(w|f, U^{(t)}, S^{(t)})$$

The word-based alignment score $a_w(w|f, U^{(t)}, S^{(t)})$ is calculated as in Eqn. (1). The category-based alignment score $a_c(w|f, U^{(t)}, S^{(t)})$ is calculated in a similar fashion, except it relies on the meaning of the word category:

$$a_c(w|f, U^{(t)}, S^{(t)}) = \frac{p^{(t-1)}(f|\text{cat}(w, U^{(t)}))}{\sum_{w_k \in U^{(t)}} p^{(t-1)}(f|\text{cat}(w_k, U^{(t)}))}$$

where the meaning probability $p^{(t-1)}(f|\text{cat}(w_k, U^{(t)}))$ is calculated as in Eqn. (3).

The relative contribution of the word-based versus the category-based alignment is determined by the function $\text{weight}(w)$. It has been shown that cross-situational evidence is a reliable cue for frequent words: Fazly et al. (n.d.) show that once their model receives a few instances of a word form, it can reliably align it with proper semantic features. On the other hand, the category-based score is most informative when the model encounters a low-frequency word. Therefore, we define $\text{weight}(w)$ as a function of the frequency of w :

$$\text{weight}(w) = \frac{\text{freq}(w)}{\text{freq}(w) + 1}$$

Once the overall alignment score is calculated for the new input pair, the meaning probabilities of words are updated through **Step 2** of the original learning algorithm, and the meaning of their corresponding categories are updated accordingly.³

Evaluation

The training data for our model consists of a sequence of utterances, each paired with a set of semantic features. We extract utterances from the Manchester corpus (Theakston et al., 2001) in the CHILDES database

³For each word w in $U^{(t)}$, the meaning distribution of the corresponding category C is incrementally updated as $p^{(t)}(f|C) = p^{(t-1)}(f|C) + \frac{1}{|C|}(p^{(t)}(f|w) - p^{(t-1)}(f|w))$.

ball	→ GAME EQUIPMENT#1 → EQUIPMENT#1 → INSTRUMENTALITY#3, INSTRUMENTATION#1 → ARTIFACT#1, ARTEFACT#1 → ...
ball:	{ GAME EQUIPMENT#1,EQUIPMENT#1,INSTRUMENTALITY#3,ARTIFACT#1, ...

Figure 1: Semantic features for *ball* from WordNet.

(MacWhinney, 1995), which contains transcripts of conversations with children between the ages of 1;8 and 3;0. We use the mother’s speech from transcripts of 6 children, remove punctuation and lemmatize the words, and concatenate the corresponding sessions as our test data. We automatically construct a scene representation for each utterance based on the semantic features of the words in that utterance. For nouns, we extract the semantic features from WordNet⁴ as follows: We take all the hypernyms (ancestors) for the first sense of the word, and add the first word in the synset of each hypernym to the set of the semantic features of the target word (see Figure 1 for an example). For verbs, we extract features from WordNet as well as from a verb-specific resource, VerbNet.⁵ For adverbs, adjectives and closed class words we use the features of Harm (2002). Words not found in these three resources are removed from the utterance.

To form the initial lexical categories, we use a non-overlapping portion of the part-of-speech tagged version of the Manchester corpus. The original corpus has 60 fine-grained tags, which we map to 11 coarser-grained categories, such as Noun, Verb, and Preposition.⁶

Learning Curves

To understand whether category information improves learning of word–meaning mappings, we compare the pattern of word learning over time for two models: the base model which only uses cross-situational evidence, and the extended model which incorporates lexical categories into learning. For each model we measure the average acquisition score (defined on page 3) of all words that the model has encountered up to each point in time.

Figure 2 shows the learning curve for each model over 5000 time units (or processed input pairs). The curves show that the extended model consistently outperforms the base model. The improvement is more pronounced as the model receives more input, since by learning more about the meanings of words the model also forms a more reliable knowledge about the meanings of categories and can use them more efficiently in aligning the novel words with their referents.

Figure 2: Avg. acquisition score for all words over time, with and without using lexical categories.

Categories and Context Familiarity

The learning curves presented above show an overall improvement when lexical categories are incorporated in word learning. However, we expect the gain from including categories to vary across different situations. For example, experimental and computational studies have shown that cross-situational learning can account for accurate mapping of a novel word to a novel object in a familiar context (see Fazly et al. (n.d.) for a discussion on this phenomenon). The same pattern is expected in our base model, where the alignment between a word and a semantic feature is in part determined by what the model has learned about the possible meanings of the co-occurring context words (see Eqn.1). Therefore, it can learn a lot about a novel word from a single exposure if that word appears in a familiar context.

We hypothesize that categories can be particularly helpful in cases where a novel word first appears in an unfamiliar context (where not all words in the utterance are accurately learned), or when an utterance contains more than one novel word. To investigate this hypothesis, we introduce a context familiarity measure CF as the mean *familiarity* of all words that co-occur with a target word, where the familiarity of a word is determined by its frequency range. The mappings between familiarity values and frequency ranges are as follows: 0 (0), 1 (1), 2 (2–4), 3 (5–9), 4 (10–29), and 5 (≥ 30), where the numbers in parentheses specify the frequency range.

Figure 3 shows the average acquisition score of words with high and low context familiarity ($CF \leq 3$ vs. $CF > 3$), and for novel words which appear in the company of other novel words (this last condition is marked as Multi-Novel in Figure 3). The average scores are calculated by both models after the first occurrence of each word. As can be seen, the inclusion of categories leads to a statistically significant improvement for words in all three conditions ($p < 0.05$).⁷ However, the improvement is much more pronounced for words with low context familiarity, and particularly when an utterance includes more than one novel word (i.e. a highly unfamiliar context). These results support our hypothesis, and suggest

⁷The p -values are measured according to a two-sided sign test for a confidence interval of 95%.

Figure 3: Avg. acquisition score for words in contexts with different degrees of familiarity.

that in learning the meaning of words, the context of a word and its lexical category can be seen as complementary sources of knowledge.

Comparing Different Categories

To better understand the impact of lexical categories on word learning, we examine the pattern of improvement for words with different parts of speech. Lexical categories differ in their frequency of occurrence and in their semantic properties. For example, open-class categories such as Verb and Noun tend to have lower token frequency, higher type frequency, and more within-class meaning variability compared to closed-class categories such as Determiner and Preposition.

Recall that words in our test corpus are tagged with one of 11 coarse-grained parts of speech. Three of these categories (Auxiliary, Infinitive and Negation) each contain only a single word type, and one (Other) is not a coherent and meaningful category. The average acquisition score in both models for the remaining categories are shown in Figure 4. Out of these seven categories, four are open-class: Noun (599 word types), Verb (261), Adjective (60), and Adverb (25), and three are closed-class: Determiner (23), Preposition (17), and Conjunction (8).

Interestingly, we observe that category information helps more with the acquisition of open-class words, in particular Noun ($p < 10^{-16}$) and Verb ($p < 0.0001$). We believe this difference is due to the high token frequency of closed-class words which makes them very easy to learn, even for the base model that does not take into account the information about their categories. Moreover, using categories does not significantly improve the acquisition of adjectives and adverbs. We suspect that this is a result of the small number and the inconsistent meaning representations of these categories in the resource of Harm (2002). In general, we predict that using better resources for extracting semantic features will boost the contribution of lexical categories in word learning.

Conclusions and Future Directions

Our computational model of word learning demonstrates the advantage of integrating lexical categories into a cross-situational model of word learning. Drawing on

Figure 4: Avg. acquisition score for different categories.

the meaning probabilities of individual words, the model gradually associates each lexical category with a meaning representation, which in turn can boost learning of novel words. Our simulations of the model over the course of acquisition show that using lexical categories consistently improves learning over a base model which only relies on cross-situational evidence. Moreover, our analyses of the results suggest that lexical categories can have a significant impact on the acquisition of open-class words which appear in less familiar context.

The model in its current form makes simplifying assumptions that must be addressed in future work. It is assumed that lexical categories are formed prior to the onset of the word learning process, and that the category of each word can be precisely determined upon its first appearance in the input data. In the future, we intend to use an incremental model of category induction to simultaneously learn lexical categories and word meanings. In fact, using a finer-grained set of categories induced by such a model might be more suitable for our purpose, since they can represent more specialized meanings (e.g., fruits and animals instead of nouns). Moreover, the categorization process can benefit from the integration of word meanings in addition to the distributional context. This extension will allow us to study how the early stages of word learning and category formation interact.

Sentence Processing Mechanisms Influence Cross-Situational Word Learning

Judith Köhne & Matthew W. Crocker

{judith, crocker}@coli.uni-saarland.de

Abstract

Word learning has traditionally examined separately the role of constraints provided by the visual context (e.g. *cross-situational learning*) and the linguistic context (e.g. *syntactic bootstrapping*). We suggest that the combined investigation of these learning scenarios is important: Firstly, to determine whether cross-situational word learning applies when words are presented in sentences and, secondly, to illuminate possible interactions of linguistic and situational learning mechanisms. We conducted three experiments to examine the role of visual and linguistic contextual constraints during foreign language word learning. In particular, our studies show that, given a visual context, syntactic verb-argument constraints together with knowledge about plausible real-world action-object relations help to further enhance cross-situational word learning.

Keywords: Cross-situational word learning in context; sentence processing; verb-derived expectations;

Introduction

Adults' foreign language learning often happens in a planned and incremental way to systematically gain increasing command of the language's structures. Parts of the vocabulary are learned very explicitly via vocabulary lists. When it comes to using and improving a foreign language in a natural situation, within an actual speech community, however, the language novice faces a less controllable, more diverse situation. When trying to understand and learn new words, there are two challenges: Firstly, words are often embedded in complex linguistic contexts and, secondly, there is a rich but ambiguous visual context containing possible world referents (*referential uncertainty*, Gleitman, 1990). One important mechanism for dealing with referential uncertainty is to keep track of words and referents co-occurring over different contexts. As previous research shows, adults as well as children are able to exploit such cross-situational learning analyses (*cross-situational word learning*, CSWL, e.g., Quine, 1960; Yu and Smith, 2007; Vouloumanos and Werker, 2009). In a study by Yu and Smith (2007), participants were asked to learn novel names for novel objects. Within a single trial, participants were exposed to 2-4 auditorily presented nouns, unconnected to each other, and the equal number of visually presented objects. Despite the referential uncertainty in each trial, participants were able to learn noun-object mappings by exploiting cross-trial co-occurrences.

In most CWSL studies, words are not presented as parts of sentences. This idealization has drawbacks, however: Firstly, language is not presented in its natural complexity (i.e., with sententially embedded words) and, secondly, possibly useful constraints provided by the linguistic context are intentionally withheld. This means that learning tasks are potentially

oversimplified in some respects and overcomplicated in others. There is some evidence that adults are able to make use of the linguistic context that words come together with to understand the language input, instead of being distracted by it. Lee and Naigles (2008), for instance, show that the verb frame of a sentence helps verb learning (*syntactic bootstrapping*, Landau and Gleitman, 1985; Fisher, 2002; Lidz, Gleitman, and Gleitman, 2003). These kinds of studies, however, are usually not visually situated.

Some sentence processing mechanisms that are generally automatically applied by adult native speakers may also interact when dealing with foreign language input. As Altman and Kamide (1999) have shown, for instance, native speakers rapidly make inferences about linguistically upcoming referents in a sentence, given a restrictive verb (such as *eat*) and a visual scene. We investigate the hypothesis that learners may use similar on-line mechanisms when learning novel nouns. Specifically, we investigate whether such on-line predictions influence CSWL by reducing the size of sets of potential world referents a novel noun refers to.

In this paper, three adult language-learning eye-tracking experiments using a pseudo-natural language (modified Indonesian) are presented, addressing three central hypotheses: 1) CSWL mechanisms operate successfully when novel nouns are embedded in sentences. 2) Verb-driven, anticipatory expectations based on semantic verbal restrictions guide learners' (visual) attention. 3) Verb-driven, anticipatory expectations based on semantic verbal restrictions identify subsets of world-referents that novel nouns are likely to denote, thereby constraining CSWL.

Experiment 1

We investigated these issues with a stepwise learning procedure. Participants first learned restrictive verbs and were then exposed to novel nouns, embedded in spoken subject-verb-object (SVO) sentences as syntactic subjects (referring to characters) and syntactic objects (referring to objects), and depicted on scenes.

Methods

Participants 32 German native speakers took part in the experiment, 8 of which had to be excluded due to technical problems. Data of 24 participants was analyzed (17 female).

Design, Materials & Procedure The language consisted of six restrictive verbs (three food verbs like *bermamema*, 'eat', and three clothing verbs like *melimema*, 'iron'), twelve nouns

(six referring to human characters such as *badut*, 'clown', three to food objects such as *sonis*, 'sausage', and three to clothing items, e.g. *oblung*, 't-shirt') and one article that preceded all nouns (*si*, 'the'). The language was based on Indonesian (word order, article, parts of the words).

The experiment comprised three phases: isolated verb learning, situated noun learning, and vocabulary testing. In Phase 1, participants learned verbs by being exposed to static depictions of actions presented together with the corresponding spoken verb. Each action was named ten times. Then knowledge of verbs was tested: Participants were presented a picture not seen before and asked to pronounce the matching verb. Feedback was provided. The eye-tracker was adjusted and verbs together with depictions were presented again.

Phase 2 consisted of the sentence-comprehension and noun-learning phase: Semi-natural scenes and spoken sentences were presented (sentence start 1s after picture). Scenes depicted the target character and the target object (the named referents), as well as one distractor character and one distractor object, together with background. There was always one food item and one clothing item. Sentences were constructed using the already learned verbs and novel nouns. Word order was SVO. The syntactic subject denoted the target character and the syntactic object referred to the target object, either the food or the clothing one, corresponding to verb type (see example in Figure 1). People were not explicitly told the word order. There were 36 trials (randomized in order), each object and each character was named six times (and each one was shown twelve times). Participants were asked to understand the sentences and learn the unknown words. Eye-movements were measured.

In Phase 3, a forced-choice vocabulary test with 12 trials, one for each new noun, was performed. Pictures for the forced-choice vocabulary test showed 4 potential referents (= characters and objects) and were presented together with a spoken noun. Combinations of the four options differed but there was always at least one competitor of the same kind (character, food, or clothing item, respectively). Participants had to mouse-click onto the appropriate picture. Learning performance was the main measurement of interest for Phase 3. The experiment lasted about 30 minutes.

Predictions Hypothesizing that participants understand the SVO-sentence structure and have similar gaze behavior as native comprehenders, we expected more looks to characters than objects during NP1 and more looks to objects than characters during NP2. Secondly, we hypothesized that to identify character referents and learn their names, participants would exploit cross-situational analysis (Hypothesis 1). This predicts differences between looks to target and distractor characters to emerge over time during NP1: While in the very beginning participants have no hint which character NP1 referred to, tracking co-occurrences of character names and depictions over trials makes it possible to identify the target. This increase in looks to the target should also become visible in the averaged data. We further hypothesized that verb

Figure 1: Example Item Experiment 1
Si badut bermamema si worel.
 'The clown will eat the sausage.'

restrictions would be exploited quickly to identify object referents and learn their names, possibly additionally to CSWL (Hypotheses 2 & 3). That means that during the verb and NP2, targets should be inspected much more than distractors even early in Phase 2. Our hypothesis that verb restrictions provide additional cues regarding target objects (Hypothesis 3) moreover predicts that object names are learned better than character names overall.

Data Analysis, Results, & Discussion

The vocabulary test revealed a noun-learning rate that is well above chance (about 55% with a baseline of 25%, $t = 9.28, p < .001$). When analyzing only the data of the participants who actually learned all verbs in Phase 1, $N = 15$, it was 64% ($t = 8.59, p < .001$). Numerically, object names were learned better than character names but this difference did not reach significance (all: $t = .90, p = .38$; only good verb learners: $t = 1.38, p = .191$).

For eye-movement analysis we examined trials with at least one inspection on our regions of interest (ROI; target character, distractor character, target object, distractor object) for three time periods linked to the unfolding sentence (from onset of NP1 to onset of verb (V), from onset of V to onset of NP2, and from onset of NP2 to offset of NP2). All time periods were shifted such that they started 200ms later than the actual starting points in the speech stream because planning of saccades takes people about that much time. We conducted logistic regressions by entering the binomial data (fixation or no fixation at certain time to a specific ROI) into linear mixed effect models with logit link function (from the lme4 package in R, Bates, 2005). Participant and item were considered as random factors. To see whether the fixed factor (ROIs) had a main effect (i.e. whether including the factor significantly improved the predictive power of the model, regarding where people looked) we compared between the models that include and exclude this factor with a Chi-Square test (Baayen, Davidson, & Bates, 2008). Contrasts between levels of a factor (i.e. single ROIs) were investigated by studying the ratio of regression coefficients and standard errors since the p-values produced by lmers (Wald z test) are anti-conservative

(Baayen et al., 2008): If the coefficient is greater than the standard error times two, the comparison is considered to be reliable. Tables of these statistical comparisons are given below. The formulas describing the lmer models are of the following form: dependent variable (inspections during time periods) is a function of (\sim) the independent variable (ROI) plus random effects (subjects and items).

Table 1: Lmer models for inspections on characters vs. objects (m1) and targets vs. distractors (m2) during time periods (Experiment 1)

m1/m2: *Inspections* during NP1/V/NP2 $\sim 1 + ROI + (1|sub) + (1|item)$, *family* = *binomial*(*link* = "logit")

	Predictor	Coef.	SE	Wald z	p

12		distractor	-0.257	0.105	-2.452	< .050

Eye-movements suggest that participants quickly understood the sentence structure: There were reliably more inspections on the characters than inspections on the objects during NP1 (Table 1, rows 1-2) and reliably more inspections on the objects than on the characters in the V interval (rows 3-4) and NP2 (rows 5-6). Moreover, the target character was inspected more often than the distractor character in NP1 (rows 7-8) and the target object was looked at more than the distractor object during NP2 (rows 11-12). This supports the hypothesis that participants succeeded in identifying the targets over the experiment. Furthermore, during V, the target object was also looked at reliably more than the distractor (rows 9-10). This likely reflects an anticipatory effect based on semantic verb restrictions. Also, the difference between looks to target and distractor objects during NP2 was greater than the difference between target and distractor characters during NP2, suggesting that verb restrictions contributed to an improved identification of objects during on-line processing (see timegraph in Figure 2).

Summarising, we found evidence that adults can learn nouns cross-situationally when words are embedded in sentences and referents are embedded in scenes, and further that they rapidly exploit semantic verb restrictions to identify referents on-line. We replicated these results with even better learning rates (72%, $t = 8.249$, $p < .001$) and for another word order (OVS, with a learning rate of 51%, $t =$

Figure 2: Timegraph Experiment 1

3.840, $p < .001$) in a follow-up experiment. It is unclear, however, whether the on-line predicting of the referent has an effect on noun learning. We take this up in Experiment 2.

Experiment 2

In Experiment 2 we manipulated the degree of verb restriction to study the interaction of CSWL and verb-derived inference learning (Hypothesis 3). The focus therefore was on object learning rather than character learning.

Methods

Participants 50 German native speakers took part in the experiment (18 excluded due to bad verb learning and technical problems). Data of 32 participants was analyzed (23 female).

Materials & Procedure The language consisted of six verbs, 14 nouns, and the same article as in the other experiments. There were 2 non-restrictive verbs (e.g., *take*) and 4 restrictive verbs: either 2 food verbs (e.g., *eat*) and 2 clothing verbs (e.g., *iron*) or the 2 food verbs and 2 container verbs (e.g., *fill*), depending on list. The nouns denoted 2 characters (man and woman) and 12 objects: 4 food items (e.g., *broccoli*), 4 clothing items (e.g., *trousers*), and 4 container items (e.g., *vase*). Word order was SVO.

The experiment consisted of five parts with very similar procedures as in Experiment 1. The main difference was that instead of one sentence comprehension phase and one vocabulary testing part, there were two each (Blocks 1 and 2). The whole experimental sequence comprised: verb learning and testing, eye-tracker preparation, and verb repetition (Phase 1); sentence comprehension (noun learning) Block 1 (Phase 2); vocabulary test Block 1 (and verb repetition) (Phase 3); sentence comprehension (noun learning) Block 2 (Phase 4); vocabulary test Block 2 (Phase 5).

Phase 1 resembled Phase 1 in Experiment 1, except that we used animated verb-learning and verb-testing pictures to improve recognizability of the actions. In Phase 2 and 4, items were manipulated according to one three-level within-participant factor (Degree of referential uncertainty). There were three conditions: the no-referential-uncertainty condition (Condition 1), the low-referential-uncertainty condition

(Condition 2), and the high-referential-uncertainty condition (Condition 3). Firstly, the conditions differed with regard to verb type: In Condition 1 and 2, a restrictive verb was used, in Condition 3, it was a non-restrictive verb. Secondly, there were differences in the visual scenes. Images always depicted one character and four objects embedded in a simple indoor scene. One of the objects was the target object. The others were competitors (= potential world referent except the target) and distractors (= objects which are not potential world referents). The combination of competitors and distractors depended on the condition the item was in: In Condition 1, there was no competitor since the verb was restrictive (e.g. *eat*) and only the depicted target fulfilled verb constraints (e.g. *food*). In Condition 2, there was one competitor: The verb was restrictive but there was one depicted object in addition to the target which was a member of the required semantic class. In Condition 3, there were three competitors because the verb was non-restrictive and did not semantically constrain the category of potential referents denoted by the post-verbal argument (see Table 2). In Block 1 (Phase 2), no target was a competitor in another trial to make sure participants could not exclude competitors based on other learned words. In Block 2 (Phase 4), however, learning was potentially simplified via the possibility to exclude already learned mappings. The 48 trials (24 per Block) were presented randomized in order with each noun repeated four times. Participants were told that sentences were of the form 'someone VERBs something'. We monitored eye-movements in Phases 2 and 4.

Table 2: Conditions Experiment 2

(Number of potential referents on scene (Column 4) as a result of verb type (Column 2) and number of competitors (Column 3))

Condition	Verb	Competitors	= Pot. referents
1: <i>No-ref. unc.</i>	restr.	0	1
2: <i>Low-ref. unc.</i>	restr.	1	2
3: <i>High-ref. unc.</i>	non-r.	3	4

For the forced-choice vocabulary tests (Phases 3 and 5) there were six depictions presented on the screen: the target (e.g. *tomato*) and another instance of the targets category (e.g. *broccoli*), two objects of one of the two other categories (e.g., *shirt* and *skirt*), and two characters. Additionally to the mouse clicks, we introduced a confidence rating to have another, more sensitive measurement because there were only two nouns to be learned per condition: Participants were encouraged to press a number on the keyboard (between 1-9) to indicate how sure they were about their choice of a referent.

Predictions We hypothesized that selectional verb restrictions help identifying target referents and interact with CSWL (Hypothesis 3). In particular, we hypothesized, firstly, that

during Phases 2 and 4, verb restrictions narrow down the search space in Condition 1 (from four to one since there was no competitor) and Condition 2 (from four to two since there was one competitor) (see Table 2); Secondly, that participants additionally conduct CSWL in Condition 2; And thirdly, that participants conduct only CSWL in Condition 3. Our predictions were, therefore, that noun learning rates and confidence ratings, as reflected in the vocabulary tests, would be highest for objects in Condition 1 and lowest for objects in Condition 3. With regard to eye-movements in Phases 2 and 4, our hypotheses predict differences for conditions during NP2: a clear preference for inspecting the target in Condition 1, a preference to inspect the target but a secondary preference to inspect the competitor in Condition 2, as well as a less strong preference for target inspection and an equally strong consideration of all competitors in Condition 3.

Finally, we hypothesized that in Block 2 participants can exclude those objects as potential referents, which have been already linked to a world-word-mapping in Block 1 (assuming the use of the principle of mutual exclusivity, Markman and Wachtel, 1988). This predicts an enhanced noun learning in Block 2 compared to Block 1.

Data Analysis, Results, & Discussion

Noun learning was reliably better than chance (25%) for all groups of interest and correlated positively with confidence ratings ($r = .452, p < .001$, see Table 3).

Learning was clearly better in Block 2 than Block 1 (all conditions: $\chi(1) = 30.77, p < .001$; Condition 1: $\chi(1) = 6.31, p < .05$; Condition 2: $\chi(1) = 10.17, p < .01$; Condition 3: $\chi(1) = 16.57, p < .001$). The same was true for confidence ratings (all conditions: $\chi(1) = 12.85, p < .001$; Condition 1: $\chi(1) = 5.42, p < .05$; Condition 2: $\chi(1) = 5.48, p < .05$; Condition 3: $\chi(1) = 10.69, p < .01$).

The direction of the differences between noun learning success and confidence ratings in the three conditions was as expected: Nouns were learned best and the decisions were rated highest in Condition 1 and worst in Condition 3. This was true for both blocks together as well as for Blocks 1 and 2 separately. We analyzed both values with linear mixed effect models, using logistic regression for the categorical learning rates (logit link function) and linear regression for the continuous confidence ratings, with participant and item as random factors. For confidence ratings we calculated Monte Carlo Markov Chain values (MCMCs) whose p-values are a good estimate of the factor's significance (but are only applicable for continuous variables), (Baayen et al., 2008). Analyses did not reveal significant main effects for noun learning rates but did for confidence ratings. There were reliable differences in confidence ratings between single conditions: Condition 1 and Conditions 3 in all parts (Block 1, 2, and 1+2), Condition 1 and Condition 2 in 1+2 and marginally in Block 2, and between Conditions 2 and 3 in all parts (Table 4: numbers in both blocks taken together).

Eye-movements were analyzed as in Experiment 1. Considering all conditions, the eye-gaze pattern for all parts of the

experiment resembles that of Experiment 1: We found referential inspections of the character during NP1, verb-driven anticipation of the target object(s) in verb region, and referential inspections of the target object in NP2.

More interestingly, differences between conditions for (referential) inspections in NP2 support the offline results: In Condition 1, the target was inspected reliably more than the character and the distractors (in all parts of the experiment) (Table 5, rows 1-5, for Blocks 1 and 2 together). In Condition 2, the target was inspected most, too (rows 6-10); However, the competitor was also inspected reliably more than the character and the distractors. The difference between looks to target and competitor was not significant in Block 1 but was in Block 2 and both blocks taken together (rows 21-25). For Condition 3, the target was inspected reliably more than the character or the distractors as well, except that the difference between looks to the target and to one distractor was significant only in Block 2, but neither in Block 1 nor in both blocks taken together (rows 11-15). This distractor shared category with the target. There were also significantly more looks to this distractor than to the other distractors and the character in Block 2 (but not for both blocks, see rows 26-30). The gaze pattern for Condition 3 is somewhat unexpected but interesting as it suggests that participants learned a new co-occurrence restriction for verbs in Block 2 (e.g., container objects and *take*) - although the verbs were non-restrictive, the distractor of the target category was preferred over the other distractors (which were of categories associated with other, restrictive, verbs).

The second experiment revealed clear effects of condition in on-line and off-line data showing that, firstly, referents are identified better when verbs provide information about the referent's category (better learning rates and confidence ratings in Condition 1 and 2 than in Condition 3) and, secondly, that cross-situational word learning interacts with the exploration of verb restrictions in that verb restrictions narrow

down the search space, lowering referential uncertainty (better learning rates and confidence ratings for Condition 2 than 3). As in Experiment 1, trials in Condition 1 made clear that verb restrictions can narrow down the number of potential referents to one, which means that there is a situation close to fast-mapping. Eye-movements during NP2 support the results except that there was an unexpected preference to look at both members of target category in Condition 3. We attribute this to spontaneous verb-argument category learning.

Summary & General Discussion

Two foreign-language learning experiments with an incremental learning scenario were conducted in order to study the influence of semantic verb restrictions on identifying world referents and learning world-word mappings. In Experiment 1, we found that nouns which are sententially embedded are successfully learned cross-situationally (with SVO and OVS sentences) and that participants additionally exploited verb restrictions rapidly to identify post-verbal referents. In Experiment 2, we additionally found evidence for the claim that verb restrictions interact with and improve Cross-Situational Word Learning.

With this investigation we have presented evidence for the claim that adult sentence processing mechanisms interact with statistical word learning and that foreign language word learners can benefit from exploiting linguistic and visual contextual cues. In particular, we revealed that semantic verb restrictions together with knowledge about plausible arguments reduces the set of potential (visual) referents, thus simplifying CSWL complexity. This highlights the co-operation of multiple learning mechanisms in situated word learning. Our findings are consistent with recent word learning models which combine co-occurrences frequency analysis with other, in particular situational and knowledge-based cues (Frank, Goodman, & Tenenbaum, 2009; Yu & Ballard, in press).

Abstract

Previous research shows that human learners can acquire word-referent pairs over a short series of individually ambiguous situations each containing multiple words and referents (Yu & Smith, 2007). In this kind of cross-situational statistical learning based on the repeated co-occurrence of words with their intended referents, the application of principles such as mutual exclusivity and contrast can leverage prior experience to reduce the complexity in situations with multiple words and multiple referents. However, these principles can also block the learning of one-to-many mappings. In a study analogous those done in traditional associative learning, we manipulate the early and late evidence for particular pairings in the cross-situational learning paradigm, and examine the effects on learning of both one-to-one and many-to-many mappings. Two major findings are: 1) participants use mutual exclusivity and contrast to facilitate learning; and 2) given sufficient evidence, learners can adaptively disregard these principles and learn many-to-many mappings.

Keywords: statistical learning; language acquisition; cross-situational associative learning; blocking; highlighting

Introduction

Human infants and adults can acquire word-object pairings after experiencing a small number of individually ambiguous situations, each of which consists of several words and referents. The abilities required in cross-situational learning are to remember at least some of the co-occurrence statistics of nouns and their objects and to integrate statistical information across multiple learning situations, if one assumes that these words often occur when their referents are present, and that words and their referents will appear together in different situations. This idea, cross-situational learning, has been proposed as an essential means by which infants acquire language (Pinker, 1989; Gleitman, 1990). Recently, Smith & Yu (2008) empirically demonstrated that young infants can learn nouns through cross-situational learning.

In the more complex adult cross-situational word learning paradigm (Yu & Smith, 2007), participants were instructed to learn which word goes with each object and were then shown a sequence of training trials. Each trial consisted of a display of a few novel objects and a few successively spoken pseudowords. Each word referred to a particular on-screen object, but the correct referent for each word was not indicated, thus making meanings ambiguous on individual trials. In one learning condition with four words and four objects on each trial, participants attempted to learn 18 word-object pairings from 27 12-second trials. Thus, each stimulus—and each correct pairing—appeared six times.

Learning was assessed by a 4AFC test of each pseudoword after training, and showed that participants on average acquired slightly more than 9 of the 18 pairs.

How might participants learn so many pairings from such a short series of trials, each of which contains 16 possible word-referent pairings? Some reasonable principles that learners may apply during training can significantly restrict the space of possible pairings. Among others, the mutual exclusivity (ME) constraint, which holds that learners will try to map words to referents in a 1-to-1 way (Markman, 1990), has been demonstrated in various word learning tasks. In the context of cross-situational learning, for example, suppose a learner hears words *A B C D* and sees referents *b a c d* on some trial. However, she realizes that she has heard *A* and *B* on some prior trial, and seen objects *a* and *b*, but the other stimuli are novel. Even if she does not know that *A-a* and *B-b* are the correct pairings (they may not even be unambiguous at this point), employing ME she may assume that $\{A, B\}$ map to $\{a, b\}$, and that $\{C, D\}$ map to $\{c, d\}$. Thus, by applying the ME constraint with some minimal previous experience the learner can whittle the 16 possible pairings down to four. This sort of mechanism was used to model cross-situational learning of pairs that appeared in consecutive trials, as well as the pairs that were not temporally contiguous, both of which were learned better than in conditions with no temporal contiguity (Kachergis, Yu, & Shiffrin, 2009b).

The role of prior knowledge has also been investigated (Klein, Yu, & Shiffrin, 2008), and it was found that participants can use pre-studied pairs to facilitate subsequent learning. Their experimental conditions were the same with that of (Yu & Smith, 2007) described above (27 trials, four pairs per trial) except that three pairs were unambiguously pre-trained, learners acquired a mean of 13.7/18 pairs (10.8 of the un-pretrained pairs). Presumably, pre-training helped participants learn more un-pretrained pairs (compared to 9.5 pairs in Yu & Smith) by reducing the number of possible pairings in trials containing any pre-trained pairs. Further evidence of bootstrapping made possible by the assumption of ME was found in a study that varied pair frequency and contextual diversity (which other pairs a given appears with during training). Kachergis, Yu, and Shiffrin (2008a) found that pairs appearing only thrice during training were learned significantly better when they were allowed to co-occur with pairs appearing nine times than when all pairs appeared solely with pairs of the same frequency.

All of these results indirectly imply that learners assume mutual exclusivity during training, and demonstrate the added power it can yield when pairings are 1-to-1. Yurovsky and Yu (2008) gave participants a cross-

situational task with some non-mutually exclusive pairings: halfway through training, half of the referents ceased appearing (e.g., $A-a_1$), and each was replaced by a second referent (e.g., $A-a_2$) which henceforth always co-occurred with the original referent's word (e.g., A). Thus, by the end of training half the words had both a primacy referent (a_1) and a recency referent (a_2). In separate 4AFC tests of primacy and recency referents, participants learned more than 50% of both the primacy and the recency referents. By the law of the excluded middle, some participants must have learned both pairings (e.g., $A-a_1$ and $A-a_2$), and thus built lexicons that violated ME. In another condition, the trials with primacy and recency referents were randomly interleaved, and learners still acquired nearly as many non-ME pairings as ME pairings (and above 50%, on average).

Ichinco, Frank, and Saxe (2009) studied ME using a different modification of the cross-situational word learning paradigm: Halfway through training, instead of replacing primacy referents with recency referents, they added an extra referent that always co-occurred with a particular old word-referent pair. That is, halfway through training, trials began to contain one more referent (i.e., 4) than words (3). Examining conjoint probability of learning ME-violating associations for each word, Ichinco *et al.* found that most learned pairings respected ME. Similar behavior was found in a condition with an added word instead of an added referent. Thus, although some participants learned some ME-violating pairings, the majority of learning behavior seems to follow a mutual exclusivity bias. This is unsurprising if one views cross-situational learning as a more complex form of traditional associative learning.

In a typical associative learning task, participants are given some subset of cues on each trial, asked to predict an outcome, and then shown the actual outcome. The subject's learning of associations between particular cues and outcomes is tracked over time. In cross-situational learning, the words can be construed as cues, and the objects as outcomes (or vice-versa). No trial-to-trial feedback is given, but the learner may generate it on the basis of the preceding training trials. *Blocking* is an associative learning effect often observed in experiments with two training stages: in the first stage, cue A is repeatedly paired with outcome X, and in the next stage A and B are jointly paired with X. The association between B and X is found to be weaker than when only the second stage training occurs: thus, B has been blocked by A's pretraining. Ichinco *et al.*'s design closely matches a blocking design (see Table 1), and their results—weak learning of the old word (or referent) to new referent (or word) association—are indeed a blocking effect.

Training Stage	Yurovsky & Yu, 2008	Ichinco, <i>et al.</i> , 2009	present study
Early	w_1-o_1	w_1-o_1	w_1-o_1
Late	w_1-o_2	$w_1-\{o_1, o_2\}$	$\{w_1, w_2\}-\{o_1, o_2\}$

Table 1: Comparison of three cross-situational ME designs. *N.b.*: these examples suppress other concurrent trained pairs.

The goal of the present paper is to systematically investigate how statistical learners accumulate and use current statistical evidence in subsequent learning. In the present study, for the first time we set up a strong test of inference, akin to associative learning's highlighting: will participants use knowledge of pairs acquired early in training, in addition to the principle of ME, to quickly learn pairs introduced late in training? If so, will this mechanism block the learning of many-to-many mappings? With two word-referent pairs sharing the same referent, one mapping appears in the early part of training and the other appears in the late training, will subjects prefer one over the other if we vary the amount of evidence (i.e., co-occurrence statistics) given during the early and late stages of training? Will they learn both pairs eventually? The set of experiments in the present paper allows us to answer those questions and examine how learners may adaptively incorporate evidence to potentially overwhelm biases.

Experiment 1

Participants are tasked with learning many word-referent pairs from a series of individually ambiguous training trials according to the cross-situational word learning paradigm (Yu & Smith, 2007). In the present study, each training trial is composed of two objects and two spoken pseudowords. On any given trial, participants can only guess which word refers to which object, since the order of presentation of the words is randomized, and there is no indication of which word refers to which object. However, since words only occur on trials with their intended referents, the correct pairings are disambiguated over the series of trials.

In the present cross-situational study, we divide each set of learning experiences into an early stage and a late stage, and systematically vary the number of times pairs appear in each stage. Half of the pairs appear in both the early training stage and the late stage, and the remaining half the pairs only appear in the late stage. As shown in Table 2, when a pair w_1-o_1 from the early stage appears in the late stage, another specific pair only appearing in the late stage (w_7-o_7) always co-occurs with w_1-o_1 . Thus, in the late stage, $\{w_1, o_1, w_7, o_7\}$ always co-occur, therefore, all of the four possible associations are reasonable (w_1-o_1 , w_1-o_7 , w_7-o_1 , w_7-o_7). In fact, there is no additional information in the late stage that can be used to identify which ones are better than others. However, the key manipulation in this experiment is to vary the strength of w_1-o_1 in the early stage. More specifically, the early pairs co-occur 0 (no early training), 3, 6 and 9 times before they appear together with the late pairs. Given that we already know that people can effectively extract co-occurrence statistics in cross-situational learning, it is reasonable to assume that participants in this study would form some form of knowledge about w_1-o_1 when they enter the late stage trials. The research questions are: 1) whether they would prefer w_7-o_7 by applying the ME constraint; 2) whether they still learn w_1-o_7 and w_7-o_1 – a violation of ME; 3) how the amount of evidence about w_1-

o1 may influence how they process the otherwise-ambiguous information in late trials with {w1,o1,w7,o7}.

Training Stage	Repetitions	Example Trials
Early [pairs 1-6]	0, 3, 6, or 9	{w ₁ , w ₂ , o ₁ , o ₂ }, ..., {w ₁ , w ₅ , o ₅ , o ₁ }
Late [pairs 1-12]	3 (Exp. 1) 6 (Exp. 2) 9 (Exp. 3)	{w ₁ , w ₇ , o ₇ , o ₁ }, ..., {w ₁ , w ₇ , o ₇ , o ₁ }

Table 2: Experiment design, with example trials. Early pairs are indexed 1-6, and late-only pairs are 7-12. Pairs 1-6 also appear in the late stage, and thus occur more than pairs 7-12.

Subjects

33 undergraduates at Indiana University participated to receive course credit. None had participated in other cross-situational experiments.

Stimuli

On each training trial, two unusual objects (e.g., sculptures) are simultaneously shown while two pseudowords were sequentially heard. The 48 computer-generated words are phonotactically-probable in English (e.g., “bosa”), and were spoken by a monotone, synthetic female voice. These 48 objects and 48 words were randomly assigned to four sets of 12 word-object pairings, one set for each learning condition. Within each set, 6 pairings only appear in the late training and the other 6 appear in both the early and late trainings. Each 8-second training trial began with the appearance of two objects, which remained visible for the entire trial. After 2 s of initial silence, each word was heard (randomly ordered, duration of 1 s) followed by 2 s of silence.

There were four learning conditions in this study. The late training was the same in those four conditions, and was composed of 18 trials. Each pair appeared 3 times late in training. Therefore, the same trial {w1,o1,w7,o7} also appeared 3 times. Four conditions varied in the early training. There was no early training in condition 1. In condition 2, each of 6 early pairs appeared 3 times, forming 9 early trials before the late training. In conditions 3 and 4, each early pair appeared 6 or 9 times. Accordingly, there were 18 and 27 early training trials in those two conditions.

Procedure

Learners were instructed that they would see a series of trials with two objects and two alien words, and that they should try to figure out what each word means for a test at the end. Participants were not told there were training stages, and there was no perceptible break. After training, their knowledge was assessed using 11-alternative forced choice (11AFC) testing: on each test trial a single word was played, and the participant was instructed to choose the appropriate object from a display of 11 of the 12 trained referents. Participants were instructed to click on the best referent for the word. Each word was tested twice in 11AFC trials: once without its corresponding early referent as one of 11 choices to test its association with the late referent (‘early-late’ and ‘late-late’), and once without its

corresponding late referent as one of 11 choices to test its association with the early referent (‘early-early’ and ‘late-early’). In this way, we tested their knowledge of all of the four possible associations showing in Figure 1 (two associations for each word), and we access their knowledge of each of four possible associations individually in this test.

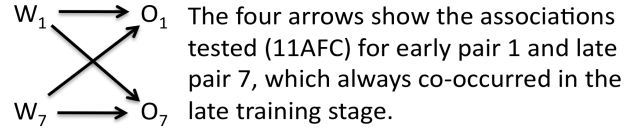

Figure 1: Example of associations tested by 11AFC.

Training condition order was counterbalanced, and each learner participated in all four conditions.

Results & Discussion

Fig. 2 displays the learning performance¹ in the training conditions with 3, 6, and 9 repetitions of early pairs. A 3x2x2 ANOVA with factors of early repetitions (3, 6, or 9), pair stage (early or late), and pairing type (within-stage or across-stage) showed only a significant main effect of pairing type ($F(1,30) = 8.62, p < .01$)². As shown in Fig. 2, learning of within-stage (i.e., early-early and late-late word-object) pairs was much greater than learning of across-stage pairs (within-stage $M = .71$, across-stage $M = .15$). Even this small proportion of mean between-stage pair learning was significantly above chance, by subject (11AFC chance = .091; paired $t(30) = 2.29, p < .05$). Thus, although within-stage pairings—those consistent with ME—were clearly favored, participants also learned some ME-violating across-stage pairings. However, the indistinguishable, high level of performance on both early-early and late-late pairings is evidence of strong, ME-based inference: a given late pair could only be unambiguously learned by filtering out the consistently co-occurring early pair.

It is surprising that the number of early pair repetitions did not have a consistent effect on performance ($F(2,30) = .90, p > .05$). That is, even three repetitions of each early pair was enough prior experience to allow participants to infer the correct late pairs, thus achieving performance equal to the proportion of early pairs learned—no benefit was conferred by additional repetitions of early pairs (i.e., 6 or 9). In the condition with no early stage (0 early repetitions), participants learned 32% of the 2-to-2 pairings, on average—well above chance (paired $t(30) = 8.83, p < .001$).

Experiment 1 demonstrated that participants can efficiently leverage the ME constraint to learn late-appearing pairs that always co-occur with early pairs, and would thus be ambiguous, if not for prior experience. Indeed, performance on pairs learned using this filtering inference technique was no less than the performance on the

¹ Data from two subjects were excluded because their average performance in all four conditions was at chance (11AFC chance = .091). The outcomes of statistical tests were unaffected.

² We will report the results of the 0-early-training condition later as those results can be used to compare the data across experiments.

early pairs, which were learned by ambiguous cross-situational training, and which appeared more times, overall. Moreover, in tests of across-stage pairings, participants showed some learning of ME-violating associations.

Learning by Early Repetitions and Relation Type (3 Late Reps)

Figure 2: Mean accuracy by condition for the four types of associations (within and between early and late pairs). Error bars show \pm SE and the dotted line shows chance (.091).

In the next experiment, we increase the amount of late evidence, which we expect will cause participants to adaptively relax the ME constraint and learn more across-stage pairings (e.g. w7-o1). If they do relax ME, will they also learn fewer late-late pairings, or can they learn both?

Experiment 2

Experiment 1 showed that participants tend to utilize the principle of mutual exclusivity in combination with prior cross-situational training to quickly infer the referents of late-appearing words. In fact, performance on late and early pairs was undifferentiated, even when early pairings appeared more frequently (in both the early and late stages) than the late pairs (only the late stage). It appears that three more repetitions of early pairs grants enough knowledge to highlight the late-late pairs—which appear only three times—and bring performance up to the same level as the early-early pairs.

Thus, to some degree, Exp. 1 is analogous to blocking studies in associative learning literature, but with multiple co-occurring cues and outcomes on each trial. We show that just three repetitions of early pairs dramatically changed how they processed statistical information later and they apparently applied ME-based learning as evident by very few across-stage pairs learned later (i.e., early-late or late-early). In Experiment 2, we provide learners with more evidence for across-pair associations via additional repetitions of late stage pairs. Will participants adapt to this change, evaluate the statistical evidence in a different way and begin to count more on statistical information in the late part? Will they learn more ME-violating pairings?

Subjects

29 undergraduates at Indiana University received course credit for participating. None had participated in previous cross-situational experiments.

Stimuli & Procedure

The sets of pseudowords and referents used in Experiment 2 are identical to those used in Experiment 1. In each condition, the late stage of training was simply doubled from 18 trials to 36 trials wherein each {w1,o1,w7,o7} appears six times (instead of three times in Experiment 1), yielding three more repetitions of late and early pairs.

Results & Discussion

Figure 3 displays the average³ levels of learning achieved in Exp. 2. Once again, a $3 \times 2 \times 2$ ANOVA with factors of early repetitions (3, 6, or 9), pair stage (early or late), and pairing type (within-stage or across-stage) showed only a significant main effect of pairing type ($F(1,24) = 5.45, p < .05$). As in Exp. 1, learning of within-stage (i.e., early-early and late-late) pairs was much greater than learning of across-stage pairs (within-stage $M = .74$, across-stage $M = .28$). Thus, the increase of statistical evidence in the late stage with three more repetitions of both early and late pairs, didn't improve the learning of within-stage pairs (Welch $t(51.8) = .55, p > .05$). Nonetheless, learning of across-stage pairings increased—as predicted—due to increased late stage pairings (Welch $t(37.5) = 2.35, p < .05$). That is, having six rather than three repetitions of each late pair with its matched early pair in the late stage increased the learning of early word to late object (and vice-versa) pairings; the pairings that violate ME. Thus, although people are initially inclined to assume mutual exclusivity, and are able to use it to quickly infer the meaning of novel words, people will also adaptively relax ME in the face of greater evidence that words are being mapped to additional objects. As in Exp. 1, there was no significant effect of the number of early repetitions on learning ($F(2,24) = .06, p > .05$).

In summary, this experiment demonstrates that learners react to increased evidence that late and early pairs go together by learning more pairings. By doing so, they exhibit the ability to violate ME in order to learn 1-to-many mappings without reduced learning of ME-compliant pairings. In Experiment 3, we increase the late stage evidence once more to determine whether learners will continue to adaptively relax the ME constraint and learn more across-stage pairings.

³ Data from four subjects were excluded because their average performance in all four conditions was at chance (11AFC chance = .091). The outcomes of statistical tests were unaffected.

Learning by Early Repetitions and Relation Type (6 Late Reps)

Figure 3: Accuracy by number of early pair repetitions and association type. Error bars show \pm SE.

Experiment 3

Experiment 2 provided six repetitions of late pairs with matched early pairs in comparison to Experiment 1's three repetitions, and learners indeed began to learn more late-early/early-late (i.e., across-stage, ME-violating) pairings. In Experiment 3, we once again increase the late stage by three repetitions (to nine), providing further evidence for cross-association of the matched early and late pairs.

Subjects

34 undergraduates at Indiana University received course credit for participating. None had participated in earlier cross-situational experiments.

Stimuli & Procedure

The same sets of pseudowords and referents were used in Experiment 3 as were used in Experiments 1 and 2. In each condition, there were 54 late-stage training trials, yielding three more repetitions of each late and early pair.

Results & Discussion

Figure 4 shows the mean⁴ learning level by condition and pair type in Experiment 3. A mixed ANOVA (3, 6, or 9 late repetitions [between-subjects] \times 3, 6, or 9 early repetitions \times early or late pair stage \times across- or within-stage pairing type) showed a main effect of pairing type ($F(1,101) = 161.76, p < .001$) and an interaction between pairing type and the number of late repetitions ($F(2,101) = 10.89, p < .01$). In brief, the patterns in Exp. 3 were consistent with what we observed in Exp. 2: participants learned within-stage pairs (e.g. w_1-o_1, w_7-o_7) quite well and also learned across-stage pairs (e.g. w_7-o_1, w_1-o_7) with the additional evidence provided in late training.

⁴ Data from three subjects were excluded because their average performance in all four conditions was at chance. The outcomes of statistical tests were unaffected.

Learning by Early Repetitions and Relation Type (9 Late Reps)

Figure 4: Accuracy by number of early pair repetitions and association type. Error bars show \pm SE.

General Discussion

When attempting to learn word meanings from a series of individually ambiguous trials, applying the mutual exclusivity constraint on each trial can significantly reduce the number of pairings a learner must consider, and even allow learner to quickly infer the meanings of novel words and referents. In the cross-situational experiments presented here, participants used such filtering—akin to highlighting in the associative learning literature—to quickly learn the same proportion of late-late pairings as early-early pairings. Thus, learners can use ME to infer the late-late pairings, even though each late-late pairing always co-occurred with one early pairing.

However, if pairings are not in fact mutually exclusive, or if word-referent mappings may change over time, assuming ME would be maladaptive. Across experiments, we increased the number of repetitions of late pairs, each of which always appeared with a particular early pair (e.g., w_1 and o_1 always appeared with w_7 and o_7 , which had never appeared before the late stage). As an early stage pair appears more often with a particular late pair, a flexible learner would relax the assumption of ME.

Exp. 1, with three late pair repetitions, demonstrated that participants learn early-early pairs very well with only three early repetitions, and use this knowledge, in combination with ME, to learn the late-late pairs at a similar rate. However, even in this experiment, participants showed evidence of learning some ME-violating pairings (i.e., late-early and early-late pairings). Results from Experiment 2, with six late pair repetitions, looked very similar, but with slightly higher learning of ME-violating pairings. With nine late pair repetitions, Experiment 3 provided further evidence that participants should disregard ME, and indeed they learned more cross-stage pairings.

Viewing cross-situational statistical word learning as a complex form of associative learning in which there are multiple cues and outcomes on each training trial, it is unsurprising to find evidence for ME in cross-situational experiments, for ME may be responsible for well-known associative learning phenomena such as highlighting and blocking. However, our results demonstrate that participants do not merely use the ME constraint for logical inference. Instead, they utilize an adaptable learning strategy: as statistical evidence for violation of ME increases, they learn more ME-violating pairs. A comparison of the results from the 0-early-stage condition in three experiments in which each early pair (e.g., w_1-o_1) always co-occurred with a particular late pair (e.g., w_7-o_7). Figure 5 shows the mean proportion of learned ME-respecting pairings (i.e., only pairings involving each stimulus once) and ME-violating pairings (i.e., pairings that involve a stimulus twice) that participants learned by the number of late repetitions (i.e., experiment), which increases as more late repetitions give evidence that the ME constraint should be relaxed.

Figure 5: The mean proportion of pairings that each participant learned that violate ME and that comply with ME (across all experiments). Chance for ME-respecting pairings is the dotted line ($2/11$). Chance for ME-violating pairings is $(1/11)^2 = \sim .01$.

In summary, the results from the present study provide a complete picture of how participants use the ME constraint and how they accumulate statistical evidence over the course of learning. By varying the strengths of word-object associations in both the early and late training stages, we were able to demonstrate various learning behaviors that have been shown in previous studies. In fact, some of those studies have produced incompatible results. Therefore, the contribution of our work is to unify different views inferred from previous results. We argue that human statistical learning is adaptable: learners are able to adjust their learning strategy over the course of learning in response to changing amounts of evidence for particular types of

pairings. One possible reason that previous results are not compatible is because each study took a snapshot of a continuous learning process. For example, many ME studies are conducted with one or two simple trials. We observe that learners' cross-situational learning strategies are dynamic and adaptable, and thus cannot be adequately portrayed by one snapshot. Rather, we need to examine learning trajectories by varying the amounts (repetitions) and types (ME-violating or -respecting) of evidence. We believe that the data presented here will quite useful in constraining models of cross-situational language acquisition. Future studies use real-time behavioral data (e.g., eye movements) to provide access online learning strategies.

Abstract

The world offers learners a seemingly infinite number of word-to-world mappings (Quine, 1960). In order to account for how learners manage to accomplish such a difficult task, theories of word learning have proposed different tools that make the task of learning words easier. However, we propose that reducing difficulty may be detrimental—difficulty may promote long-term word learning. We tested this hypothesis in a cross-situational paradigm in which object-label mappings were ambiguous during each learning event. The three conditions of learning (2 x 2, 3 x 3, and 4 x 4) varied in the degree of difficulty. Results revealed that, although difficulty deterred immediate performance, difficulty promoted long-term performance. We suggest that theory and research should shift from focusing on in-the-moment learning to examining both immediate *and* long-term learning. A complete theory of word learning not only accounts for word learning in the moment and on each time scale, but also integrates them in order to understand how they influence each other over time.

Keywords: word and category learning; statistical learning; cross-situational learning; long-term memory

Introduction

The world offers learners a seemingly infinite number of word-to-world mappings (Quine, 1960). Thus, an essential question for research on word learning is: How do learners manage to accomplish the difficult task of mapping words to objects, actions, and events in the world?

Theories of word learning typically focus on tools that learners use to make word learning easier. In this study, we examine word learning from the radical perspective that reducing difficulty may be detrimental. This study explores the idea that some difficulty may promote word learning, even in difficult tasks in which learners must track mappings across events, such as cross-situational word learning.

Theories of Word Learning. Three main classes of theories have sought to explain word learning: the Constraints/Principles theories, the Social-Pragmatic theories, and the Domain-General theories. All three of these theories propose tools that make word learning easier but differ in the nature of the task simplification tools.

The Constraints/Principles theories suggest that word learning is made easier and more feasible by constraints that narrow the search space for possible word-to-world mappings, such as mutual-exclusivity (e.g., Markman, 1989) and the novel-name nameless-category assumption (e.g., Golinkoff, Mervis, & Hirsh-Pasek, 1994). These

constraints guide learners' interpretations of new words and thus reduce the degree of indeterminacy. For example; the mutual-exclusivity principle (Markman, 1989) proposes words have mutually-exclusive meaning—one object can have only one referent. Consequently, when learners hear an unfamiliar label, they will assign an unfamiliar label to an unfamiliar object rather than an object that has already been named.

A second class of theories, the Social-Pragmatic theories, propose that word learning is simplified because learners are embedded in a social world in which they are guided by expert word learners (e.g., Bloom, 1993; Tomasello & Barton, 1994). Adults, as expert word learners, resolve the ambiguity of the word-learning scenario by guiding children's attention and thus make the task of word learning easier. For example, adults commonly talk about objects, events, and actions that learners are already focused on and consequently make it easier for learners to make word-to-world mappings (Bloom, 1993).

A final class of theories, the Domain-General theories, assert that general cognitive mechanisms such as perceptual saliency, association, and frequency make word learning straightforward (e.g., Smith, 1995)—learners notice objects and actions that are most salient in their environment and pair them with the most frequently associated label. For example, in one study (Samuelson & Smith, 1998), children were able to learn a novel word-novel object link by using saliency cues in the absence of other cues, suggesting that saliency cues alone guided children's word learning.

Word Learning and Memory. Although the three classes of theories make different predictions about many aspects of word learning, in this study we investigated a cognitive mechanism that is inevitably a critical part of each theory: memory. For example; the Constraint/Principles theories argue that constraints promote memory for words—if everything had a multiple unique labels it would be impossible to store and recall all of these words from memory. Social-Pragmatic theories rely on processes of memory and attention for establishing joint attention among two people—learners must attend and remember what others are focusing on in order to adequately label words and actions (e.g., Bloom, 1993). Domain-General theories assert that word learning is guided by global principles of attention, association, and frequency, which are basic cognitive mechanisms associated with memory (e.g., Smith, 1995). In sum, memory is a critical component to word learning theories because it supports every part of the word learning process—learning words requires attending to

words, encoding the properties of the word, binding words to objects in the world, and recalling words when needed in order to communicate with others.

Although it is clear that memory matters for learning words, relatively little work has investigated the role of memory and retention in word learning. In fact, only a handful of studies have imposed a delay between learning and testing (see Horst & Samuelson, 2008, for a discussion of this issue). Consequently, the vast majority of word learning theories are based upon immediate performance rather than performance over time.

Examining word learning both immediately and over time is essential for two reasons. First, a complete theory of word learning accounts for developmental changes in word learning and retention abilities. Moreover, such a theory not only accounts for word learning and retention on each time scale, but also integrates them in order to understand how they influence each other over time.

Second, immediate performance may not be a reflection of long-term performance. The few studies that have examined word learning and retention have yielded mixed results as to whether performance remains constant over time (e.g., Horst & Samuelson, 2008; Markson & Bloom, 1997). Alternatively, the memory literature has provided countless examples of how the factors that promote immediate learning do not necessarily promote long-term learning (e.g., Bjork, 1994). Immediate performance may not predict long-term performance because the degree of difficulty in learning influences long-term performance.

Desirable Difficulties in Learning. There has been a long history of research that has investigated the conditions under which long-term memory is enhanced. The principle goals of this research have been to discover factors that promote adults' ability to (1) produce and store a representation of knowledge and (2) create a representation that remains accessible and recallable over extended periods of time. Research has revealed that several manipulations of learning events can enhance long-term memory, such as varying the conditions of practice (e.g., Smith & Rothkopf, 1984), providing contextual interference (e.g., Mannes & Kintsch, 1987), distributing practice and the spacing effect (e.g., Cepeda et al., 2006), and reducing feedback to the learner over time (e.g., Schmidt, 1991).

These manipulations promote long-term memory because they introduce difficulty for learners while knowledge is being acquired (e.g., Bjork, 1994). Although learning tasks that are designed to make learning easy initially show greater learning, retention tests reveal that more difficult learning tasks promote more long-term memory and learning (and hence the term 'desirable' difficulty is commonly used). Thus, the memory literature suggests that, instead of making tasks easy for learners, the best way to promote long-term memory is to create difficulty for learners during learning.

An example of a desirable difficulty in learning is the spacing effect (e.g., Cepeda et al., 2006). The spacing effect

describes the robust phenomenon whereby memory is enhanced when learning events are distributed across time (i.e., spaced), instead of being presented in immediate succession (i.e., massed). Spaced learning is more difficult than massed learning because the time between learning events creates greater opportunities for forgetting (e.g., Bjork & Allen, 1970). Massed presentations prevent forgetting because presentations are in immediate succession. In fact, upon immediate testing, massed presentations lead to a greater amount of learning than spaced presentations. However, if a test is administered following a delay, a spaced presentation schedule will yield more learning than the massed presentation schedule.

Several researchers have long suggested that, although introducing difficulty during memory tasks is beneficial, these difficulties may be detrimental in more difficult cognitive tasks (e.g., Gagne, 1950). For example, spaced learning was thought to be particularly detrimental in generalization tasks. In fact, spaced learning was coined the "enemy of induction" (e.g., Gagne, 1950; see Kornell & Bjork, 2008, for a discussion).

Desirable Difficulties in Word Learning. Despite speculations that desirable difficulties may be the "enemy of induction", recent research suggests that imposing difficulty during learning promotes long-term word learning and generalization (e.g., Kornell & Bjork, 2008; Vlach et al., 2008). For example, one study (Vlach et al., 2008) presented children with novel objects and labels in an object category learning paradigm. Category exemplars were presented on two schedules, massed and spaced. Children were tested after a three minute delay and were required to generalize a word to a novel instance of a category. The results revealed that spaced presentations promoted more learning than massed presentations. Thus, a spaced learning schedule, a more difficult learning schedule, promoted word learning and generalization.

One limitation of research on desirable difficulties in word learning is that all of the studies have been artificially simplistic—a linguistic label could only be mapped onto one object. In real word learning contexts, mapping words to objects is generally not this straightforward. Word learners must figure out what words map onto in the world (Quine, 1960). Thus, because learners must track possible mappings across learning events, real world word learning is much more difficult than tested in recent research on desirable difficulties in word learning.

Research on cross-situational learning has indicated that the more objects and labels in each learning event, the more difficult it is for learners to determine mappings (e.g., Smith & Yu, 2008; Yu & Smith, 2007; Yurovsky & Yu, 2008). For example, when adult learners are presented with two words and two objects in learning events, they demonstrate relatively high performance, ~90% correct mappings on an immediate test. However, when learners are presented with four objects and four labels in each word learning event, learners perform significantly lower, ~55% correct

mappings on an immediate test (Yu & Smith, 2007). Thus, it appears that the more objects and labels in each learning event, the more difficult it is to track mappings across learning situations.

The memory literature would suggest that increasing the number of objects and labels in each word learning event presents several forms of desirable difficulty. First, increasing the number of object and labels in each learning event creates more spaced learning because each object-label pairing is interleaved between more possible pairings (e.g., Cepeda et al, 2006; Vlach et al., 2008). Second, an increase in the number of objects and labels in each learning event creates more contextual variation and interference between word learning events (e.g., Mannes & Kintsch, 1987). Both of these factors have been shown to promote long-term retention (e.g., Bjork, 1994).

Although recent research suggests that difficulty may promote word learning, this hypothesis has only been tested in artificially simple tasks where object-label mappings are straightforward. It may be the case that adding more difficulty to an already difficult task of mapping words to objects is not beneficial. Consequently, too much difficulty may deter both in-the-moment and long-term word learning. The current study investigates this possibility.

Current Study. The current study investigated the role of difficulty during word learning in a cross-situational word learning paradigm. Participants were presented with word learning events in which determining the object-label mappings were increasingly difficult. In the 2 x 2 condition, each trial presented two words and two objects. In the 3 x 3 condition, each trial presented three words and three objects. Finally, in the 4 x 4 condition, each trial presented four words and four objects. There were also three testing delay conditions: immediate, 30 minute delay, and one week delay. These conditions allowed for a direct comparison of the effects of varying degrees of difficulty in both in-the-moment and long-term word learning.

Method

Participants

Participants were 95 undergraduates at University of California, Los Angeles. Participants received course credit for their participation.

Design

This study used a 3 x 3 design. Learning Condition (2 x 2, 3 x 3, and 4 x 4) and Testing Delay (immediate, 30 minutes, and one week) were both between-subjects factors. Participants were randomly assigned to one of the nine conditions of the study.

Stimuli

Pictures of objects were presented on a 15-inch computer screen and the sound for the labels was presented by the

computer’s speakers. As Figure 1 shows, the objects were pictures of novel objects. There were a total of 18 objects. The labels were novel words following the phonotactic probabilities of English (e.g., ‘blicket’, ‘dax’). There were a total of 18 labels. Objects and labels were randomly paired together, for a total of 18 object-label pairs. In all conditions, there were a total of 6 presentations of each of the 18 object-label pairs. There were also an additional four objects and four labels presented during the training trial. These objects and labels were not used during the learning phase of the experiment.

In the 2 x 2 condition, two objects and two words were presented in each learning trial (see Figure 1). In the 3 x 3 condition, three objects and three labels were presented. In the 4 x 4 condition, four objects and four labels were presented.

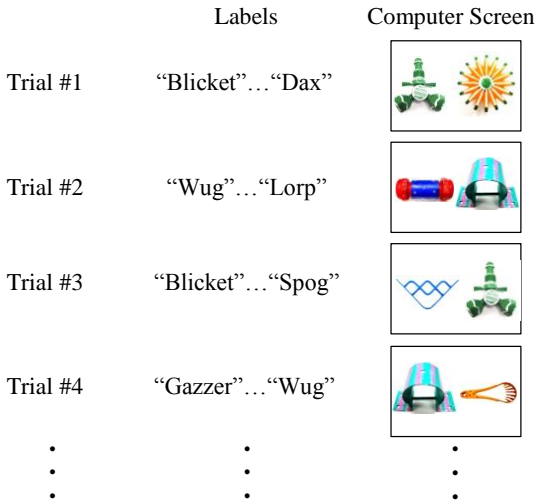

Figure 1. Example stimuli from the 2 x 2 condition.

Because the same number of object-label pairs (18 pairs) were presented in each condition, the same number of times (6 presentations each), other presentation factors varied across conditions in order to ensure equivalent exposure to the object-label pairs. Table 1 outlines these variations, which were adapted from Yu and Smith (2007). Although the number of trials and time per trial varied, the total exposure time remained constant across the conditions (see Table 1).

Table 1. Three Learning Conditions

Condition	Number of Trials	Time per Trial (in secs)	Total Time (in secs)
2 x 2	54	6	324
3 x 3	36	9	324
4 x 4	27	12	324

Procedure

Participants were told that they would be shown children’s toys and it was their job to figure out which word went with which toy. They were also instructed that it would be

ambiguous as to which words went with which objects on each trial. Participants were then given a brief training exercise to demonstrate what the experiment would be like. The training consisted of three learning trials, each with two objects and two labels, immediately followed by a forced-choice test. Objects and labels used during training were not included during the rest of the experiment.

After the training trial, participants were informed that they would now be beginning the learning phase of the experiment. Participants were presented with learning trials according to the condition in which they were assigned (2 x 2, 3 x 3, or 4 x 4). The number and length of trials was also set according to the condition (see Table 1).

After viewing all of the trials, participants were given a forced-choice test, depending upon the testing condition in which they were assigned. In the immediate condition, participants were given a test immediately following learning. In the 30 minute delay condition, participants were asked to play tetris for 30 minutes, and then were given a test. In the one week delay condition, participants were asked to come back exactly 7 days after the learning session and complete a test.

The test consisted of four force-choice questions. Each question presented one label and asked participants to identify the corresponding object among four objects. The three foil objects were other objects used in the experiment. No one object was repeated in the tests. Thus, 16 of the 18 objects were used in the test. The labels and objects used during the test were randomly assigned.

Results

We asked whether difficulty would promote learners' long-term word learning in a cross-situational learning paradigm. If difficulty promoted word learning, we would expect to see lower performance immediately, but stronger performance long-term. However, if difficulty did not promote word learning, we would expect to see lower performance regardless of testing delay.

We first conducted a 3 (Learning Condition) x 3 (Testing Delay) ANOVA, with the number of correct responses as the dependent measure. Results of this test revealed a significant main effect of learning condition, $F(2, 86) = 20.582, p < .001$, a significant main effect of testing delay, $F(2, 86) = 17.294, p < .001$, and a significant interaction of learning and testing delay, $F(4, 86) = 2.542, p = .045$.

First, three univariate ANOVAs were conducted within each testing condition. We then computed three planned comparisons using t-tests with Bonferroni corrections ($p < .05$) to determine the nature of the differences between learning conditions within each testing delay condition. If difficulty promoted word learning, we expected there to be differences in performance between learning conditions across the testing conditions.

When the immediate testing condition, there was a main effect of learning condition, $F(2, 32) = 10.997, p < .001$. Participants in the 2 x 2 condition ($M = 3.85$ correct mappings out of 4, $SD = .376$) had significantly higher performance than in the 4 x 4 condition ($M = 2.00$ correct mappings out of 4, $SD = 1.195$), $p < .001$. Performance was also marginally higher in the 2 x 2 condition than the 3 x 3 condition ($M = 3.07$ correct mappings out of 4, $SD = .997$),

Figure 2. Average number of correct responses (out of 4) by learning condition (2 x 2, 3 x 3, 4 x 4) and testing condition (immediate, 30 minute delay, one week delay). The dashed line represents chance performance.

$p = .086$. Finally, performance in the 3 x 3 condition was significantly higher than the 4 x 4 condition, $p = .029$. Thus, greater the number of object-label pairings in each learning trial, the lower the performance.

However, there was a different pattern of results in the 30 minute delay condition. There was a main effect of learning condition, $F(2, 28) = 5.304$, $p = .011$. Participants in the 2 x 2 condition ($M = 3.11$ correct mappings out of 4, $SD = 1.167$) had similar performance to participants in the 3 x 3 condition ($M = 3.00$ correct mappings out of 4, $SD = .784$), $p > .05$. Participants in the 2 x 2 and 3 x 3 conditions both had significantly higher performance than participants in the 4 x 4 condition ($M = 1.75$ correct mappings out of 4, $SD = 1.035$), $p = .022$ and $p = .021$.

In the one week testing delay condition there was a particularly interesting pattern of results. There was a main effect of learning condition, $F(2, 26) = 11.286$, $p < .001$. Participants in the 3 x 3 condition ($M = 2.54$ correct mappings out of 4, $SD = 1.127$) had higher performance than both the 2 x 2 condition ($M = 1.62$ correct mappings out of 4, $SD = .518$), $p = .071$, and 4 x 4 condition ($M = .75$ correct mappings out of 4, $SD = .463$), $p < .001$. Participants in the 4 x 4 condition performed similarly to participants in the 2 x 2 condition, $p > .05$. Thus, although initially participants in the 3 x 3 condition had lower performance than the 2 x 2 condition, one week later participants in the 3 x 3 condition had higher performance than participants in the 2 x 2 condition.

In addition to examining the differences within each testing condition, we also examined differences in each learning condition across the testing conditions using ANOVAs and three planned comparisons with Bonferroni corrections ($p < .05$). In the 2 x 2 condition, there was a main effect of testing delay, $F(2, 27) = 12.255$, $p < .001$. Immediate performance was marginally higher than performance in the 30 minute delay condition, $p = .085$, and the performance in the 30 minute delay condition was significantly higher than performance in the 1 week condition, $p = .001$. Thus, there was significant decrease in retention across each of the testing delay conditions.

There was also a main effect of testing delay in the 4 x 4 condition, $F(2, 21) = 3.868$, $p = .037$. There was not a significant difference in performance between immediate and 30 minute delay conditions, $p > .05$, or the 30 minute delay and one week delay conditions, $p > .05$. However, there was a significant difference in performance between the immediate and one week delay condition, $p = .047$. Thus, there was a significant decrease in retention between the immediate test and one week delayed test. Finally, in the 3 x 3 condition, there was not a main effect of testing delay, $F(2, 38) = 1.172$, $p > .05$. Thus, there was not a significant decrease in retention between the immediate and delayed tests.

Discussion

The results of this study support the idea that difficulty imposed during learning can promote long-term word

learning (e.g., Vlach et al., 2008). Moreover, difficulty promoted word learning in the already difficult task of cross-situational word learning, in which learners must track mappings across events. We found that, when tested immediately, learners had the highest performance in the 2 x 2 condition and the lowest performance in the 4 x 4 condition. Performance in the 3 x 3 condition was somewhere in between. These findings replicate that of Yu & Smith (2007). However, when tested 30 minutes later, there were no differences in the performance between the 2 x 2 and 3 x 3 conditions. Finally, when tested a week later, performance in the 3 x 3 condition was higher than performance than in both the 2 x 2 and 4 x 4 conditions. Thus, although difficulty yielded lower immediate performance (i.e., the 2 x 2 condition had higher performance than the 3 x 3 condition), there was a benefit of difficulty for long-term performance (i.e., one week later the 3 x 3 condition had higher performance than the 2 x 2 condition). This study demonstrates that, even in the seemingly difficult task of mapping words to objects (Quine, 1960), adding difficulty promoted long-term word learning.

The findings from this study also have implications for research on cross-situational word learning and, more generally, statistical word learning. Recent research on statistical word learning has focused on the factors that promote immediate performance in order to discover the mechanisms by which words are acquired over time (e.g., Kachergis, Yu, & Shiffrin, 2009; Lany & Saffran, 2010). However, this study suggests that this may not be the best approach for describing long-term trajectories of word learning. This study clearly demonstrates that immediate performance does not always reflect long-term performance. Thus, in order to assert that a mechanism promotes word learning over time, evidence should be provided from not just an immediate test, but an immediate *and* delayed test.

The broader impact of this study is that it highlights the intimate relationship between word learning and memory. Learning new words and categories requires perceiving an object, attending to relevant features, mapping a label to the object, binding this mapping to other instances of the label and object, abstracting across instances, and, finally, generalizing to novel objects. Memory is a critical factor in this process, both during category formation (e.g., remembering relevant features and binding instances and labels) and recall (e.g., retrieving stored instances and categories).

Despite the clear relationship between word learning, memory, and retention, we have failed as word learning researchers and developmentalists to explore the mechanisms underlying this relationship. Fundamental questions have remained unexamined. For example, the few studies that have asked whether children retain words over time have provided conflicting evidence. While one study finds children retain words for a month (e.g., Markson & Bloom, 1997), other studies have found that children forget words in a matter of minutes (e.g., Horst & Samuelson,

2008; Vlach et al., 2008). What are the implications of our research if participants do not remember words after a few minutes? Why are we speculating about long-term word learning from immediate performance, rather than empirically investigating word learning over time? Are we really uncovering the mechanisms of word learning?

In sum, future research should investigate both in-the-moment and long-term word learning. Exploring in-the-moment word learning is essential for understanding how words and categories are initially encoded. However, in theories of word learning, the common assumption is that performance will remain constant over time. This study clearly demonstrates that this is not always the case.

In order to account for real-world word learning, research should incorporate testing over longer time-scales—over the course of weeks, months, and years. A complete theory of word learning not only accounts for word learning in the moment and on each time scale, but also integrates them in order to understand how they influence each other over time.

Abstract

Even before birth, infants attend to the statistical properties of their sensory environments to learn about events in world. Tracking these statistics is crucial to mastery of visual, social, linguistic, and cognitive tasks. However, the degree to which their sampling follows prescriptions of rational statistical inference is unclear. Do infants' attentional preferences reflect efficient information gathering? We investigated using an ideal observer model (a Markov Dirichlet-multinomial). We predicted infants' attention to sequential events would be moderated by information content. We tested infants (7-8 months) with 32 unique event sequences (objects popping out of boxes) on a Tobii eye-tracker. Each sequence continued until look-away. Controlling for other variables, we found infants were significantly more likely to look away at either highly informative or uninformative events according to the model. This suggests infants allocate visual attention to maintain intermediate rates of information processing, avoiding committing cognitive resources to either overly predictable or surprising events. This "Goldilocks effect" may reflect a general strategy for efficient learning from environmental statistics.

Keywords: Statistical learning; statistical inference; idealized learner; infant gaze behavior; infant methods; infant eye-tracking; Bayesian modeling; information theory; infant visual attention.

Introduction

Infants have a lot to learn in the first few years of life, and a limited set of resources with which to do it. The world is brimming with potential sources of information, but where among this spatiotemporal array of events should infants begin their learning? From birth, infants survey their sensory environments, sampling the visual data that surrounds them at the incredibly rapid pace of two or more fixations a second during 90% of their waking hours (Haith, 1980). This process, of surveying and sampling, provides infants with rich information from which they can start to learn about the world.

Previous empirical work has demonstrated that infants are able use the statistical properties of their environment in a diverse array of learning tasks pertaining to sounds, words, people, shapes, and objects (Fiser & Aslin, 2002; Maye, Weiss, & Aslin, 2008; Saffran, Aslin, & Newport, 1996; Saffran, Johnson, Aslin, & Newport, 1999; Yu & Ballard, 2007)¹. In many complex cognitive systems (e.g., object recognition,

language), infants obtain the representations of higher-level structures by tracking the low-level statistical cooccurrences. For example, newborn infants must track the distribution of acoustical properties of speech sounds in their target language in order to infer its phonological categories (White, Peperkamp, Kirk, & Morgan, 2008). Researchers of visual, conceptual, and social learning find similar patterns. Recent technologies (e.g. eye-tracking, brain imaging techniques) have elucidated many of the mechanisms infants employ in building high-level structures from low-level environmental statistics. Though the topic has been of great interest to researchers, the mechanisms and representations infants employ during the process of collecting environmental statistics are still not well understood.

Amid the unbinned and unsorted masses of sensory data available in the world, an undirected search would be inefficient. Infants have too many things to do—motor actions to program, words to learn, categories to form—to waste time. How then should the infant allocate her visual attention?

Several researchers attempted to unify this work by identifying an overarching stimulus feature that could generally account for all of infants' preferences for various stimulus properties. Sokolov (1960) postulated that the primary driver of infants' attention is stimulus novelty. Consistent with this theory, infants commonly prefer the novel stimuli in preferential looking/listening tasks such as those use in the Fantz paradigm (Fantz, 1964), high-amplitude sucking procedure (Siqueland & DeLucia, 1969), and head-turn preference procedure (Kemler Nelson et al., 1995). The novelty account is also consistent with habituation behavior, during which infants' attention to recurring stimuli decreases over time. However, the novelty hypothesis does not account for infants' *familiarity* preferences in many preferential looking and listening studies. Notable examples include infants' affinity for their native languages and for faces, especially those of their mothers.

Roder and others attempted to reconcile infants' preference patterns by relating preference and processing load (Hunter & Ames, 1988; Roder, Bushnell, & Sasseville, 2000; Wagner & Sakovits, 1986). Roder suggested that the process of memory formation was responsible for preference. Under this theory, infants would be expected to exhibit a familiarity preference early in processing as they form a memory of

¹The literature detailing these statistical learning abilities is so large, in fact, that if it were printed and stacked in a pile, it would be more than 140 infants tall (based on 161,000 unique articles cataloged by Google Scholar at time of publication and 26-inch mean height of 8-month-olds).

the stimulus, and a novelty preference later after memory formation was complete. While this account correctly predicts age and experience-related shifts in visual preference, it does not on its own account for all types of visual preferences. It does not, for example, make clear predictions of why infants would prefer one novel object to another entirely novel object, since infants would not possess a memory for either item. Kinney and Kagan similarly suggested a processing-based account of preference. Their *moderate discrepancy hypothesis* states that infants will preferentially attend to stimuli that are “optimally discrepant”, meaning those that are most distinct from the representations they already possess. Like Roder’s memory-based account, Kinney and Kagan’s theory relates stimulus preferences to stimulus representations established by past experiences (Kinney & Kagan, 1976). The moderate discrepancy hypothesis has the added advantage of accounting for preferences among completely novel stimuli, since it defines the representation formation process as pertaining to the infants’ existing representations. Unfortunately, attempts to test this theory behaviorally were hindered by methodological difficulties. First, researchers had no direct access for determining the type, quantity, and nature of infants’ existing representations, which are crucial to the theory for generating testable predictions. Second, manipulating the identity of stimulus items to test for visual preferences forced researchers to rely on *qualitative* judgments of discrepancy rather than a quantitative metric.

Yet another account, Dember and Earl’s *theory of choice/preference*, suggests that *stimulus complexity* drives looking behavior. Dember and Earl posited that every stimulus contains a certain “complexity value, and that each individual² has a certain preferred complexity level it seeks to maintain (Dember & Earl, 1957). In this context, complexity can be thought of as information content. The theory predicts that individuals will seek out stimuli containing the ideal level of complexity with respect to their own preferred complexity rates. The amount of information an individual will derive from a stimulus decreases as experience accumulates. Thus, like other processing-based accounts, this complexity-driven one can theoretically predict age and experience-related shifts in visual preference. Berlyne noted that a complexity-driven preference would be an optimal strategy for learning (Berlyne, 1960). It provides a rational solution to the infant learner’s problem of deciding where best to allocate attention in the world. As with the attempts to test memory-based theories of attention, the collection of empirical evidence for this theory was hindered by the use of stimuli varied along *qualitative* dimensions rather than quantitative metric.

All prior models of infant visual attention, using the standard 2-second look-away criterion, have been based on hypothetical underlying processes such as information complexity, processing speed, and stimulus salience. Unfortunately, none

of these underlying processes were validated by an independent assessment. As a result, the precise way in which these processes were combined could not be estimated, except by observing the outcome of their integrated effect on gaze durations. Here we seek to provide a quantitative model of visual attention to sequential events by systematically manipulating information complexity while holding processing speed and stimulus salience constant.

We used an idealized statistical model—a Dirichlet-Multinomial Markov model—to predict infant looking behavior to a display of sequential events. Our results suggest that infants’ behavioral responses to a stimulus are influenced by its information content. Further, we find evidence that infants allocate their attention to maintain a certain information rate under a statistical model of the world. We present this as evidence that infants use rational statistical inference in understanding the world and deciding where to allocate attention and other cognitive resources.

Infant Behavioral Data

Participants

Twenty-five infants (mean = 7.9 months, range = 7.0 - 8.8) were tested. All infants were born full-term and had no known health conditions, hearing loss, or visual deficits, according to parental report. All participating infants completed the study.

Stimuli

We presented each infant with 32 unique event sequences, with the order of the sequences randomized across infants. The events each sequence consisted of were three unique objects that were animated to pop out from behind three occluding surfaces, which simulated an array of boxes. The sequences of object “pop ups” were chosen to vary in their information-theoretic properties (e.g., entropy, surprisal). Thus, some sequences were highly predictable (e.g., AAAAAAAA), and others were less predictable (e.g., CAAABBCABAC).
