For each infant, the Matlab script generated an animated scene based on each of the 32 event sequences. Each event sequence was implemented by creating a scene consisting of three uniquely patterned and colored boxes, each concealing a unique familiar object (e.g., a cookie). The locations of the three boxes for a given sequence were chosen randomly but remained static throughout a scene. The box locations were randomly shuffled between event sequences, but no more than two boxes appeared on either half of the screen. Neither the patterns on the boxes nor the objects were repeated across event sequences so that each object-box pair was independent and unique.

The objects, boxes, and the order in which the 32 event sequences were presented were randomized across infants. The same 32 event sequences were presented to every infant. This design ensured that differences in looking time across event sequences were not driven by differences in scene items or

²Individuals referred to not only baby humans, but also adults and animals

presentation order. Each event in a sequence consisted of an object that popped out of a box (1 s), and then back into the box (1 s). The total duration of each event was 2 s, and events were presented sequentially with no overlap or delay.

Procedure

Each infant was seated on his or her parent's lap in front of a table-mounted Tobii 1750 eye-tracker. The infant was positioned such that his or her eyes were approximately 23 inches from the monitor, the recommended distance for accurate eye-tracking. At this viewing distance, the 17-inch LCD screen subtended 24 X 32 degrees of visual angle. Each of the 3 boxes was 2 X 2 inches. To prevent parental influence on the infant's behavior, the parent holding the infant was asked to wear headphones playing music, lower their eyes, and abstain from interacting with their infant throughout the experiment.

The experiment consisted of 32 trials, one for each event sequence. Each trial was preceded by an animation designed to attract the infant's attention to the center of the screen—a laughing and cooing baby. Once the infant looked at the attention-getter, an experimenter who was observing remotely pushed a button to start the trial.

For each trial, an animated scene depicting one of the event sequences was played. The animated sequence of events—objects popping out of boxes one at a time—continued until the infant looked away continuously for 1 sec, or until the sequence timed out at 60 sec. The 1-sec look-away criterion for trial termination was automatically determined by the Tobii eye-tracking software. If the infant looked continuously for the entire 60-sec sequence, the trial was automatically labeled as a “time out” and discarded before the analysis (3.5% of trials). If the trial was terminated before the infant actually looked away, the trial was labeled by an experimenter as a “false stop” and also discarded. False stops occurred as a result of the Tobii software being unable to detect the child's eyes continuously for 1 sec, usually due to the infant inadvertently blocking the his or her own eyes with head or arm movements (18.5% of trials).

Every infant saw all 32 event-sequence trials. The dependent measure for the subsequent computational modeling was the event at which the infant looked away in each trial; that is, at what point in the sequence did infants look away from the display for more than 1 consecutive second? We predicted that infants were more likely to look away during events that contained either too little or too much information for a particular infants' preferred information-intake rate. We predicted infants would be least likely to look away during events that were “just right”—those that were neither too predictable, nor too surprising. Our Ideal Observer Model was used to determine the amount of information for each event in the event sequences (i.e., which event contained more or less information). If infants' attention to a stimulus is governed by the amount of information it contains, we would expect infants' look-aways to be predictable given the model. We tested our hypothesis by comparing the model's predicted probabilities of an infant looking away for each event in the

sequence to the infants' actual look-aways in test.

Ideal Observer Model

We used a Markov Dirichlet-multinomial model (MDM) to evaluate the relationship between the statistical properties of the event sequences and infants' attention to events in that sequence. The model allows us to test the best-fitting set of parameters for predicting from the event sequence whether the infant will continue looking or terminate a trial by looking away from the display. The MDM is a general-purpose statistical model that infers an underlying (multinomial) probability distribution on events, using the history of how many times each event has been observed. The MDM makes parametric assumptions about the form of the prior probability of an event and the likelihood of the event, and is often used in Bayesian statistics because it is computationally simple. Intuitively, infants observe how many times each event in the world occurs, and then use these event counts to infer an underlying probability distribution on events, just as readers extract an underlying word frequency distribution using a set of observations of individual words. An observer who sees only a single event happen would not likely infer that that single event is the only possible event (e.g., has probability 1.0). Instead, observers likely bring expectations to the task. In the version of a MDM used here, this prior expectation is parameterized by a single free parameter, α which controls the prior degree of belief that the distribution of events is uniform (e.g., that all unobserved events are equally likely). As α gets larger, the model has stronger prior beliefs that the distribution of events in the world is uniform; as $\alpha \rightarrow 0$, the model believes more strongly that the distribution is closer to empirically observed counts on events.

Formally, if there are three events, A , B , and C , which have been observed to occur c_A , c_B , and c_C times respectively, then the model assigns probability to a distribution on these three events proportional to

$$P(A)^{c_A+\alpha-1}P(B)^{c_B+\alpha-1}P(C)^{c_C+\alpha-1}, \quad (1)$$

where P is a hypothesized distribution on the events A , B , and C . That is, after observing each event occur some number of times, the infant may form a representation P , which gives the true underlying distribution of events. Every distribution can be “scored” according to Equation 1, allowing one to compute a distribution of beliefs about the state of the world according to the model. This simple model allows us to quantify an ideal observer's degree of belief that any given distribution on events is the true one. Importantly, because of the parametric form of the MDM, statistical measures such as the most likely true distribution of events, can be computed analytically.

We used two different forms of the MDM. In the first, the events A , B , and C correspond to events in the behavioral experiment (objects appearing from behind the occluding boxes). This model does not represent the transitions between events in the world; that is, the sequence $AAABBBCCC$

would have the same expectation as *ABCABCABC*. In the second model, we treated the events *A*, *B*, and *C* as transitions (or bigrams): for each object, we created a separate MDM for events that happen next. This model represents three separate MDMs that capture the transitions between events.

Both of these forms of the MDM provide an estimate of what an ideal observer would infer about the structure of the world. However, a model of infant’s beliefs alone is not sufficient to predict their behavior: what is needed additionally is a set of linking assumptions that relate beliefs to actions. Here, we assume that the infant’s looking behavior is at least partially determined by the information-theoretic properties of the model. Specifically, we test whether the predictability of a stimulus according to an idealized learning model influences infants’ looking behavior. Formally, we use the negative log probability of the current event according to the model, conditioned on observing all the previous events. As this negative log probability increases, the current event is more surprising: for instance, after seeing a long sequence of *As*, a *B* would have a high negative log probability. Negative log probability is a convenient measure because it corresponds to the number of *bits* of information conveyed by the stimulus. Thus, negative log probability provides a measurement at each point in time of the unpredictability of an event, using a measure that is typically used as a measure of information content. Because of the form of the MDM, the model roughly predicts that events in the future will tend to occur with their already-observed probability. However, the model essentially adds a small amount of smoothing—parameterized by α —that prevents unseen events from having probability zero.

Results & Analysis

At each event in a sequence, infants make an implicit decision to either look away or keep looking at the scene. Figure 1 shows their raw probability of looking away at each item, as a function of that item’s negative log probability according to the model, and collapsing across infants and sequences. The blue line shows the results for the non-transitional model, and the red line shows results for the transitional model. Both show a U-shaped relationship between raw look-away probability and model-based estimate of surprisal, with infants looking away to events that are especially surprising or especially predictable. There is a “Goldilocks” value of surprisal around 1.5, corresponding to infants’ preferred rate of information in this task³ which corresponds roughly to the point in the graph where infants have the lowest raw probability of looking away.

Survival analysis

Although the MDMs in Figure 1 provide a revealing picture of the relationship between indexes of surprisal and looking durations, there are likely other factors that influence infant

³This information rate must be interpreted relative to the frequency with which events in the sequence are presented, one every 2 seconds

Figure 1: Infant look-away probabilities as a function of non-transitional surprisal (top) and transitional surprisal (bottom).

look-aways. For instance, it might be the case that events in sequences generally become higher probability as infants form a picture of the statistical properties of the stimulus. If infants generally looked for a fixed amount of time, rather than paying attention to the statistical properties of the stimulus, then generally increasing predictability could make it look as though they preferred a certain information rate. To address this, we performed a regression analysis to control for the influence of other factors on look-away probability.

When infants look away, their trial ends and they provide no more additional data for that sequence⁴. This means that there is only a data point for an infant at time t if they have not looked away before t . We used a type of regression that respects this statistical relationship between look-aways and future data called a *survival analysis*. The type of survival analysis we used, Cox regression, measures the log linear influence that predictors have on the probability of a look-away at each point in time, but controls for a baseline look-away distribution. In the variety of survival analysis we used, the baseline looking distribution is fit nonparametrically to the data, meaning that the analysis conservatively removes the

⁴In the statistical literature, this type of data is called *censored*.

influence of an “average” distribution of looking times, before testing the significance of predictors.

We used a stepwise procedure for the Cox regression that tested whether each of several variables improved the model fit (AIC). Thus, at each iteration, the regression only added variables if they contributed positively, and at the same time removed variables if they contributed negatively. We included the following predictors in the survival analysis as control covariates.

- **TRIAL-NUMBER:** The number of sequences the child has already observed
- **FIRST-APPEARANCE:** A boolean factor corresponding to whether this event is the first time an object has been observed.
- **UNSEEN-ITEMS:** The number of objects that have not yet been observed.
- **SAME-EVENT :** A boolean factor for whether or not the current event is the same as the one that just happened.

The primary predictors we included in the survival analysis is the negative log probability of the event according to the MDM. Table 1 revealed that this variable is likely related to look-away probability quadratically, so we also included the squared negative log probability of the event according to the model⁵. A significant effect of squared predictability tests the significance of the U-shaped effect observed in Figure 1. As discussed above, we formed both transitional and non-transitional versions of the model, corresponding to models that treat each event independently, or each transition independently. Because the predictions of these two models are highly-correlated, we performed separate analyses on each.

Figure 2 shows the results of the survival analysis, including all predictors that were added via the stepwise procedure. These results can be interpreted by multiplying each coefficient by the value of the covariate and then exponentiating. This number represents an amount by which the probability of looking away is scaled, according to the best-fitting model. For instance, the coefficient of TRIAL-NUMBER is 0.033, meaning that by the 10th sequence the child sees, they have a $\exp(10 * 0.033) = 1.39$ greater factor of looking away. This effect of TRIAL-NUMBER is a plausible effect of fatigue. The results also show a significant effect of SAME-EVENT: children are a factor of $\exp(0.316) = 1.37$ more likely to look away when the event is a repeat of the most recent event. This effect is also plausible: infants search for other things to keep their interest when the experiment shows a repeating—and therefore boring—event.

The regression results also reveal significant effects of NEG-LOG-PROB-SQUARED. Because these variables were standardized, the outcome can be interpreted as the response

to changing the negative log probability by one standard deviation from those seen throughout the entire experiment. If the negative log probability of the event changes by one standard deviation, the probability of looking away changes by a factor of $\exp(0.099) = 1.10$ for the non-transitional model and $\exp(0.194) = 1.21$ for the transitional model. That is, infants are a factor of 1.1 to 1.21 more likely to look away on events that are either highly surprising or highly non-surprising according to an idealized statistical model for learning the structure of the sequences they observe.

The predictions of the the transitional and non-transitions models are difficult to distinguish because they are closely related: the information content of both models are correlated at $R = 0.62$ ($p < 0.001$). However, if both are entered into a stepwise Cox regression, the transitional NEG-LOG-PROB-SQUARED is significant at $p < 0.001$ (coef=0.25, $z = 5.74$)⁶, while the non-transitional information content is not significant $p > 0.1$. This provides strong evidence that infants track transitional probabilities, but the null result for the non-transitional model is difficult to interpret due to its correlation with the transitional model and the noise inherent in infant data.

Conclusions & Discussion

These results have explicitly tested two interrelated hypotheses related to infants’ looking behavior. First, we constructed a rational, statistical model that used observed events or transitions between events to form probabilistic expectations about what events are most likely in the future. This model embodies a simple, but non-trivial learning theory under which infants follow at least approximately rational statistical inference in inferring properties of the world. Second, we used this model to test whether infants have a preferred information rate in deciding where to allocate attention. The model was necessary in determining what information content a stimulus should convey, to an idealized observer. A failure of either theses assumptions—the probabilistic model or the linking assumption of the relevance of information content—would have yielded a null result.

In our analysis, we we used a Cox regression survival analysis, which allowed us to test the predictions of the model controlling for potential confounds such as the number of items that have not appeared yet, item repeats, and an arbitrary baseline distribution of look-away probabilities. To our knowledge, the hypothesis that infants prefer a fixed information rate has not been tested controlling for these other variables; nor has previous work used this type of formal model in measuring information rate. As such, this work provides several methodological advances. Rather than predicting infants’ average looking time to a stimulus, our analysis attempted to predict the precise item in a sequence that an infant would look away on. We found that the information-theoretic properties of a formal model were a significant predictor of infant

⁵Covariates were standardized before including them in the analysis and before squaring them.

⁶The Variance Inflation Factors are small for these variables (< 3.1), suggesting that collinearity is not a substantial problem in computing statistical significance.

Non-transitional model				
Variable	Coef.	Std. Error	z	p-value
TRIAL-NUMBER	0.033	0.006	5.867	0.000
SAME-EVENT	0.213	0.100	2.140	0.032
NEG-LOG-PROB-SQUARED	0.099	0.049	2.024	0.043

Transitional model				
Variable	Coef.	Std. Error	z	p-value
TRIAL-NUMBER	0.033	0.006	5.791	0.000
SAME-EVENT	0.316	0.114	2.772	0.006
NEG-LOG-PROB-SQUARED	0.194	0.047	4.134	0.000
UNSEEN-ITEMS	-0.175	0.089	-1.959	0.005

Figure 2: Included variables using a stepwise Cox regression analysis to predict infant look-aways. In predictions of both transitional and non-transitional models, the squared (standardized) negative log probability is a significant predictor of look-aways.

look-aways, over and above the effects of other variables, but that their effect was U-shaped. Thus, the Cox regression validates the trend observed in Figure 1, showing that it does not result from other confounds.

We take these results as strong evidence for the theory that infants are the Goldilocks of the “blooming, buzzing confusion,” preferring stimuli with a certain moderate level of information, and are at least approximately rational in their decisions about where to allocate attention.

Abstract

Longitudinal measures of infant visual processing of faces and objects were collected from a sample of healthy infants ($N=40$) every month from 6 to 9 months of age. Infants performed two habituation tasks each month, one with novel female faces as stimuli, and another with novel complex objects. Different individual faces and objects served as habituation (i.e., visual learning) and dishabituation (i.e., novelty response) stimuli. Measures included overall looking time to the habituation stimuli, slope of habituation, and recovery to the dishabituation stimuli. Infants were more interested in faces than objects, but this was contextualized by task order. The order effect suggests a “habituation of habituation” effect. Infants showed an age-related decrease in interest in objects, but no decrease in interest in faces. This contradicts claims that infants shift around 6-7 months from interest in faces to interest in objects. The results showed modest between-month stability of interest in faces, but little stability in any other behavioral measures. This implies that habituation is driven more by unexplained subject \times session \times stimulus variance than by “infant IQ.”

Keywords: Infant habituation; face processing; longitudinal studies; object perception; infant cognition; stimulus effects; visual preferences.

Introduction

Visual stimulus processing in infants is typically studied in a habituation paradigm. An infant is presented with a stimulus repeatedly until she or he habituates (i.e., meets some criterion of diminished looking time). A novel stimulus is then presented. If the new stimulus is perceived as different, the infant increases the duration of looking at the stimulus. This paradigm is a robust, reliable way to assess visual discrimination in the first year (Fagan, 1970; Fantz, 1964).

Habituation is used to assess more than stimulus discrimination. Psychologists commonly use habituation to estimate infants' cognitive capacity. Total looking time, or longest look to a stimulus, are considered inversely related to cognitive efficiency (Bornstein, Pêcheux, & Lécuyer, 1988). Whereas processing speed in children and adults is used as a proxy for overall cognitive efficiency (Salthouse, 1996), there is no analogous measure of cognitive speed in infants. Thus, speed of habituation is taken to indicate how

quickly infants process a stimulus. Also, dishabituation might relate to infants' interest in novelty, which might reflect curiosity. These ideas are bolstered by findings that infant habituation predicts later cognitive skills. For example, Thomson, Faulkner, and Fagan (1991) found a correlation between infants' novelty preference and Bayley Scales of Infant Development scores (BSID, a standardized test of cognitive, language, and social skills) at 12 and 24 months of age. Also, a meta-analysis by McCall and Carriger (1993) showed a consistent relation between habituation in the first year and IQ from 1 to 8 years. Thus, there is correlational evidence of a relation between infant habituation speed and later cognitive performance.

If this correlation is the result of some broad factor such as cognitive efficiency, we might expect individual infants to show consistent habituation speed (relative to their cohort) across time and task. However, few studies have tested longitudinal stability of habituation. In one study of infants at 3, 4, 7, and 9 months, the strongest long-term stability was found in longest-look (i.e., peak) duration (Colombo, Mitchell, O'Brien, & Hotowitz, 1987). However, cross-age stability was modest. Also, Bornstein and Suess (2000) found low stability of total looking time over several months. Thus, it is unclear how stable individual infant's rate of habituation is.

A complication in addressing this question is that infants might habituate differently to different stimuli (Arteberry & Bornstein, 2002). For example, infants like to look at high-contrast, colorful, moderately complex objects (e.g., baby toys) (Fantz, 1964). They also like to look at faces (Johnson, Dziurawiec, Ellis, & Morton, 1991). However, it is not clear whether infants like to examine pictures of objects and faces to the same degree, or prefer one to the other. If the latter is true, we do not know how uniform these preferences might be across infants. For instance, children with autism spectrum disorder spend less time looking at faces than age-matched controls (Hutt & Ounsted, 1966). Perhaps some children are relatively faster to habituate to only one kind of stimulus (e.g., faces) but not the other. A related question is, how stable are individual differences in preferences? Does an infant who strongly prefers faces show a long-lived face-preference in looking time?

The answers to these questions will affect how we interpret infant habituation. If habituation is an index of individual differences in cognitive speed, we should find consistent performance from month to month. We might also find consistency in dishabituation (akin to curiosity or attraction to novelty). However, there is no guarantee of stability across different classes of stimuli. For example, perhaps infants show stable processing time (or interest) for faces, but no month-to-month consistency in looking times to objects. Thus, one of our goals was to address how infants' stable or changeable interests or preferences impact their information-processing speed.

Method

Participants

Forty healthy infants (18 girls, 22 boys) were recruited between three to four months of age to participate longitudinally at six months (mean age = 188 days), seven months (mean age = 219 days), eight months (mean age = 249 days), and nine months (mean age = 278 days). Each monthly visit was scheduled within a 10-day window based on the child's birthday. Infants were recruited through announcements and flyers at local hospitals, and visits and flyers at mother-infant recreational groups and infant play groups in San Diego, CA. Infants and parents were of middle-class socioeconomic level; 88% were white and 12% were of African American, Asian American or Hispanic descent. Parents' mean age was 32.4 years and mean education was 16.6 years. Recruitment and testing procedures were approved by the UCSD Human Research Participants Protection committee.

Stimulus and Apparatus

Pictures of 8 faces and 8 objects were used as habituation and dishabituation stimuli. Faces were taken from the Computer Vision Center's AR Face Database (Martinez & Benavente, 1998). We selected faces of young women of apparent Euro-American ethnicity, with mildly pleasant expressions but not full smiles. Lighting, angle, image size, and image resolution are all controlled in the database. All faces are photographed in front of a light background and are stripped of salient non-facial objects like large jewelry or eyeglasses. (See Figure 1.)

Object stimuli were pictures of unfamiliar geometric objects. All objects were colorful and had similar levels of detail. (See Figure 2.) A group of parents had rated a large set of candidate object pictures for familiarity and attractiveness to infants. Low-familiarity but attractive objects were chosen based on these results. All objects were photographed on a white background.

Different face and object stimuli were presented at each testing session. The stimuli were projected onto a white screen, and measured 30.5cm^2 . The room lights were kept low while the infant and parent were seated and prepared for testing; the light was gradually dimmed to near-darkness for the test session. Infants requiring postural

support sat in a Bumbo® placed on the caregivers lap. Caregivers wore shaded glasses and earphones playing music so that they could not see the pictures or hear infants' vocal reaction. A Cannon GL camera placed directly in front of infants was used to capture a zoomed-in frontal view of infants' faces. (See Figure 3.)

Figure 1: Example of habituation and novel face stimuli (from Martinez & Benavente, 1998)

Figure 2: Example of habituation and novel object stimuli

Figure 3: Infant participant orienting attentively to stimulus image. Even though infant has shifted away from the center of the camera field and twisted her body, the stimulus image is clearly reflected (as a white box) in the center of her cornea.

Design and Procedure

During each visit infants performed two habituation tasks. At 6 and 8 months object-habituation was the first task and face-habituation was the second task (see Figure 1 and 2). At 7 and 9 months face-habituation was the first task and object-habituation was the second task.

Parents were seated 91 cm from the projector screen and instructed to secure the infant on their lap. The experimenter then placed the earphones and glasses on the parent and exited. Another experimenter (E2) in an adjacent room then darkened the room and began the task.

Training and Coding. E2 watched the infant's face from a monitor in the control room, and recorded the infants' fixations and look aways. E2 was trained extensively to record infant looking by watching previously taped habituation sessions, until a high accuracy criterion was

attained. E2 watched for white squares reflected on infants' corneas; these are reflections of the stimulus that are centered on the cornea when the infant looks at the stimuli. E2 depressed a button whenever an infant was looking, and released the button when the infant looked away or most of the stimulus square was outside of the pupil.

To calculate reliability, 15% randomly chosen sessions were coded frame-by-frame off-line. A different coder found the first and last frames for the fixation in each trial. Correlations between online and offline coding were $r = .998$ ($p < .01$) for peak looking times, and $r = .995$ ($p < .01$) for total looking time to the habituation stimulus.

Task and Trials For each habituation task, infants were presented with one stimulus for a maximum of 12 trials. Custom software (InfAttend) tracked the looking time on each trial while E2 depressed the button, and ended when the button had been released (i.e., look-away periods) for 1 s. The program then imposed a 1 sec ISI and advanced to the next presentation. The presentation automatically ended if the infant looked for 20 sec. Habituation was monitored automatically: when looking duration of the last two trials averaged less than 50% of the mean of the two peak (i.e., longest) trials, the next trial presented the novel (dishabituation) stimulus.

After the first task was completed, the infant and parent took a 1-3 min break to have a snack or drink, or diaper change, so they would be comfortable for the second task.

When infants participated at 6 months they had already been to the lab twice to participate in other cognitive tests, including habituation. Thus, in every session infants were already familiar with laboratory settings and personnel, procedures in the testing room, and even habituation tests. Thus, task or setting familiarity cannot explain age differences. Also, infants saw different stimuli in each session, so stimulus novelty was constant across sessions.

Measures

Several habituation measures were calculated for both tasks (i.e., object; face): looking durations on each trial, and total looking time until habituation; number of trials to habituate (i.e., slope); and peak looking duration. Novelty response was calculated as looking time to the dishabituation stimulus, compared to the mean of the two shortest looking times to the habituation stimulus.

Results

Stimulus Type Effects

Infants were more interested in faces than in objects. Although this difference was mediated by an interaction with order (see below), the face preference was reflected in total looking time (Figure 4). To show this we examined total looking time in a 4 (Age) X 2 (Stimulus) MANOVA. The multivariate age effect was not significant, $F(3, 12) = 1.24$, $p = .337$. However, the effect of Stimulus was,

$F(1,14) = 6.60$, $p = .022$ ($\eta^2 = .32$), as was the Age X Stimulus interaction, $F(3,12) = 4.45$, $p = .025$ ($\eta^2 = .53$).

Within-subjects contrasts reveal a cubic age X stimulus effect, $F(1,14) = 12.00$, $p = .004$ ($\eta^2 = .46$), related to the order-related interaction described below.

Figure 4: Infants' looking time to faces and objects at each month. Note that presentation order reversed monthly; this explains the oscillation across months of looking times to objects. Bars = SE. Best-fitting linear regression lines are shown for each stimulus, with R^2 indicating the age effect for each stimulus type. Note the significant age-related trend of declining attention to objects.

Figure 5: Trials to habituate to faces and objects, by age. Bars = SE. Best-fitting linear regression lines are shown with R^2 indicating the age effect for each stimulus type.

The same pattern of effects was apparent in the number of trials to habituation. A 4 X 2 MANOVA found a non-significant age effect, $F(3, 12) = < 1$, but a significant Stimulus effect, $F(1,14) = 12.6$, $p = .003$ ($\eta^2 = .47$), and Age X Stimulus interaction, $F(3,12) = 10.67$, $p = .001$ ($\eta^2 = .73$). Again, within-subjects contrasts reveal a cubic Age X Stimulus effect, $F(1,14) = 29.4$, $p < .001$ ($\eta^2 = .68$).

For both the face habituation and object habituation task, there are no significant total looking time differences between the months that had the same order of presentation (i.e. 6 and 8; 7 and 9 months). Similarly, for both face and

object habituation, there are no significant number-of-trials differences between months with the same stimulus order.

Task Order Effects

Order effects (i.e., which test was first or second) were found in total looking time to objects. At 6 and 8 months, when objects were first, infants looked longer at the object than they did at 7 and 9 months (Tables 1 and 2) when objects were second. Follow-up *t*-tests showed that total looking times for objects significantly differed between 6 and 7, 6 and 9, 7 and 8, 8 and 9 months (all with a value of $p < .005$). Total looking times to faces also was lower when the face task was second; however, the difference was not significant.

Table 1: Mean total looking time to habituation stimulus at 6 and 8 months (*SD* in parentheses).

	6 months	8 months
Task 1: Objects	61.62 <i>s</i> (50.58)	55.06 <i>s</i> (28.35)
Task 2: Faces	52.93 <i>s</i> (36.44)	56.81 <i>s</i> (41.48)

Table 2: Mean total looking time to habituation stimulus at 7 and 9 months (*SD* in parentheses).

	7 months	9 months
Task 1: Faces	68.99 <i>s</i> (38.17)	60.44 <i>s</i> (35.61)
Task 2: Objects	35.13 <i>s</i> (18.86)	27.36 <i>s</i> (17.83)

This task order effect was also found for both objects and faces in number of trials to habituate. For each stimulus type, it took more trials to habituate if that stimulus was used in the first task than in the second (Tables 3 and 4). Follow-up *t*-tests showed that number of trials to habituate to objects differed between 6 and 7, 6 and 9, 7 and 8, and 8 and 9 months (all $ps < .05$).

Table 3: Mean total number of trials to habituate at 6 and 8 months (*SD* in parentheses).

	6 months	8 months
Task 1: Objects	6.97 (2.97)	7.30 (2.81)
Task 2: Faces	6.04 (2.22)	5.93 (2.62)

Table 4: Mean total number of trials to habituate at 7 and 9 months (*SD* in parentheses).

	7 months	9 months
Task 1: Faces	7.72 (2.77)	7.31 (2.47)
Task 2: Objects	4.60 (1.61)	4.36 (1.56)

The second- versus first-task differences shows that overall interest in visual examination of stimuli declined across time in the experimental context. This can be interpreted as a “habituation to habituation” effect (see Sirois & Mareschal, 2002). However, the effect is not uniform: it is modulated by infants’ face-preference. Infants’ interest is maintained or renewed if after habituating to an object, they are shown a face. In contrast, infants’ interest significantly decreases when an object is presented after the face habituation task. We do not know what stimulus properties or biases produced this difference in habituation-of-habituation, but it highlights the importance of examining stimulus-by-task interactions in infant habituation.

Individual Stability: Looking Time

Significant individual stability for total looking time to habituation faces was found between 6 and 8 months ($r = .56, p = .002$), 7 and 8 months ($r = .43, p = .020$), 7 and 9 months ($r = .49, p = .004$), and 8 and 9 months ($r = .43, p = .020$). Stability for looking time to objects was not significant between any pair of months.

There were no significant correlations between sessions in the number of trials to habituate to faces or objects.

Individual consistency across the object and face task within a month was found at 6 months for total looking time to habituate ($r = .53, p \leq .002$). No significant across-task correlation was found in later months.

Individual Stability: Dishabituation

Stability of dishabituation, or recovery of looking-time to a novel stimulus, was tested. At 6 months, total looking at the habituation face moderately predicted a greater novelty response to the new face ($r = .39, p = .024$). The same effect was found at 8 months ($r = .52, p = .002$) and at 9 months ($r = .41, p = .015$). For objects, the same effect was present at 6 months ($r = .44, p = .009$), at 7 months ($r = .43, p = .017$), and at 8 months ($r = .36, p = .033$).

Gender Differences: Stimulus Preference

Connellan, Baron-Cohen, Wheelwright, Batki, and Ahluwalia (2000) argue that male newborns prefer objects whereas female newborns showed preference for faces (mean age = 36. 7 hrs). Baron-Cohen (2002) claims that there are deep-seated gender differences in social inference and intelligence. However, we did not find gender differences in interest to faces and objects at any age.

Connellan et al. (2000) suggest that the gender effect for stimuli preference present in 1-day-old infants could be due to a biological nature since none have yet had exposure to stimuli. However, infants learn prenatally as well as in their first minutes and hours (Butko, Fasel & Movellan, 2006). Infants between 6 and 9 months of age have had much more exposure to social and non-social stimuli, which might be expected to amplify any nascent gender-based preferences suggested by Connellan et al. (2000). However, no such difference was found.

Discussion

These findings suggest that infant habituation to faces is moderately stable between 6 and 9 months of age, at least with respect to total looking time. However, there was no stability across months in looking-time to objects. Also, there was no stability in the slope of habituation (i.e., number of trials to habituate) for either faces or objects.

These results complement Colombo et al.'s (1987) findings of moderate stability in visual habituation from 3 to 9 months. They found stability in duration of looking to faces, but not in trials-to-habituate or in dishabituation. Consistent with Colombo et al.'s findings, we found stability in looking time to faces, but not in trials-to-habituate or in dishabituation. Our results establish that those effects are somewhat specific to faces. However, we found moderate stability between habituation time and dishabituation at some months, for faces and objects. The reason for this is unclear; perhaps general attention or arousal states contribute to consistent patterns of visual examination from habituation to dishabituation trials.

Some studies of habituation use peak (i.e., longest single trial) looking time as a measure of processing efficiency or of interest. We focused on total looking time on the assumption that it would carry less trial-by-trial error variance. However, we did examine peak fixation times (not reported here). This revealed very limited stability across months.

One implication is that longitudinal prediction of infant cognitive efficiency is stimulus-dependent. Researchers have not known how different stimuli in habituation tests predict individual differences in infants' cognitive speed. Our data show that stability is dependent on the type of stimulus tested, as well as the type of response measured and the age of the infant. It is unclear why stability is greater for faces than for objects. It might be that interest in faces is related to dimensions of temperament that relate to sociability; these dimensions show some stability in infants (Garcia-Coll et al., 1992). Conversely, interest in objects—particularly pictorial representations of objects, which do not allow typical multimodal exploration—might be highly subject to episodic and stimulus-specific preferences. It was not true, contrary to claims by Baron-Cohen (2002) and colleagues, that gender predicted stimulus-interest.

It should be noted that "stimulus" here, and in most studies, refers to pictorial representations, which are unnatural in many ways. The use of live models and real

objects might considerably alter these patterns, and this would be an intriguing direction for future research. Notably, in ongoing research we are testing whether the face-habituation trends generalize from static faces to dynamic faces (i.e., videos of rotating faces).

Our findings do not support the claim that infants' interest in faces declines, and interest in objects increases, after about 6 or 7 months (Adamson & Bakeman, 1991). We found no decrease in face interest, but a mild decline in object interest from 6 to 9 months. Although the claim that interest in faces declines during this period is based on very different types of data, our results suggest that there is not a general reversal of interest, but perhaps only a task-specific one. Currently there are no data or theories to explain this. One possibility is that as infants' response capabilities in dynamic environments expand, their relative interests in faces and objects start to differentiate. Their interest might become primed by the response "channels" that become viable in a given situation. Notably, during this age range infants gain response capabilities for object manipulation and for social interaction. These capabilities can be enacted only when responding to real, near-at-hand objects, on the one hand, and live, interactive people, on the other. Thus, we would expect infants' interests to be governed by situations that permit these expanding response channels. By contrast, in a narrow response channel like looking time, with stimuli that are static and non-interactive, we might detect only muted effects of changing interests in people and objects. Thus, infants' expanding action repertoire might influence their interest in people and objects.

Infants attend to objects and faces for approximately equal durations when presented first. However, this is not true when they are presented second. The comparable first-task interest to faces and objects could be due to the novelty of the task. It is known that habituation itself declines with repeated testing (Thompson & Spencer, 1966); this is known as "habituation of habituation." However, these data suggest that infants from 6 to 9 months show more habituation of habituation when a more interesting stimulus, a face, is followed by a less (or less-consistently) interesting stimulus, an object.

For this reason, we cannot make broad generalizations about infants' relative interest in faces versus objects. The differences depend on the sequential context of exposure, as well as the infant's age. Also, infants' familiarity with faces and objects cannot be controlled in any obvious way. We used novel exemplars of faces and objects, but it is unlikely that unfamiliar objects are novel to infants in the same way as unfamiliar faces. Infants have much experience with face processing, and are likely able to make fairly fine discriminations. They also have fast-growing experience with objects, but the nature of their experience is quite different. We can, nonetheless, compare the same infant on the same stimulus types across months, and see if they show parallel stability across stimulus types. The current data show that they do not

The results show that it is not possible to use a single—or even several—visual habituation tasks to draw valid inferences about individual infants' visual information-processing traits. Stable traits, such as they are, appear to be conditional and subtle.

Mechanisms of Sustained Selective Attention in 3- to 5-year-old Children: Evidence from a New Object Tracking Task

Anna V. Fisher (fisher49@andrew.cmu.edu)

Department of Psychology, 5000 Forbes Avenue
Pittsburgh, PA 15213 USA

Abstract

Sustained selective attention is a crucial component of many higher-order cognitive processes; yet there is little research into the mechanisms of this ability early in development. One of the challenges in investigating mechanisms of sustained selective attention in young children is lack of appropriate experimental paradigms. This paper reports findings from a novel paradigm designed to investigate mechanisms of sustained selective attention in young children - the Object Tracking task. Results of two experiments with 3- to 5-year-old children provided support to the notion that development of the endogenous component of selective sustained attention lags behind the development of the exogenous component of this process. Importantly, the Object Tracking paradigm allowed investigating both of these components within the same task, thereby making it possible to attribute changes in performance to different mechanisms of attentional control rather than to differences in the level of motivation and engagement in different tasks.

Keywords: Selective attention; Sustained attention; Focused Attention; Cognitive Development.

Introduction

The ability to selectively sustain attention is crucially important because it is an essential component of most higher-order cognitive processes, such as categorization, language comprehension, reasoning, and problem solving. For example, it takes preverbal infants as little as 500 ms to locate a target object among eight distracters (Adler & Orprecio, 2006), whereas it takes them approximately twenty times longer to categorize a single object (Quinn & Eimas, 1996). Similar latency differences between simple visual search tasks and higher-order categorization tasks are also present in older children and adults (Fisher, in press; Gerhardstein & Rovee-Collier, 2002; Trick & Enns, 1998). However, development of the mechanisms of sustained selective attention, also referred to as focused attention, has been sparsely investigated. The goal of the research presented below was to investigate mechanisms of sustained selective attention in 3- to 5-year-old children.

When several objects are present in a scene and one needs to focus attention on a single object, how is the competition resolved? One of the paradigms that has been widely used to explore this question in the domain of visual attention is the visual search paradigm pioneered by Treisman and Gelade (1980). The classic finding from this paradigm is that when adults are asked to search a visual array for a target object defined by a conjunction of features (e.g., color and shape), their reaction time increases with the increase in the number

of distracter objects in the display. However, when displays contain target objects defined by a single feature (e.g., color) visual search reaction times remain constant regardless of the number of distracters, as the target object seems to instantly “pop-out” from the display.

While there is no consensus on the mechanisms of visual search, many theories distinguish between two broad ways in which competition between multiple objects in a scene can be resolved. One way has been characterized as stimulus-driven, effortless, bottom-up, and passive, whereas the other way has been characterized as participant-driven, effortful, top-down, and active (Lavie, 2005; Lavie & Tsai, 1994; Kastner & Undergleider, 2000; Norman & Shallice, 1986; Schneider and Shiffrin, 1977; Schneider & Chein, 2003).

Research on the development of selective attention indicates that even newborns are not indifferent to what they attend to, and prefer to attend to some stimuli over others (Colombo, 2001; Fantz, 1963). However, this selectivity has been characterized as stimulus-driven or automatic (i.e., driven by exogenous factors), rather than participant-driven or voluntary (i.e., driven by endogenous factors). In particular, selective attention in newborns and young infants is driven to a large degree by the properties of the stimulus, such as its frequency and duration (for auditory stimuli) and intensity and brightness (for visual stimuli), rather than by infants’ intentions (Bornstein, 1990; Ruff & Rothbart, 1996).

By the time infants reach seven months of age, their allocation of attention is driven by a complex interaction of exogenous and endogenous factors (Oakes, Kannass, & Shaddy, 2002). For instance, exogenous factors, such as stimulus brightness and complexity still exert a strong pull on attention allocation; however, reorientation to salient distracters is less likely when infants are in a state of focused attention (i.e., concentrating on a particular toy or activity) than when infants are in a state of casual attention – suggesting that internal state of an infant (an endogenous factor) plays a role in how attention is allocated (Tellinghuisen, Oakes, & Tjebkes, 1999).

Considerable evidence suggests that when several objects compete for attention and one of these objects is defined by a unique feature, similar to adults, infants as young as 3 ½-months of age exhibit the “pop-out” effect (Adler & Orprecio, 2006; Gerhardstein & Rovee-Collier, 2002; Treisman & Gelade 1980). Search for objects defined by a conjunction of features has not been studied with preverbal infants, however findings with 12- to 36-month old toddlers

indicate that their response latency increases with increased number of distracters in the display – a pattern that is similar to that in adults (Gerhardstein & Rovee-Collier, 2002; Scerif, Cornish, Wilding, Driver, & Karmiloff-Smith, 2004; Treisman & Gelade 1980). Despite considerable quantitative differences in performance of children and adults persisting until at least until ten years of age (Trick & Enns, 1998), the qualitative pattern of results from the visual search tasks with young children is similar to that of adults.

However, higher-order cognitive processes (such as categorization, language comprehension, and reasoning among many others) impose greater demands on attention than simply selecting an object for processing. One of these demands is sustaining attention to the selected object for at least brief periods of time. Development of this ability has been often examined in natural settings (such as free play) in prior research as well as computerized vigilance-type tasks (Oakes, Kannass, & Shaddy, 2002; Ruff & Lawson, 1990; Sarid & Breznitz, 1997; Tellinghuisen, Oakes, & Tjebkes, 1999). These studies indicate dramatic improvements in this ability between 12 months and six years of age. For example, studies utilizing the context of free play suggest that duration of focused free play increases from approximately four minutes in 2- and 3-year-old children to over nine minutes in 5- and 6-year-olds (Ruff & Lawson, 1990; Sarid & Breznitz, 1997). Furthermore, these studies indicate that older children are markedly less distractible than younger children, and also more likely to return to an interrupted activity.

Another kind of paradigm that has been successfully used to investigate sustained selective attention in young children is a Continuous Performance Test – a vigilance-type task modeled after tests used with adults (Warm & Jerison, 1984). In this task participants are asked to attend to a stream of visual stimuli and to respond to a target stimulus while withholding response to non-target stimuli. For example, participants might be presented with a series of images depicting ducks and turtles, and instructed to press a button every time they see a duck and avoid pressing the button when they see turtles (Akshoomoff, 2002). The goal of this task is to investigate whether participants can remain alert for prolonged periods of time (e.g., 5- to 9-minute intervals) and accurately detect infrequently appearing target objects. A typical finding of such studies is that approximately 50% of 3 ½-year-old children fail to complete this task, indicating difficulty in sustaining their attention (Akshoomoff, 2002; Corkum, Byrne, & Ellsworth, 1995). Those 3-year-olds who can complete the task (thus demonstrating their ability to maintain attention for prolonged periods of time) exhibit high rates of both misses and false alarms, suggesting difficulty with the voluntary control of selectivity. Marked improvement on this task (in terms of proportion of children completing the task, response time, and accuracy) is observed between four and five years of age.

Studies of sustained selective attention in the context of free play and vigilance-type tasks provide valuable insights

regarding the milestones in the development of this important ability. However, these studies are limited in their ability to assess the mechanisms of sustained selective attention in young children and changes in these mechanisms in the course of development. One of the challenges in investigating this question stems from the lack of appropriate experimental paradigms. For example, it has been argued that differences in the level of performance on existing tasks of focused attention between younger and older children may arise as a result of differential levels of motivation and engagement in the task rather than developmental changes in mechanisms of attentional control (Ruff & Rothbart, 1996). Furthermore, there is currently no task that makes it possible to assess contribution of exogenous and endogenous factors to selective sustained attention within the same task, thus making it difficult to uniquely attribute changes in performance to different attentional mechanisms rather than to task-specific factors. The goal of the present research was to develop a task suitable for investigation of the mechanisms of sustained selective attention in young children, and to use this task to investigate the contribution of exogenous and endogenous factors to sustained selective attention in 3- to 5-year-old children.

The Object Tracking Task

The Object Tracking task is reminiscent of the Multiple Object Tracking (MOT) task used with adults to study properties of visual attention (Pylyshyn & Storm, 1988; Yantis, 1992). In the MOT task participants are asked to visually track several identical target objects moving along random trajectories among a larger set of identical objects, also moving along random trajectories. In this paradigm target objects are distinct only at the beginning of each trial (all target objects pulsate for a brief period of time at the onset of each trial), however adult participants (often to their own surprise) are capable of tracking four targets in the field of eight distracters with accuracy approaching 90% (Pylyshyn & Storm, 1988). While this paradigm has been successfully used to investigate properties of object-based attention in adults for over twenty years, our pilot testing suggested that the task is prohibitively complex for young children. Furthermore, the MOT paradigm does not allow assessment of automatic and voluntary components of sustained selective attention within the same task. The new Object Tracking task was created specifically to investigate mechanisms of sustained selective attention with young children.

In the Object Tracking task participants are presented with a three by three grid, with each of the nine grid locations identified by a popular cartoon character, and a target object moving on the grid along a random trajectory. Participants are asked to visually track the target and identify the grid location last visited by the target before it disappears. The moving target in this task can be accompanied by zero to eight distracters, also moving along a random trajectory. Target and distracter objects are randomly selected on each trial from a pool of nine different

geometric shapes. At the beginning of each trial participants are presented with still objects, and the object designated as the target is clearly marked at the beginning of each trial by being encircled in red (see Figure 1 for a schematic depiction of the task).

There are no restrictions on the motion paths of distracter objects, but there are two restrictions on the motion paths of the target objects. First, the target object has to disappear in the middle of one of the nine cells to reduce possible confusion if the target disappears on the border of two or more cells. Second, the target object must visit all nine screen locations at least once before disappearing. In all the experiments presented below, the speed of motion for all target and distracter objects was set at 800 pixels per frame at 30 frames per second (this speed was chosen during pilot testing with a separate group of 3- to 5-year-old children). Average trial duration was approximately 11 sec (a more detailed description of trial duration is provided in the Methods section).

When presented with the task, participants are explained that (1) objects will start moving when the experimenter pushes a button, (2) the goal of the task is to watch the object encircled in red, (3) the red circle will disappear as soon as objects start moving, and (4) once all objects disappear from the screen participants will need to point to the grid location last visited by the target object. Notice, that participants are not asked to perform visual search since the target is clearly marked at the beginning of each trial.

Figure 1. Schematic depiction of the Object Tracking task.

It has been demonstrated that salient objects engage attention automatically, whereas less salient objects may require voluntary processing (Koch & Ullman, 1985; Smith, et. al., 1996; Trick & Enns, 1998; Underwood, et. al., 2006). Therefore, distracter manipulations in the Object Tracking task can allow assessment of the contribution of exogenous and endogenous factors to selective sustained attention in the visual domain. In particular, it is expected that target objects will be more salient when distracters are identical to each other and different from the target (All Same Distracters condition) than when distracter objects are different from the target and from each other (All Different Distracters condition) (Treisman & Gelade, 1980). Thus, tracking accuracy in the All Different Distracters condition will reflect the contribution of predominantly endogenous

factors, whereas tracking accuracy in the All Same Distracters condition will reflect the contribution of both exogenous and endogenous factors. The difference in performance between these conditions will be reflective of the unique contribution of exogenous attention. Experiment 1 investigated mechanisms of sustained selective attention in 3- to 5-year-old children using the Object Tracking task in which target objects were accompanied by two distracters, and Experiment 2 investigated performance with six distracters.

Experiment 1

Method

Participants

Participants were 15 3-year-old children ($M = 3.66$ years, $SD = .28$ years; 5 females and 10 males), 17 4-year-old children ($M = 4.49$ years, $SD = .25$ years; 5 females and 12 males), and 18 5-year-old children ($M = 5.23$ years, $SD = .23$ years; 7 females and 11 males).

Design and Procedure

There were two within-subject conditions in Experiment 1: All Same Distracters and All Different Distracters condition. The order of these two conditions was counterbalanced across participants; both conditions were completed on two separate testing sessions that were spaced one to two weeks apart.

As described in the introduction, the Object Tracking task is designed such that the target objects have to appear at least once in each of the nine on-screen locations and disappear in the middle of one of these locations. Due to these restrictions, trial duration is not fixed but varies slightly from trial to trial. In Experiment 1, minimum trial duration was set to 10 s and mean trial duration was 11.00 s ($SD = 0.95$ s) in the All Same condition and 10.98 s ($SD = 1.03$ s) in the All Different condition.

To control for the possibility that any observed differences in tracking accuracy may stem from children being more likely to remember what object they were supposed to track in the All Same Distracters condition than in the All Different Distracters condition, at the end of each trial participants were asked to identify which object served as target on the trial they had just completed. Children were presented with a card depicting all nine shapes that could serve as target objects in this task, and asked to point to the shape they had been tracking.

All participants were tested by hypothesis-blind experimenters in quiet rooms in their day care centers. Participants completed 11 trials of the Object Tracking task in each condition. The first trial was completed with assistance from the experimenter who traced the moving target with their index finger. Participants were then explained that they needed to complete the rest of the task by themselves, tracking the target objects only with their

eyes. Data from the first experimenter-assisted trial were discarded from the analyses.

Results

Memory Accuracy

Accuracy with which children recognized the target object (among 9 possible objects) at the conclusion of each trial is presented in Table 1. Memory scores were submitted to a mixed ANOVA with age as a between-subject factor and condition (All Same vs. All Different) as a within-subject factor. This analysis indicated a main effect of age, $F(2, 47) = 5.77$, $p < .01$, $\eta^2 = .20$. Post-hoc Tukey HSD tests indicated that overall memory accuracy was lower in 3-year-old children ($M = .67$) than in both older age groups ($p < .05$), and statistically equivalent in 4- and 5-year-old children ($M = .83$ and $M = .86$, respectively). Most importantly however, there was no effect of condition and no age-by-condition interaction, both F s < 1 , ns. Therefore, results of the memory check indicate that if any significant differences in object tracking accuracy are observed between the All Same and the All Different Distracters conditions, these differences are unlikely to stem from differential demands on working memory.

Table 1: Memory accuracy in Experiments 1-2 (standard deviations in parentheses).

	All Same Distracters	All Different Distracters	t-test p-values
Experiment 1 (2 Distracters)			
3-y.o.	.69 (.22)	.65 (.22)	$p > .53$
4-y.o.	.83 (.17)	.83 (.17)	$p > .83$
5-y.o.	.86 (.13)	.86 (.22)	$p > .95$
Experiment 2 (6 Distracters)			
3-y.o.	.47 (.31)	.44 (.39)	$p > .75$
4-y.o.	.75 (.29)	.73 (.29)	$p > .83$
5-y.o.	.79 (.19)	.85 (.2)	$p > .44$

Object Tracking Accuracy

Tracking accuracy scores were averaged across 10 trials for each participant and submitted to a mixed ANOVA with experimental condition (All Same and All Different Distracters) as a within-subject factor and age (3-, 4-, and 5-years of age) as a between-subject factor. Results of this analysis revealed a main effect of experimental condition, $F(1, 47) = 11.46$, $p < .002$, $\eta^2 = .19$ and age $F(2, 47) = 8.04$, $p < .002$, $\eta^2 = .25$. These main effects were qualified by an age by condition interaction, $F(2, 47) = 3.43$, $p < .05$, $\eta^2 = .13$.

Planned comparisons indicated that participants in all conditions in all age groups identified the final location of the target object at above chance level (chance = 11% given nine response options), all one-sample t s > 5.85 , p s $< .0001$. Five-year-old children were equally accurate in both conditions (83% and 84% of correct in the All Same and All Different condition, respectively) paired-sample $t(17) < 1$,

ns. However, younger children exhibited higher tracking accuracy in the All Same than in the All Different condition (see Figure 2): 4-year-olds averaged 76% and 65% of correct responses, respectively, paired-sample $t(16) = 2.26$, $p < .05$, Cohen's $d = .57$; and 3-year-olds averaged 67% and 48% of correct responses, respectively, paired-sample $t(14) = 2.63$, $p < .05$, Cohen's $d = .77$.

Figure 2. Tracking accuracy scores in Experiment 1.

Overall, results of Experiment 1 suggest that the ability to accurately track an object amidst heterogeneous distracters shows more protracted development than the ability to accurately track an object amidst homogenous distracters. Notice however, that 5 year-old children in Experiment 1 exhibited no effect of condition on tracking accuracy. At the same time, it has been shown that voluntary control of attention continues to mature well beyond the preschool years (Casey, Tottenham, & Fossella, 202; Trick & Enns, 1998). It is possible therefore, that condition differences in tracking accuracy will emerge in 5-year-old children if the task difficulty is increased (e.g., by increasing the number of distracters in the task). This possibility was investigated in Experiment 2.

Experiment 2

Method

Participants

Participants were 15 3-year-old children ($M = 3.33$ years, $SD = .27$ years; 6 females and 9 males), 16 4-year-old children ($M = 4.41$ years, $SD = .32$ years; 8 females and 8 males), and 20 5-year-old children ($M = 5.33$ years, $SD = .37$ years; 11 females and 9 males).

Design and Procedure

Design and procedure of Experiment 2 were identical to that of Experiment 1 with one important exception: the number of distracter objects was increased to six (compared to two distracters in Experiment 1). Mean trial duration was 11.00s

($SD = .94s$) in the All Same condition and $10.92s$ ($SD = .86s$) in the All Different condition.

Results

Memory Accuracy

Memory accuracy data are presented in Table 1. Memory scores were submitted to a mixed ANOVA with age as a between-subject factor and condition (All Same vs. All Different) as a within-subject factor. The analysis indicated a main effect of age, $F(2, 48) = 11.08, p < .0001, \eta^2 = .33$. Post-hoc Tukey HSD tests indicated that overall memory accuracy in 3-year-old children ($M = .45$) was lower than in older children ($p < .05$), and statistically equivalent in 4- and 5-year-old children ($M = .74$ and $M = .82$, respectively). Similar to Experiment 1, there was no effect of condition and no age-by-condition interaction, both $F_s < 1, ns$.

Object Tracking Accuracy

Tracking accuracy scores were submitted to a mixed ANOVA with experimental condition (All Same and All Different) as a within-subject factor and age (3-, 4-, and 5-years of age) as a between-subject factor. Results of this analysis revealed a main effect of experimental condition $F(1, 48) = 23.40, p < .0001, \eta^2 = .32$, and a main effect of age $F(2, 48) = 8.93, p < .005, \eta^2 = .27$. Unlike Experiment 1, the age by condition interaction did not reach significance, $F(2, 48) < 1, ns$.

Figure 2. Tracking accuracy in Experiment 2.

Similar to Experiment 1, participants in all conditions in all three age groups identified the final location of the target object at above chance level (chance = 11%), all one-sample $t_s > 2.44, ps < .03$. However, unlike Experiment 1, 5-year-old children exhibited the effect of condition with higher accuracy in the All Same condition (66%) than in the All Different condition (55%), paired-sample $t(19) = 2.52, p < .05$, Cohen's $d = .35$. Similarly, 4-year old children exhibited higher accuracy in the All Same condition compared to the All Different condition (60% and 39%, respectively), paired-sample $t(15) = 3.71, p < .005$, Cohen's $d = .97$, as did 3-year-old children (34% and 20%, respectively), paired-sample $t(14) = 2.07, p = .05$, Cohen's $d = .69$.

Across the two experiments, it appears that overall level of performance in all three age groups was lower in Experiment 2, when six distracters were present, than in Experiment 1, when two distracters were present. Indeed, when the data from both experiments were submitted to a mixed ANOVA with age and number of distracters (two vs. six) as between-subject factors and type of distracters (All Same vs. All Different) as a within-subject factor, the analysis revealed a main effect of the number of distracters, $F(1, 95) = 34.09, p < .0001$. This main effect was qualified by the distracter number by distracter type interaction, $F(1, 95) = 33.88, p < .0001$, suggesting that decrease in accuracy with the increase in the number of distracters was greater in the All Different condition than in the All Same condition (mean decrease in accuracy across all age group was 27% and 22%, respectively).

General Discussion

This paper presents findings from a novel task in which children were asked to track a moving target object accompanied by distracters that varied in type (all same versus all different) and number (two versus six). The results pointed to several novel findings. First, tracking accuracy improved with age. Second, tracking accuracy was higher in the All Same Distracters condition than in the All Different Distracters condition for all age groups when target objects were accompanied by six distracters; a similar difference between conditions was observed in 3- and 4-year-old children when targets were accompanied by two distracters. Third, unlike the visual search tasks, increase in the number of homogenous distracters resulted in lower accuracy for all three age groups tested in this study. Finally, there was no effect distracter type on children's ability to remember which object they were supposed to track; therefore, effects reported in this paper can not be attributed to differences in memory demands in different conditions.

The central finding reported in this paper is that preschool-age children are more successful at tracking targets moving among homogeneous than among heterogeneous distracters. This pattern of performance may arise for two different reasons. Consistent with the notion that the speed of engaging attention (or attention-getting) and speed of releasing attention (or attention-holding) are separate factors (Cohen, 1972), one possibility is that homogeneous distracters provide less competition for attentional resources and therefore children are less likely to glance away from the target moving amidst identical distracters. In other words, low competition for attentional resources may enhance attention-holding properties of the target. Alternatively, it is possible that children are equally likely to glance away from the target regardless of the type of distracters; however children are more successful in locating the target after glancing away in the homogeneous than in the heterogeneous distracter condition. In other words, low competition for attentional resources may

enhance attention-getting properties of the target. These possibilities remain to be addressed in future research.

Overall, findings presented above support the notion that development of endogenous attention (probed by the All Different Distracters condition) lags behind the development of exogenous attention (probed by the All Same Distracters condition). Importantly, the Object Tracking task makes it possible to assess both mechanisms within the same paradigm and quantify this lag in terms of the differences in tracking accuracy. Therefore, this new paradigm allows attributing changes in performance to different mechanisms of attentional control rather than to differences in the level of motivation and engagement in different tasks.

Acknowledgments

I thank children, parents, teachers, and administrators for their participation. This research was supported by NICHD though Grant 1R03HD060086-01A1.

The Influence of Route Planning and its Execution on Spatial Learning

Abstract

We propose that spatial inferences made during planning and executing a route influence the learning of relative locations through wayfinding. In Experiment 1, separate and combined route plans were compared. The results suggest that inferring multiple directions during the initial stage of planning leads to more accurate representations of relative locations than planning a single route. In Experiment 2, regular and irregular updating modes during the execution phase were compared. The results suggest that irregular updating, which involves multidirectional self-to-object updating, also leads to more accurate representations than regular updating. We conclude that the requirement to make spatial inferences about multiple multidirectional metric interconnections in egocentric reference frames during wayfinding facilitates spatial learning.

Keywords: spatial learning; route planning; wayfinding; egocentric reference frames

Introduction

The means by which humans and animals develop knowledge about their surrounding environments has been a controversial topic for a long time. One theory of the development of spatial knowledge assumes a qualitative change from route knowledge to survey-type knowledge over time (Siegel & White, 1975), and thus the knowledge should become more elaborate as experiences of traveling increase. It is also thought that the qualitative change could occur by automatic and unconscious reorganization of the route knowledge (Thorndyke & Hayes-Roth, 1982). However, there are studies that showed that experiences of an environment do not facilitate spatial learning automatically (Moeser, 1988; Rossano & Reardon, 1999), and repetitive learning does not always efficiently promote the accurate development of knowledge (Ishikawa & Montello, 2006).

The present study examines the relationship between human spatial learning and route planning during wayfinding. Though wayfinding includes a wide range of cognitive activities and behaviors (Gärling, Böök, & Lindberg, 1984), after a destination has been set the basic process of wayfinding is planning and executing of a route in which one decides on and follows between a point of origin and a destination (Golledge, 1999). Specifically, we focused on route planning when moving through environmental spaces such as cities or the interior of buildings. In previous studies, route planning, which incorporates factors such as “short cuts”, is often used as a dependent variable that changes with the development of spatial cognition. However, to our knowledge, no study has

yet examined the effects of route planning on spatial learning.

Here we assume that spatial inferences during planning and executing a route facilitate the learning of relative locations. This might sound paradoxical because knowledge of relative locations is often thought to be a precondition for planning. Spiers & Maguire (2008) pointed out that when planning a route, the relative direction from the origin to the destination is determined before a specific path can be chosen. In the case when very little is known about a particular environment, how is it possible to find the way to a destination that is out of sight? Given that, to facilitate wayfinding, spatial knowledge of a particular environment is manipulated using rules of inference (Kuipers, 1978). A relative direction must be inferred by representing and manipulating the incomplete knowledge that has already been acquired. For example, when one is not sure which path to take at a four-way intersection in an unfamiliar environment, he or she can express a vague direction to a destination by pointing a finger, which is a spatial inference that people make routinely in their daily lives. The core idea in this study is that the inference of this type will be effective to develop spatial knowledge.

The relationship between relative locations can be described in either an environmental reference frame (object-to-object relations) or an egocentric reference frame (self-to-object relations). However, when deciding on a direction of movement within an environment during wayfinding, it is necessary for a traveler to represent one's body and the destination in an egocentric reference frame (Sholl, 1996) in order to translate one's spatial knowledge into action. On theoretical grounds, self-to-object relations can be represented in a number of ways, for example, as location-dependent reference direction (Poucet, 1993) or in a network of reference frames (Meilinger, 2008). However, the representations commonly contain metric information, defined as the direction and distance from one place to another.

Our expectation was that spatial inferences about self-to-object metric relations would have a facilitating effect when planning a route and updating self-position and orientation at the decision point (e.g. intersections). Gärling et al. (1984) suggested that metrical relations only between important reference points are represented for travel. Naturally, an origin and a destination are such reference points for determining a route at the initial stage. In addition, the decision point should also be the key reference point for following the route. Unlike on-line-type spatial inferences such as narrowly defined path integration, which are based

on continuous updating, people pay attention to metric relations during wayfinding mostly when the need arises such as when one chooses a path at the decision point.

Two experiments were conducted to compare incidental learning outcomes when planning and executing different types of the routes using a direction estimation post-test that reflects the structure of self-to-object representations.

In Experiment 1, separate and combined route plans were compared. We assumed that number of the goal directions that participants were required to infer at the start would affect their learning of relative locations within an environment. When a traveler is visiting multiple places, if he or she makes separate route plans (i.e. plan a route to the first place, move to that place, and then plan the route to the next one), one will just compute one direction each time. In contrast, to make a combined route plan for the complete round of visits, the traveler would have to consider multiple interconnections between the origin and the destinations at the same time and effectively learn the interconnections.

In Experiment 2, two types of order of visiting, which led to regular or irregular updating, were compared. In regular updating one constantly updated one's position to destinations situated in the same self-to-object relation. In irregular updating the destinations were situated in multidirectional self-to-object relations. We assumed that a requirement for different types of directional inference when updating would also affect learning relative locations. If a traveler has to infer multidirectional self-to-object relations through the updating process, rather than constantly updating, they would be able to utilize egocentric reference frames over a wide range of the environment.

The Environments and Settings

A real environment was used to observe spontaneous spatial inferences. Additionally, to achieve a natural response from the participants, we set up the wayfinding task as a role-playing game that involved stories (Appendix A). The experiments took place on the campus of Waseda University with participants aged 18 and older attending a school festival and agreeing to participate in the experiments.

Experiment 1

Method

Participants Out of a total of fifty-six participants, who were randomly assigned to each group (Single-Goal or Multiple-Goals), fifty people (mean age 22.0) were included in the analyses. Three women in the Multiple-Goals group made errors in the wayfinding task and were excluded from the analyses. Thus the last three female participants in the Single-Goal group were also excluded, so that both groups contained 25 people with the same male-to-female ratio (9:16).

Materials Labyrinth 1 (7 by 7 meters) was built in a classroom using identical fiberboard sheets (Figure 1, left panel; each panel was 2 meters long and 1 meter wide). Figure 2 shows the layout of the labyrinth and the locations

of the four targets, which corresponded to computer displays that showed illustrations of the four residents in the story (Appendix A) and instructions for the wayfinding task. No two displays could be seen at the same time. We developed two programs that were written in Visual Basic for Applications: one controlled the task and recorded the responses, and the other was used for the post-test. The left panel in figure 3 is an example of the operation screen used in the post-test to record the judgments of the participants.

Figure 1: Images of the Labyrinth

Figure 2: Layout of Labyrinth 1

Figure 3: An operation screen and correct angles

Order of Visiting The orders were devised so that the participants did not encounter the same positional relations (Table 1).

Table 1: Orders of Visiting

First round	Second round
1. Target A → B → C → D → A and A → D → C → B → A	
2. Target A → D → C → B → A and A → B → C → D → A	
3. Target A → B → D → C → A and A → C → D → B → A	
4. Target A → C → D → B → A and A → B → D → C → A	
5. Target A → C → B → D → A and A → D → B → C → A	
6. Target A → D → B → C → A and A → C → B → D → A	

Procedure The wayfinding task consisted of two phases: (i) exploring and (ii) visiting (two rounds). The participants were escorted individually from an anteroom to the labyrinth by an experimenter, who monitored the progress of the task from outside the labyrinth.

During the exploring phase, the participants walked around freely and found the four computer displays. When they found a display, they pressed a keypad that was placed in front of each display (Figure 1, right panel). The visiting phase started when the participant found the last display.

This formed the point of origin of the visiting phase; the point of origin varied depending on how the individual had explored, but because the labyrinth was fully symmetric, each order of visiting involved similar components regardless of the location of the origin. The participants were asked by the resident in the last display to revisit the other residents. In the Single-Goal procedure, only the first target goal was given at the point of origin, and when the participants reached that goal they received the next one. In contrast, in the Multiple-Goals procedure, all three target goals and the order in which they should be visited were given at the point of origin. When the participants reached a target, they pressed the keypad. The task ended after two rounds of revisiting.

After the task, the participants were escorted to another room and took the post-test. They were informed that the experiment included “easy quizzes about your memory and sense of direction”. After five filler questions that asked about the story, they were asked to indicate 12 relative directions in the following manner: “if you were standing and facing the target X, indicate the direction of target Y”. A computer display used in the test was placed horizontally on a table. The participants viewed the operation screen (Figure 3, left panel) from above and indicated the directions by turning the arrow clockwise or counterclockwise using keypads. The graphic shows a birds-eye view of a participant standing in front of a computer display. Instructions of 12 combinations of X and Y were presented one by one randomly at the top of the screen. Three solid lines in the right panel of Figure 3 shows 3 correct angles for 12 relative directions (there were four groups of 3 directions that had the same correct angle).

Results

To analyze the 12 relative directions for each group as one data set for each condition, all judgments were adjusted such that the correct angle was 0 degrees. The twelve judgments by each person were analyzed individually to avoid cases where the mean angle corresponded to the correct angle fortuitously (for instance, if two judgments were +120 degrees and -120 degrees, the mean angle would be 0 degrees, the correct angle). Figure 4 shows the mean angles, values for v (a measure of the clustering around a correct direction that decreases as the dispersion increases and varies from -1 to 1), and the results of the V-tests that revealed each data set clustered around the correct angle. The Watson-Williams test revealed that there was no significant difference between the mean angles for the two groups. The accuracy of the judgments was represented by the amount of dispersion, because a greater degree of dispersion meant that more data departed from the correct angle than for a lower value. We compared the dispersions of the two groups by the Mann-Whitney Test, as suggested by Batschelet (1981), and found that the dispersion of Multiple-Goals was smaller than that of Single-Goal ($Z=-2.29$, $p<0.05$).

A T test revealed there was no significant difference between the mean total required times for the two groups. Next, we conducted a two-way analysis of variance (ANOVA) on the required time using the following factors: (F1) the number of goals and (F2) sections (see Figure 5). An effect of F2 ($F(11,528)=76.40$, $p<0.01$) was observed, together with an interaction between the two factors ($F(11,528)=3.05$, $p<0.01$). Student-Newman-Keuls test revealed that among the comparisons between all possible pairs of factor levels, there was only a significant difference between the groups for Section 5 (the first section of the visiting phase). There was no correlation between individual values for v (using 12 judgments per person) and those for the total required time ($r=0.13$ in Single-Goal and -0.33 in Multiple-Goals).

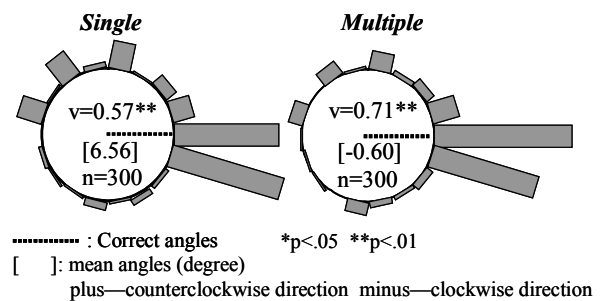

Figure 4: Frequency distribution graphs

Figure 5: Mean required time for 12 sections

Discussion

The result that the participants in the Multiple-Goals group performed better in the post-test than those in the Single-Goal group supported the hypothesis that combined route planning facilitates the learning of relative locations. We conclude that inferences about multiple interconnections that were made when planning the route improved the accuracy of the judgments made in the post-test. Detailed analysis of the required time showed that participants assigned to the Multiple-Goals group spent more time on Section 5, during which the participants received their first instructions for the visiting phase and reached the first target.

Presumably, this was because the participants in Multiple-Goals had to recall the relative locations of three targets to make a combined-route plan, as well as having to absorb instructions that contained the next three target goals and the order of visiting. Simultaneously, they had to infer three self-to-object relations from their current position to the targets. In contrast, those in the Single-Goal group had to infer just one direction to the next goal. Thus, the difference in time taken shows the complexity in processing the additional directional inferences in Multiple-Goals as compared with Single-Goal.

In both groups a large proportion of clockwise errors appeared (Figure 4) because angles A and C tended to be considered just in front of and on the right hand side respectively from the imagined standing points of the participants. Though there was no difference between mean angles for the two groups, the angle in Single-Goal containing clockwise error shows that more participants in the group had this tendency than in Multiple-Goals.

After the participants became aware of the position of the target at the initial stage of the planning, they could revisit the targets relatively easily and without taking the wrong path because the shape of the labyrinth gave them a reasonably good view of the access aisles and there were multiple accessible paths. Although the specific pathways that were taken during the task were not recorded in Experiment 1, both conditions involved a similar amount of walking because there was no difference in the total required times between the two groups.

Experiment 2

Method

Participants Out of the forty-four participants who were randomly assigned to each group (Circle-Order and Non-Circle-Order), thirty-eight people (mean age, 20.7; male-to-female ratio in each condition, 11:8) were included in the analyses. Three women in each group who made errors in the wayfinding task were excluded from the analyses.

Materials We partially rearranged Labyrinth 1 into the format shown in Figure 6 without changing the locations of the targets and set it up in the same classroom used in Experiment 1. Camcorders were used to record the paths taken by the participants. The other basic materials were the same as those in Experiment 1, except the post-test program the filler questions were redrafted to correspond to the new story (Appendix A).

Order of Visiting Visiting orders 1 and 2 (Table 1) corresponded to the Circle-Order procedure in which the participants visited three targets in a clockwise or counter-clockwise order, for example visiting A→B→C→D→A in the first round, and then A→D→C→B→A in the second round, so that they turned constantly to the right or left at a decision point during each round. The other visiting orders, for example visiting A→B→D→C→A in first round, and then A→C→D→B→A in second round, represented the

Non-Circle-Order procedure in which the participant turned right and left turns and going straight ahead at decision points.

Procedure The basic procedure was the same as that of Experiment 1, except that all participants were informed of the three target goals with their visiting order at the point of origin and they carried camcorders during the wayfinding task.

Value for leg 1= 0.5, leg 2=1.5, leg 3, 4, 5, 6=1

Figure 6: Layout of Labyrinth 2

Results

All the judgments were analyzed in the same way as Experiment 1. Figure 7 shows the mean angles, values for v (refer to results of Experiment 1), and the results of the V-tests that revealed each data set clustered around the correct angle. The Watson-Williams test revealed there was no significant difference between the mean angles for the two conditions. The result of the Mann-Whitney Test showed that the Non-Circle-Order group had a smaller degree of dispersion than the Circle-Order group ($Z=-3.13$, $p<0.01$).

Figure 7: Frequency distribution graphs

Figure 8: Mean required time for 12 sections

A T test revealed that there was no significant difference between the total required times for the two conditions. We conducted a two-way ANOVA on the required time using

the following factors: (F1) the orders of visiting, and (F2) sections (12 levels). We only detected an effect of F2 ($F(11,396) = 43.67, p < 0.01$) (Figure 8).

The paths that each participant took inside Labyrinth 2 were detailed by video. The aisles of Labyrinth 2 were divided into 10 legs, and to count and compare the amount of walking, we assigned a value to each leg (Figure 6) and summed the values based on the paths taken by each participant, with the exception of legs 7, 8, 9, and 10, which no one walked. The averages of the total were 23.97 in Circle-Order and 23.87 in Non-Circle-Order. T tests revealed that there was no significant difference between them. During the exploring phase, one person in each group seemed to locate the targets first without pressing the keypads; during the visiting phase 12 people (5 in Circle-Order and 7 in Non-Circle-Order) realized that they had gone the wrong way and retraced their steps. We did not exclude these people from the analyses because, during the exploring phase, only one person in each group did not press the keypads immediately, and during the visiting phase, all the participants remembered the required order and corrected their course. The other participants took the shortest paths of which the total was 22.5. There was no correlation between individual values for v and the following two values: the total required time ($r = 0.08$ in Circle-Order and 0.31 in Non-Circle-Order) and the average of the values based on the paths ($r = -0.23$ in Circle-Order and -0.26 in Non-Circle-Order).

Discussion

The result that the participants in the Non-Circle-Order group performed better in the post-test than those in the Circle-Order group supported the hypothesis that irregular updating facilitates the learning of relative locations. We conclude that multidirectional self-to-object updating at decision points improved the accuracy of the judgments made in the post-test.

It is noteworthy that the value for v of the Circle-Order group was equivalent to that of the Multiple-Goals group in Experiment 1. This can be interpreted as a replication of the effect of multiple goals because the participants in both groups planned combined routes. Unlike Experiment 1, it was not possible to execute the plan only with an awareness of the targets' locations because of the fylfot-shaped labyrinth. To reach the next target goal, the participants had to choose one path by updating their positions to the next target at the decision point. Whereas those in the Circle-Order group inferred the same direction to the targets that were always to the right or left of their body in a given round, those in the Non-Circle-Order group had to infer multiple directions to the targets that were backward right, to the right and to the left in a given round.

The length of time spent in the labyrinth and the amount of walking did not show a direct correlation to performance. There were no differences between the groups with respect to, total required time, time in each section and the number of legs that the participants walked during the task.

General Discussion

The results of the experiments revealed that, regardless of physical experience (e.g. the amount of walking and minor differences in both the migration pathways taken and the number of legs walked), the need to infer metric interconnections between multiple points during the initial stage of planning and while executing a route plan improves the accuracy of representations of relative directions within an environment.

The effect of the initial planning in Experiment 1 is consistent with spatial theories and models that propose that the acquisition of representations about spatial structures through wayfinding involves the integration of local perspectives and views that a traveler has learned independently (e.g. Meilinger, 2008; Poucet, 1993; Sholl & Nolin, 1997). The improved accuracy can be interpreted as the consequence of profound and extensive integration because combined route planning involved the representation of greater amounts of local information and the computation of more metric relations in egocentric reference frames at one time than separate route planning. There are navigational strategies that do not involve inferring metric relations. However, in the experimental situations described here the participants were instructed unexpectedly to revisit three unfamiliar targets in a specific order in a completely new environment. They had to recall which display corresponded to which resident and where it was located. In addition, they had to consider object-to-object positional relations between three targets in order to plan a combined route. These combined-route plans, which contained more directional components than those of the simple plans, appeared to facilitate the integration of the local perspectives and views.

We have addressed the question of why regular updating facilitated learning while irregular updating did not in the discussion of Experiment 2. The effect of irregular updating was different from the effect of direct directional inferences to the targets, which was observed in Experiment 1. In Experiment 2, the participants updated their positions relative to the targets at the decision point in the center of Labyrinth 2, and not in front of the displays; however, in the post-test, they were required to estimate directions from the displays. Thus it can be interpreted that the inferences through the updating had a spillover effect on the estimation of self-to-object directions between the targets. We assume that this effect was due to strong interconnections between the decision point and the targets' locations. During irregular updating the decision point, which was one of the key reference points in a spatial structure of Labyrinth 2, was far more important than that of regular updating (as discussed in the next paragraph), and thus it would be strongly interrelated to the other reference points. If we compare the reference point and path to a node and edge, respectively, in a graph, the participants in Non-Circle-Order might have recognized the interrelation of the points as a graph with five nodes and eight edges (e.g. like a square with diagonal lines), while those in Circle-Order have

recognized that as a graph with four nodes and four edges (i.e. just a square). Though we do not make a decisive conclusion here, it seems reasonable that the former structure of interrelation would have been more advantageous in representing relative locations in an egocentric reference frame than the latter.

The ineffectiveness of regular updating might be caused by a difference in the hierarchical levels of navigational strategies between the two conditions. Trullier, Wiener, Berthoz, & Meyer (1997) proposed a classification of strategies that is based on levels of complexity of required processing and the information that is perceived, represented, and processed. According to the classification, route following that involves regular updating can be substituted with a lower level strategy that requires the participant to regularly turn left or right at the decision point rather than having to compute a metric relation to choose a path at the decision point each time. Thus, this type of regular decision-making during wayfinding might be ineffective at improving representations of relative directions.

Our findings reflect the natural behavior of humans because our participants in the game-like experiments did not know that they were going to be asked the directions in the post-test. The utilization of inferences for planning and executing a route might be one of the key mechanisms by which individuals refine and modify their representations of relative locations in an environment. Differences in the inferences made might be one of the reasons why “individuals with equal levels of exposure to a place will differ in the extent and accuracy of their spatial knowledge (Montello, 1998)”.

Appendix A

Experiment 1 Labyrinth 1 was set in an imaginary town where a cat and four residents lived: an old lady, an elementary school girl, a vegetable shop owner, and a middle-aged lady. The last resident found by the participants in the exploring phase was determined to be the cat owner. Participants were told by the owner that their cat was missing and were asked to revisit the other residents and get information about the cat.

Experiment 2 Labyrinth 2 was set in an imaginary rural town in Asia where four residents lived: a village headman, a Buddhist monk, an elephant driver, and an old lady. Participants were told by the last resident found that a hidden gem had been stolen by a monkey. Then, the resident asked them to revisit the other residents and get information about the monkey.

The Direction Bias and the Incremental Construction of Survey Knowledge

Abstract

This study examines how spatial memory acquired from navigation is used to perform a survey task involving pointing. Participants learned a route through a virtual city by walking it multiple times in one direction on an omnidirectional treadmill. After learning, they were teleported to several locations along the route, self-localized and pointed to multiple other locations along the route. Pointing was done away from or towards the current location. Preliminary data show that participants were faster in pointing away. This suggests that pointing was based on an incremental process rather than an all-at-once process which is consistent with mentally walking through a cognitive map or constructing a mental model of currently non-visible areas of the city. On average participants pointed faster to targets located further down the route towards the end than to targets located route upwards towards the start. Analysis of individual performance showed that more participants than expected by chance showed such an effect of target direction also in their pointing accuracy. The direction of this effect differed between participants. These direction biases suggest that at least some participants encoded the environmental space by multiple interconnected locations and used this representation also for pointing.

Keywords: Reference frame; environmental space; spatial memory; survey knowledge; cognitive map; mental walk; mental model; pointing; virtual environment

Introduction

When navigating through an environmental space such as a city or a building we experience multiple views of parts of this environment from various perspectives (Montello, 1993). The knowledge acquired from these experiences can be used to retrace familiar routes, plan novel routes, point to distant locations, or look for shortcuts. The last two tasks are examples of survey tasks (Ishikawa & Montello, 2006; Siegel & White, 1975). To solve a survey task, one has to consider metric relations (distance, relative direction) between two locations not mutually visible. Often, these two locations are our current location and a target location we want to point to, estimate the distance to, or find a shortcut towards. In order to do so at least our current location and the target location have to be represented within a single reference frame. This could be our egocentric reference frame within which the direction and distance of the target is represented in relation to our body. It could also be an allocentric world-centered reference frame within which our

current location and the target are represented. Unless we obtain our environmental knowledge from a map which already provides this information within a single reference frame we have to integrate the multiple pieces of information acquired during navigation to represent them within one single reference frame. This work aims to cast some light on how this integration process might work. We will introduce theories of survey knowledge, derive predictions from these theories, and test them in an experiment.

Theories of Survey Knowledge

Most spatial memory theories which explain survey knowledge assume that navigators form a global world-centered reference frame within which all relevant locations are represented. Such a global reference frame might be formed very quickly, with all novel locations represented within it (Mou, McNamara, Valiquette & Rump, 2004; O'Keefe, 1991; Stachniss, 2009). Alternatively, this global reference frame is eventually formed from multiple local representations (Kuipers, 2000; Mallot & Basten, 2009; McNamara, Sluzenski & Rump, 2008; Poucet, 1993; Trullier, Wiener, Berthoz & Meyer, 1997). It then either works as an additional layer embedding local representations within a metric reference frame or as the top-level in a hierarchical memory structure subsuming lower level reference frames. In the following a global world-centered reference frame will be called a cognitive map.

Survey relations can be obtained from a cognitive map in several ways. The easiest way is to simply *read out* the coordinates of the relevant locations (e.g., the current location and the target location) and compute the relative direction, the distance between the locations, etc., by subtracting these coordinates from each other. If required by the task these parameters are then transformed into an egocentric reference frame, for example, when pointing to a target.

Alternatively, navigators could *mentally walk* through a cognitive map. While mentally moving from one point to another, they integrate the metric survey relation between the start and the mental position in the map until reaching the target (Byrne, Becker & Burgess, 2007). Thus the relative direction, the distance, etc. are derived. The activation pattern of hippocampal place cells is a plausible mediator for this process – although the conscious imagery of the mental walk might take place in posterior parietal cortex.

Place cells represent locations within an environment (O'Keefe & Nadel, 1978). Even in the absence of sensory stimulation (e.g., during sleep) they can fire in an ordered fashion as they would do when walking a route (Skaggs & McNaughton, 1996). Similar neural processes might happen during mental walks when performing a survey task.

A different position assumes that an environmental space is not represented within a single global reference frame (i.e., a cognitive map), but by multiple local interconnected reference frames (Meilinger, 2008). The integration within a single reference frame which is required for survey tasks happens during retrieval by constructing a *mental model* of the non-visible environment (a related model was presented for updating by Fujita, Klatzky, Loomis & Golledge, 1993). For example, navigators imagine what the environment would look like if the surrounding walls were transparent. First, they imagine the adjacent street from their current position, then they add the street branching off from it, etc. In this way all locations from the current location along a route leading towards the target location are imagined step-by-step within the current egocentric reference frame (this could also be done from a different imagined viewpoint). The mental model of the non-visible environment is constructed piecewise from a certain perspective. No one mentally walks through this constructed environment and the underlying memory structure is no cognitive map, but a network of reference frames interconnected by directed links (i.e., the links point in certain direction). The construction of the mental model is assumed to be easier when done along the direction of the links (i.e., imagine a distant location the link point towards). Otherwise these links have to be inverted which is computationally costly.

The Prediction of Performance Differences

The three positions, read out from a cognitive map, mentally walking through a cognitive map, and constructing a mental model from a network of reference frames predict specific performance differences due to incremental vs. all-at-once process of deriving survey relations and due to direction biases in the underlying memory.

All-at-once vs. Incremental Estimation of Survey Relations Reading out coordinates of two locations from a cognitive map and subtracting them is an all-at-once process in the sense that the survey relation (e.g., the relative direction of the target from a current location) is determined as whole. Contrary, mentally walking to a target or extending a mental model of the environment until it includes the target are incremental processes. The further we walk and the further the model is constructed the better we can estimate the direction and distance towards our target. Due to the incremental character locations in-between have to be represented during this process. This is not the case for reading out. One way to test this is to have navigators point to multiple locations in an ordered way. For example, they point to all locations along a route from the current location to a location B. When they do so in an order away from the cur-

rent location (i.e., first point to the adjacent location, then the second closest, etc., until finally pointing to B) they can mentally walk or construct a model up to the first location, point there, extend this model or mentally walk to the second location, point there, etc., until mentally reaching location B. In the opposite case when they point in an order towards the current location (i.e., first to location B, then the second last location until finally pointing to the location closest to the current location) they first have to construct the whole model up to B, respectively mentally walk the entire distance up to location B. Then they either shift their attention to the second last target in the model, mentally walk back to the second last target or do it all over again from the current location to the second last location. No matter how navigators precisely do this, this process should last longer and/or be more error prone than pointing to targets in an order away from the current location. When reading out locations from a cognitive map navigators cannot profit from their last pointing. They have to compute the survey relation for each target individually no matter in which order they point to the locations. Order thus should not lead to different performance as in the case of a mental walk or a mental model.

The Direction Bias A cognitive map does not show direction specificity between locations (although the whole map might be oriented in a certain way such as north-up in a paper map). That means that no matter whether one points from A to B or from B to A the result should not differ in performance. This is just the same for reading out as well as for mental walk. On the contrary, a direction bias is expected in certain cases for the mental model explanation, because of the underlying memory. The mental model is based on directed interconnections between local reference frames. Constructing a model in the direction of the interconnection is easier as no inversion is required. It should yield better performance.

In order to predict performance differences one has to know where the directedness in memory originates from. According to Meilinger (2008) navigators encode local reference frames during navigation (e.g., corresponding to a street or a room). The interconnections between these local reference frames represent the metric relations (i.e., relative direction, distance, and orientation) between them. They can be derived in at least two ways. First, navigators might obtain interconnections from their visual input. They see that a street branches off to the right in 20 meters. The reference frame of this street is located 20 meters to the front and is oriented 90° to the right. This results in a forward connection, for example, expressed by vector pointing forwards. Alternatively, they could walk up to the next street while updating the origin of their current street (i.e., the origin of the memory reference frame representing the street). The interconnection to the last reference frame is the updated vector pointing back to the last street (i.e., a backwards interconnection). Here an individual navigator is expected to apply only one kind of strategy (i.e., either forward or

Figure 1: The virtual city as seen from navigation perspective (left side) and from bird's eye view with the route marked in red (right side). During learning the start, the end and each of the six intersections in-between were marked with white crosses on the floor. They worked as pointing locations and targets during the test phase.

backward encoding), at least over some time interval such as an experiment. Thus walking a route in one direction will result in directed interconnections (either forwards or backwards). Using these interconnections for constructing a mental model is easier along the direction of interconnections and should lead to better pointing performance. Depending on the encoding strategy this direction bias should be in forward or backwards direction.

Methods

For the experiment we used an immersive virtual city environment presented via a head-mounted display (HMD). In the learning phase, participants experienced the virtual environment by walking through it on an omnidirectional treadmill. They only walked the route in one direction. In the testing phase, participants were teleported to different locations in the environment, without walking physically. They were then asked to identify their location and heading and were instructed to point towards multiple targets on the route. Pointing order could be either towards their current location or away from it. Direction biases were examined by comparing pointing performance for pointing to targets located route upwards (to the start) with pointing performance for targets route downwards (to the end).

Participants

So far eleven participants (5 females and 6 males) aged between 21 and 34 ($M = 26.6$ years, $SD = 4.5$ years) participated in the experiment. They were recruited via a subject database and were paid for their participation. All participants signed an informed consent approved by an ethical committee before participating in the experiment.

Material

The Virtual City In the learning phase, participants had to learn a route through a virtual city. Figure 1 shows a snapshot of the city as seen during walking, as well as a bird's eye view of the route. The route consisted of a start, six intersections and an end. During learning, all eight locations were marked with a white X on the floor, as were all inter-

sections visible from this route. The type of houses changed along the route, as did street width and the heights of houses. In addition, individual houses ensured sufficient landmark information to identify each location.

The Setup Participants walked on a 4x4 meters omnidirectional treadmill (Figure 2 left side). It allowed them to walk for infinite distances in any direction by moving them back to the centre of the treadmill. This unique interface allows for realistic proprioceptive and vestibular feedback as well as efference copies while walking in virtual environments. Participants wore a climbing harness for the unlikely event of falling and hurting themselves on the moving platform. To obtain participants' location on the treadmill their head position was tracked by 16 high-speed motion capture cameras at 120 Hz (Vicon® MX 13). This data was used both to control the treadmill and to update the visualization of the virtual environment. The visual surrounding at a location was rendered in real time (60Hz) using a NVIDIA Quadro FX 4600 graphics card with 768 MB RAM in a standard PC. Cables connected the PC to the display via the ceiling. Participants viewed the scene in stereo using a nVisor SX head-mounted display that provided a field of view of 44×35 degrees at a resolution of 1280×1024 pixels for each eye with 100% overlap. The setup thus also provided important visual depth cues such as stereo images and motion parallax.

Figure 2: The virtual reality setup. The left image depicts a participant walking on the omnidirectional treadmill during the learning phase. The right image shows a participant pointing to a target during the testing phase by facing the target and pressing a button on a gamepad.

Procedure

In the *learning phase*, participants walked the route at least six times from start to end. They were instructed to first learn the route, and secondly be able to self-localize when teleported to an X along the route after the learning phase. Participants were free to look around as long as they wanted. In their first run, they walked up to an intersection, looked around, and the experimenter pointed out the street to take when the participant looked down the correct street

by stating “the route is this direction” (the experimenter was in the same room and could task with the participant). No verbal turning information (e.g., “left”, “straight on”, etc.) was given. When reaching the end and having looked around participants were teleported back to the start. From the second run onwards participants were asked to approach an intersection, look into the direction the route was going on and say “this way”. The experimenter gave feedback whether this was right or wrong, before participants proceeded. They were not allowed to leave the route. For each new run, the virtual environment was rotated 90° clockwise relative to the lab. Sound sources within the lab could thus not be used to derive global orientation. The learning phase ended when participants walked the route at least six times and at least two runs were error-free. This criterion ensured comparable levels of route knowledge for all participants. Participants briefly trained walking on the treadmill before starting the experiment.

In the following *test phase*, participants were teleported to locations on the route formerly marked by an X (i.e., the start, the end or one of the six intersections in between). They were now asked to self-localize and then successively point to multiple target locations which had all been formerly marked by an X. For self-localization, participants could look and rotate around, but not walk around – a circular handrail around them with 0.48 meters diameter prevented them leaving their location during the test phase (Figure 2 right side). As soon as they subjectively knew their location and orientation, they were asked to press a button on a gamepad they were holding. Then they pointed to multiple targets. Pointing was done by turning on the spot until a vertical black line in the middle of the display matched the direction in which the participant thought the target was located. They thus would look directly at the target location if the surrounding houses were transparent. When participants thought they faced the target, they pressed a button and then pointed to the next target. No feedback was provided. After they had pointed to all targets, participants pressed a second button on the gamepad and were teleported to a new position.

Four conditions determined the targets and the order in which participants were asked to point towards them (Table 1). They should point either (1) first to the start and then to all locations between start and the current location in the order of walking (i.e., start, 1st intersection, 2nd intersection, etc.). (2) They should point to the same locations, but in reverse order (i.e., first the intersection before the current location, then the second last, etc. until finally pointing to the start). (3) They should point to the next intersection along the route after the current location, then the second next, etc. until pointing to the end. Or they should (4) point first to the end, then the last intersection, the second last intersection, etc. until pointing to the intersection after the current location. Consequently, we varied the two factors ‘target direction’ (route upwards to start vs. route downwards to end) and ‘pointing order’ (away vs. towards the current location; see Table 1). Please note that the adjacent

intersections to point towards were always visible during pointing (although the Xs were removed). From the eight locations on the route (including start and end) participants pointed to every other location twice (in the order away and towards the current location). All 28 pointing sets were presented in random order for each participant (pointing downwards from seven locations, upwards from seven locations, both in two orders). This whole procedure was repeated resulting in 56 pointing sets altogether. After finishing a pointing set participants received feedback about the number of pointing targets they pointed towards: whether they pointed towards the right number of targets, how many targets they missed; or how many superfluous targets they pointed towards. No feedback about pointing accuracy was provided. Pointing sets with too few or too many pointings were not analyzed as the target locations could not be assigned to pointings. We recorded self-localization time (not further reported), pointing time and pointing direction for each pointing in a complete pointing set. After pointing participants drew a sketch map and we asked for subjective strategies with a questionnaire. The whole experiment lasted approximately two hours.

For the analysis we used pointing time and computed the absolute pointing error (i.e., the deviation between correct and estimated pointing direction irrespective of the direction of the error). Values deviating more than two standard deviations from a participant’s mean were not analyzed. Only if a participant’s mean absolute pointing error significantly differed from 90°, indicating that some survey knowledge was acquired, data were analyzed (90° error is the average error you get when randomly pointing in all directions). For analyses within participants we used t-tests. For analyses across participants we computed mean values per participant and condition and used within-participants ANOVA and t-tests. Cohens *d* and partial eta-square (η_p^2) are presented for the estimation of effect sizes.

Table 1: The Four Pointing Conditions

<i>Target direction on the route</i>		
<i>Pointing order</i>		
<i>(relative to the current location)</i>		
<i>Instruction: Point from...</i>		
Upwards	Away	current location to start
Upwards	Towards	start to current location
Downwards	Away	current location to end
Downwards	Towards	end to current location

Results

For all but one participant pointing accuracy differed significantly from chance (t ’s > 10.9, p ’s < .001). They did acquire survey knowledge and were thus further analyzed. Their average absolute pointing error was 19.6°; mean pointing time was 2.8 seconds per pointing.

Mental walk and mental model theories of survey knowledge predicted performance differences for pointing order.

Figure 3: Average pointing time as a function of target direction and pointing order. Both main effects were significant as indicated by the asterisks. Means and (between participants) standard errors are displayed.

Indeed, participants pointed faster away ($M = 2.6s$) than towards the current location ($M = 3.0s$; see Figure 3; $F(1, 9) = 9.50$, $p = .013$, $\eta_p^2 = .51$; accuracy: towards $M = 22^\circ$, away $M = 18^\circ$, $F(1, 9) = 2.21$, $p = .171$, $\eta_p^2 = .20$). This difference was not predicted by a process of reading out from a cognitive map.

According to the mental model of survey knowledge, participants' performance should differ as a function of target direction – although the direction of the effect might differ between participants. When averaging across all participants they pointed faster to targets located further down the route to the end ($M = 2.7s$) than to upward targets ($M = 2.9s$; $F(1, 9) = 8.22$, $p = .019$, $\eta_p^2 = .48$; accuracy: upwards $M = 17^\circ$, downwards $M = 23^\circ$, $F(1, 9) = 2.21$, $p = .151$, $\eta_p^2 = .22$). Looking at the effect of target direction on pointing accuracy for each participant individually a more differentiated picture emerges: Six out of the ten participants showed an effect of target direction in their pointing accuracy (i.e., their pointing accuracy differed between pointings upwards to the start vs. downwards to the end $t's > 1.99$, $p's < .049$, $d's > 0.19$). Three of them pointed more accurately downwards the route ($M = 7.0^\circ$ vs. $M = 10.5^\circ$), three participants pointed more accurately upwards ($M = 23.6^\circ$ vs. $M = 45.1^\circ$). Four participants did not show a significant effect of target direction (upwards $M = 16.2^\circ$, downwards $M = 18.7^\circ$; $t's < 1.88$, $p's > .063$, $d's < 0.21$). If there was no target direction effect each participant has a chance of 5% to (erroneously) be classified as being direction biased in any direction by a t-test. The observed proportion of 6 out of 10 participants showing such an effect is highly unlikely to originate from such a 5% chance rate (binomial test $N = 10$, $\pi = 5\%$: $p < .001$). Consequently, the null-hypothesis that there is no effect of target direction on accuracy is rejected. Since individual participants showed opposite direction biases, we observed no average global bias in pointing accuracy in one specific direction. When looking at differences in pointing time on the level of individual participants only one partici-

pant significantly pointed faster downwards the route ($t(207) = 2.29$, $p = .023$, $d = 0.22$). This proportion (one out of 10) does not significantly differ from a 5% chance rate (binomial test $N = 10$, $\pi = 5\%$: $p = .401$).

We found no effect of pointing in walking order which is expressed by the interaction between target direction and pointing order (time and accuracy both $F(1, 9) < 1$). Pointing to multiple targets in walking order (i.e., from start to current location or from the current location to the end) did not differ significantly from pointing in opposite walking order (i.e., from end to current location or from current location to start).

Discussion

The present study examined predictions from three different theories about how survey relations are derived from spatial memory. The three positions (read out from a cognitive map, mentally walking through a cognitive map, and constructing a mental model from a network of reference frames) predict specific performance differences for target directions and pointing order.

We found an effect of pointing order. Participants pointed faster to targets in the order away from the current location than towards the current location. This result suggests that pointing is based on an incremental rather than an all-at-once process. Navigators might mentally walk through a cognitive map and integrate the walked distance (Byrne et al., 2007) or they could stepwise construct a mental model of the non-visible environment until this model includes the target (Meilinger, 2008).

There was also an effect of target direction. On average, participants pointed faster to targets further down the route, than to targets route upwards to the start. When looking at target direction effects for each individual, more participants than expected by chance showed a significant effect of target direction in their pointing accuracy. Half of these pointed more accurately towards locations further down the road, the other half pointed more accurately towards targets upwards the route. These results in pointing accuracy suggest different strategies in the encoding of an environment. Some participants might have encoded multiple local environments (e.g., rooms, streets, etc.), updated the last environment while walking to the next environment and stored the updated vector pointing backwards to the last environment. Deriving survey relations from this string of backwards connected locations should be easier in a backwards direction. For locations route downwards the connection would have to be inverted which is an additional process and thus an additional source of errors. Another group of participants seems to have encoded multiple local environments in the opposite direction (i.e., in the direction they walked the route). They could have derived the interconnections from their visual input: they saw how the route was going on (e.g., 30 meters straight on, then turn to the right) and used this information for connecting encoded locations, thus resulting in a forward connection. For them, constructing a mental model in forward direction did not involve in-

version of the interconnection and thus resulted in more accurate pointing. The third group of participants did not show a significant effect of target direction on the level of the individual. They might have formed a cognitive map and used this representation for pointing (likely by mental walk). Alternatively, their orientation bias was not strong enough to reach the significance level. The time advantage for pointing route downwards when averaging across participants might simply be an effect of averaging across the groups and could suggest that forward encoding was more likely than backward encoding.

The results reported here were found in a virtual reality setup. Therefore, we cannot exclude the possibility that participants might behave differently in real environments. However, the present setup provided most of the bodily and visual cues also available when walking through a real environment (proprioceptive feedback, efference copy, vestibular stimulation, motion parallax, stereo vision, texture gradient, familiar size cues, etc.). Also, on average pointings were quite precise. A generalization to real environments does, thus, not seem implausible.

One major limitation is the small sample size. More participants are needed to see whether the effects observed are really stable. With more participants we will also be able to directly compare the different subgroups in target direction and have a closer look at their strategies.

This study examined how navigators derive survey relations used for pointing or short cutting from memory of an environmental space which they have to navigate through in order to experience it. Our results suggest that pointing is based on an incremental process as predicted by mentally walking a cognitive map or by constructing a mental model of the non-visual environment. At least for some participants we found indications for a direction specific encoding of such an environment (i.e., a string of location representations connected via directed links). Their pattern of performance is consistent with a mental model construction based on such a memory. Future experiments will have to clarify the exact circumstances which yield which kind of memory.

Acknowledgments

This research was supported by the DFG grant “The functional, computational and neural basis of human survey knowledge – comparing mental maps and mental graphs”, the Max Planck Society and by the WCU (World Class University) program through the National Research Foundation of Korea funded by the Ministry of Education, Science and Technology (R31-2008-000-10008-0). The authors thank Jan Souman for help in planning the experiment, discussing the results and writing the paper, Nadine Simon for help in data collection, Joachim Tesch, Michael Kerger, and Harald Teufel for intensive technical support, as well as Johanna Steffen for proof reading.

Alignment of Spatial Perspective

Elena Andonova (andonova@uni-bremen.de)

SFB/TR8, University of Bremen, Cartesium, 7 Enrique-Schmidt Str.,
Bremen, Germany

Abstract

Most of the experimental research on dialogue that has provided evidence for interactive alignment focuses on speakers aligning at the lexical and syntactic levels of representations and dialogic contributions, i.e., having converging choices of lexical and syntactic means of referring to pictured objects and events. Less is known about alignment at the conceptual level, or situation models. This paper addresses alignment in spatial perspective (route vs. survey perspective) between speakers in a confederate experimental task taking turns in describing routes on schematic maps. The findings of two experiments show that speakers' spatial perspective choices are aligned with those of their partners both before and after partners switch perspective. Furthermore, this alignment effect holds both if partners show consistency adhering to the same perspective for a sequence of descriptions and when they display inconsistency by switching spatial perspective for every new description they provide.

Keywords: spatial perspective; interactive alignment.

Introduction

Imagine asking someone on the phone for directions on how to go some place while looking at a simple map. Now imagine being told to go 'left' while your current orientation is facing 'downward' on the map. This is potentially a problem because of the ambiguity inherent in this term. It is unclear if *left* is mapped onto your perspective and orientation at a given time as situated in the environment or to be interpreted from the external viewpoint of looking at the map as if from above. Now imagine further that it is your turn to make a suggestion for a route to the person on the phone. How likely are you to use the same perspective your partner used just now vs. another? The inherent ambiguity of terms such as *left* and *right* when produced and understood within different perspectives and frames of reference is an excellent testing ground for frameworks of interaction and coordination in a dialogic situation.

The interactive alignment model (Pickering & Garrod, 2004) posits that much of speech production choices in dialogic situations can be explained via an automatic mechanism involving priming at multiple levels of linguistic representation and percolation between these levels. Furthermore, alignment of situation models is achieved on the basis of such lower-level alignment of representations. While the model also allows for alignment via explicit reasoning and modeling of the partner's mental states and mental model updating, it places a particular emphasis on

these low-level mechanisms. Alternative accounts of dialogue behavior question the explanatory power of automatic priming in dialogic convergence and underline the role of (explicit) modeling of partners and their mental states of representation. Common conversational ground is the outcome of a joint effort on behalf of interlocutors who attend to the degree to which information is mutually shared (Clark, 1996).

Research on dialogue has addressed how speakers deal with variability and ambiguity in order to achieve alignment of situation models. One and the same object or event can trigger multiple perceptual and conceptual representations. For example, in a study of goal-directed dialogue (Garrod & Anderson, 1987), different description schemes were used by speakers referring to a maze and movement in it (path, coordinate, line, figural schemes). Similarly, in a study of how people describe complex multiple-object scenes, speakers' choices varied significantly depending on the nature of the array (Andonova, Coventry, & Tenbrink, in press).

Multiple perspectives, or ways of speaking about the world, are reflected on different levels of language but also in variation at a conceptual level. In spatial reference, different conceptualizations can be found in the choices of spatial perspective and frames of reference. In particular, perspective taking involves abstracting from the visual scene and organizing and packaging information in accordance with one or another type of viewpoint. Spatial perspective varieties can be characterized in different ways. Here we will adopt a binary distinction which is a simplified yet common typology. A route or environment can be described from an embedded (route or egocentric) perspective, that is, from within the environment, based on the way-finder, as embedded in the path, or from an external (survey or allocentric) perspective, that is, a viewpoint external to the environment, commonly associated with maps and cardinal directions, the way people would look at a map or a drawing of a route. For the sake of brevity and simplicity, here we will refer to these as the route perspective and the survey perspective. Previous studies have demonstrated that a number of individual, environmental, and learning factors are sources of variation in spatial perspective in verbal descriptions. Mode of acquisition has been shown to affect perspective choices in spatial memory; for example, participants who studied maps gave more accurate responses later in survey perspective tasks whereas those who were navigating gave more accurate responses to route perspective tasks (Taylor, Naylor, & Chechile, 1999). Taylor & Tversky (1996) tested

the influence of four environmental features on spatial perspective choices and found that although overall most participants' descriptions followed a survey or a mixed perspective, preference for the use of route perspective was enhanced in environments that contained a single path vs. multiple paths and environments that contained landmarks of a single size scale vs. landmarks of varying size. Bugman, Coventry, and Newstead (2007) found that context of retrieval (frequency of visitation vs. importance of activities) can affect spatial perspective choices, too.

Variability in spatial perspective choices is frequently accompanied with perspective switching behavior—participants tend to mix perspectives quite regularly, for example, 27 out of 67 participants in Taylor & Tversky's (1996) first experiment and 74 out of 192 participants in their second experiment mixed perspectives in their descriptions. There are multiple reasons why a speaker may switch from one perspective to another, for example, because of some features of the environment or the task. However, although most studies have researched spatial perspective choices in a monologue setting, one important reason for initial perspective choice and subsequent switches may be the behavior of the interlocutor (conversation partner) in a typical dialogue setting of giving road instructions, for example. Two exceptions to the dominant monologue settings of spatial perspective research are a study by Schober (1993) which showed that speakers set spatial perspectives differently with actual addressees than with imaginary ones and another by Striegnitz, Tepper, Lovett, & Cassel (2008) in which there was an increased use of survey perspective in response to clarification questions and in re-phrasal of previously given route descriptions.

The variability of spatial perspective and perspective switching make this phenomenon a suitable testing ground on coordination of speakers' choices in dialogue. Thus, two strands of research and related questions are in the combined focus of this paper—spatial perspective use and interactive alignment.

When dialogue partners refer to the same scene, they select a frame of reference or a perspective for the description. Thus, in dialogue, perspective use and perspective switching are part of the overall process of coordination. Does choice of perspective depend then on the previous use or preference for a certain perspective shown by one's dialogue partner, i.e., do speakers align in their choices of a spatial descriptive schema? If so, to what extent can this influence be modulated by the degree of consistency of partners' choices? Furthermore, how flexible is this process of coordination and perspective choice? Does the first 'conceptual pact' one strikes implicitly with one's partner remain dominant throughout an interaction, or alternatively, if the partner switches perspective, is one more likely to adhere to the previously used perspective, or to switch along, and re-align?

In the studies presented here, there were two clearly possible perspectives on the scene and route to be described: survey and route perspective. Route perspective is by far the

more natural way to describe routes whereas survey perspective is more typical of location descriptions. In order to enhance the probability of use of survey perspective and to bring the two more into balance, the maps to be described were positioned vertically, which also corresponds to viewing maps on a screen.

In the first experiment, we ask first whether speakers align choices of spatial perspective when their partner follows one perspective consistently in a short sequence of descriptions (four maps with routes). We also ask whether spatial perspective alignment persists even when the partner switches perspectives and offers a subsequent series of descriptions in an alternative perspective.

Experiment 1

As stated above, this experiment was designed to examine two related questions. First, whether speakers align on spatial perspective, and second, if they continue to align with their partners even when their partners switch perspective between an early and a later experimental block. If speakers rely only on a general model of partner preferences built on the basis of their experience during the early block, then perspective switch by the confederate would not reverse speakers' choices in accordance with the new spatial perspective bias exhibited in the later block. If speakers are sensitive not only to initial partner preferences but they also update their model of their partner (after the switch), then they should also show a tendency to switch perspective in a similar way. A third possibility also exists—the fact that their partners have used both route and survey perspectives and that they switched between them may reduce speakers' preferences for either perspective and lead them to choose between perspectives more or less randomly.

Method

The design of the experiment included prime perspective (route vs. survey) and experimental block (early vs. later) as independent variables and mean percent choice of route perspective on each experimental block as the dependent variable.

Participants 24 participants (3 male) took part in the experiment. They were university students with a mean age of 21.08 years (range 19 – 31) who received course credit or were paid for their participation. All were native German speakers.

Stimuli Thirty-two simplified map drawings were used in the study. Six different maps were created and a total of 16 different routes. Stimuli were pseudo-randomized with the constraints that no two consecutive maps should be the same, and neither the start nor the end points of the routes on consecutive maps should be the same. Routes were pre-drawn on the maps so as to exclude a route planning component in the task and focus exclusively on choice of spatial perspective (see Fig.1 for an example). There were

16 experimental trials (8 prime-target pairs) and 16 fillers. The maps and routes on the experimental prime-target trials were designed to be compatible with both route and survey perspective descriptions. Confederates' descriptions of routes were either in a route perspective or a survey perspective. Filler maps and routes were drawn in such a way as to minimize the use of spatial perspective, for example, a circular trajectory. Furthermore, confederates' scripted descriptions on these trials did not contain any indication of spatial perspective.

Each experimental prime-target pair was preceded by two filler items. There were two blocks of experimental pairs, an early and a later one. In accordance with the design of the experiment, the perspective of the confederate primes was consistent within each block and was either route or survey. However, confederates' scripted descriptions on the two blocks differed in spatial perspective, i.e., the confederate switched perspectives between the early and the later block of trials.

Figure 1: Example of a map and its pre-drawn route. The triangle indicates the position and orientation at the start.

Procedure Each participant was seated across a desk from the confederate and a visual barrier was placed between them and a stack of cards with identical maps and routes drawn were placed in front of them on a vertical stand. Cards were positioned vertically to motivate more the use of the generally weaker and less common survey/gaze perspective. In addition, the confederate used a list of pre-scripted descriptions matching their cards in either route or survey perspective. The scripted responses of the confederate were not visible. We took special care to minimize possible suspicions on behalf of the participants that their partner in the experiment may not be a naïve participant such as they were, including greetings, familiarization procedures, instructions, etc. Confederates were student assistants of the same age and population generally who were trained to act naïve. Participants and confederates took turns in describing the routes on these cards. A red and a green dot marked on the back of each card were used to indicate whose turn it was to speak. Confederates were the first to speak, thus ensuring that their utterances (primes) precede those of the participants on target trials. Participants were instructed to monitor the

descriptions of their partner for accuracy and to offer a correction whenever they noted an incorrect description. Three deliberate errors were built into the script on filler items. This instruction ensured that participants were attending to their partners' descriptions and choice of perspective. At the end of the experimental session, participants filled out a questionnaire which included questions asking participants to say what they thought the experiment was about and what they thought about their partner's behavior. As nobody indicated any suspicions that their partner may not have been a naïve participant such as they were, the data of all participants were accepted for analysis.

This procedural setup is a close replica of the procedure in Branigan, Pickering, McLean & Cleland (2007) which studied the effects of participant role on syntactic alignment.

Results

The pre-analysis procedure was identical for the data in Experiment 1 and Experiment 2 and will be described here jointly. Participants' responses were classified according to the spatial perspective used as belonging to one of three categories: route perspective, survey perspective, or mixed perspective. Experimental pairs on which the confederate made a mistake (1.99%) were excluded from the analysis, as well as those when the participant offered a correction to their partner's description of an experimental item (20.39%). Route perspective was the preferred default option and in the majority of these cases participants offered a 'correction' of the confederate's survey perspective description into a route perspective one. The following are examples of participant responses to the map and route in Fig.1 coded as route perspective (a), survey perspective (b), and mixed perspective (c) in their original German and in translation:

(a) *hier gehst du geradeaus und biegst dann links ab*
E. here you go straight and then turn left

(b) *hier gehst du erst nach äh links und dann nach unten*
E. here you first go uhm left and then down

(c) *hier geht's geradeaus und dann nach unten*
E. here one goes straight and then down

The data for each participant for each block (early and late) were converted into mean percent use of route perspective.

The hypothesis that speakers align at the conceptual level of spatial perspective was tested in a 2 (prime: route vs. survey) x 2 (block: early vs. later) analysis of variance on the mean percent use of route perspective. A main effect of prime perspective was found, $F(1, 44)=12.49$, $p=.001$, $\eta_p^2=.22$. No effect of experimental block (early vs. later) was found, and there was no interaction between experimental block and prime perspective. On the early block, participants in the *survey* prime condition described the routes drawn on

their maps in the route perspective only 54.92% of the time while those in the *route* perspective condition did so 88.92% of the time (Table 1). On the later block, following their partner's switch, participants primed by the *survey* perspective also produced significantly fewer descriptions in the route perspective than those who were primed by the route perspective (69.42% vs. 95.17%, respectively).

Table 1: Mean percent use of route perspective before and after prime perspective switch in Experiment 1.

	Early block (pre-switch)	Later block (after switch)
Prime: Route	88.92	95.17
Prime: Survey	54.92	69.42

Experiment 2

The results of the first experiment provided evidence for speakers' alignment with their partner at the conceptual level of spatial perspective both before and after their partner switched from route to survey perspective or the other way round. However, within each of the two experimental blocks, confederates adhered consistently to one perspective only. Thus, when they switched perspective on the later block, prime perspective also remained constant for all four experimental pairs within that block. It is not clear, however, whether speakers' alignment on spatial perspective may have been influenced by this high degree of consistency within an experimental block. The second experiment set out to test whether speakers would also show conceptual alignment of spatial perspective with their partner even if the partner showed high inconsistency and switched perspective all the time, that is, between trials rather than between experimental blocks (as in Experiment 1). Constantly switching perspective may make the confederate's choices appear more random and may thus lead participants to adopt a generally 'random' choice approach themselves. To distinguish between this possible outcome and systematic alignment with one's partner even in the face of the partner's inconsistency, a second experiment was conducted in which speakers' choices were analysed as a function of the immediately preceding prime for each target item.

Method

The design of the second experiment was basically the same with one exception. It included prime perspective (route vs. survey) and experimental block (early vs. later) as independent variables and mean percent choice of route perspective on each experimental block as the dependent variable. However, prime perspective in this case was inconsistent, i.e., constantly alternating between trials.

Participants 19 participants (3 male) took part in the experiment. They were university students with a mean age

of 21.32 years (range 19 – 28) who received course credit or were paid for their participation. All were native German speakers.

Stimuli The same visual stimuli were used as in Experiment 1. However, in this second experiment, the confederate switched between route and survey perspective on each trial. The first description they gave was route in one of the experimental lists and survey in the other. Thus, the perspective of the confederate primes was inconsistent.

Procedure The procedure was identical to the one used in Experiment 1.

Results

Participants' responses were classified according to the spatial perspective used as in Experiment 1. The data for each participant for each block (early and late) and for each prime condition (survey vs. route) were converted into mean percent use of route perspective.

A 2 (prime: route vs. survey) x 2 (block: early vs. later) analysis of variance on the mean percent use of route perspective revealed a main effect of prime perspective, $F(1, 61)=5.47$, $p=.023$, $\eta_p^2=.08$. No effect of experimental block (early vs. later) was found, and there was no interaction between experimental block and prime perspective. On average across early and later blocks, participants in the *survey* prime condition described the routes drawn on their maps in the route perspective 68.52% of the time while those in the *route* prime condition did so 88.16% of the time (Table 2).

Table 2: Mean percent use of route perspective on the early and later block in Experiment 2.

	Early block	Later block
Prime: Route	84.21	92.11
Prime: Survey	73.33	62.50

Discussion and conclusions

Experiment 1 showed that speakers do align spatial perspectives with their partners. Those who heard their partner use a survey perspective consistently on the early block of four consecutive experimental trials were less likely to adhere to the otherwise preferred default of route perspective and used instead survey perspective themselves or a mix of the two perspectives in their descriptions. The magnitude of this alignment effect on the early block was 34% and although it was reduced somewhat on the second block to 26%, it nevertheless occurred on this later block of four experimental trials as well. What is more, the 8% reduction was not so considerable as to produce a statistically significant interaction between prime perspective and experimental block, i.e., the alignment

tendency appeared to be equally strong across blocks. This is particularly striking in view of the nature of the second (later) experimental pairs. During those trials, the confederate used the alternative perspective to the one he or she used on the early block, thus displaying a switch from survey to route perspective or vice versa. In this sense, although on each set of four consecutive trials the confederate had made consistent perspective ‘choices’ in their descriptions, across the two experimental blocks their behavior appeared inconsistent, and yet, participants had the same tendency to align with their partners later as well as earlier during the experimental session. This is notable for two reasons. First, it shows that spatial perspective is used flexibly, and that speakers make use of the possibility to switch perspective with relative ease. Second, it also shows that speakers were not entrained on the first perspective only that they heard their partner use but that they updated. In this sense, this experiment has provided evidence for speakers’ sensitivity to their partners’ changes in behavior and preference for a representation scheme.

Participants’ alignment with their partners in spatial perspective in the first experiment was not significantly reduced on the later post-switch experimental block. However, one good reason for this persistence of alignment even after the switch *between* experimental blocks may have been that the behavior of their partners *within* experimental blocks remained consistent. Experiment 2 put this possibility to the test. Here confederates’ pre-scripted descriptions switched between the two perspectives constantly, i.e., if their first, third, fifth, etc. utterances were in a route perspective, then their second, fourth, sixth descriptions were in survey perspective, and vice versa. The analysis of the data revealed that participants aligned even in this case, i.e., they were more likely to use a survey perspective description after they heard their partner use one than if they heard their partner use a route perspective description, an alignment effect of almost 20% difference in choices. Furthermore, this effect did not interact with experimental block (early vs. late), that is, the alignment tendency did not become weaker as time went on. Although the interaction did not reach statistical significance, it is worth noting here that numerically the perspective alignment effect in the later experimental block was much greater (almost 30%) than in the early block. If nothing else, the tendency to align appeared to have been enhanced later. Note that there was no general difference between the early and the later block in this second experimental design, i.e., no sudden change of partner behavior unlike the switch between blocks in the first experiment. In this sense, the growing alignment tendency could be interpreted not as enhanced activation of one of the spatial perspective schemes but more of a general (perspective non-specific) convergence across speakers and accumulation of priming. However, this interpretation can only be offered with a proviso. As described earlier, items where the participant objected to the description used by their partner were not included in data for analysis as priming could not be tested

because of an interruption of direct the prime-target sequence and possible interference from self-priming by the alternative ‘correction’ that participants used in both experiments, although such trials occurred less frequently in the second experiment. Nevertheless, the important finding from Experiment 2 was that speakers aligned in spatial perspective even in cases where their partners exhibited a highly inconsistent descriptive behavior by constantly switching between the two perspective schemas. Such inconsistency by the partner did not lead participants to view either perspective as equally suitable and then adopt one of the two as the easy, less effortful strategy. It did not lead them to make random choices, either. Instead, participants aligned systematically with their partners, i.e., they were prepared to switch perspectives regularly.

Further research into spatial perspective alignment will help solve more mysteries. A memory task experiment (Andonova & Coventry, 2009) has revealed spatial perspective priming. A comparison of the two studies indicates common underlying mechanisms that need to be explored further.

The main conclusions of the two experiments described here are as follows. We found evidence for spatial perspective alignment across speakers in a route description task. Perspective alignment was sensitive to consistency of use by one’s partner in the early stages of the interaction (a much weaker alignment tendency of approximately 10% on the early block in Experiment 2 in comparison with the robust 34% effect in Experiment 1). Perspective alignment persisted even after a switch in partner behavior, i.e., alignment persisted even when perspective did not.

Abstract

Establishing and updating spatial relationships between objects in the environment is vital to maintaining situation awareness. Wang et al. (2005) found that updating of spatial representations in the intrinsic frame of reference (IFOR) can be prioritized based on salience of task demands. But their study used a task environment with only one IFOR. Often a task environment has several objects in it which may be task-relevant, and they may conflict with each other in one or more ways such as by being oriented in differing directions. Two experiments manipulated relative spatial orientation and task salience of two task-relevant objects such that the objects' orientations conflicted with each other and the task probabilistically demanded response based on the orientation of one or the other object. It was found that spatial updating in the IFOR was constrained by the limits of human attentional processes. Furthermore those constraints can be relaxed with practice.

Keywords: prioritized representation updating; conflicting spatial representations; spatial cognition; intrinsic frame of reference.

Introduction

Spatial cognition is crucial to our everyday interactions with our environment and other people including, for instance, maintaining awareness of one's task environment. A large body of evidence suggests that people organize spatial representations and reason about spatial relationships using frames of reference (FORs, (Levinson, 1996; Wang, Johnson & Zhang, 2001). FORs can be based on our own viewpoints, expressing spatial representations that are centered on ourselves (the egocentric FOR, "EFOR"). EFORs represent spatial affordances within our immediate vicinity, such as a pencil that is within reach. FORs based on navigable environments (the allocentric FOR, "AFOR"), such as rooms, buildings, or cities, represent the shapes of those environments and what affordances they give to wayfinding (Klatzky, 1998; Mou & McNamara, 2002; Wang & Spelke, 2002).

Most research in spatial cognition has focused on the EFOR and AFOR (May & Klatzky, 2000; Shelton & McNamara, 2001) though it is possible to distinguish a third type of FOR, the intrinsic (IFOR), so named because it is intrinsic to the person or object of focus (Mou & McNamara, 2002; Wang, Sun, Johnson & Yuan, 2005). The IFOR is a unique FOR that brings the spatial representation affordances of the EFOR outside the observer's body. The IFOR enables us to imagine spatial relationships from positions other than the one we currently occupy, including the positions of other people. This is important for action

planning, interpersonal communication of specific spatial representations, and even theory of mind. For instance, spatial relationships such as, "John is sitting to Mary's right." are represented in the IFOR. Here Mary is the reference anchor around which the framework for the spatial relationship of John's position is based (Levinson, 1996).

Given the importance of IFOR-based spatial representations in everyday tasks, one fundamental question is how easily IFOR representations can be updated within the context of a changing environment. It has been shown that egocentric representations can be updated fairly easily whereas updating allocentric representations other than self-locations often requires effort. Wang, Sun, Johnson, and Yuan (2005) studied IFOR spatial representations and how they may be updated to reflect changes in the task environment, particularly as a function of a target object's task salience. They found that updating of spatial representations in the IFOR can be prioritized based on salience to task demands and that IFOR updating is often, but not always, easy for those salient objects. However their study used a task environment with only one IFOR-supporting object. Often a task environment has several such objects in it which may be task-relevant and they may conflict with each other in one or more ways such as by being oriented in differing directions. In the above example regarding John and Mary, we may also notice that "John is sitting to Sam's left." In this case, John's spatial location is represented in an IFOR centered on Sam and that spatial relationship to John is not the same for Mary and Sam. When John moves, both Mary's and Sam's spatial representations should be updated.

Presumably increasing the number of task relevant IFOR-supporting objects would increase task complexity and consequently demand more attentional resources. At a certain point people will have to prioritize not only their updating of spatial representations of the targets of their actions but also the reference anchors of those spatial representations. In other words, if there are multiple IFOR-supporting objects that must be attended in a task environment then people will need to prioritize their updating not only of the action-target objects but also of the IFOR-supporting objects.

A "Two Cannons" pointing task was designed to test hypotheses regarding updating priority in a two-IFOR spatial task environment. In this task participants needed to determine which way a depicted cannon should turn to point at a designated target. Salience of the two cannons varied so as to make one or the other more important to the completion of the task. If people can attend to only one

IFOR at a time then in a an environment where multiple IFORs may exist updating those representations must be prioritized somehow. If priority of updating between IFORs goes according to salience, as Wang et al. (2005) found for updating target priority within one IFOR, then response time should vary with the targeted IFOR's relative salience. That is, when two IFORs conflict the conflict should be resolved most easily in favor of the more salient IFOR. Furthermore, if people can only form one IFOR at a time they may wait to see which IFOR to use before they invest the time in forming it. Then we would expect an effect of conflict as they wait to see which IFOR to use but no effect of relative IFOR anchor angle since anchor angle would be irrelevant to IFOR selection. On the other hand if people can form and maintain multiple IFORs simultaneously then when the IFOR anchor objects conflict with each other on some dimension (e.g., orientation) there should be an effect of relative IFOR orientation angle such that at one angle the irrelevant IFOR may be easier to inhibit than at another angle.

Experiment 1

We designed a “two cannons” turning response task to investigate how people represent spatial information with multiple conflicting IFORs and how they resolve the conflicting attentional demands of updating spatial relationships involving multiple IFORs. The task required participants to determine the location of a designated target relative to a matching-color IFOR anchor, one of the two cannon stimuli. Orientation of the cannon stimuli varied so that turning direction responses dependent upon those orientations would conflict based on the orientations of the two IFOR anchors, the cannons, with respect to the indicated target. Task salience of the two anchors also varied so as to weight the conflict in favor of one IFOR or the other. If IFOR updating tends to be prioritized according to salience as Wang et al. (2005) found, then response time for each IFOR should be a function of that IFOR's relative salience. That is, when two IFOR spatial relationships conflict, the conflict should be resolved most readily for the more salient IFOR.

Figure 1. Experiment displays depicting 0° relative cannon angle (A, left), 90° cannon angle (B, center), and 180° cannon angle (C, right). Here blue is depicted as dark gray and red is light gray. In A both cannons (depicted as half red, half blue) are at 270° orientation. The highlighted blue dot indicates the target. In this case the correct response would be to punch the up arrow key to indicate that no turn is required. In B the correct response would be to punch the left arrow key, indicating that the blue cannon would have to turn to its left to face the target. In C the correct response would be to punch the right arrow key, indicating that the red cannon would have to turn to its right to face the target.

Method

Participants Ten graduate students and postdoctoral fellows were paid to participate in Experiment 1. Subjects had a mean age of 32.1 years ($SD = 7.75$) and five were female.

Design Table 1 enumerates the conditions for Experiment 1. We established conflict in the cannon IFORs by manipulating relative angle between the two cannons so that the two cannons either were on top of each other as in Figure 1A, at 90° to each other (Figure 1B), or 180° to each other (Figure 1C). We used 90° & 180° to compare degree of conflict. The ratio of blue dots to red dots varied sequentially within each trial block, always starting at 8 blue to 0 red and transitioning in increments of 2 dots to 0 blue to 8 red. Color ratio conditions occurred as sub-blocks of eight trials, each of which exhausted the set of eight possible target locations. Thus each block of 40 trials exhausted each of five color ratio conditions once and each of eight target location conditions five times for one combination of relative cannon angle and cannon orientations. Relative cannon angle and cannon orientations varied randomly by block.

Materials The experiments ran on a PC in E-Prime version 1.2. The two cannons subtended a viewing angle of

Table 1. Combinatorial table of conditions of Experiment 1. All factors varied within-subjects, except color ratio.

Relative Cannon Angle	Cannon Orientation (specific to each cannon angle condition)	Target Position (all cannon angle conditions)	Target Color (all cannon angle conditions)	Dot Color Ratio (all cannon angle conditions)
0°	90°(blue & red)	0° – 315°, with 0° being up and incrementing clockwise in steps of 45°. 8 positions total. Varied randomly, without replacement, within each color ratio cycle.	red or blue, varied randomly within each color ratio cycle, constrained by color ratio condition.	8 blue : 0 red – 0 blue : 8 red, in increments of 2 dots. 5 color ratios total. Varied sequentially within each trial block.
90°	270°(blue & red)			
	45° (blue) & 315° (red)			
180°	135° (red) & 225° (blue)			
	90°(blue) & 270°(red)			
	90°(red) & 270°(blue)			

approximately 6° while the entire display of cannons and surrounding dots subtended a viewing angle of approximately 12°. The cannon stimuli were constructed such that they each had an obvious intrinsic orientation (Figure 1). They appeared as though viewed from above, with wheels at their rear and a barrel in the middle, extending far forward.

Procedure Upon onset of the stimulus display, the experiment paused for one second before it flashed a yellow ring around one dot to indicate that it was the target. The matching-color cannon thus became task-salient. Participants were to then respond as quickly and accurately as possible which way the salient cannon should turn to face the dot: left, right, or no turn. Responses had the stipulation that the turn was to be the shortest way round. Participants indicated their responses with the left, right, and up arrow keys, respectively. In the case wherein the target was directly behind the indicated cannon, participants could respond either left or right as turning either way would result in a change in cannon orientation of 180°. The experiment played a “zap” sound as feedback for a correct trial. In the case of incorrect trials the experiment paused for two seconds to discourage random guessing and it played a distinctive “uh oh” sound. Subjects erred on fewer than 5% of trials on average.

Results and Discussion

Data from both experiments were filtered for subject error and outliers, outliers being outside the subject’s mean \pm 3 standard deviations. This removed approximately 5% of observations. Figure 2 depicts effects on response time of the interaction of target color and dot color ratio. Again, in Experiment 1 color ratio sequence began with all blue dots

Figure 2. Experiment 1 response times as a function of the interaction of target color and dot color ratio. Within-block color ratio sequence progressed left-to-right along the x-axis. Error bars depict standard error of the mean.

and transitioned gradually to all red dots (i.e., from 8 blue : 0 red to 0 blue : 8 red, hereafter abbreviated #blue:#red for Experiment 1). Repeated measures ANOVA found that target color by color ratio linear by linear interaction contrast was reliable, $F(1, 9) = 39.25$, $p < .001$, meaning that the RT function of blue targets and red targets over color ratio differed. In addition, Color ratio’s main effect was reliable, $F(3, 27) = 8.38$, $p < .001$.

The results suggest that for the blue targets as the blue cannon became less salient as the number of dots transitioned from blue to red, the ability of subjects to respond to the blue cannon did not fall off, it stayed the

Figure 3. Experiment 1 RTs by target color, cannon angle, and color ratio condition. Error bars depict SEM.

Figure 4. Experiment 1 RTs by target bearing at color ratio 8:0. Error bars depict SEM.

same. This is surprising given that as the blue cannon decreased in salience subjects should have paid less attention to it, thus taking longer to recognize and respond to a rare blue target trial. Additionally, the preservation of the ability to respond to blue did not come at the cost of responding to red, as red targets showed a dramatic decrease in response time across the color ratio condition progression. This indicates little or no strategic trade-off of prioritizing one IFOR over the other.

Breaking the interaction down to more specific experimental conditions, it is clear that IFOR conflict mattered when interacting with color ratio (Figure 3). Collapsing across 90° and 180° cannon angles gives an abstracted conflict versus no conflict (0° cannon angle) contrast. With five post hoc comparisons for this family of tests of the target color by color ratio by conflict interaction, the Bonferroni-corrected $\alpha' = .01$. Conflict by target color was not reliably different for blue targets ($t(9) = 3.028, p = .014$), but was for red ($t(9) = 3.821, p = .004$). This means that conflict in IFORs was a product of task demands, which in turn was a combination of IFOR spatial properties and probabilistic IFOR selection properties. The 90° versus 180° cannon angle difference was not reliable (for red targets in the 2:6 color ratio condition, $t(9) = 3.095, p = .013$). Furthermore the slope of the conflict versus no conflict by color ratio interaction function was different for blue targets, but not for red targets: $t(9) = 3.903, p = .004$; and $t(9) = -1.779, p = .109$, for blue and red respectively. This means that for blue targets as the color ratio progressed from blue to red RTs got slightly faster for 0° cannon angle trials but slower for 90° and 180° cannon angle trials. This indicates that participants really saw the two overlapping cannons as one IFOR in the 0° cannon angle condition, whereas the 90° and 180° cannon angle conditions worked well as a manipulation to induce IFOR conflict. When the color ratio was 6:2 the cost to switch attention on the IFORs can be calculated as the difference between the RTs for the blue and red targets within the conflict condition. That switching cost was 257 ms.

The 8:0 condition might be taken as a base case of the two cannons task in that the color ratio of the dots perfectly

predicts target color, and therefore which cannon participants should attend. Here, then, we can get a sense for target bearing's RT function (Figure 4). It shows that targets at 135° and 225° bearing took longer to respond to than targets at other bearings (except 180°, which was subject to Hick's Law since participants could respond either direction to this target bearing), $t(9) = -3.848, p = .004$.

Kessler & Thomson (2010) used a similar response scheme in their perspective alignment task. They found a flat target bearing function except for longer RTs at 135° rotation in either direction. They speculated that visual comparisons could be made up to about 90° of rotation but that greater degrees of rotation required complex imaginal transformations that took longer. Presumably the same cognitive and perceptual-motor processes take place with the two cannons task since it also requires the alignment of perspectives with the IFOR of the designated cannon.

However, the target bearing function went flat for conditions where a switch of attended cannon was likely, namely when the target belonged to the non-salient IFOR. For instance, when the color ratio was 2:6, a red target was more likely to appear than a blue target. That probability difference made the red cannon more task-salient. Subjects could therefore save some response time by attending the red cannon during the SOA. But if the target turned out to be blue then subjects would have to move attention to the blue cannon and establish a new IFOR around it. When this happened RTs were not longer for 135° or 225° target bearing, contrast for blue targets at 2 blue to 6 red $t(7) = -.997, p = .352$; contrast for red targets at 6 blue to 2 red, $t(7) = -2.087, p = .075$. Note that $df = 7$ for these two analyses as two subjects were missing data for these cells, likely due to subject error or outlier RTs. The 135°/225° target bearing effect probably went away for these two conditions because target position would already have been known when it became clear that the non-salient cannon must form the basis of the response. Target bearing could then be integrated during the IFOR attention switch latency rather than, as in the 8:0 color ratio condition, having all other representations formed before target onset and being the last representation left to be formed before responding.

It could be that each piece of the spatial information is acquired and represented as it becomes available, and that pieces are retrofitted into the rest of the representation as needed. This could mean that in 6:2 with a red target, for example, the potential targets have their representations built first (maybe in association with the more likely IFOR), and after the target onset the targeted IFOR is built and retrofitted to the extant spatial environment representation.

Experiment 2

The asymmetry of the target color interaction with color ratio found in Experiment 1 was unexpected, and if real, could imply that people, with practice, may be able to maintain representation more than one IFOR at a time. As trial blocks progressed and blue became less salient then response times for blue targets should have become longer as the blue cannon reduced in updating priority relative to the red cannon. Instead a practice effect on the blue IFOR was apparently sufficient to cancel the expected probability

Figure 5. Experiment 2 RTs as a function of the interaction of target color and dot color ratio. Within-block color ratio sequence progressed left-to-right along the x-axis. Error bars depict SEM.

matching effect for the blue IFOR. However, it is also possible that the interaction effect could be due to sequence effects of color ratio presentation order. Experiment 2 was designed to test this possibility by replicating Experiment 1 except that dot color ratios were sequenced in the opposite order, this time going from red to blue within each block.

Method

Ten graduate students and postdoctoral fellows were paid to participate in Experiments 2. Subjects had a mean age of 32.1 years ($SD = 6.03$) and four of them were female.

Experiment 2's design duplicated Experiment 1's except that color ratios incremented from all red to all blue rather than blue to red as in Experiment 1. Experiment 2 replicated Experiment 1's materials and procedures identically.

Results and Discussion

The target color by conflict by color ratio interaction of Experiment 1 replicated in Experiment 2 (Figures 5 and 6), the different color ratio sequence notwithstanding (linear by linear interaction contrast of color ratio with target color $F(1, 9) = 96.6, p < .001$). With four post hoc comparisons for this family of tests, the Bonferroni-corrected $\alpha' = .0125$. Blue targets with conflicting IFORs took longer for subjects to respond to than blue targets with no conflict, contrast $t(9) = 4.629, p = .001$; and likewise for red targets $t(9) = 4.119, p = .003$. Also for red targets with conflict RTs got longer as the color ratio transitioned to more blue dots while the RTs became shorter for red targets with no conflict ($t(9) = -5.865, p < .001$), but the same was not true for blue targets ($t(9) = 3.035, p = .014$), all blue target RTs got shorter regardless of conflict status. This means that when subjects had to choose between IFORs (conflict), practice effects interacted with the time costs associated with switching attention between IFORs and the fact that target color was selected probabilistically from the set of dots. The time costs existed in turn because only one IFOR could be attended at any one time and moving attention from one to the other cost 215 ms.

As for target bearing, 135° and 255° were again slower than other target bearings, 180° excluded, in this experiment's color ratio and target color "base case," $t(9) = -2.706, p = .024$ (Figure 7). The two target bearings were not reliably different for blue targets at 2 blue to 6 red ($t(6)$

Figure 6. Experiment 2 RTs by target color, cannon angle, and color ratio condition. Error bars depict SEM.

Figure 7. Experiment 2 RTs by target bearing at color ratio 0:8. Error bars depict SEM.

= -1.193, $p = .278$), nor for red targets at 6 blue to 2 red ($t(9) = -1.721$, $p = .119$). So again, having to switch IFORs precludes the kind of processing that yields the Kessler and Thomson (2010) type of target bearing effect.

General Discussion

People use IFORs every day. In social contexts, for example, we often infer various inter-personal relationships based on the spatial relations (such as position and distance) among people. Humans must know how to prioritize updating of IFORs so that the most relevant IFORs are represented sufficiently richly to support the task at hand. The present study extends the findings of Wang et al. (2005) to study prioritization and updating among multiple IFORs. Spatial updating was found to be significantly constrained by the limits of human attentional processes as evidenced by a switching cost of approximately 236 ms (averaged across the two experiments). But those constraints can be relaxed somewhat with practice, as our interaction effect of target color with color ratio showed. The results indicated that subjects engaged in little strategic trade-off of prioritizing one IFOR over the other, as apparently the cost of attending one IFOR-supporting object or the other, and engaging the target bearing representation based on that IFOR, decreased somewhat with practice. In a larger sense this suggests that since the cognitive mechanisms supporting IFOR-type representation are apparently susceptible to practice effects, that reasoning comes relatively late in the human attentional stream.

Meanwhile the conspicuous absence of a target bearing effect for the conditions in which a switch of attended IFOR was likely hints that the establishment of an IFOR is able to take advantage of spatial representations already in working memory. IFORs, therefore, may be limited to one instantiation at a time as a function of human working memory capacity, but they may be disbanded and instantiated dynamically, taking advantage of whatever spatial representation may be available at the time to be incorporated into the IFOR to support task performance as necessary.

It is clear that attention plays a central role in mediating IFOR representational conflicts and in modulating salience.

Future work should clarify the computational mechanisms underlying spatial salience and people's capacity to effectively process spatial relationships in multi-IFOR task environments.

Learning from Environmental Regularities is Grounded in Specific Objects not Abstract Categories

Abstract

This paper examines statistical learning in the presence of predictive regularities at multiple levels of abstraction. Participants were presented with streams of pictures where picture order was predicted by both object identity and the categories these objects belong to. In Experiment 1, we establish that participants do learn based on the specific objects and not solely at the abstract, categorical level. In Experiment 2, we discount the possibility that participants gain abstract knowledge in addition to more concrete, object-based knowledge. Moreover, we consistently find equal learning in those who viewed the atypical exemplars and those who viewed the typical exemplars of the categories. Overall, our results suggest that when learning from environmental regularities, object-specific information takes precedence over more abstract, category level information when both are predictive.

Introduction

Throughout our lifetimes, it is clear that experience shapes our mental model of the world. Focusing on adulthood, adults learn to recognize new objects and categories as well as new properties of familiar objects; they learn new words and adapt to changing patterns in the ambient language, all by adapting future behavior based on experience. Despite the clear importance of learning from information in the environment, the nature of the mechanisms that support learning from real-world experience is largely unknown. A central problem in this literature is how learning mechanisms operate given the richness of the information we get from the world. Are learning mechanisms *a priori* constrained to learn particular patterns? Can learning proceed along many types of perceptual information and/or at different levels of abstraction¹ simultaneously?

In this paper, we focus on a type of learning called “statistical learning” where participants passively learn from

stimuli embedded with probabilistic information². Previous research has supported the view that these experiential learning mechanisms are unconstrained: statistical learning has been demonstrated in multiple sensory modalities (Conway & Christiansen, 2005), across a wide range of perceptual input. For example, in the visual modality, learning can occur from sequences of gestures (Baldwin, Andersson, Saffran, & Myers, 2007) as well as abstract shapes (Fiser & Aslin, 2001). While the majority of these studies have focused on learning probabilistic relations of individual items or objects, there is evidence that learning can occur at higher levels of informational abstraction including over new categories of nonsense words (Saffran, 2002) and based on familiar semantic categories (Brady & Oliva, 2008).

Overall, these studies support the view that environmental learning is unconstrained. That is, if there is any reliability probabilistic information in the environment, humans can learn from it regardless of level of abstraction or perceptual properties. If learning is entirely unconstrained, it is unclear how learning mechanisms operate in complex environments where information from multiple sources and at many levels of abstraction abounds.

However, these behavioral demonstrations of an entirely unconstrained learning mechanism arise from paradigms in which information is only predictive at a single perceptual and/or informational dimension. For example, while Brady and Oliva (2008) demonstrate learning of categories of scenes, participants were presented with a new scene from the category during each successive presentation. In this paradigm, individual scenes (e.g. beach₁ and beach₂) are not predictive of picture order, only the category of pictures are (e.g. a beach predict a kitchen but beach₁ does not predict kitchen₁), thus it would be impossible for participants to learn based on individual scenes. Thus, these results provide an existence proof of an unconstrained learning mechanism but they arise under specific, restricted conditions.

In actuality, environmental stimuli exhibit statistical regularities at many levels of abstraction, simultaneously.

¹ By “levels of abstraction” we are broadly referring to the multiplicity of ways in which a cognitive system can represent a given object or experience: e.g. your pet could be “Rex”, a beagle, a dog, an animate being, a brown object etc.

² In the current paradigm, a stream of pictures is embedded with regularities that predict picture order—predictive regularities. If participants learn from this probabilistic environmental information, they should be able to distinguish picture orders that they observed from scrambled or foil orders of pictures.

For example, the predictive relationship between dogs and leashes exists based on abstract categories as well as in the actual objects or exemplars seen in the world (e.g. dogs have their specific leashes). The learning paradigms reviewed above do not reflect this important aspect of information that we receive from the world: information is often redundant across multiple levels of abstraction.

The current paper systematically investigates learning where participants are exposed to environmental regularities at multiple levels of abstraction. Do participants learn from the multiple levels of predictive dependencies simultaneously or are they biased to information at a certain level of abstraction? To address this question, we devised a novel statistical learning task where predictive regularities are learnable and redundant at multiple levels of abstraction. Specifically, participants were presented with sequences of new exemplars from known categories. Both the categories (e.g. dogs-fish, flowers-birds) and the individual exemplars of these categories (e.g. dog₁-fish₁, dog₂-fish₂) were predictive of picture order (see Figure 1). In two studies, we examined whether participants learn simultaneously based on both types of information or whether participants learn preferentially based on categorical or object-based regularities.

We believe that the current experimental design provides ample opportunity for learning at the abstract, categorical level. First, previous research has established that the categories used in the current experiment are initially processed at the basic-level (dog as opposed to the subordinate level of beagle; Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976) which is the level of categorical regularities of the picture stream. Second, we employed the same stimulus timing (short durations and long inter-stimulus-intervals) as employed by Brady and Oliva (2008) which will likely tap into the fast, gist-based recognition of the pictures. Finally, the stream has fewer pairs of categories than objects (see Figure 1). Thus, category level learning is, in some sense, easier than object-based learning.

Using the same methodology as Brady and Oliva (2008) as described above, pilot testing confirmed that when categorical regularities are predictive of picture order but individual objects or exemplars are not participants can learn based on categorical regularities: mean = 62.6%, $t(13) = 2.80$, $p < 0.05$. These results confirm that if object-based regularities are not present, category-level statistical learning is possible using the current stimuli and categories.

Finally, in order to more closely examine how learning proceeds at the categorical level of information, we manipulated the typicality of the exemplars that participants viewed: roughly half the participants were familiarized with typical exemplars of the categories and the rest were familiarized with atypical exemplars (see Appendix 1 for the atypical exemplars). Research has consistently shown that atypical exemplars are processed differently from typical exemplars (Dale, Kehoe, & Spivey, 2007) and tend to be more quickly processed below the basic-level categories (e.g. penguin as opposed to bird; Jolicoeur,

Gluck, & Kosslyn, 1984). Thus, we expect the participants familiarized with atypical exemplars to have weaker learning at the category-level but equivalent learning at the object or exemplar specific level. This typicality manipulation provides another way to examine performance for evidence of learning across different levels of abstraction.

Experiment 1: Testing for Object-Level Learning

The first experiment examines learning based on regularities of individual objects where both objects and object categories are predictive of picture order. Figure 1 illustrates a sample familiarization stream. We employed a testing procedure that is well-established in the statistical learning literature (e.g. Brady & Oliva, 2008; Fiser & Aslin, 2001): participants were asked to distinguish pairs of pictures from familiarization (e.g. bird₁-dog₁) from a foil pair created from the same pool of pictures but which violates contingency pattern of the familiarization stream. To isolate knowledge at the object-specific level, the foils were designed to violate object-based regularities while maintaining categorical regularities (e.g. bird₁-dog₂, see top panel of Figure 2). Thus, participants *require* object-level knowledge of the familiarization stream in order to distinguish the foils from the pairs. Given this experimental design, if participants are able to consistently distinguish pairs from foils, this is evidence for learning based on the objects and not the categories presented during familiarization.

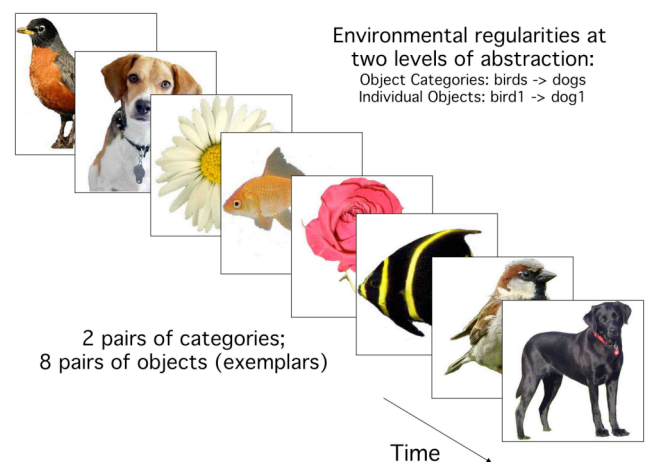

Figure 1: A sample familiarization stream. Pictures were organized into pairs of categories (e.g. birds > dogs) as well as specific objects within these categories (e.g. robin > beagle). Thus, predictive regularities were redundant across multiple levels of abstraction resulting in two pairs of categories and eight pairs of objects or exemplars of these categories.

Methods

18 undergraduate students participated in Experiment 1 (age: mean = 20.7, std = 1.75; 2 left handed; 10F) and randomly assigned to each condition: 10 participants viewed the typical pictures, and 8 viewed the atypical pictures. All participants were from Cornell University, participated in exchange for course credit, and provided informed consent.

Familiarization A statistically-structured familiarization sequence was presented, using PsyScope X B53 on a MacMini computer with a 17in CRT monitor. Each picture was displayed for 300ms with a 700ms inter-stimulus interval (Brady & Oliva, 2008)

There were 4 categories of pictures: birds, dogs, fish, and flowers. For each category 4 different exemplars were used (dog₁, dog₂, etc.). The pictures were grouped into 8 pairs such that both the categories and the specific exemplars were predictive of picture order. For example, bird₁-dog₁ would always occur as a pair, as would bird₂-dog₂, bird₃-dog₃, and bird₄-dog₄. Thus, the familiarization stream contains multiple, redundant levels of predictive information: both the exemplar level and the more abstract category level of information are predictive. See Figure 1 for an illustration of the familiarization sequence. To ameliorate any effect of specific pairings on learning, different categories and object pairings were employed across participants. Participants saw each pair 28 times presented in random order without pairs repeating each other and were simply instructed to look at the pictures.

Testing After familiarization, the participants performed a test in which two pairs of pictures were presented sequentially: 700ms between pictures in the same pair, and 1200ms separating the pairs. One pair was from the familiarization (e.g. bird₁-dog₁), and one was a foil pair (e.g. bird₁-dog₂; see Figure 2). The foils were designed to violate the structure *only* at the exemplar level, and not the category level. Thus, participants require exemplar level knowledge of the familiarization stream in order to distinguish the foils from the true pairs. This test determines whether participants learn the familiarization sequence at the level of exemplars or specific figures or at the level of abstract categories. The participants were instructed to choose which of the pairs seemed more familiar, based on the familiarization task. No time constraint was imposed for their responses. There were 64 test trials.

After the experiment, the participants completed a survey in which they rated the pictures they had seen on a scale of 1-5 for interestingness and typicality. They were also asked to repeat the instructions of each task, to ensure they understood them correctly. Finally, they were asked whether they noticed any patterns during the familiarization sequence, to check for explicit knowledge of the sequence structure.

Results and Discussion

The current experiment was designed such that only exemplar specific knowledge could distinguish pairs seen during familiarization and foils. Performance was evaluated against chance (50%) for evidence of learning. Overall, participants demonstrate evidence of significant learning (mean = 72.7%; std = 23.2; $t(17) = 4.15$, $p < 0.0001$) indicating that participants acquired object-specific knowledge. See the bottom panel of Figure 2 for a graphical presentation of the results of this experiment.

12 participants reported evidence of explicit knowledge via the post-test questionnaires. The majority of these reports involved category level knowledge, some with knowledge of specific pairings within these categories (e.g. “particular flower with certain fish” and “maybe bird w/dog, flower w/fish”). A very small number of reports were exclusively at an object level (“white bird with white flower combo” and “black lab, sunflower, etc”).

Data were submitted to an ANOVA examining the effects of exemplar typicality (Atypical vs. Typical) and explicit knowledge on test performance. Consistent with the findings mentioned in the introduction, we hypothesized that any contribution of categorical knowledge would be modulated by the typicality of the exemplars. We report no main effect of exemplar typicality ($F(1,14) = 0.307$; $p > 0.5$) nor interaction of typicality and explicit knowledge. The uniform performance across atypical and typical groups, as indicated in Figure 2, suggests no contribution from category-level knowledge in the current experiment.

We do, however, report a marginal effect of explicit knowledge of sequence structure ($F(1,14) = 3.96$; $p < 0.07$). We will address this issue more deeply in the results section of Experiment 2. Given that the current experiment was designed such that categorical knowledge could not be used to distinguish foils from pairs, and most evidence for explicit knowledge came as a report of predictive dependencies involving category level knowledge, it is unclear how explicit knowledge boosts performance. One possibility is that participants who achieve a high level of knowledge also achieve lexical access to the categories. Possibly knowledge of many of the pairs of exemplars induces category-level explicit knowledge.

In sum, participants were exposed to a sequence of pictures containing predictive dependencies redundant at the level of individual object and at a more abstract level of the categories these objects belonged to. Test performance indicates that participants gained object-specific knowledge. In addition, results suggest that participants do not acquire additional knowledge from more abstract, categorical regularities. We hypothesized that if participants do acquire categorical level knowledge, it would be modulated by object typicality. Results indicate no difference in learning between participants who received exposure to typical or atypical exemplars. Failing to find any difference between these groups suggests that participants learned from object-level regularities exclusively.

However, some participants do report explicit knowledge of the sequences. The majority of these reports included and sometimes were exclusive to abstract, object categories. These results indicate some awareness of the abstract properties of the stream. Moreover, we find that explicit knowledge has a marginally significant effect on test performance. It is unclear how explicit knowledge of this kind could aid in performance given that the experiment was designed to tap into object-specific knowledge only. Thus, while Experiment 1 provides strong evidence for object level learning, it does not entirely exclude the possibility that participants acquire some more abstract knowledge. In the second experiment, we more directly examine the possibility that participant learn from both categorical and object level predictive dependencies.

Experiment 2: Testing for Additional Category-Level Knowledge

The current experiment addresses whether participants learn from the predictive dependencies at multiple levels of abstraction simultaneously (e.g. objects: bird₁-dog₁; abstract, categories: birds-dogs). To this end, we modified the foils used in Experiment 1 while keeping all other aspects of the experiment the same (e.g. bird₁-dog₂). The foils in Experiment 1 violated the statistical regularities at the level of individual objects but preserved categorical regularities. Thus, object-specific knowledge but not category level knowledge would be essential in order to distinguish the pair from the foil.

In Experiment 2, we changed the foils to violate both object-level and category-level statistical regularities (e.g. bird₁-flower₃). Therefore, category knowledge as well as object-specific knowledge could be used at test. If it were the case that participants learn from predictive dependencies at *both* levels of informational abstraction, we hypothesize that it would be easier to distinguish foils in the current experiment, which violate both forms of statistical regularities, compared to the foils used in Experiment 1, where only object-level regularities were violated. However, if participants do not acquire abstract knowledge during familiarization, they will still be able to perform the test in the same manner as Experiment 1. Thus, if participants acquire abstract knowledge, we hypothesize a significant increase in performance in Experiment 2 from Experiment 1, and failure to observe a significant increase in test performance would indicate that learning does not occur at the abstract categorical level.

As in Experiment 1, participants viewed either typical or atypical exemplars. If participants acquire categorical knowledge during familiarization, this knowledge will likely be modulated by the typicality of exemplars. In Experiment 1, we did not observe any asymmetry of performance between these groups; however, categorical knowledge would interfere with test performance in this case. In the current experiment, categorical knowledge would be of benefit. Thus, we hypothesize that, if participants have access to category level knowledge after familiarization, participants who view typical exemplars will have a greater boost in test performance than those who view atypical exemplars.

Methods

Another 24 participants were recruited from the same subject pool and randomly assigned to each condition (16F, 1 left handed, age: mean = 19.6, std = 1.28): 12 viewed the typical pictures, and 12 viewed the atypical pictures. The procedure in this experiment differed from Experiment 1 in only one respect: the foil pairs during the test were designed to violate the statistical structure of the familiarization sequence at the exemplar *and* the category level.

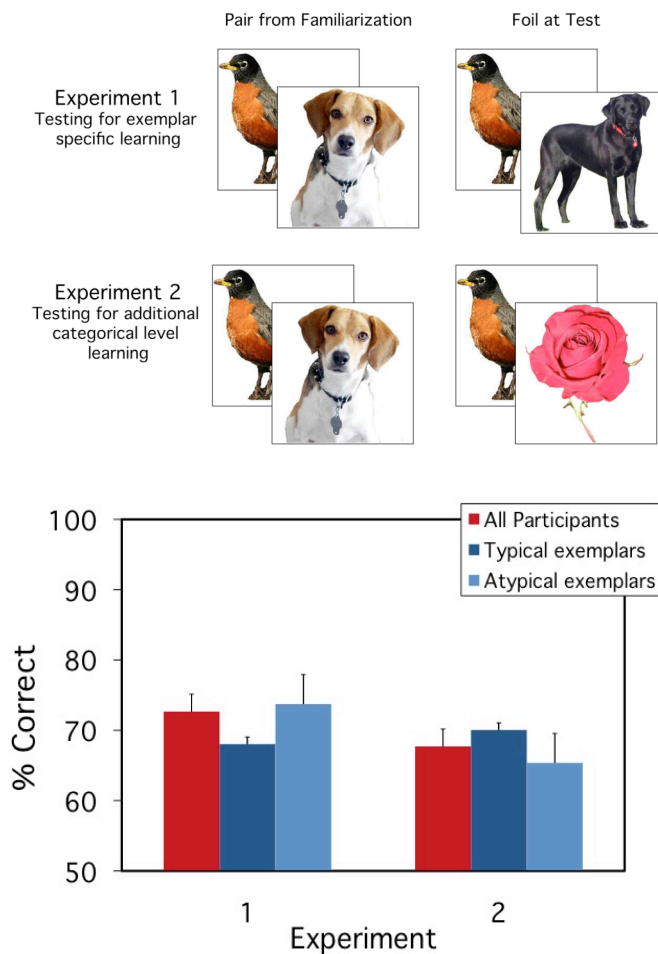

Figure 2: **Top Panel:** The sole difference between experiments was the composition of foils used at test. In Experiment 1, foils were designed to assess learning at the object or exemplar-specific level, while Experiment 2 foils allow for knowledge at both levels of abstraction (object and category) to influence test performance.

Bottom Panel: Results across Experiments 1 and 2 indicate no effect of exemplar typicality or foils on test performance.

Results and Discussion

We report significant learning overall in Experiment 2 (mean = 67.7%, std = 21.2; $t(23) = 4.10$, $p < 0.0001$). The data were submitted to a two-way ANOVA to evaluate the effects of typicality of exemplars and explicit knowledge. There is a main effect of explicit knowledge ($F(1, 20) = 110.2$; $p < 0.001$) and, as seen in Experiment 1, we report no main effect of typicality ($F(1, 20) = 0.537$, $p > 0.5$) or interaction between these factors. We hypothesized that if categorical knowledge was acquired during exposure that it would be modulated by the typicality of exemplars. The consistent null effect of exemplar typicality indicates that participants do not acquire abstract, category level knowledge during exposure to environmental regularities at multiple levels of abstraction.

We also hypothesized that if participants learned from statistical regularities about objects as well as categories, participants in Experiment 2 would performance better at test than participants in Experiment 1. Results from both experiments were analyzed in a 3-way ANOVA, to test for effects of experiment, typicality, and explicit knowledge on test performance. This analysis confirmed the pattern of results seen in the bottom panel of Figure 2: there is no main effect of Experiment ($F(1,35) = 0.440$, $p > 0.5$). Additionally, we confirm that across both experiments there is no main effect of typicality of exemplars ($F(1,35) = 0.081$, $p > 0.5$) and no interaction between these factors. Thus, test performance is equivalent across experiments indicating that participants likely did not acquire categorical knowledge during exposure to the familiarization stream.

Consistent with results found in both experiments separately, there is a main effect of explicit knowledge: $F(1,35) = 35.9$, $p < 0.001$. Pooling participants from both experiments, we find that participants with explicit knowledge performed better than those without (mean performance: 85.3% vs. 54.4%). However, both groups performed significantly better than chance (with knowledge: $t(20) = 8.07$, $p < 0.001$; without knowledge: $t(20) = 2.21$, $p < 0.02$). Thus, regardless of explicit knowledge there is evidence for learning in both groups.

To determine whether explicit knowledge is related to any of our experimental manipulations (e.g. typicality of exemplars), we examined whether number of participants who demonstrate explicit knowledge is biased towards either a particular experiment (Exp. 1 or 2) or typicality of the objects seen. Of the 42 subjects in both experiments, 21 reported knowledge of the structure, while 21 reported no such knowledge. Chi-square tests show that the proportion of participants who had explicit knowledge of the sequence structure was not significantly different between any of the experimental factors: Experiment 1 vs. Experiment 2: $\chi^2(1, N = 42) = 3.5$, $p > 0.05$; typical vs. atypical: $\chi^2(1, N = 42) = 1.09$, $p > 0.25$. These results indicate that explicit knowledge, while a significant factor affecting performance, is equally distributed across groups and thus should not disproportionately bias overall performance.

Finally, all participants rated both typical and atypical pictures on “interestingness” and typicality. T-tests comparing ratings within categories revealed that participants rate atypical and typical exemplars distinctly and also rate the atypical exemplars as more interesting ($t(134) > 3.5$; $p < 0.001$ within categories for both typicality and “interestingness”). These results validate the assumption that participants view atypical and typical exemplars differently.

Along with Experiment 1, these results support the view that participants learn from statistical regularities at the lowest level of representational abstraction even when more abstract statistical regularities are available to any learning mechanism. Specifically, the results from Experiment 2 cast doubt on the possibility that participants learn from predictive regularities at both levels abstraction.

General Discussion

Humans are able to learn from experience where complex regularities are present. We investigated behavior in a novel learning task designed to investigate a key aspect of the complexity of daily experience: participants viewed streams of pictures with predictive dependencies at multiple levels of abstraction. Specifically, both individual objects or exemplars and the semantic categories that these objects belonged to predicted picture order, thus both object and categorical information could be used determine the structure of the familiarization stream. We consistently find evidence for learning at the lowest level of abstraction: participants respond at test according the predictive dependencies of specific objects or category exemplars and do not show evidence of having learned at the more abstract level of categories even when abstract knowledge could aid test performance. Moreover, we find no modulation of learning by exemplar typicality. These findings suggest that while participants can learn from regularities of categories, they do not learn from more abstract regularities when less abstract, more grounded statistical information is present.

Interestingly, while we systematically find that categorical knowledge has no influence on test performance, some participants acquire explicit knowledge of the categorical knowledge of the sequence. This result is strikingly similar to Brady and Oliva (2008): in their Exp. 3, after viewing streams with regularities present solely at the categorical level, participants were able to perform consistently in a test where pictures were replaced with category labels. In Exp. 4, Brady & Oliva (2008) include regularities at the scene specific or object level in addition to categorical regularities and again find evidence for lexical access. We argue that lexical access results in Exp. 3 and 4 of Brady & Oliva (2008) are similar to the demonstration of abstract level explicit knowledge in the current experiment.

While demonstration of lexical access to categories is interesting and important, we repeatedly show that abstract knowledge does not have a clear effect in test performance, raising questions about the nature and function of this lexical knowledge. To date, there has been no demonstration

of generalization, an important hallmark of abstract categorical knowledge, when less abstract regularities are present. This is an important avenue for future study to clarify this lexical result. An alternative possibility is that the lexical access is a byproduct of the participant strategy of using mental labels for the familiar objects and scenes as they are being presented. Previous statistical learning studies have been careful to avoid recognizable visual objects for this reason (Conway & Christiansen, 2005; Fiser & Aslin, 2001).

Despite our findings that adults did not learn from abstract, category level regularities when object-based regularities were present, it is nevertheless clear that in a natural environment we do acquire knowledge of higher order regularities. Thus, our results may simply point to a direction of how this learning occurs: learning starts in the relation of specific objects when statistical regularities are comparable at multiple levels of abstraction. One possibility is that when once the least abstract regularities have been mastered, learning can proceed along more abstract dimensions. Nevertheless, this finding may have important implications for more efficient teaching methods and could inform computational modeling of learning and development of human cognitive processes where the abstraction of representation is often an assumption built into the model.

Overall, this study aims to uncover how simple learning mechanisms operate in complex, naturalistic environments. We increased the complexity of the learning task, relative to previous experiments, by having predictive dependencies at multiple levels of abstraction. Results indicate that participants learned based on the more concrete, less abstract predictive dependencies. Results also suggest that participants did not additionally learn the more abstract relationships as this knowledge consistently did not influence test performance. These results inform the ongoing debate as to whether domain-general learning mechanisms are largely unconstrained, as previous behavioral studies would have suggested. We believe that these results show some level of constraint on learning where more grounded, less abstract statistical relationships are learned preferentially when categorical and object specific knowledge is redundant.

Acknowledgments

Adult language learners under cognitive load do not over-regularize like children

Abstract

The “less is more” hypothesis suggests that one reason adults and children differ in their language acquisition abilities is that they also differ in other cognitive capacities: for instance, the relatively poor memory and/or processing abilities of children may make them more likely to over-regularize inconsistent input (Singleton & Newport, 2004; Hudson Kam & Newport, 2005). We investigate this hypothesis by placing adults under a high cognitive load using a standard task. Does their tendency to over-regularize in a simultaneous language-learning task increase? Results indicate that although the cognitive load is high enough to impair overall learning, neither the presence of load nor poor working memory predicts greater over-regularization. This suggests that if the “less is more” hypothesis explains over-regularization in children, the relevant cognitive capacity is not one that was impaired by our load task.

Keywords: language acquisition; over-regularization; statistical learning; memory; processing; development

Introduction

Children and adults differ both qualitatively and quantitatively in their ability to acquire a new language. Adults have difficulty with many aspects of language acquisition, from phonetic perception (Werker & Tees, 1984; Werker & Lalonde, 1988; Kuhl, 2004), to language processing (Clahsen & Felser, 2006), to certain aspects of syntax (e.g., Johnson & Newport, 1989; Birdsong, 2006). Scientists have proposed many theories to account for the difference between children and adults; these theories differ in both the degree and type of contribution made by pre-existing language-specific biases. Although nearly everyone agrees that (due to the inherent logical problem of induction posed by language learning) some bias must be necessary to explain successful language acquisition, explanations about the nature of the bias – and the difference between children and adults – vary considerably.

Some argue that there is a fundamental difference between first- and second-language acquisition. They posit that acquisition in children is guided by an innate Universal Grammar and by language-specific acquisition procedures, whereas adult acquisition is directed by more domain-general learning mechanisms (e.g., Bley-Vroman, 1990). However, there are many other possibilities, since children and adults also differ profoundly in their cognitive capabilities, knowledge, assumptions, and typical linguistic input. For one thing, learning a second language is made more difficult by interference from the first language; the evidence that experience with a first language influences acquisition of a second language is extensive (e.g., Mayberry, 1993; Iverson et al., 2003; Tan, 2003; Weber & Cutler, 2003; Hernandez, Li, & MacWhinney, 2005). This observation overlaps considerably with the related point that adult brains are less malleable than the brains

of children (Elman et al., 1996; MacWhinney, 2005). Adults and children also differ in their style of learning (Ullman, 2004) and in the nature of the social support (Snow, 1999) and linguistic input (Fernald & Simon, 1984) they receive.

The observation that children perform more poorly than adults across most domains of cognitive ability, including memory and processing speed, has led to another hypothesis, often called “less is more.” It suggests that the relative cognitive deficits in children may actually *help* with language acquisition by enabling them to isolate and analyze the separate components of a linguistic stimulus (Newport, 1988), or by leading them to over-regularize inconsistent input (Hudson Kam & Newport, 2005; Singleton & Newport, 2004). Indeed, it is apparent that children over-regularize while adults often do not. Deaf children exposed to the inconsistent sign language of hearing parents will over-regularize that language and produce regular grammatical forms (Singleton & Newport, 2004), as will children exposed to inconsistent input in an artificial language (Hudson Kam & Newport, 2005; Goldowsky, 1995). By contrast, adult language learners are known to produce highly variable, inconsistent utterances, even after years of experience with the language and after their grammars have stabilized (Wolfram, 1985; Johnson, Shenkman, Newport, & Medin, 1996).

The difference between children and adults has also been found in non-linguistic domains. If adults must predict some phenomenon (e.g., a light flashing or a certain card being drawn from a deck), they will tend to probability match: if the phenomenon occurs 70% of the time, they will expect it 70% of the time they are asked (see, e.g., Myers, 1976; Shanks, Tunney, & McCarthy, 2002, for an overview). Children are more likely to predict that the phenomenon will occur closer to 100% of the time (e.g., Weir, 1964; Derks & Paclisanu, 1967). A similar pattern has been found in causal reasoning: children over-regularize by assuming that causes are deterministic, while adults do not (Schulz & Sommerville, 2006).

Although the tendency toward over-regularization is well-established, the reason for the difference between adults and children is far from clear. As previously mentioned, the “less is more” hypothesis suggests that over-regularization may be due to some aspect of children’s cognitive capacities, such as their poorer memory or slower processing speed (Newport, 1988). Adults do tend to over-regularize more when the input is complex, when the probabilities involved are small (Gardner, 1957; Weir, 1964; Gluck & Bower, 1988; Hudson Kam & Newport, 2009), or when lexical retrieval is more difficult (Hudson Kam & Chang, 2009). This may be because

more complex input imposes more of a load on their cognitive resources. The hypothesis is also supported by empirical (Kersten & Earles, 2001) and computational (Elman, 1993) work suggesting that learning is easier when early input is simpler (although that work does not speak directly to the issue of over-regularization). In general, there has been little research that directly measures or manipulates memory or processing speed and evaluates whether these are associated with different degrees of over-regularization in adults.

Here we begin to investigate this question more directly. Our goal is to evaluate whether we can effectively turn adults into children by placing them under cognitive load. If deficiencies in the particular capacities involved in the load tasks are what cause children to over-regularize, then adults under heavy load should behave more like children in their pattern of over-regularization. We find that, although the cognitive load is high enough to impair adult performance in other ways – and although their working memory capacity predicts overall performance on the task – neither increased cognitive load nor poor working memory predicts or leads to increased over-regularization. This suggests that, if the “less is more” hypothesis is the explanation for childrens’ tendency to over-regularize, the cognitive capacity that is “less” in children is not one that is impaired by the load tasks we used.

Method

75 adults were recruited from the University of Adelaide and surrounding community and were paid \$10 for their participation. In the first part of the experiment, individual differences in working memory capacity were measured using a standard complex span task (Conway, Jarrold, Kane, Miyake, & Towse, 2007; Unsworth, Redick, Heitz, Broadway, & Engle, 2009). In the second part of the experiment, subjects completed a word-learning task (modelled on the paradigm described by Hudson Kam and Newport (2009)) in which they were taught 10 two-word labels from a new language. Interspersed with the word-learning task, participants in the OPERATIONAL LOAD and VERBAL LOAD conditions completed an interference task (involving either solving equations or reading sentences aloud, respectively). In a control condition, the NO LOAD condition, participants performed the word-learning task only. Specific details of the initial complex span task and the subsequent word-learning task follow.

Complex span task

Complex span tasks are widely used to measure the capacity of the working memory system (Conway et al., 2005; Unsworth et al., 2009). In a complex span task, items to be remembered (e.g., random letters, digits, shapes, or spatial locations) are interspersed with an unrelated cognitive activity (e.g., solving equations, reading sentences, or evaluating the symmetry of patterns). After several trials, participants are asked to recall the items to be remembered in the correct serial order. This sort of task is differentiated from a simple span task (e.g., Digit Span from the Wechsler scales), which only includes the memorization component; it has been

argued that complex span tasks provide a measure of working memory (as opposed to span memory) because they entail the requirement to process as well as to store information. Complex span tasks have been shown to correlate with cognitive processes that are believed to depend on working memory (Conway et al., 2007; Unsworth & Engle, 2007), and are linked to disorders including Alzheimer’s disease (Rosen, Bergeson, Putnam, Harwel, & Sunderland, 2002). They have also been widely used to explore age differences in working memory capacity (Case, Kurland, & Goldberg, 1982; Salt-house & Babcock, 1991).

Two common span tasks incorporate demands on either operational span (Turner & Engle, 1989) or on verbal span (Daneman & Carpenter, 1980), respectively. In an operational span task, participants are presented with equations such as $4/2 + 2 = 3$ and told to say, as quickly as possible, whether the equation is correct. In a typical verbal span task, subjects are presented with an 11-15 word sentence and told to say, as quickly as possible, whether the sentence makes sense. In order to enable comparison across participants, in the first part of the experiment all participants were presented with an operational span task regardless of condition. On each trial people first saw an equation and were asked whether it was correct or not. After each response, a random letter was shown. At the end of a set of n letters, participants were asked to repeat the list of letters in order, given unlimited time to do so. To make sure that they understood the task, they were first trained on two sets of two trials each. The full task comprised two sets each of sizes ranging from an n of three to an n of seven, for a total of 50 trials. For each participant a working memory capacity score was calculated, reflecting the number of correct letters recalled in the correct position.

Word-learning task

After the complex span task, all participants took part in an artificial language learning task modelled after a similar task described by Hudson Kam and Newport (2009). Their language contained 51 words, including 36 nouns and 12 verbs, among other lexical items, taught over the course of eight separate sessions extending for 9-12 days. Of critical interest in their study was the evaluation of performance on the determiners, which were associated with nouns in an inconsistent fashion: participants heard the main determiner only 60% of the time. In one condition, they heard nothing the other 40% of the time; in four other conditions, they heard increasingly more *noise* determiners (e.g., two determiners (each 20% of the time), and so forth up to 16 determiners (each 2.5% of the time)). Performance was measured in a sentence completion task in which participants had to provide the noun and determiner associated with a scene and sentence.

We sought to remove extraneous elements of the task so as to focus on the determiner-production aspect while still retaining the important details. We therefore presented participants with a “language” of 10 nouns, all two-syllable non-

sense words¹ mapped to images representing common objects.² Each noun was followed by a one-syllable determiner:³ the *main* determiner occurred 60% of the time, and each of the four *noise* determiners occurred 10% of the time. The specific mapping of the word to the meaning and which determiner was the *main* determiner were randomized for each participant.

Over the course of the task, participants saw 200 trials of image-label pairs. On each trial, an image appeared on the computer screen and, at the same time, the person heard a female voice provide the label: for instance, they might see a picture of a baby and hear *churbit mog*. In the NO LOAD condition, participants went to the next trial by clicking a next button; in the two load conditions, the image remained visible for 1.5 seconds and then the next phase of the trial began automatically (as explained below). In all conditions, learning was tested with 10 questions every 50 trials, for a total of 40 test questions. At each test, the participant was presented with an image and asked to verbally produce the label for it, which the experimenter wrote down. No feedback was given.

Subjects in the two load conditions completed the same word learning task, except that after each image-label pair, they were asked to perform an unrelated task designed to increase their cognitive load. In the OPERATIONAL LOAD condition, the task was modelled after the operational span test (Turner & Engle, 1989): participants were presented with an equation and told to respond as quickly as possible whether it was correct or not. Half of the equations were correct, and half gave an answer that was one digit away from correct. In order to encourage them to be as fast and correct as possible, a running total of their number correct and elapsed time was displayed on the screen. In the VERBAL LOAD condition, the task was modelled after the verbal span test (Daneman & Carpenter, 1980): participants were presented with an 11-15 word sentence, told to read it aloud, and then asked to respond as quickly as possible whether it was sensible or not. Half of the sentences were sensible, and half were made non-sensible by replacing a content word with a semantically inappropriate one.⁴ As before, accuracy and elapsed time was displayed in order to encourage peak performance.

Results

There are three natural questions we must answer in order to properly understand this experiment. First, is the load task difficult enough? Second, did participants in either of the load conditions over-regularize by producing the *main* determiner more than 60% of the time? Third, did individual differences in performance on the initial complex span

¹Noun words used were: dragnip, raygler, churbit, tramdel, shelbin, pugbo, wolid, foutray, nipag, and yeetom.

²Objects used were: babies, balls, beds, birds, books, cars, cats, cups, dogs, and shoes.

³The five determiners were: mot, ped, sib, kag, and zuf.

⁴For example, a typical sentence is "Cats really love to sit in the sun, since they are desert animals" while the corresponding non-sensible sentence would replace animals with chimneys.

Figure 1: Performance by condition in the noun-learning task. Participants in the two load conditions learned significantly fewer nouns, indicating that the load task provided sufficient cognitive challenge to impair performance.

task predict performance on the word-learning task? The answer to the first question is an essential pre-requisite to interpreting the answers to the other two because if the load task was not challenging enough, comparisons between conditions are meaningless. The answers to the other two bear directly on the questions motivating this work: does putting adults under cognitive load cause them to make the same over-regularization errors that children do? Are adults with poorer performance on the complex span task (and hence lower working memory capacity) more likely to make those errors? We address each of these questions in turn.

Was the load task difficult enough?

There are several ways to evaluate whether the load tasks were sufficiently challenging to the cognitive capacities of our participants, whilst still being easy enough so that people could acquire at least some of the image-label mappings in the word-learning task. One indication is that participants in both conditions scored far above chance on the load items, suggesting that they took that task seriously.

To evaluate the degree of difficulty the tasks imposed, we can compare how well participants in each of the three conditions learned the correct noun-image mappings. One would expect that performance would be substantially worse in the two load conditions if the secondary task provided a sufficient challenge to the cognitive capacities of our participants. To explore this, we coded each person's answers as *correct* if the noun they produced was identical to or phonologically similar (e.g., *wolin* instead of *wolid*) to the correct noun for that image. Figure 1 demonstrates that participants in both load conditions got fewer nouns correct than in the NO LOAD condition, indicating that the interference tasks were, indeed, imposing significant strain on their cognitive resources. There was no difference in the number of nouns correct between the OPERATIONAL LOAD and VERBAL LOAD conditions.⁵

⁵A one-way Anova on nouns correct by condition was significant: $F(2, 72) = 4.63, p = 0.0129$. Post-hoc comparisons using the Tukey-Kramer test indicated that the mean score for the NO LOAD condition ($M = 0.667, SD = 0.05$) was significantly different than the

Figure 2: Performance by condition in determiner production. There was no significant difference between conditions in tendency to over-regularize, and in no condition did people produce the main determiner beyond the 60% it appeared in the input.

Did adults over-regularize more when under cognitive load?

The central question motivating this research was whether adults placed under cognitive load could be made to look more like children. To evaluate this, following Hudson Kam and Newport (2009), we excluded all participants who did not get at least 9 out of the final 20 nouns correct on the test trials.⁶ Then, on every valid trial (i.e., every trial for which a correct noun was produced), we calculated the percentage of time either the *main* determiner, a *noise* determiner, or *no* determiner was produced. Figure 2 demonstrates that there were no significant differences between conditions in terms of *main* determiner production: that is, participants in the load conditions did not over-regularize.⁷ If anything, participants in the OPERATIONAL LOAD condition tended to *under*-regularize, which is the opposite of what one would expect if limited available memory or processing power was the driving force behind over-regularization.

This is suggestive, but because it is an analysis of mean performances this outcome may be hiding individual over-regularization in different directions. To evaluate this possibility, we followed Hudson Kam and Newport (2009) and set a “consistency threshold” of 90%: each participant was coded as *consistent main*, *consistent noise*, or *consistent none* if they produced the determiner type in question on at least 90% of the valid trials, and *not consistent* if they did not.⁸ Figure 3 shows that few participants were consistent in any

mean for the OPERATIONAL LOAD ($M = 0.479, SD = 0.05$) and VERBAL LOAD ($M = 0.482, S = 0.05$) conditions, but the latter two were not significantly different from each other.

⁶This resulted in 23 subjects in the NO LOAD condition and 17 in each of the others. We ran each of these analyses without this exclusion and results were qualitatively identical in all cases.

⁷One-way Anova on main determiner production by condition: $F(2, 54) = 2.64, p = 0.0806$. To further explore this outcome, a post-hoc comparison using Tukey-Kramer indicated no significant difference between any of the conditions compared pairwise.

⁸Results are qualitatively identical even with thresholds of 70% or 80%: there are more consistent participants in those cases, but still no difference between conditions.

Figure 3: Individual consistency in determiner production by condition. For the most part, few participants showed any consistency in their pattern of determiner usage, and those in the load conditions did not tend to be more consistent.

way, and differences between conditions were minor. In order to determine if the tendency to over-regularize changed as they acquired more of the language, we repeated the analyses shown in both Figure 2 and 3 at each of the four stages of testing. There were no differences in behavior at any stage.

Does working memory span have any effect on performance?

The results presented thus far suggest that people with less available working memory capacity (i.e., those in the two load conditions) did not over-regularize the main determiner more than did those in the control condition. Our experiment also provides another way to evaluate how working memory capacity affects over-regularization: by analyzing whether individual differences in performance on the initial complex span task predicts differential performance on the word-learning task. As one would expect, performance on the complex span task is positively and significantly correlated with the ability to learn the noun-image mappings ($\rho = 0.3811, p = 0.0013$): participants with greater working memory capacity learned more noun labels. However, there is no relation between working memory capacity and the tendency to produce the main determiner ($\rho = 0.1066, p = 0.387$), nor do the scatterplots indicate a non-linear relationship.

Discussion

On first glance, our findings might appear to contradict those of Hudson Kam and Chang (2009), who found that over-regularization in adults could be diminished by improving the ease of lexical retrieval. There are three notable differences here. First, they aimed to make adults *less* like children by making the cognitive load easier, rather than to make adults act *more* like children by making it harder. It is possible that there is an inherent asymmetry to adults’ performance: that it is relatively easy to make adults over-regularize less, but that getting them to regularize more is difficult. This is certainly the case in the decision-making literature, in which great efforts have been made to stop adults from probability match-

ing (e.g., Shanks et al., 2002). Second, and more importantly, the study by Hudson Kam and Chang (2009) examined a different aspect of cognitive load (lexical retrieval rather than working memory capacity). It is possible that differences in lexical retrieval abilities are related to differences in over-regularization between children and adults, but that differences impaired by our load task were not. Third, our language was far simpler than theirs; it is possible that our participants treated the task like paired-associate learning rather than like learning a language with rich internal structure, unlike adult learners in other studies that tasked load (Pitts Cochran, McDonald, & Parault, 1999). We think this would be a rather surprising explanation of our findings, given that the task itself (learning determiner-noun pairings) was the same in both studies, and the main difference was the complexity of the rest of the system they were embedded in; however, it is an open question that we seek to resolve with future work.

The central issue, of course, is what abilities *were* impaired by our load task? In many ways, the two load tasks were quite different: one involved solving equations, while the other involved reading sentences aloud and answering questions about them. Despite this, it has been shown that the complex working memory tests related to these tasks tend to load highly on the same broad working memory factor (e.g., Oberauer, Süß, Wilhelm, & Wittmann, 2003). It may therefore not be a surprise that both load tasks had similar effects. The interesting aspect of this is that these tasks were specifically designed to create a load on multiple different cognitive capacities at once: unlike simple span tasks (such as Digit Span on the Wechsler), which capture only the storage component of memory, these require processing as well. In general, these load tasks should be disrupting many aspects of cognition: among other things, they require people to retrieve information from long-term memory (word meanings in the VERBAL LOAD condition, number and symbol meanings in the OPERATIONAL LOAD condition), to store information in short-term memory (the words in the current sentence or numbers in the current equation), to manipulate representations (to determine the correct answer to the questions), to regulate attention, and to perform the load task while simultaneously learning word-referent mappings. It is interesting that, despite their generality, the load tasks still did not lead to over-regularization in word learning.

How might we interpret these results? One possibility is that the “less is more” hypothesis is incorrect: that children’s tendency to over-regularize does not stem from differences in cognitive capacity. Such a possibility is consistent with previous studies finding no effect of load on adult learners (Ludden & Gupta, 2000) as well as other empirical findings in language acquisition showing that children with better memories or faster processing speed actually do *better* at learning language (e.g., Fernald, Perfors, & Marchman, 2006; Rose, Feldman, & Jankowski, 2009).

That said, we cannot be certain that “less is more” is incorrect. It is in theory possible that our load tasks did not

sufficiently challenge our subjects enough, and that more difficult ones would result in more over-regularization. This is unlikely, not only because the participants anecdotally seem to have found the task extremely difficult (one person called it the hardest psychology experiment he had ever done), but also because the load tasks had such strong effects on the ability to learn the nouns in the first place. The task would somehow have to be difficult enough to cause over-regularization but not so difficult as to render the task impossible: a balancing act that, if nothing else, seems unlikely to precisely describe the state of child language learners.

This point, however, raises the converse possibility: perhaps our language-learning task was so difficult (such that even in the no-load condition, participants were only about 70% correct overall⁹) that with longer training, the pattern we observed might change. While always a possibility, we think this is more unlikely than other explanations, since we observed no detectable change in tendency to over-regularize over the course of the experiment.

Another possibility is that, because our load task items were interspersed rather than concurrent with the words to be learned, it was less of a burden on concurrent memory and processing speed, and more of a burden on executive control. If so, this would suggest that the differential abilities between children and adults is not due to cognitive control, as has been suggested in a different context (Thompson-Schill, Ramscar, & Chrysikou, 2009). We plan to explore this issue in future work using a concurrent load task like verbal shadowing.

Even if our load task does impair memory and processing speed, there remain some likely possibilities for how the “less is more” hypothesis might be correct and still be consistent with our results. In addition to memory and processing speed, children and adults also differ in the ability to use metacognitive strategies (e.g., Flavell, Green, Flavell, Harris, & Astington, 1995). It may be that adults’ ability to introspect and reason about their own cognition makes them more likely to rely on explicit rather than implicit learning (Ullman, 2004) – a difference that has been hypothesized to be the root of child-adult differences in language acquisition. Such metacognitive ability might also make adults more likely to try to capture or imagine patterns in the input that do not exist; this tendency has been suggested as an explanation for why adults probability match in non-language tasks (Estes, 1976). It might result from a generalized preference for simplicity (or tendency to ignore exceptions) on the part of children. It is also possible that having limited memory or processing abilities is especially important for language learning *as a child* but not as an adult, analogously to a similar hypothesis found in other developmental domains (Turkewitz & Kenny, 1982). A great deal of work remains to be done to investigate the many possibilities that remain open.

⁹Keeping in mind that, since there were 10 objects and it was a free-response task, this is actually far above chance performance.

Acknowledgments

We thank Natalie May for her invaluable help recruiting participants and running the experiment.

Abstract

Jeffrey (1983) proposed a generalization of conditioning as a means of updating probability distributions when new evidence drives no event to certainty. His rule requires the stability of certain conditional probabilities through time. We tested this assumption ("invariance") from the psychological point of view. In Experiment 1 participants offered probability estimates for events in Jeffrey's candlelight example. Two further scenarios were investigated in Experiment 2, one in which invariance seems justified, the other in which it does not. Results were in rough conformity to Jeffrey (1983)'s principle.

Keywords: Jeffrey's rule; invariance; probability updating;

Introduction

Consider an idealized agent whose beliefs are represented by a (subjective) probability distribution Pr_1 over an outcome space \mathcal{S} . Let $B \subseteq \mathcal{S}$ be such that $Pr_1(B) > 0$ and suppose that experience intervenes to convince the agent that B is certainly true. What probability distribution Pr_2 should represent the agent's new state of belief? The Bayesian answer (Hacking, 2001, Ch. 15) identifies Pr_2 with the result of conditioning Pr_1 on B , that is, $Pr_2(\cdot) = Pr_1(\cdot|B)$. Much can be said in favor of the latter equation from the normative perspective. For example, it follows from compelling axioms on belief change (Gärdenfors, 1988, §5.2), and its violation exposes the agent to sure-loss betting contracts (Harman, 1999, §4.12). Updating has also been examined from the psychological perspective with focus on the use of Bayes' Theorem to compute conditional probability (see Stanovich (2010, Ch. 3)).

Conditioning is not always suited, however, to represent the impact of new information. In particular, Jeffrey (1983, §11.1) notes that the passage of experience need not raise the probability of any event to one. He gives the example of examining cloth by faint candlelight. The cloth's potential colors might correspond to different events over \mathcal{S} but none may become certain as a result of the examination. Nor is it feasible to augment \mathcal{S} to include visual sensations, with the idea of setting one of them to unity. Such sensations are too difficult to express and individuate. Instead, says Jeffrey, "the best we can do is to describe, not the quality of the visual experience itself, but rather its effects on the observer," for example, that the probability of blue has shifted to .75 from its original value.

To fill in the rest of Pr_2 after experience has set the value of $Pr_2(B)$, Jeffrey relies on the law of total probability. Let $G \subseteq \mathcal{S}$ be given, and suppose that $0 < Pr_2(B) < 1$. Then:

$$(1) \quad Pr_2(G) = Pr_2(G|B)Pr_2(B) + Pr_2(G|\bar{B})Pr_2(\bar{B}).$$

If experience has not influenced the conditional probability of G given B nor that of G given \bar{B} then *invariance* is said to hold (Jeffrey, 2004, §3.2). That is:

$$(2) \quad Pr_2(G|B) = Pr_1(G|B) \quad \text{and} \quad Pr_2(G|\bar{B}) = Pr_1(G|\bar{B}).$$

Substituting (2) into (1) yields:

$$(3) \quad Pr_2(G) = Pr_1(G|B)Pr_2(B) + Pr_1(G|\bar{B})Pr_2(\bar{B}).$$

(3) is known as "Jeffrey's rule." It shows how change in the probability of B is propagated to G , without experience directly affecting G . It is straightforward to generalize (3) to finer partitions, in place of the binary partition B, \bar{B} .

Assuming invariance, it is easy to show that (3) defines a genuine probability distribution Pr_2 , and in the special case of $Pr_2(B) = 1$, that it agrees with conditionalization. Moreover, Williams (1980) proves that Pr_2 as given by (3) is the closest distribution to Pr_1 that yields the new probability of B , where "closeness" is measured by cross-entropy with respect to Pr_1 . The normative status of Jeffrey's rule has nonetheless been questioned because successive uses produce distinct distributions depending on the order in which events are considered (Doring, 1999). In our view, such doubts disappear upon closer inspection of the evidential weight of probability judgments (Wagner, 2002; Osherson, 2002).

It is important to observe that Invariance (2) is not normatively justified in every situation. Sometimes the conditional probabilities are shifted by experience. For example, let G represent vigorous growth of a potted plant, and let B represent the decision to place it in the bedroom. Then noticing ample sunshine in the bedroom would increase not just the probability of B but also the probability of G given B . In contrast, if all you notice is the absence of plants in the bedroom then the probability of B increases without a change in the probability of G given B , yielding invariance.

To decide whether invariance is warranted in a given situation, we rely on an observation due to Pearl (1988). Given an experience e that intervenes between times 1 and 2, we expect invariance to hold if at time 1, G is conditionally independent of e given B , that is:

$$(4) \quad \text{Conditional independence of } G \text{ from } e$$

given B : $Pr_1(G | B, e) = Pr_1(G | B)$.

To see that invariance depends on (4), observe that $Pr_2(GB) = Pr_1(GB, e)$ since e is what transpires between times 1 and 2, and the latter term equals $Pr_1(GB)$ just in case (4) holds.

The focus of the present paper is whether invariance is descriptively accurate when mandated normatively. In Experiment 1 undergraduates offer probabilities for events in Jeffrey's candle example. Of particular interest is the extent to which invariance is honored. Two further scenarios are then investigated, one in which invariance seems justified, the other in which it does not. The results show modest deviations from invariance where it seems justified normatively.

Experiment 1

Participants

Ninety-six undergraduates from Princeton University participated in exchange for partial course credit (41 female, mean age 19.4 yrs, $SD = 1.0$).

Materials

We simulated Jeffrey's candle example by having participants examine colored paper cards with a dim flashlight. There were 12 blue cards and 38 purple cards. Each card was marked with either a hippopotamus or a giraffe on one side. Of the blue cards, eight were marked with a hippo and four with a giraffe. Of the purple cards, 24 were marked with a hippo and 14 with a giraffe. We chose *giraffe* and *blue* as the categories G and B evoked in the Introduction. Table 1 summarizes the objective probabilities figuring in the experiment.

Procedure

Sixty-four participants performed the *experimental* condition, and 32 performed the *control* condition. The purpose of the control condition was to assess the impact of being asked to evaluate the same probabilities a second time. In the experimental condition, the experimenter first shuffled the cards and showed each to the participant. Then the experimenter turned away from the participant, drew one card from the shuffled deck, and put it in her pocket. The draw appeared to be random but in fact was guaranteed across participants to deliver equal numbers of blue and purple cards (for statistical purposes). The participant was informed that the card was randomly chosen, and then answered the following questions about the card, via computer interface (the order was randomized for each participant):

PROBABILITY QUESTIONS:

$Pr(G)$	What's the probability that there is a giraffe on the card?
$Pr(B)$	What's the probability that the card is blue?
$Pr(G B)$	What's the probability that there is a giraffe on the card assuming that the card is blue?
$Pr(G \bar{B})$	What's the probability that there is a giraffe on the card assuming that the card is purple?
$Pr(B G)$	What's the probability that the card is blue assuming that there is a giraffe on the card?
$Pr(B \bar{G})$	What's the probability that the card is blue assuming that there is a hippo on the card?

The estimates $Pr(B|G)$ and $Pr(B|\bar{G})$ served as a contrast with $Pr(G|B)$ and $Pr(G|\bar{B})$. Given our procedure (see below), the former estimates were not expected to be invariant across the flashlight experience whereas the latter were.

The participant was then informed that s/he would briefly see the card under dim light. The card would be placed face down on the table so that the participant would not see the animal but only the color of the card. The experimenter then turned off the lights in the room, moved the card from her pocket to the table, and flashed the light for about one second. The card was then returned to the experimenter's pocket, and the participant answered the same set of questions shown above (in a different random order). Since participants had to give their estimates twice to the same questions, we informed them that they were free to provide the same estimate or a different estimate the second time around.

In the control condition, the procedure was the same except that the light was applied to the chosen card immediately after its draw. Participants in the control condition thus answered the questions shown above just once, after briefly seeing the card under the dim light.

Results

Average responses. We separately analyzed results for participants exposed to blue cards (Blue group) and those exposed to purple cards (Purple group). In the experimental condition we use Pr_1 to refer to probability estimates before the light experience and Pr_2 for estimates after the experience. For each condition and each color group, we averaged Pr_1 and Pr_2 estimates. The results are shown in Table 1.

Table 1: Average probably estimates by participants and objective probabilities in Experiment 1 (standard deviations in parentheses).

	$Pr(G)$	$Pr(B)$	$Pr(G B)$
Blue Pr_1	0.36(0.12)	0.33(0.11)	0.36(0.16)
Blue Pr_2	0.38(0.15)	0.71(0.26)	0.37(0.19)
Purple Pr_1	0.37(0.12)	0.31(0.12)	0.34(0.15)
Purple Pr_2	0.37(0.12)	0.17(0.16)	0.28(0.20)
Blue control	0.37(0.18)	0.70(0.26)	0.39(0.16)
Purple control	0.35(0.09)	0.22(0.11)	0.35(0.12)
Objective	0.36	0.24	0.33
	$Pr(G \bar{B})$	$Pr(B G)$	$Pr(B \bar{G})$
Blue Pr_1	0.34(0.16)	0.39(0.20)	0.36(0.14)
Blue Pr_2	0.39(0.16)	0.51(0.27)	0.53(0.25)
Purple Pr_1	0.36(0.14)	0.34(0.16)	0.34(0.17)
Purple Pr_2	0.36(0.14)	0.23(0.25)	0.27(0.26)
Blue control	0.30(0.16)	0.58(0.26)	0.48(0.27)
Purple control	0.31(0.11)	0.32(0.20)	0.24(0.15)
Objective	0.37	0.22	0.25

Control vs. experimental conditions. As experimental participants provided estimates twice to the same questions, Pr_2 estimates were compared to those of control group. Independent-sample t -tests for each of the six questions revealed no reliable differences between Pr_2 and the control estimates. Thus, these participants seem not to have been influenced by having to evaluate the same probabilities twice.

Analysis of the Experimental Blue group. We report the Experimental Blue and Experimental Purple participants separately, starting with Blue. As a manipulation check, we first determined whether $Pr(B)$ increased after participants saw the blue card under dim light. As expected, $Pr_2(B)$ was reliably larger than $Pr_1(B)$ [paired $t(31) = 7.0$, $p < .01$, Wilcoxon $p < .01$].

To see whether invariance holds as described in (2), we compared $Pr_1(G|B)$ to $Pr_2(G|B)$ via paired t -test and found no reliable difference [$df = 31$, $p > .05$]. Of the 32 Blue participants, 18 offered a different $Pr_2(G|B)$ estimate from $Pr_1(G|B)$. For these 18 participants, the average signed difference between $Pr_1(G|B)$ and $Pr_2(G|B)$ is -0.02 which is not reliably different from 0 [$t(17) = 0.3$, $p > .05$]. $Pr_1(G|\bar{B})$ was likewise found to be close to $Pr_2(G|\bar{B})$ [paired $t(31) = 1.3$, $p > .05$]. Eighteen out of 32 participants gave a different $Pr_2(G|\bar{B})$ estimate from $Pr_1(G|\bar{B})$. The average signed difference between $Pr_1(G|\bar{B})$ and $Pr_2(G|\bar{B})$ is -0.09 which is reliably different from 0 [$t(17) = 2.2$, $p < .05$].

To more precisely quantify violation of invariance, for each participant we calculated the absolute movement between two estimates as a percentage of the original estimate, via:

$$(5) \text{ Invariance violation} = \frac{|Pr_2(G|B) - Pr_1(G|B)|}{Pr_1(G|B)}$$

We compared invariance violations to the movement of the converse probability (i.e., blue given giraffe), computed via:

$$(6) \text{ Converse movement} = \frac{|Pr_2(B|G) - Pr_1(B|G)|}{Pr_1(B|G)}$$

Following an analysis due to Pearl (1988), we expected the converse movements to exceed the invariance violations. This is because giraffe seems to be conditionally independent of the light-experience given blue (once you know that the card is blue, the light provides no further information) whereas blue seems not to be conditionally independent of the light-experience given giraffe (the light here provides additional information about the color). Consistent with this expectation, the means for invariance violations and converse movements were 37.6% and 88.3%, respectively. This difference is reliable by paired t -test ($p < .05$) and Wilcoxon test ($p < .01$).

For each participant we also computed invariance violation for $Pr(G|\bar{B})$ via the following:

$$(7) \text{ Invariance violation for } \bar{B} = \frac{|Pr_2(G|\bar{B}) - Pr_1(G|\bar{B})|}{Pr_1(G|\bar{B})}$$

The mean invariance violation of $Pr(G|\bar{B})$ was 45.9% and was not reliably different from the 37.6% violation of $Pr(G|B)$ reported above [paired $t(31) = 0.6$, $p > .05$].

From the results above, invariance seems to hold at least approximately. We therefore asked about its use in updating the probability of G . Specifically, for each participant, we computed the value of $Pr(G)$ via the law of total probability (1), relying on the participant's estimates

for the quantities at the right of the equality. We will call this value the *total* probability of G , or $Pr_{total}(G)$ for short. Likewise, for each participant we computed the value of $Pr(G)$ via Jeffrey's rule (3). We will call this value the *Jeffrey* probability of G , or $Pr_{Jeff}(G)$ for short. The latter estimates were compared to the participant's direct evaluation of $Pr_2(G)$ via absolute difference:

$$(8) \quad \begin{aligned} \text{total error} &= |Pr_2(G) - Pr_{total}(G)| \\ \text{Jeffrey error} &= |Pr_2(G) - Pr_{Jeff}(G)| \end{aligned}$$

The means for total and Jeffrey error were .07 and .10, respectively, not reliably different via paired t -test [$t(31) = 1.7$, $p > .05$] or Wilcoxon test ($p > .05$).

Analysis of the Experimental Purple group. We first determined whether $Pr(B)$ decreased after participants saw the purple card under dim light. As expected, $Pr_2(B)$ was reliably less than $Pr_1(B)$ [paired $t(31) = 5.6$, $p < .01$, Wilcoxon $p < .01$].

We compared $Pr_1(G|B)$ to $Pr_2(G|B)$ via paired t -test and found no reliable difference [$df = 31$, $p > .05$]. Of the 32 Purple participants, 21 offered a different $Pr_2(G|B)$ estimate from $Pr_1(G|B)$. The average signed difference between $Pr_1(G|B)$ and $Pr_2(G|B)$ was 0.10 which was not reliably different from 0 [$t(20) = 1.8$, $p > .05$]. $Pr_1(G|\bar{B})$ was also found to be close to $Pr_2(G|\bar{B})$ [paired $t(31) = 1.6$, $p > .05$]. The average signed difference between $Pr_1(G|\bar{B})$ and $Pr_2(G|\bar{B})$ was -0.01 which was not reliably different from 0 [$t(15) = 0.3$, $p > .05$].

Just as for the Blue group, we computed invariance violations of $Pr(G|B)$ using (5) and converse movement of $Pr(B|G)$ using (6). The means for invariance violations and converse movements were 48.6% and 60.3%, respectively. This difference is reliable by paired t -test ($p < .05$) and Wilcoxon test ($p < .05$). The mean invariance violation for $Pr(G|\bar{B})$ via (7) was 18.9%, reliably smaller than the 48.6% violation of $Pr(G|B)$ [paired $t(31) = 2.9$, $p < .01$].

Once again, invariance seems to hold at least approximately so for each participant, we computed the value of $Pr(G)$ via the law of total probability (1), again denoting this value by $Pr_{total}(G)$. Likewise, for each participant we computed the value of $Pr(G)$ via Jeffrey's rule (3), denoting this value by $Pr_{Jeff}(G)$. The latter estimates were compared to $Pr_2(G)$ via the absolute differences shown in (8). The means for total and Jeffrey error were .05 and .07, respectively, not reliably different via paired t -test [$t(31) = 1.5$, $p > .05$] or Wilcoxon test ($p > .05$).

Discussion of Experiment 1

In the procedure of Experiment 1, respect for the invariance principle (2) seems normatively mandated inasmuch as experience with the light provides no further information about G once it is granted that the card is blue. In other words, $Pr_2(G|B) = Pr_1(G|B, \ell) = Pr_1(G|B)$, where ℓ is the experience provided by the light (as discussed in the Introduction).

A majority of participants, in contrast, gave different estimates for $Pr_2(G|B)$ compared to $Pr_1(G|B)$ after gaining new information about color via the light.

As a percentage of $Pr_1(G|B)$, the absolute difference between $Pr_2(G|B)$ and $Pr_1(G|B)$ was not trivial but nonetheless reliably smaller than the absolute percentage difference for the converse probabilities $Pr_2(B|G)$ and $Pr_1(B|G)$. Normatively, invariance is not expected with respect to $Pr(B|G)$. When used to estimate $Pr_2(G)$ via the law of total probability, we saw that $Pr_1(G|B)$ could be substituted for $Pr_2(G|B)$ with little loss of accuracy [total versus Jeffrey error, as in (8)]. This provides another indication of the relative modesty of invariance violations in Experiment 1.

Experiment 2

For another assessment of invariance, we asked a new group of participants to estimate probabilities for events in two different scenarios. The *lottery* scenario was designed to justify invariance whereas the *ultimatum game* scenario was not.

Participants

One hundred undergraduates from Princeton University participated in exchange for partial course credit (58 female, mean age 19.5 yrs, $SD = 1.1$). None had served in Experiment 1.

Materials and procedure

Fifty participants served in the *experimental* condition, and another 50 in the *control* condition. As in Experiment 1, the purpose of the control condition was to assess the impact of being asked to evaluate the same probabilities a second time. Each participant in both conditions was presented with the lottery and the ultimatum game scenarios (the order was counterbalanced).

Lottery scenario. In this scenario we substitute C (*buying a car*) for G and W (*winning the lottery*) for B . The following description was presented on the computer screen for each participant:

Imagine that a randomly chosen adult (call him Mr. X) in New Jersey has just purchased the *Jersey Cash 5* lottery for this week. In this lottery, there are 5 numbers to be drawn, each from 1 to 40. Each number is drawn from the bowl and then put aside. The lottery jackpot is \$240,000 which will be shared by players who have all 5 winning numbers (the order of the numbers doesn't matter). The numbers on Mr. X's lottery ticket are 12 17 24 32 39.

In the experimental condition, the participant answered the following questions before the lottery numbers were drawn (the order was randomized for each participant):

LOTTERY PROBABILITY QUESTIONS:

$Pr(C)$	What's the probability that Mr. X will buy a new car in the next two years?
$Pr(W)$	What's the probability that Mr. X will win the jackpot?
$Pr(C W)$	What's the probability that Mr. X will buy a new car in the next two years assuming that he wins the jackpot?
$Pr(C \bar{W})$	What's the probability that Mr. X will buy a new car in the next two years assuming that he does NOT win the jackpot?

The participant was then presented with the following additional information.

It's the night of the lottery, and the numbers are being drawn. Mr. X becomes excited because the first four draws are 32, 12, 24, and 17. In other words, the first four numbers drawn match the numbers on his ticket.

The participant answered the same set of questions shown above (in a different random order) before the last number was drawn. Since participants had to give their estimates twice to the same questions, we informed them that they were free to provide the same estimate or a different estimate the second time around. In the control condition, participants saw the description of the lottery immediately followed by the results of the first four numbers, and then answered the questions shown above just once.

In the lottery scenario knowing the results of the first four draws provides no further information about W once it is granted that Mr. X wins the lottery. In other words, $Pr_2(C|W) = Pr_1(C|W, f) = Pr_1(C|W)$, where f is the experience of knowing the results of the first four draws. For this reason, invariance seems justified.

Ultimatum game scenario. Here we use A (*accepting the offer*) and O (*offering at least \$4*) to replace G and B . The following description was presented on the computer screen for each participant:

Imagine that two undergraduate students are randomly chosen from Princeton University to play a game. The game works as follows. The two students are given the opportunity to split \$10. One student is the proposer and the other is the responder. The proposer makes an offer as to how \$10 should be split between the two. The responder can either accept or reject this offer. If the responder accepts the offer, the money is split as proposed, but if the responder rejects the offer, then neither of them receives anything. The students have just finished the first trial of the game.

In the experimental condition, the participant was informed that the two students were about to play the second trial. The participant then answered the following questions (randomly ordered) about the second trial *prior to learning the outcome of the first trial*.

ULTIMATUM GAME PROBABILITY QUESTIONS:

$Pr(A)$	What's the probability that the responder will accept the offer from the proposer in the second trial?
$Pr(O)$	What's the probability that the proposer will offer AT LEAST \$4 to the responder in the second trial?
$Pr(A O)$	What's the probability that the responder will accept the offer assuming that the proposer offers AT LEAST \$4 in the second trial?
$Pr(A \bar{O})$	What's the probability that the responder will accept the offer assuming that the proposer offers LESS THAN \$4 in the second trial?

The participant was then presented with the following additional information about the scenario:

Now you learn that in the first trial the responder rejected the proposer's offer and neither of them received anything. They are about to play the second trial.

The participant answered the same set of questions shown above (in a different random order) about the second trial of the game. Again we informed participants that they were free to provide the same estimate or a different estimate the second time around. In the control condition, participants saw the description of the ultimatum game immediately followed by the outcome of the first trial, and then answered the questions shown above just once.

In this scenario invariance is not normatively required because the outcome of the first trial suggests that the responder is sensitive to the fairness of offers. Thus, $Pr_2(A|O) = Pr_1(A|O, t) < Pr_1(A|O)$, where t is the experience of knowing the outcome of the first trial.

Results

Average responses. In each scenario we use Pr_1 to refer to probability estimates before the experience and Pr_2 for estimates after the experience. Average probabilities are shown in Table 2.

Table 2: Average estimates in Experiment 2 (standard deviations in parentheses).

lottery	$Pr(C)$	$Pr(W)$	$Pr(C W)$	$Pr(C \bar{W})$
Pr_1	0.29(0.22)	0.01(0.01)	0.77(0.22)	0.21(0.14)
Pr_2	0.33(0.25)	0.03(0.02)	0.76(0.20)	0.20(0.15)
Control	0.31(0.19)	0.04(0.04)	0.70(0.29)	0.29(0.20)
ultimatum	$Pr(A)$	$Pr(O)$	$Pr(A O)$	$Pr(A \bar{O})$
Pr_1	0.65(0.22)	0.61(0.29)	0.75(0.19)	0.44(0.30)
Pr_2	0.68(0.22)	0.74(0.24)	0.72(0.20)	0.38(0.30)
Control	0.62(0.25)	0.63(0.28)	0.70(0.25)	0.36(0.29)

Control versus experimental conditions. We found no reliable differences between Pr_2 and the control estimates for each scenario using independent-sample t -tests. Thus, experimental participants seem not to have been influenced by having to evaluate the same probabilities twice.

Analysis of the lottery scenario. We first determined whether $Pr(W)$ increased after participants saw the results of

the first four draws. As expected, $Pr_2(W)$ was reliably larger than $Pr_1(W)$ [paired $t(49) = 7.7$, $p < .01$, Wilcoxon $p < .01$].

To see whether invariance holds, we compared $Pr_1(C|W)$ to $Pr_2(C|W)$ via paired t -test and found no reliable difference [$df = 49$, $p > .05$]. Of the 50 participants, only 12 offered different values for $Pr_2(C|W)$ versus $Pr_1(C|W)$. The 12 non-invariant participants made highly variable estimates, with average signed difference of 0.15 between $Pr_1(C|W)$ and $Pr_2(C|W)$ (SD = .57), not reliably different from 0 [$t(11) = 0.9$, $p > .05$]. $Pr_1(C|\bar{W})$ was likewise found to be close to $Pr_2(C|\bar{W})$ [paired $t(49) = 1.0$, $p > .05$]. Fifteen out of 50 participants gave a different $Pr_2(C|\bar{W})$ estimate from $Pr_1(C|\bar{W})$. For these 15, the average signed difference between $Pr_1(C|\bar{W})$ and $Pr_2(C|\bar{W})$ was 0.04 (SD = 0.12), again not reliably different from 0 [$t(14) = 1.0$, $p > .05$]. The average invariance violation was only 1.42% with a median violation of 0. The mean invariance violation for $Pr(C|\bar{W})$ was 1.33% with a median of 0. Since we obtained no estimate for $Pr(W|C)$, converse movement was not computed.

From the results above, invariance seems to hold rather well. For each participant, we therefore computed $Pr_{total}(C)$ via (1) and $Pr_{Jeff}(C)$ via (3), with G and B substituted by C and W . These estimates were compared to the participant's direct evaluation of $Pr_2(C)$ via absolute difference. The means for total and Jeffrey error were .15 and .13, respectively, not reliably different via paired t -test [$t(49) = 1.5$, $p > .05$] or Wilcoxon test ($p > .05$).

Analysis of the ultimatum game scenario. We first determined whether $Pr(O)$ increased after the reported rejection in the preceding trial. As expected, $Pr_2(O)$ was reliably larger than $Pr_1(O)$ [paired $t(49) = 4.2$, $p < .01$, Wilcoxon $p < .01$].

Of the 50 participants, 33 offered a different $Pr_2(A|O)$ estimate from $Pr_1(A|O)$. Thirty-eight out of 50 participants gave a different $Pr_2(A|\bar{O})$ estimate from $Pr_1(A|\bar{O})$. The average invariance violation was 18.71% with a median of 12%. As expected, this violation was reliably greater than that in the lottery case (1.42%) [paired $t(49) = 3.7$, $p < .01$]. For $Pr(A|\bar{O})$ the mean invariance violation was 17.38%, reliably greater than $Pr(C|\bar{W})$ in the lottery case (1.33%) [paired $t(49) = 2.9$, $p < .01$]. Thus, invariance was violated to a greater extent here than in the lottery scenario.

Discussion of Experiment 2

In the lottery scenario, invariance held for a majority of participants, and the absolute difference between $Pr_2(C|W)$ and $Pr_1(C|W)$ as a percentage of $Pr_1(C|W)$ was quite small. When used to estimate $Pr_2(C)$ via the law of total probability, we saw that $Pr_1(C|W)$ could be substituted for $Pr_2(C|W)$ with little loss of accuracy. In the ultimatum scenario, however, a majority of participants gave different estimates for $Pr_2(A|O)$ compared to $Pr_1(A|O)$ after learning the outcome of the first trial. Thus, invariance seems not to hold for the ultimatum scenario, as it ought not on normative grounds.¹

¹Without giving details, we note that Experiment 2 was repeated with 330 participants recruited over the internet via Amazon Turk.

General Discussion

In Experiment 1, experience with the light changed the probability that the chosen card was blue, but had only mild impact on the probability of the giraffe *given that* the card was blue. That is, $Pr_2(G|B) \approx Pr_1(G|B)$ as well as $Pr_2(G|\bar{B}) \approx Pr_1(G|\bar{B})$. These results conform to Jeffrey (1983)'s invariance requirement for updating a distribution on the basis of events whose probabilities are modified without reaching certainty. As a result, the updated probability $Pr_2(G)$ was equally well predicted from the law of total probability on the basis of $Pr_1(G|B)$ and $Pr_1(G|\bar{B})$ versus $Pr_2(G|B)$ and $Pr_2(G|\bar{B})$.

The invariance documented in Experiment 1 was selective inasmuch as greater movement was seen between the converse probabilities $Pr_1(B|G)$ and $Pr_2(B|G)$ than between $Pr_1(G|B)$ and $Pr_2(G|B)$. The difference in movement makes normative sense because the giraffe is conditionally independent of the light given the color of the card whereas the color of the card is not conditionally independent of the light given the giraffe. Experiment 1 thus provides evidence that the participants were sensitive to the normative appeal of Jeffrey's rule, distinguishing (at least partially) between situations where it legitimately applies and where it does not.

The same conclusion is suggested by the results of Experiment 2. Only one of the two scenarios — involving the state lottery rather than the Ultimatum game — gave grounds for invariance, and participants honored the principle more in the lottery context. In the latter setting, $Pr_2(C)$ (the revised probability of a car purchase) was predicted equally well from the law of total probability based on $Pr_1(C|W)$ and $Pr_1(C|\bar{W})$, as it was from $Pr_2(C|W)$ and $Pr_2(C|\bar{W})$.

Although the experiments support the hypothesis of (tacit) respect for Jeffrey's rule, the fact remains that a majority of our participants (51 of 100) changed their estimate of $Pr(G|B)$ or $Pr(C|W)$ between times 1 and 2. A slightly larger majority (54 of 100) did so for $Pr(G|\bar{B})$ or $Pr(C|\bar{W})$. [The events G (iraffe), B (lue), C (ar), and W (in) come from the flashlight and lottery scenarios, where invariance is warranted.] In percentage terms, these shifts were sizeable in Experiment 1 (averaging around 47%) although much smaller in Experiment 2 (less than 2%). The psychology of updating is incomplete without an explanation of why invariance is not respected scrupulously in settings where it seems to be required normatively.

The mere fact of evaluating the same probabilities twice might explain some of the violation of invariance. The results of our control conditions, however, suggest that this effect was minor. Recall that control participants responded just once, in the phase 2 setting (e.g., after the light), yet produced estimates that were not reliably different from those gathered in phase 2 of the experimental condition. Another source of invariance violation might be illicit conversion of conditional probability statements, e.g., evaluating $Pr(B|G)$ in place of the requested $Pr(G|B)$. This explanation is consistent with

studies that highlight such conversion (as in Dawes, Mirels, Gold, and Donahue (1993)), but inconsistent with our own examination of conditional probability judgments (Zhao, Shah, & Osherson, 2009) in which little conversion was observed. Perhaps the variability of previous findings about conversion is somehow connected to the difference between the flashlight and lottery studies in their conformity to invariance.

A third possibility is that the flashlight procedure drew attention to the color dimension of the stimulus, reminding the participant of its predictive value. This realization might have been translated into more extreme conditional probabilities (higher for blue, lower for purple). The less vivid experience in the lottery scenario (merely being told about the first four numbers) would have had less impact, explaining the difference between the two experiments. As an alternative to vivacity, the greater impact of the flashlight might be related to the ineffable character of sensory impressions (as stressed by Jeffrey (1983, §11.1)); there is no such difficulty for the event of matching the first four lottery numbers. Of course, more data are needed to test hypotheses such as these.

Abstract

We reported results from a study on the effects of different training methods on complex perceptual-motor skill acquisition using a version of the Space Fortress game, which was originally designed to study the acquisition of complex perceptual-motor and cognitive skills in a multi-tasking environment. Participants were randomly assigned to the Fixed Priority (FP) and Varied Priority (VP) training conditions. Action sequences for controlling the spaceship in a frictionless environment using a joystick were analyzed and compared across conditions. Consistent with the previous findings, VP training was in general more successful than FP training. However, we found that VP training benefited participants more in the low performance group than in the high performance group. Participants in the VP training condition showed faster learning of optimal action sequences and faster reduction of suboptimal action sequences. In addition, results showed that in the high performance group, participants in the VP training condition used significantly more optimal action sequences than in the FP training condition. The findings have important implications on how the effectiveness of different training methods can be optimized for people with different cognitive abilities.

Keywords: Space Fortress game; Fixed Priority training; Varied Priority training, High performance group, Low performance group.

Introduction

Effectiveness of training perceptual-motor skills in complex, multi-tasking environments has been an important cognitive science research topic and has been studied for decades. Examples of tasks in complex, multi-tasking environments involved flying a military jet, driving a vehicle, operating a machine, etc. Operators in these environments are required not only to learn the necessary information regarding operation modes, control procedures, regulations and limitations, but also to apply these details under real-time constraints with competing cognitive demands.

Although in complex multi-tasking environments, practice generally improves performance in different training methods, researchers have found that practice time alone is not sufficient to explain differences in effectiveness of these methods. This has directed more focus towards comparing different training methods through computer-based cognitive simulations such as the 'Space Fortress' game (Mane & Donchin, 1989). This kind of synthetic training environment not only allows careful manipulation of multiple variables to carefully tease apart the multiple cognitive processes that interact dynamically to influence

performance, but also allow direct measurement of how performance improves in different training environments.

Among the different training methods, the differences between whole-task training (e.g. learning to steer a bicycle and operate the pedals simultaneously) and part-task training (e.g. separately learning to steer a bicycle and operate the pedals) have been studied most extensively by researchers. In general, research shows that whole-task training is ineffective because the trainee may be overwhelmed by the complexity of the task; while part-task training is ineffective because the trainee may not have sufficient experience in coordinating between different sub-components of the tasks (Ioerger et al., 2003). As a result, a hybrid training method, often called part-whole training, was proposed. Under this approach, the whole task is decomposed into segments. Participants are trained on each of the segments separately before moving to practice the total task as a whole. Although part-whole training has shown to be effective for training in complex, multi-tasking environments (Adams 1987, Wightman & Lintern 1985, Schneider 1985), it still has two problems. First, it is difficult to select the parts to train. Second, by isolating segments, it still suffers from the same problem as in part training, in which training effectiveness may decrease because of the removal of the broader context in which the parts were performed (Gopher et al., 1989).

Varied Priority (VP) training (e.g., Kramer et al., 1995) is a training method that manipulates only the relative emphasis of selected subcomponents in the multi-tasking environment and leaves the whole task intact (Gopher et al., 1989). Gopher et al. showed that systematically varying levels of priorities on attentional control through instruction and feedback could lead to better learning and performance in multi-tasking tasks. They argued that VP training enabled participants to explore different strategies and thus develop a better match between the requirements of the tasks and the efficiency of their efforts. They suggested that participants under VP training condition not only could receive more information on their performance on the emphasized element, but could also learn the costs to performance decrement on the de-emphasized task. As a result, VP training makes people better able to strategically allocate attention to multiple components of the task to comply with the change in emphases during training.

Although benefits of VP training on global performance have been demonstrated through a number of studies, there is still a lack of understanding on the specifics of how it promotes learning of perceptual-motor control. The current

study used a version of the original Space Fortress game to study the impact of VP training on learning a complex perceptual-motor skill. The goal is to understand the impact of VP training on learning of action sequences in a dynamic multi-tasking environment.

The Space Fortress Game

The Space Fortress game was originally developed to study the acquisition of complex perceptual-motor and cognitive skills in fast-paced multi-tasking environments (Mane & Donchin, 1989). The main objective of the game was to maximize the total scores by shooting missiles at and destroying the space fortress, while maintaining a spaceship within a certain velocity limit and pre-specified boundaries on the screen. Missiles were fired from the spaceship, whose movement was controlled by the participant. In addition to destroying the fortress, the participant had to protect his/her spaceship against damage from the fortress and mine. Participants used a joystick to control the spaceship. Forward movement (thrust) of the stick caused the spaceship to accelerate. Left and right movements caused the spaceship to rotate counter-clockwise and clockwise respectively. Because the spaceship flew in a frictionless environment, it would continue to fly in the direction to which it was pointing unless it was rotated and a thrust was applied. In that case, the spaceship would change its direction of movement. This change of movement was essential not only in controlling the spaceship within boundaries, but also in maintaining its velocity within limits because of the frictionless environment (accelerating in a frictionless environment would lead to higher and higher velocity unless there was a change in flying direction).

Participants were instructed to learn to control and maintain the spaceship within a particular range of velocity and a bounded area on the screen. These two subtasks were reflected by the velocity and control scores respectively, which were continuously updated on the screen. Participants also had to protect the spaceship from being hit by bombs emitted from the fortress and mines that periodically emerged on the screen. Participants could also shoot the mines to gain points. The four subscores: points, control, velocity, and speed added up to the total scores, which were also continuously displayed on the screen.

A cognitive task analysis (Schraagen et al., 2000) was conducted to identify major components of the task and to explicate the hierarchical relationship between internal goals and external cues. Figure 1 shows the overall structure of the cognitive task analysis of the Space Fortress game. The overall objective of the game is shown at the function purpose level. The four major subscores are shown at the abstract function level, and each of the subscores is mapped to one or more generalized functions. These generalized functions were assumed to be the major subgoals that participants had when they were learning to do the task, and they were explicitly taught how to accomplish these subgoals before they began the training. Each generalized function is then mapped to the various state indicators (e.g.,

PNTS indicated the points subscore, CNTRL indicated the control subscore, etc.) at the physical function level, which were continuously updated on the display as participants interacted with the task, and they were directly influenced by moment-to-moment actions (joystick or mouse) executed by the participants at the physical form level.

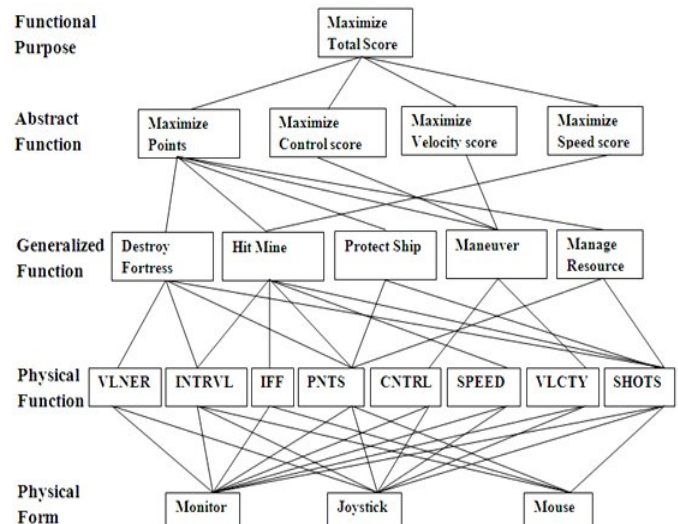

Figure 1: Cognitive task analysis of the Space Fortress game.

In the Fixed Priority (FP) training condition, participants were instructed to give equal weight to the subscores throughout the sessions. In the Varied Priority (VP) training condition, participants were instructed to emphasize one of the four subscores in each game, and the emphasis changed throughout the sessions. Due to space limitation, we will focus on effects of the training conditions on the velocity subscore, which reflected how well the participants could successfully control the velocity of the spaceship. This subscore was also the most predictive of overall performance for all participants.

Method

Participants

Thirty-nine participants recruited from University of Illinois community were randomly assigned to either the Fixed Priority (FP) training or the Varied Priority (VP) training condition. Participants had no more than a moderate amount of video game experience.

Tasks

Figure 2 shows the Space Fortress game display. The starting position of a computer-controlled fortress was centered within two concentric hexagons. And a spaceship controlled by a joystick was located between two hexagons. The fortress rotated to track and fire shots at the spaceship. The small diamond between two hexagons is a shot from the fortress. The arrow is a missile from the spaceship. The

larger diamond is a mine, which appeared every few seconds. The dollar sign indicated an opportunity for bonus.

A control panel was shown below the area in which the spaceship and mines flew. It displayed four subscores, including points (PNTS), control (CNTRL), velocity (VLCTY), and speed (SPEED). It also displayed the vulnerability (VLNER) of the fortress, an indicator to identify friend or foe (IFF), an interval (INTRVL) which indicated the time between IFF responses, and shots (SHOTS) which indicated the number of missiles remaining on the spaceship.

Figure 2: The Space Fortress game display

Participants in both FP and VP conditions initially completed the same three trials of an aiming task to destroy as many mines as possible. This aiming task was designed to demonstrate how to use the joystick to control the spaceship in a frictionless environment. The total aiming score was a function of the number of destroyed mines and the speed with which they were destroyed.

After completing the aiming task, participants in each condition received instructions for the actual Space Fortress game. Participants were instructed that the main objective of the game was to maximize the total score, and this was the same for both conditions. However, participants in the FP condition were told to emphasize each of the four main subscores (points, control, velocity, and speed) equally throughout the whole experiment. On the other hand, participants in the VP condition were told to improve and monitor only one particular subscore while maintaining focus on other subscores in any one of the trials.

Procedure

All participants completed the training in 10 consecutive days. Each day they did a 2-hour session, with each session consisting of 7 blocks. The first and last blocks are test blocks in which participants are required to emphasize total scores. Participants are told these are not practice blocks.

There were 5 emphasis (practice) blocks between the test blocks. For the VP group, in each emphasis block participants were asked to emphasize some aspect of the game in the order of control, velocity, speed, points, and total score, and every other day, the reverse order. All emphasis conditions were communicated to participants by pop-up windows between sessions. Additionally, for the VP group, reminder text appeared at the corner of the display telling participants what they should be focusing on (see Figure 2). For the FP group, participants did the same amount of trials but are told to always emphasize total score.

Results

Due to technical difficulties, two participants did not complete all of the tasks. The total score of one participant was 3 standard deviations away from the mean and was excluded from further analysis. We therefore had data from 36 participants in the following analyses.

Figure 3: Average total scores across test blocks for the High (H) and Low (L) groups in each condition

Based on previous findings that VP training had different benefits for low and high ability participants (Gopher et al., 1989), we performed a median split on the total scores of the first test block to identify the High (H) and Low (L) performance groups in each condition. Figure 3 shows the total scores for each group across the 20 test blocks. Analysis of Variance (ANOVA) showed a significant main effect of blocks ($F(19, 627) = 106.946, p < .001$), H-L ($F(19, 627) = 106.946, p < .001$), but not for conditions (FP vs. VP). However, there was a significant interaction between blocks and H-L ($F(19, 627) = 3.891, p < .001$), and between blocks and conditions ($F(19, 627) = 1.745, p < .05$). Participants in the High and VP groups learned significantly faster across blocks than the Low and FP groups, respectively. The three-way interaction conditions \times HL \times blocks was marginally significant ($p = 0.18$).

The results showed that, in general, VP training was more successful than FP training. Interestingly, the difference was

larger in the Low performance group, in which participants started with a much lower score and was consistently lower throughout the 20 test blocks. In fact, Figure 3 shows that for the High performance group, participants in the VP condition were only slightly better than those in the FP conditions. However, for the Low performance group, the total scores for participants in the VP condition increased to almost the same level as the High performance group at the last block, but participants in the FP condition had a much lower total score even after 20 hours of training.

Analysis of Action Sequences

To further understand the effects of VP training on perceptual-motor skill acquisition, action sequences were extracted from the game and compared across conditions. The game was designed such that clockwise rotation of the spaceship was better than counter-clockwise direction. Participants were informed of this optimal strategy upfront before the training began. To study how well participants learned to use this optimal strategy, we focus on the analysis of the number of clockwise rotation (CW), counter-clockwise rotation (CCW), and thrust (T) actions across blocks. Given that participants were instructed to control their spaceships by clockwise rotation, it was expected that participants would performed more CW and fewer CCW actions across blocks. In addition, given that the velocity score would decrease when velocity of the spaceship was too high, it was also expected that the number of T actions would decrease across blocks.

First-order Action Sequences Figure 4 shows that the number of T (thrust) actions in each condition. ANOVA showed significant main effect of H-L ($F(1, 33) = 26.313, p < .001$), but not for conditions. The interaction between conditions and H-L was marginally significant ($F(1, 33) = 3.849, p = .058$). As shown in Figure 4, participants used significantly fewer T actions in the High than the Low group. Participants in the FP-L group used much more T actions than those in the VP-L group, but the difference was much smaller between the FP-H and VP-H groups. ANOVA also showed that the main effect of blocks was significant ($F(19, 627) = 3.331, p < .001$), confirming the obvious downward trend, suggesting that participants were successful in reducing the use of thrust in controlling the spaceship. The interaction between blocks and H-L was also significant ($F(19, 627) = 3.859, p < .001$). The interaction between blocks and conditions and the three-way interaction was not significant.

Figure 5 shows the number of CCW (counter-clockwise) actions across 20 test blocks. ANOVA on the number of CCW actions showed significant main effects of conditions ($F(1, 33) = 6.842, p < .05$) and H-L ($F(1, 33) = 28.116, p < .001$). The interaction between conditions and H-L was also significant ($F(1, 33) = 5.08, p < 0.05$). The main effect of blocks and the interaction between H-L and blocks was significant ($F(19, 627) = 11.306, p < .001$ and $F(19, 627) = 3.161, p < .001$ respectively). However the interaction between conditions and blocks was not significant, nor was the three-way interaction.

Participants in the FP condition and Low group used significantly more CCW actions than the VP condition and High group, respectively. As shown in Figure 5, the number of CCW actions in the FP-L group was significantly higher than the VP-L group, but there was almost no difference between the FP-H and VP-H groups.

Figure 4: The number of T actions across test blocks for the High (H) and Low (L) groups in the Fixed Priority (FP) and Varied Priority (VP) conditions.

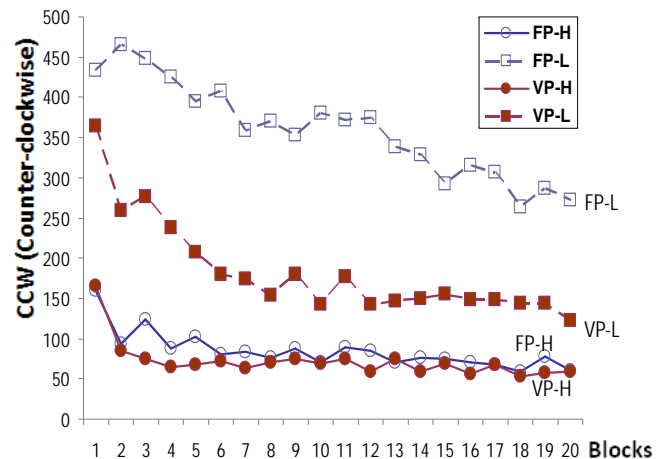

Figure 5: The number of CCW actions across test blocks for the High (H) and Low (L) groups in the Fixed Priority (FP) and Varied Priority (VP) conditions.

The overall behavioral patterns shown in Figure 4 and 5 were very similar, both showing that the number of “suboptimal” actions decreased across test blocks. However, similar to the improvements in total scores (Figure 3), participants in the High performance groups did not differ between conditions. On the other hand, participants in the Low performance groups showed a large difference: the FP-L group used significantly more “suboptimal” actions than the VP-L group. This pattern of results again supported the notion that VP training was more effective than FP training for the Low performance group. Apparently, participants

who were already good at controlling the joystick did not benefit much from either training method.

Figure 6: The number of CW actions across test blocks for the High (H) and Low (L) groups in the Fixed Priority (FP) and Varied Priority (VP) conditions.

Figure 6 shows the number of CW (clockwise) actions across test blocks. ANOVA on the number of CW actions showed that main effects of conditions, H-L and their interaction were not significant. However, the main effect of blocks was significant ($F(19,627)=10.210, p<.001$). The interaction between conditions and blocks was significant ($F(19,627)=2.358, p<.001$). As shown in Figure 6, although all participants used more CW actions across test blocks, the improvement differed across conditions. The improvement was bigger in the VP than the FP condition in the Low performance group, but not in the High performance group. Results again supported the notion that VP training was more effective to learn the optimal strategy to control the spaceship. Overall, we see that participants not only learned to reduce the number of actions needed to control the spaceship, but also learned to use more effective actions and reduced the use of suboptimal actions.

Higher-order Action Sequences We also extracted the transitions between actions to investigate further how the different training conditions influence learning of these higher-order action sequences. We extracted all second and third order transitions among the three actions CW, CCW, and T (e.g., CW-CW indicates a clockwise rotation followed by another clockwise rotation). There were a total of 9 second order and 27 third order transitions. None of the third order transitions showed significant differences between conditions. Due to space limitation, we will focus on two most frequent second-order transitions that showed significant differences between conditions.

Figure 7 shows the number of CW-T (clockwise-thrust) actions across test blocks. One major function of this action sequence was to change direction of the spaceship, and to control the spaceship to rotate in a clockwise direction and aim (and fire) at the fortress or mines to gain more points. ANOVA on the number of CW-T actions showed that the main effects of conditions (FP vs. VP) was marginally

significant ($p=.085$). Three-way interactions blocks \times conditions \times H-L was significant ($F(19,627) = 2.178, p<.005$). No other effect was significant.

Figure 7: The number of CW-T actions across test blocks for the High (H) and Low (L) groups in the Fixed Priority (FP) and Varied Priority (VP) conditions.

Figure 7 clearly shows that the three-way interaction was caused by the higher number of CW-T in the VP-H group. Although we did not see major differences between the VP-H and FP-H in previous analyses, the higher number of CW-T showed that participants in the VP-H group not only were successful in controlling the spaceship (like the FP-H group), but they were also better at chunking the actions required to control and aim than the other groups.

Figure 8: The number of CCW-T actions across test blocks for the High (H) and Low (L) groups in the Fixed Priority (FP) and Varied Priority (VP) conditions.

Figure 8 shows the number of CCW-T (counter-clockwise-thrust) actions across test blocks. CCW-T allowed participants to rotate in a counter-clockwise direction (which was suboptimal) and aim at the fortress or mines. ANOVA on the number of CCW-T actions showed that the main effect of H-L, and the two-way interaction blocks \times conditions were marginally significant ($p=.054$ and $p=.108$ respectively). The main effect of blocks was significant ($F(19,627) = 11.804, p<.001$), so was the three-

way interaction blocks x conditions x H-L ($F(19,627) = 1.620, p < .05$). Results showed that participants were better at reducing the use of the suboptimal action sequences, and this improvement was faster for the VP-L than the FP-L group.

Conclusion and Discussion

The current results in general provided further support for the VP training method for perceptual-motor skill learning in complex, multi-tasking environments. In the Space Fortress game, perceptual-motor skill learning (controlling the spaceship) was the most difficult and critical skill for performance. The total scores across test blocks showed that for the High performance group, participants in the VP condition were only slightly better than those in the FP conditions. However, for the Low performance group, participants in the VP condition were much better than those in the FP condition.

CW actions were designed to be better than CCW actions in the game, and T actions were expected to decrease across test blocks to obtain a higher velocity score. Therefore CW actions were identified as optimal first-order action sequence, and T actions, CCW actions, and CCW-T actions were separated into suboptimal action sequences. All participants used more CW actions (optimal) across test blocks, and similar to the improvements in total scores, the increases in CW actions were bigger in the VP than the FP condition in the Low performance group, but not in the High performance group. The results of T actions, CCW actions, and CCW-T actions showed that the number of suboptimal action sequences decreased across test blocks, and participants in the VP-L group used much fewer suboptimal action sequences than those in the FP-L group, but the difference was much smaller between the FP-H and VP-H groups. In addition, the analysis of CW-T action sequences showed that participants in VP-H group not only could successfully control the spaceship, but also perform better at chunking the actions required to control and aim than the other groups.

Research has shown that VP training is often better than whole-task, part-task, and part-whole training because VP training not only can reduce task complexity but also can keep the task components as a whole. Our results showed that VP training was more effective for people who started off with a lower performance level. Given that the Space Fortress game is a difficult task that requires efficient attention allocation strategies, it was possible that performance were largely limited by cognitive resources available to the individuals. Participants in the Low performance group were therefore likely reached the resource limits earlier than the High performance group. Given that under FP training, the trainees have to simultaneously split their resources over different subcomponents, but under VP training, the trainees can invest all resources in one subcomponent at one time and then shift to other subcomponents in other trials, participants in the VP group would therefore more likely able to practice each subcomponent with more resources available, and thus would more likely to acquire better action sequences than in the FP group.

In addition to more resources available for each subcomponent, experiences of how different subcomponents were dynamically related to each other were also important in the game. Under FP training, participants received feedback based on the total score that represented the sum of subcomponents (control, velocity, speed, points); while under VP training, participants received feedback on different subcomponents in different trials. Thus, in VP training, participants obtained more diverse feedback and a wider range of experiences of different attention allocation strategies than the FP group. In other words, not only did participants in the VP group able to learn to improve each subcomponent better, they were also more likely to learn when and how to shift attention to different subcomponents and experience the performance consequences. Participants in the VP group would therefore more likely learn to acquire the better action sequences than in the FP group.

In general, participants in the Low performance group tended to benefit most from the VP training, as they showed the biggest overall improvement through faster learning of optimal action sequences and reduction of suboptimal action sequences. However, even in the High performance group, participants were better at acquiring complex action sequences in the VP condition. Our studies complement previous research by showing exactly how the training method has an impact on the acquisition of optimal action sequences in a complex multi-tasking environment, and highlight how the method interacts with the initial learning ability of participants, which is important for realistic training consideration. Future research will further investigate the effectiveness of different training methods for people with different cognitive profiles to understand how these methods can be optimized for them.

Abstract

This study examined people's non-verbal reactions to being ignored or included during a social interaction. It was hypothesized that external judges could determine, on the basis of non-verbal cues, whether a person was ignored or included. Moreover, we expected that people who were ignored would become less non-verbally expressive, which could be indicative of cognitive withdrawal. It was found that persons who had been ignored reported lower average mood scores than included persons. External judges were, on average, also able to distinguish individuals who were ignored from those who were included. In terms of people's specific non-verbal behaviors, however, the findings are less clear. Even though persons who were ignored engaged less in affiliative behaviors than included persons, they did not display more non-verbal behaviors that are indicative of withdrawal than included persons (e.g., flight). Limitations of the study and future directions are discussed.

Keywords: Exclusion; non-verbal behaviors; cognitive deconstruction

Introduction

Human beings are deeply motivated to form stable, lasting connections with other people. They strongly desire social attachments and seem inclined to form relationships even in the absence of ulterior motives. Moreover, they are willing to spend considerable time and effort in fostering supportive relationships with others and are generally reluctant to end relationships, even when these relationships have become unnecessary or dysfunctional. This tendency to strive for strong social attachments presumably has an evolutionary basis. There is evidence that, over evolutionary time, human beings who were well-integrated into social groups were most likely to survive, reproduce, and successfully raise their offspring (Baumeister & Leary, 1995; Leary, 2001).

When people's belonging needs are threatened, they respond in a variety of negative

ways. Laboratory studies show that being excluded or rejected, even if it is for only a short period of time, is a painful experience (e.g., Eisenberger, Lieberman, & Williams, 2003) that increases self-defeating behaviors (e.g., Twenge, Catanese, & Baumeister, 2002) and may lead to aggression toward others (e.g., Twenge, Baumeister, Tice, & Stucke, 2001; Twenge & Campbell, 2003). For example, Twenge et al. (2001) found that participants who had been excluded by other participants or who had been told that they would have a lonely future administered more unpleasant noise blasts to others than those who had been included or who had been told that they would have rewarding relationships throughout their life.

Surprisingly, however, researchers have not always found relationships between social exclusion and emotional distress (e.g., Twenge et al., 2001; Twenge et al., 2003). Instead, several laboratory studies suggest that people seem to respond to social exclusion in a detached and emotionally indifferent manner. To account for these findings, it has been hypothesized that social exclusion or rejection may initially lead to feelings of inner numbness or a state of cognitive deconstruction. For example, Twenge et al. (2003) found that rejected participants were more lethargic, displayed slower reaction time, were more likely to agree that life is meaningless and avoided self-focused attention. According to Twenge et al. (*ibid.*) such a deconstructed state may serve as a temporary defense against the negative experience of social rejection.

Most studies to date, however, have only relied on self-reports of people's affective states or moods. So far, little research has focussed on the non-verbal behaviors of excluded persons. The purpose of the current investigation was to how people respond non-verbally when they are being ignored during a conversation with others. It was hypothesized that judges could determine, on the basis of non-verbal cues, whether a person is ignored or included. In line with the 'numbness hypothesis', it was also expected

that, compared to included persons, people who were ignored would become less non-verbally expressive, which could be indicative of cognitive withdrawal. One could argue that this could be an adaptive response to cope with the emotional stress caused by the exclusion. For example, according to Engel (1962, 1975) psychological and physical inactivity during stressful situations (e.g., the withdrawal of attention, self-preoccupation or sleep) may protect individuals from overstimulation or excessive trauma. Persons who are being ignored or excluded may also engage in displacement behaviors. For example, Troisi (2002) argued that displacement activities may be adaptive in that they reduce autonomic activation.

It is also possible, however, that people's non-verbal reactions during social interactions are influenced by how socially anxious they are. For example, previous research has shown that individuals with a higher fear of negative evaluation try to avoid being evaluated unfavorably (Watson & Friend, 1969), generally feel worse about receiving negative feedback (Friend & Gilbert, 1973), and are also more concerned with and try harder to make a good impression on others during interactions (Leary, 1983). In our analyses, we therefore controlled for fear of negative evaluation.

Method

Participants and Design

Participants were 58 undergraduate students (37 women) from the University of Tilburg who participated for partial course credit (M age = 20.8, SD = 2.4). Participants were randomly assigned to the inclusion or exclusion condition (29 in each condition).

Procedure

The experiment was presented as a study on group decision-making under time pressure/stress, and participants were led to believe that they would be engaging in a decision-making discussion with two other participants. In reality, they would communicate with a pair of actors (one male, one female) operating on an elaborate script.

At the start of the experiment, participants were led into a room and told that the other two "participants" were in separate rooms as well. After the global procedure was explained, participants signed a consent form, and six electrodes were applied to measure heart rate. Following the APA guidelines for ethics, participants were informed that they could stop their participation at any moment, without having to give a reason. None of our participants used this right.

After having received the instructions about the

experiment, participants filled out a first questionnaire to assess their mood. Subsequently, they were exposed to a 7-minute film fragment, consisting of underwater scenes filmed in the Red Sea and accompanied with relaxing music to make sure that participants in both conditions were in a comparable state of mind at the start of the discussion. To check whether this was indeed the case, participants were asked to fill out the same mood questionnaire a second time. Subsequently, participants were accompanied to the discussion room, where they met with the other two "participants" (the confederates). All three were seated at a hexagonal table, so that each person had one conversation partner on the left-hand and one on the right-hand side, and each had a digital DV camera (25 fps) in front. Both the participant and the confederates were recorded, and participants were told that these recordings would be needed to analyze the decision making process afterwards.

At this point, participants read a text about the case to be discussed, containing the description of a communication problem in a local sport school. Participants were instructed to collectively answer two questions (How did the problems arise? And how could they be solved?), and they were given 4 minutes to answer each one. The actual experimental manipulation occurred during the discussion of the second question. In the inclusion condition, the confederates continuously focussed on the contributions of the participant and emphasized how much they appreciated these ("yes, that's an excellent suggestion!"); in the exclusion condition, the confederates discussed the case solely among themselves, ignoring any contributions from the participant.

After 2 x 4 minutes, the experimenters re-entered the discussion room, and each guided one conversation partner (the participant or one of the two confederates) back to one of the individual rooms. Once there, participants were asked to fill in the mood questionnaire once more. After this, they were shown a second, 7-minute Red Sea underwater scene with soothing music, in an attempt to bring the participants' mood back to more neutral levels. Finally, participants filled out the mood questionnaire one last time.

Subsequently, the participants were fully debriefed about the experiment. None of them was suspicious about the experimental set-up; in particular, all believed that they had been interacting with other, "real" participants. Participants also signed a non-disclosure agreement, to make sure that future participants were uninformed about the actual nature of the experiment. Overall, the experiment lasted about one hour.

Measures

Nonverbal measures. The non-verbal behaviors of the participants were analyzed in two ways. To examine whether outside observers could actually see whether a person is included or excluded, 25 undergraduate students (8 women) judged, on the basis of two fragments, whether participants had been included or excluded. For each of the 59 participants in the experiment, two fragments of 8 seconds (200 frames) were selected. One fragment was selected from the beginning of the four minutes experimental manipulation (frames 1000 - 1200, i.e., 0.40 - 0.48 minutes), and one from the second half (frames 4000 - 4200, 2.40 - 2.48 minutes). This resulted in $59 \times 2 = 118$ stimuli. We opted for fragments of 8 seconds to keep the overall length of the judgement study within reasonable limits. The stimuli were presented to the individual judges in one of two random orders, to control for potential learning effects. Judges had to indicate by forced choice for each fragment whether they believed the person in the film-clip was included or excluded, and on a five point scale how certain they were of their choice. For data processing perceived inclusion was mapped to “1” and perceived exclusion to “-1”, and these scores were multiplied with the certainty score. This resulted in a score ranging from -5 (“very certainly excluded”) to +5 (“very certainly included”). The evaluation of the fragments was preceded by a short training session of five stimuli (consisting of random 8 second fragments not used in the actual experiment), to make participants acquainted with the experimental setting.

To examine the specific non-verbal behaviors of the participants, two independent raters who were blind to the experimental manipulation coded two 30-second fragments (0.30 - 1.00 and 2.30 - 3.00) for each participant. Fragments of 30 seconds were chosen to obtain a good estimate of the different non-verbal behaviors that participants showed. These selections were coded using the Ethological Coding System for Interviews (ECSI); see, for example, Troisi (2002) or Troisi & Moles (1999). The ECSI is a validated non-verbal behavior scale, consisting of 8 behavioral categories and a total of 37 easy to code nonverbal cues. We selected four behavioral categories for coding, namely “Affiliation” (which is associated with ECSI behaviors 2-6, e.g., smile, head tilt, eyebrow flash), “Flight” (behaviors 10-15, e.g., look away/down, chin to chest), “Displacement” (24-32, e.g., hand-face touching, yawning), and “Relaxation” (33-37, e.g., settle, fold arms, laugh). Coding was done blind to condition, and without sound (as required by the ECSI guidelines). For each individual ECSI behavior, the agreement between the raters was measured using Cohen’s kappa. We found that kappa scores for the different behaviors indicate moderate to substantial agreement, where discrete

behaviors (e.g., fold arms) generally resulted in higher kappa scores than continuous ones (e.g., head tilt). Disagreements between raters were resolved after discussion.

Fear of Negative Evaluation. Participants completed the brief Fear of Negative Evaluation Scale (Leary, 1983). This scale consists of 10 items (e.g., “I am afraid others will approve of me”) that were measured on scales ranging from 1 (not at all characteristic of me) to 5 (extremely characteristic of me). Cronbach’s alpha was .83.

Control measures. At several points throughout the experiment, participants were asked to fill out a self-report mood scale derived from Mackie and Worth (1989) and Krahmer et al. (2004). The scale consisted of six 7-point bipolar semantic differential scales (“At this moment, I feel . . .”), using the following adjective pairs (English translations of Dutch originals): happy/ sad, pleasant/ unpleasant, satisfied/ unsatisfied, content/ discontent, cheerful/ sullen and in high spirits/ low-spirited. Alpha’s were $> .80$.

Results

Manipulation Check

To check whether the experimental manipulation worked, we analyzed the self-reported mood scores. Table 1 contains the average scores for the four mood measurements.

Table 1: Average mood scores (standard deviations between brackets)

	Ignored	Included
Mood 1: Initial	5.09 (.81)	5.21 (.76)
Mood 2: After film 1	5.41 (.73)	5.41 (.61)
Mood 3: After manipulation	4.92 (.83)	5.69 (.64)
Mood 4: After film 2	5.73 (.78)	5.56 (.68)

The average mood scores were submitted to a within-subjects Analysis of Variance, with the experimental manipulation (Ignored vs. Included) as a between-subjects factor. Most relevant for our current purposes is that a significant interaction was found between Condition and Time, $F(1, 57) = 7.69, p < .001$. In particular, as can be seen in Table 1, average mood scores for the two conditions are exactly the same after the first film fragment (as intended), but after the experimental manipulation a clear difference between the conditions can be observed: participants who had been ignored reported lower average mood scores than participants who had been included. After watching the second film fragment this effect

Figure 1: Randomly selected stills of 10 participants that were ignored (top panel) and of 10 participants that were included (bottom panel).

disappeared again. Interestingly, there was also a main effect of Time of the mood measurement, and inspection of Table 1 reveals that participants actually felt better after than before the experiment (irrespective of the condition they had been in), $F(1, 57) = 5.01, p < .01$. In fact, various participants indicated during the debriefing phase that they thought the experiment was about the effects of watching underwater scenes, which indeed took up a large part of the experimental procedure.

Perceptions of External Raters

To examine whether external raters could, on the basis of non-verbal cues, determine whether participants were included or ignored, we subjected their evaluations of the second film fragments to an Analysis of Variance. Raters' evaluations of the first film fragments were included as a covariate. We also controlled for participant's sex and their fear of negative evaluation. This analysis revealed a main effect for the experimental manipulation, $F(1, 54) = 10.62, p < .01$. Participants who were ignored were perceived as more excluded ($M = -1.36, SD = 2.48$) than included participants ($M = 1.26, SD = 2.54$).

Note, however, that the standard deviations are relatively large. There was also a main effect for fear of negative evaluation, $F(1, 54) = 5.21, p < .05$. External raters more often considered persons with a lower fear of negative evaluation as included than persons with a higher fear of negative evaluation.

We also examined whether there was an interaction between the experimental manipulation and fear of negative evaluation. We also found an interaction that was significant at the .10 level, $F(1, 54) = 3.04, p < .09$. Persons with a lower fear of negative evaluation were perceived as more included in the inclusion condition. There was no difference in how persons with a higher or lower fear of negative evaluation were rated in the exclusion condition.

Non-verbal behaviors

We also examined the specific non-verbal behaviors of the excluded and included participants. For this purpose, we first conducted a MANOVA, with the four ECSI-categories (Affiliation, Displacement, Relaxation, and Flight) as the dependent variables. This analysis only revealed a main effect for Affiliation, $F(1, 55) = 12.76, p = .001$. Included

participants displayed more non-verbal affiliative behaviors ($M = 1.60$) than participants who were ignored ($M = .88$). The means for all the four categories are presented in Table 2.

Table 2: Average number of non-verbal behaviors across the 4 ECSI-categories

Category	Ignored	Included
Affiliation	0.88 (0.80)	1.60 (0.97)
Flight	1.20 (0.44)	1.17 (0.38)
Displacement	2.12 (1.39)	2.28 (1.46)
Relaxation	0.85 (0.48)	0.83 (0.50)

We then examined the non-verbal behaviors of the participants in more detail. We conducted a series of MANOVAs on the specific non-verbal behaviors within each category of the ECSI coding system. These analyses showed that included participants more often quickly raised and lowered their eyebrows ($p < .01$) or kept their eyebrows up for some time ($p < .05$), and smiled more often than participants who were ignored ($p < .01$). They also seemed somewhat more relaxed ($p < .10$) and more often displayed a neutral face ($p < .05$). Compared to included participants, persons who were ignored touched their face more often ($p < .05$) and twisted their mouth ($p < .01$), licked their lips ($p < .10$) or bit their lips more often ($p < .10$).

Conclusion and Discussion

Being excluded, rejected or ignored is a painful experience that can evoke a host of negative reactions within individuals, ranging from sadness to anger. These reactions, however, may not always occur immediately. Instead, it has been argued that people's immediate reaction to exclusion may be cognitive withdrawal. This withdrawal may be adaptive, in the sense that it may protect individuals from the pain of being excluded.

In this study, we examined whether persons who are being ignored also become less non-verbally expressive. For this purpose, we compared the non-verbal behaviors of persons who were being ignored to the non-verbal behaviors of persons who were being included. We expected that external raters could reliably determine, on the basis of a person's non-verbal behaviors, whether he or she was being ignored or included and we also expected that participants who were being ignored would display non-verbal behaviors that reflect a tendency toward withdrawal. Moreover, we expected that being ignored would result in more displacement behaviors.

The results of this study are somewhat mixed. On the one hand, we found that persons who had been ignored reported lower average mood scores than included persons. External judges also rated

participants who were ignored as more excluded than included participants. Generally, persons with a lower fear of negative evaluation were more often perceived to be included than persons with a higher fear of negative evaluation. In terms of people's specific non-verbal behaviors, however, the findings are less clear. For example, even though persons engaged in less affiliative behaviors when they were ignored, they did not display more non-verbal behaviors that are indicative of withdrawal than included persons (e.g., flight). To some extent, however, they did engage in more displacement behaviors.

The data suggest that persons who are being ignored do, in terms of their non-verbal behaviors, seem to become somewhat more lethargic than included persons but do not entirely disengage from the interaction. It is possible, however, that participants may have evoked display rules to mask or neutralize their feelings because they found themselves in the presence of others. The fact that the interaction was recorded may have also contributed to this. Moreover, the ECSI-coding system that we used to analyze people's non-verbal behaviors may not have been sufficiently detailed to assess the more subtle non-verbal behaviors of our participants.

Nevertheless, the results of the study indicate that even though it is distressful to be ignored or excluded, it does not lead to an overt outburst of emotional distress. Moreover, the tendency of individuals to display less affiliative behaviors while they are being ignored may also be useful, because it may help them avoid doing or saying anything that would make things worse. Future studies should, however, examine in more detail how people cope, cognitively and emotionally, with the stress they experience while they are being ignored or excluded.

Abstract

We measured the continuous bodily motion of participants as they lied to experimenters. These lies were spontaneous rather than elicited, and occurred for different motivations. In one situation, participants were given the opportunity to lie about their performance on a maths test in order to win money. In another, they witnessed one experimenter accidentally break a laptop. When asked what had happened, participants were motivated to lie and deny any knowledge. Across these situations, participants lied 61% of the time, allowing us to contrast the body movements of liars with truth tellers as they answered neutral and critical questions. Those who lied had significantly reduced bodily motion. In one case this motion appeared before the experimenter had even asked the critical question. We conclude that a person's bodily dynamics can be indicative of their cognitive and effective states, even when they would rather conceal them.

Keywords: deception; social cognition; action; body motion

Introduction

While running in between parallel sessions at the next Cognitive Science conference, you catch the eye of a colleague from your university. They smile and ask what you thought of the talk they gave that morning, the one you promised to attend. Since you know that the sessions were both crowded and dimly lit, you take a chance, smile, and say, 'Of course I was there. It was fantastic, as always.' Will they believe your deliberate falsehood? What in your choice of words, gestures and behaviour will make you sound either convincing or conniving?

The good news for you is that it is very unlikely your colleague will be able to tell that you are lying. Regardless of their training or self belief, people are able to detect deception in others at only a fraction above chance levels (Bond & DePaulo, 2006, 2008; DePaulo, Stone, & Lassiter, 1985; Köhnken, 1987; Vrij 1993, 2000). The bad news for your colleague, professionals who need to know if people are lying, and those studying deception is that many researchers have found no unique and reliable behavioural signature for deception (Vrij, 2008; Ekman, 1992; Buller & Burgoon, 1996; DePaulo et al., 1985, 2003).

One reason is that deception is a daily activity and a diverse phenomenon (DePaulo et al., 1996). Sometimes a lie means making up a story, sometimes it means a simple denial. Lying can be done out of kindness or out of self interest. It can have different consequences and place different emotional and cognitive demands on the liar (Vrij & Mann, 2004).

It may not be surprising, then, that a clear link between deceit and bodily activity has proven elusive (DePaulo et al.,

2003). Whilst some researchers have demonstrated increased movements of the fingers, arms, hands, legs and feet whilst deceiving (McClintock & Hunt, 1975), even if only anecdotally (Porter & ten Brinke, 2009), others report decreased limb movements (Vrij, 2008).

Set against this long tradition of deception research are more recent findings in cognitive science regarding the relationship between motor control and cognitive processing. Thinking about the past versus the future shifts the direction that your body tilts (Miles, Nind, & Macrae, 2010) moving marbles upwards rather than downwards changes the emotional content of the memories you recall (Casasanto & Dijkstra, in press), swaying in time with another person and mimicking their actions they make causes you to like each other (Chartrand & Van Baaren 2009), and how you move your mouse cursor when asked 'Do you like Black people?' reveals the influence of negative stereotypes (Wojnowicz et al., 2009). Many of these recent findings rely on fine grained, continuous measures or manipulations of motor activity, rather than discrete, categorical behaviours such as button presses (see Spivey, 2007 for a motivation). Is it possible to use these continuous methods to detect a behavioural signal to deception?

Recently, Duran, Dale & McNamara (in press) adapted a standard paradigm in deception research, and asked people to respond yes or no to certain questions about themselves. They were instructed to give false answers in some cases and truthful answers in others. In this experiment, they signalled their responses using a Wiimote-controller that translated their hand movements into movements of a cursor. They found that deceitful answers had a characteristic movement trajectory, with increased complexity and competition from other responses. This exciting evidence suffers from only one flaw - it is rare that people ask us to lie to them. Regardless, Duran et al's findings suggest that perhaps there is more in motor behaviour than has typically been measured by deception researchers.

In deception research, bodily behaviour is usually videotaped and coded by experimenters. However, this is a laborious, costly and inaccurate method as reliability between coders must be established, extensive training can be necessary and only bodily movements discernible to the human eye can be analysed. Furthermore, because it is necessary to be selective in such a coding method, it requires an understanding of what bodily movements are potentially interesting to examine before it is possible to begin coding. As we have noted, the consensus is that there is no reliable behavioural profile for deceit. An ideal, for

Figure 1. A participant wearing the motion tracking shirt and hat (right) and the 3D position of the markers reconstructed by the motion tracking system (left)

both practical and theoretical goals, is an automated system which will record accurate bodily changes and provide an objective approach to the study of deception (Burgoon et al., 2005; Vrij & Mann, 2004). Such a method, we believe, must be able to maintain the complexity of continuous variables.

Our goal in this experiment was to use continuous, objective measures of the bodily activity of participants who were engaged in spontaneous deceptive behaviour. Participants were told they were in a study about posture and mental arithmetic. This gave us an excuse to measure their body position at 24 locations 200 times a second. It also provided the opportunity for them to lie. We offered them £5 for improving their score in a second round of the maths test. Although the task became much harder, so that score was most likely to decrease, only the participants could know how well they had performed. Therefore, participants were given the opportunity to tell a lie for a monetary reward, without the risk of being caught out.

During the experiment, the participants witnessed the junior experimenter accidentally knock a laptop off of a table. The laptop belonged to a senior experimenter who was absent at the time. Later, when he was unable to turn on his laptop, he asked the participants if they had seen anything happen to it. The junior experimenter was very friendly and the senior experimenter quite unpleasant, and we assumed that this would have provided a second motivation to deceive. We hoped that the participants would be motivated to cover up for her, and falsely deny knowledge of the incident. During these moments, when participants thought that the real experiment had finished, and when they could freely choose to tell the truth or lie, we captured their bodily motion.

Methods

Participants

32 participants took part in two experiments, run in a single session. They were UCL students or members of UCL's subject pool, and received course credit or a payment for their participation. There were 20 females and 12 males, with a mean age of 22.5 years old.

Apparatus

The experiment took place in UCL's Multimodal Lab. Six high speed infrared cameras were mounted on a rail around the perimeter of a 5m square area. Participants wore a tight, stretchable shirt and a cap which had 20 plastic markers arrayed over them (see *Figure 1*). The markers were approximately 2cm in diameter and are highly reflective in infrared light. Additional markers were attached to the hands, tips of the index fingers and the face. Image data from the cameras was passed to the Vicon Nexus motion tracking system at a rate of 200 Hz. The 3D position of each marker was reconstructed with an accuracy of 0.1mm. A digital camera recorded a view of the participants' actions, and a *ladybug 2*, 360° panoramic camera recorded all events in the lab. A ceiling mounted omnidirectional mic provided a sound recording. Participants carried out the experiment sat 50cm or stood 200cm away from a Mac laptop.

Procedure

Three experimenters ran the study. One operated the motion tracking systems and did not interact with the participant. The other two experimenters dealt with the participants according to a well rehearsed script. The senior, male experimenter acted in a cold and unpleasant manner

throughout. The junior female experimenter, who was an undergraduate like the participants, was friendly and engaging. The experimental procedure was designed to put participants in two situations in which they might choose to lie spontaneously to the experimenters. For clarity, we will describe those two situations separately, even though the events they describe partially overlapped with each other. In each, motion is captured in two periods: as the participants reply to a neutral question, and as they reply to a question that has a motivation for deception. Participants were unaware that each of these periods were the critical portions of the experiment and that their behaviour was being recorded.

Participants were told the study was investigating the relationship between body sway and mathematical ability. After donning the motion capture clothes, they stood in a T-pose with arms outstretched for a brief calibration recording. The participants then took part in a simple maths test. After the experiment they were debriefed to the true aim of the study, and gave additional retrospective consent with the option to withdraw their data, which none chose to do.

The Maths Test Following calibration, participants were seated at a table and given a maths test on a laptop. There were 30 multiplication questions with three multiple choices. Participants had a limited time to respond and were given feedback on their answer. A pilot test showed that people scored around 75% on the test.

After completing the test, participants were shown their score. The junior experimenter told them that they were now required to repeat the test, but this time standing up while the motion tracking system measured their balance. She explained that our hypothesis was that standing would improve maths performance. She said that was what we had found so far, and hoped to prove conclusively. In violation of good experimental practice, she deliberately increased the demand characteristic of the ‘experiment’ by telling participants how they should perform. In addition, she explained that participants would receive a £5 reward if their results followed the hypothesised pattern and they scored better while standing.

The participants were told that since they were standing out of reach of the keyboard, they couldn’t enter their answer. They were instructed not to voice their answers aloud but keep count of how many they had calculated correctly. The time given for participants to respond in the standing phase gradually reduced. Norming tests confirmed that this made the test considerably harder, but since they were not inputting their answers, only the participants themselves could ever know their score on the standing phase.

Once they had completed the study, the junior experimenter asked two questions, with the order counterbalanced between participants. The neutral question was “Did you feel the second stage took more or less time to complete?” The critical question was “Did your performance improve on the second test?”. Participants’ body motion was captured from the time she began asking the question to the end of their reply.

Participants who answered ‘yes’ to the critical question received their £5 reward and were categorised as liars. Even though it is possible that the participants scored higher on the second test, the increased difficulty made this unlikely. Therefore overall, we assumed that people who said yes were more likely to be deceptive than those who said no.

The Accident At the start of the experiment, while the participant was signing the consent form, the senior researcher precariously placed a laptop down on a table saying, “I’ve got that report of yours on my laptop. Remind me about it at the end”. After the first stage of the maths test, the senior experimenter left the lab and the junior experimenter prepared them for the standing phase. While walking backwards, the junior experimenter knocked into the laptop that had been left on the table edge, and sent it crashing to the floor. She exclaimed loudly, made eye contact with the participant and said, “Thank God the cameras were off”. Therefore, only the participant witnessed this ‘accident’.

After the second maths test, the senior experimenter came back to the lab and told the participant that he needed to take a backup copy of the data. While the junior experimenter was stood in a corner of the lab preparing herself to leave, he asked the participant the neutral question, “Did the maths experiment run okay?” He then opened his laptop and attempted to turn it on without success. He then turned to the participant and asked the critical question, “Did you see anything happen?” During both questions and the participant’s replies, their body motion was recorded. Participants were categorised as liars if they denied knowledge about the incident, and as truth tellers if they made any reference to the accident or the junior participant.

Debriefing Following the experiment, participants were fully debriefed about the true nature of the experiment and asked if they suspected that deception was being investigated. We framed all their behaviour in a positive light. For example, if they chose to deceive the senior experimenter about the accident, we referred to this as their choice to ‘protect’ the junior researcher. Contact details of psychological services were provided in the event that they felt concerned about deceiving or being deceived.

Data Analysis

Marker positions were reconstructed offline using the Vicon Nexus software. Standard procedures were used for identifying markers and excluding noise. For each marker we calculated the distance it moved in 5msec. We summed those values for series of 20 frames to get the total number of millimeters travelled in each 100ms period. Finally, across every marker and across every 100ms period during the data capture, we averaged those values. Our measure of general body motion is operationalized as the average distance in millimeters that a marker traveled every 100ms.

Figure 1. Total upper body motion during neutral and critical questions in the maths test and accident situations

Results

Participants data was discarded if they guessed our real hypothesis, in cases of experimenter error or deviations from the script. The complexity of the equipment and the spontaneous nature of the behaviour meant that data loss was a risk in this experiment. In the event, 34 (out of 128) trials produced unusable data. Since a full analysis of the data would require that we have data for all four periods for all subjects, we carried out planned comparisons on the maths deception and the accident data separately, giving us 18 and 23 subjects respectively. However, the same pattern of means and significance was still found when we analysed the smaller set of 16 subjects who had a full set of data for each cell.

This study is a quasi experiment, as participants placed themselves in the truth or lie conditions rather than being assigned. Overall, they chose to lie 61% of the time, allowing a between subjects comparison of the body motion of truth tellers and liars. Their (dis)honesty was consistent: 73% of participants either lied or told the truth on both occasions. Body motion data were analysed in a 2 (deception: truth teller/liar) x 2 (question type: neutral/critical) ANOVA.

The Maths Test

Participants moved less if they attempted to deceive the experimenter and lie about their maths score. They moved more when asked the critical question than when asked the

neutral question, though the difference between truth tellers and liars was greater in response to the critical question. This pattern of results is shown in panel A of *Figure 2*, and supported by a main effect of deception ($F(1,21)=7.97$, $p=.01$), a main effect of question ($F(1,21)=9.04$, $p=.007$) and a significant interaction ($F(1,21)=6.24$, $p=.021$). Post hocs show that the participants did not significantly differ in their motion in response to the neutral question, but moved significantly more when telling the truth in response to the critical question.

The Accident

Participants moved less if they attempted to deceive the experimenter and deny knowledge of the accident. They also moved less overall in response to the critical question. This pattern of results is shown in panel B of *Figure 2*, and supported by a main effect of deception ($F(1,21)=7.97$, $p=.01$) and a main effect of question ($F(1,21)=9.04$, $p=.007$). The interaction was not significant ($F(1,21)=1.11$).

General Discussion

When people spontaneously lied to us, they reduced their bodily motion. Behind this simple finding, robustly supported by our data, lie two more nuanced stories. One concerns the directionality of the relationship between body motion and deceptive behaviour. The other concerns the difference between the two situations and the two types of lie.

In the maths test, there was no obvious negative consequence to the participants' lie. The junior experimenter gave clear signs that she would prefer a particular answer, and participants were given a monetary reward for providing it. It was clear from the situation that there was no way in which participants could be found out if they lied, since they could be the only people who knew the truth. Therefore, participants had everything to gain and nothing to lose by lying. In this situation, participants' body motion was not different in response to the neutral question, but those who chose to lie for the reward showed less motion when answering the critical question.

This result aligns with other findings (Vrij, 2000) that during cases of deception, bodily motion can decrease. One explanation is that even though there is no logical way that another person can know that we are telling a lie, we suffer from an 'illusion of transparency' (Gilovich, Medvec & Savitsky, 1998). We are prone to thinking that since our own internal mental states are highly salient to us, they must be at least partially visible to others. Therefore, when we think about something that we don't want others to know, we try to suppress our overt actions in an attempt to suppress the (nonexistent) cues to our mental states. As often happens, it is not the lie that causes people to be caught, but the cover-up.

In the accident situation, the motivation and the consequences for lying are quite different. By lying, participants are acting in the interest of another person, the junior experimenter. Our intention was that the participants would feel some affiliation with her, due to her overt friendliness to the participants and their similarity in age and position. In sharp contrast, the senior experimenter asserted his authority over everyone else in the lab, and was curt and unpleasant when speaking to the participant. By lying to him, the participants are aligning their interests with their in-group, which is a strong motivation for social behaviour. However, unlike the maths test situation, there could conceivably be negative consequences to this lie. Something did indeed happen to the laptop, and it's possible that the senior experimenter could find out what happened in the future - perhaps the junior experimenter would confess. In this case, the participants would be discovered to have lied to someone in authority.

Both the motivation (DePaulo et al., 2003) and the possible consequences of the social lie are related to affective outcomes. In contrast to the maths lie, where material reward is at stake, in the accident situation, participants lie to foster an affiliation between themselves and the junior experimenter, but risk the aversive consequences of lying to an authority figure. We hypothesise that these differences produced an unusual feature of our data.

For the accident situation, the difference between liars and truth tellers emerged in responses to both the neutral and the critical questions. The neutral question was always asked before the critical question in the accident situation, as pilot studies showed that it seemed very unnatural for the experimenter to interrogate the participant about his broken laptop, and then switch to innocuous questions.

So why is it that participants who are going to lie to the experimenter in the near future already show a distinctive pattern of body motion when answering his neutral question? In looking back over the situation we constructed for participants, it seems that they may have already been thinking about the laptop and the incident they witnessed during the neutral question. While asking the neutral question, "Did the maths experiment run okay?" the senior experimenter was walking towards the table where the broken laptop was sat. This, coupled with the fact that he mentioned he was taking a backup of the data, makes it plausible to suggest that the participants realised he was about to use his laptop. At that point, perhaps they were considering the affective consequences of him discovering the accident, accusing the junior researcher, and asking them for information. In other words, even during the neutral question, participants' body motion was revealing their relation to the whole scenario of the accident and the two different researchers, and their own potential involvement.

This claim brings us to the second issue raised by these findings. Is it the case that there are some individuals, or some individuals' moods, that correlate with higher levels of bodily motion and higher levels of honesty? Or does the act of forming a lie or preparing to tell the truth produce a particular pattern of bodily motion? In the context of the accident situation, for example, it could be that during the neutral question some individuals are feeling heightened anxiety (because of what they witnessed), and that anxiety produces more bodily motion and higher rates of telling the truth. Alternatively, it could be that during the neutral question, some participants are already acting to suppress their overt behaviour as they prepare to tell a lie to the experimenter, or at least, distance themselves from the awkward situation.

In short, does body motion reveal differences between *people* who tell the truth and people who lie, or does it reveal differences in the *process* of lying and truth telling? There is some evidence for the latter proposal in our maths test situation. If it were true that some people simply move more and are more disposed to honesty, then we would expect to see truth tellers moving more in response to the neutral maths question as well as the critical question. Furthermore, supporting evidence for a direct link between motion and deception comes from experiments which instruct participants to lie or tell the truth, and thereby cause differences in bodily movements (Duran et al., in press). At present though, our data are equivocal on this point, and calls for further investigation.

Conclusion

People who spontaneously lie, or are about to lie, showed reduced body motion in our experiment. Though this pattern was found across two different types of situation, we are not rushing to make any claims to have found a unique bodily signature for deceptive behaviour. Differences in the two types of situation produced distinct patterns in degree of bodily motion and the conditions under which it emerged. We have speculated that these bodily differences are related to differences in the underlying motivations and consequences of deception in the two situations. We take

this work as establishing that motion capture systems are a new telescope that we can point at deception, and reaffirming the complexity of cognitive and affective states that underlie spontaneous deceptive behaviour.

It remains the case that almost no-one is much better than a coin toss at detecting deception in others (Bond & DePaulo, 2006). A notable exception are the FBI interrogators trained and tested by Ekman and O'Sullivan (1991). In their article, 'Who can catch a liar?' they reported a deception detection rate of 64%. Recently Bond (2008) came across a passage in Ekman's (1992) book giving further details of that experiment. As it is described, the study has a striking similarity to our own maths test situation that was designed to evoke spontaneous lies:

"Immediately after taking the test I would give the correct answers. Then I asked them to raise their hands if they got all ten correct, nine correct, and so forth. I tallied the results on a blackboard so that they could evaluate their own performance against that of their group. . . . In September 1991, our findings on these professional lie catchers were published"

(Ekman, 1992; pp. 282–285)

As Bond (2008) concluded, "Who can catch a liar? It would appear to be Secret Service agents who get to score their own tests." It is an intriguing thought that these FBI agents, might themselves have displayed signature patterns of bodily movement that betrayed the fact that they were actually lying about their ability to detect liars.

Acknowledgments

We would like to thank Geoff Bird, Rick Dale, Natasha Kirkham and Michael Spivey for many insightful discussions. This research was carried out as part of NME and SB's undergraduate dissertations, and authorship is equal.

Exploring the mental space of autonomous intentional agents

Abstract

How do we use the motion of animate objects to make inferences about their intentions? We investigate this question using displays containing a number of autonomous, independently programmed agents moving about the screen and interacting with each other. Each agent behaves according to an independent autonomous program, controlled by a small number of parameters that define its “personality.” We probe subjects’ impressions of the similarities among the behaviors of the various agents, and then use multidimensional scaling to recover the subjective parameters defining the mental space of agent types. The most important variable turns out to be one that determines how the agent reacts to a nearby agent at one critical distance. A followup experiment suggests that variation along this parameter contributes to modulating a higher-level percept of how “hostile” or “friendly” the agents appear to be.

Keywords: animate motion perception; theory of mind; intentionality; action understanding; goal inference.

Introduction

Intelligent agents can and must distinguish between animate and inanimate objects that they encounter. Even infants make this distinction, and apparently possess a naïve theory of other beings’ mental states and intentions (Gergely, Nádasdy, Csibra, & Bíró, 1995; Keil, 1994; Johnson, 2000). Socially intelligent agents naturally conceive of other humans as animate, mentalistic agents with independent perceptions and motivations. We further benefit from being able to infer the *intentions* of other agents in the environment. This is essential for understanding and predicting others’ behavior, a prime skill both for chess players contemplating their moves, and gazelles and lions engaging in mutual scrutiny on the African plain.

This research explores how adult subjects use an observed agent’s motion to make inferences about its mental architecture. For this task, motion is only one cue among many (Gelman, Durgin, & Kaufman, 1995), but it is a particularly salient one, with subjects readily ascribing intentionality even to simple moving geometric figures (Heider & Simmel, 1944). A handful of studies have shown that varying the motion of simple geometric figures along certain parameters (e.g. speed, trajectory) can influence the perception of animacy and intentions (Dittrich & Lea, 1994; Tremoulet & Feldman, 2000, 2006). But the factors determining these percepts are still very poorly understood.

Baker, Tenenbaum, and Saxe (2006) and Baker, Saxe, and Tenenbaum (2009) have proposed a Bayesian framework for “inverse planning,” that is, inferring or estimating the goals or intentions of an agent assumed to be rational. Sloman, Fernbach, and Ewing (2009) use Bayesian belief networks to describe causal reasoning in the domain of morality. We

too presume a Bayesian formulation of the problem, in which the goal is to assign a posterior probability to the mental state (behavioral disposition, goal set, payoff matrix, or some other representation of the other agent’s mind) A on the basis of its motion:

$$p(A|\text{motion}) \propto p(\text{motion}|A)p(A). \quad (1)$$

Ultimately, such an inference maps a visual input (the motion observed) onto a distribution of possible agent types. The prior $p(A)$ is defined over the set of possible agent types, that is, the space of behavioral dispositions the observer is in principle willing to entertain as explanations for the observed motion. The nature and structure of this space have been discussed only very speculatively in the literature; Barrett, Todd, Miller, and Blythe (2005) have argued that it probably includes such natural action classes as chasing, courting, following, guarding, fighting, and playing. Some studies have presented subjects with scenes constructed to resemble these different “natural categories” of dyadic interaction, and demonstrate that subjects are reliably able to categorize these scenes, even in degraded forms for which motion is the only salient cue (Barrett et al., 2005; McAleer & Pollick, 2008).

In contrast to most previous experiments, the scenes we present to subjects have *not* been pre-constructed to convey particular categories of interaction. Our aim is to show subjects a broad array of agent interactions—from a richer and more general collection of possibilities—in an attempt to allow subjects’ minds to impose *their own* structure on the agent space. The way we produce the desired scenes is also novel: We program the agents inhabiting these scenes to behave *autonomously*, which results in often chaotic multi-agent interactions that we cannot predict in advance.

In Exps. 1 and 2, we use multidimensional scaling (MDS) in an attempt to extract the natural clusters and cleavages present within this stimulus space of intentional behavior. Exp. 3 is explicitly designed to help clarify the results of Exps. 1 and 2 by unraveling the “semantics” of the features uncovered by the MDS. Displays were programmed using the breve Simulation Environment (Klein, 2002), an open-source software package freely available at <http://www.spiderland.org>.

Programming Lifelike Automata

In designing and coding the agent behaviors, we aimed to employ a simple programming scheme that would impose minimal structure on the agents’ interactions but, nonetheless, would be capable of producing a rich variety of lifelike agent

behaviors.¹ We programmed the triangular agents to behave autonomously, each running its own independent program. Inspired by the work of Braitenberg (1984), we aimed to create rule-governed agents which, notwithstanding the simplicity of their programs, yield vivid and lifelike behaviors that give subjects a strong impression of intentions.

Agent design Rather than presenting subjects with pre-fabricated animations, we populate simulations with autonomous agents and then allow these simulations to run for a predetermined length of time (15 seconds). Each agent starts off in the simulation environment with a randomly-assigned velocity and location. The agent always orients one vertex of its triangular body (that which lay on its axis of symmetry) in the direction of its movement, inducing the impression that the front end is the agent's "head" (see Tremoulet & Feldman, 2000). When an agent either collides with another agent or the edge of the scene, it "bounces off" for one iteration of the simulation.²

At each iteration of a simulation, an agent finds the nearest *other* agent within the scene and then accelerates toward or away from it to an extent determined by a set of six parameters contained in its program. The parameters control the direction and magnitude of the agent's acceleration—relative to the nearest other agent—at six respective distances from this other agent: 0–5 "units", 5–10, 10–20, 20–40, 40–70, or > 70. A schematic of these 6 radii around an agent, along with a snapshot of Experiment 1, is shown in Figure 1.

One example agent might approach another agent from afar but then veer away as it gets to a closer radius. Others might consistently accelerate away from another agent. Depending on how this other agent is programmed, their interaction might resemble chasing/fleeing, or one pushing the other, or even one agent circling the other.

We constructed a pool of 12 agents, each with 6 randomized parameters within the programming scheme.

Experiment 1

Method

Subjects Eight students between the ages of 18 and 24 participated in an approximately one-hour experimental session in exchange for course credit.

Stimuli Scenes were presented to subjects on a 1440 x 900 LED display, on a 15 inch MacBook Pro laptop with a 2.2 GHz dual core processor. The simulation environment itself measured 33.0 x 16.5 cm, and the viewing distance was approximately 45 cm. The programming library employed units

¹It is important to note that the programming scheme we employ here is only one possible choice among many. The design of life-like agents is a complex and multifaceted problem that extends far beyond the scope of our research. For us, these simple automata are merely tools for aiding an empirical study of the perception of intention.

²In Experiment 1, this sometimes resulted in jerky and unnatural-looking behaviors at agent collisions, so in Experiments 2 and 3 we changed collision behavior slightly: agents in these experiments bounced off each other for a full .2 s at some random velocity vector.

Figure 1: Screenshot from Experiment 1 (colors inverted), with black circles and numbers superimposed onto the scene to help illustrate the programming scheme for the automata. The black automaton in this scene accelerates toward or away from the nearest other agent in the scene. The direction and magnitude of this acceleration depends on the distance to this nearest other agent, with possible distances divided into six zones. Zone #5 seems to be most psychologically relevant.

that were equivalent to 8.7 units/cm. The triangular agents had bases of 1 unit length and heights of 4 unit length.

Procedure In each 15 s scene, the subject observed 7 agents interacting: 3 red, 3 blue, and 1 white. The reds behaved according to the same parameters as the other reds, the blues according to a different set of parameters, and the lone white according to a third set of parameters. The agents were drawn from a larger 12 agent pool; thus, there were 220 possible triads of these 12 agents.³ For each scene, one of these 220 triads was selected at random, and each of the three programs in the selected triad was randomly assigned to either red, blue, or white. Each subject saw 220 such scenes, exhausting the possible triads.

Subjects were openly encouraged to construe the triangular agents as animate. At the end of each scene, they were asked "Is the white agent behaving more like a red, or more like a blue?" They answered by clicking on a button in a dialog box.

We constructed a 12 x 12 symmetric distance matrix for each subject, to be fed into the individual differences multi-dimensional scaling (MDS) algorithm (INDSCAL/ALSCAL; Takane, Young, & Leeuw, 1977). Within this matrix, an agent was assigned a distance of 0 from itself. As two different agents appeared in the same trial of an experimental session 10 times, the distance in this matrix between any two agents was initially set at 11.

³Strictly speaking, because the status of the white agent in each trial is special, and, as a result, during a given trial the subject cannot respond that he actually believes the blue and red agents to be most alike, 660 possible arrangements actually exist. Rather than show all 660 possibilities, we randomized the procedure so that no agent type would be more or less likely to be "white" during a trial. Nevertheless, this presents a source of noise in the data, and we altered the procedure in Experiment 2 to address this issue.

Figure 2: The 2-dimensional MDS solution for the 12 agents, fitting data from Experiment 1.

If the subject chose “red,” then the agent whose programming was used for the red agents in this trial was made to be closer together (more similar) in this distance matrix with that of the white agent, and likewise for if the subject chose “blue.” That is, the distance between these two agents in the matrix was reduced by 1. Previous studies have used similar methodologies to gauge subject similarity ratings of visual stimuli (e.g., Kahana & Bennett, 1994; Pantelis, van Vugt, Sekuler, Wilson, & Kahana, 2008).

Results and Discussion

We derived a 2-dimensional (2D) MDS solution in order to visualize the space of agents that subjects (on average) perceived (see Figure 2). For this amount of points in the space, the INDSCAL algorithm allows for fits of 2-5 dimensions. Deriving higher-dimension solutions will always result in better fits to the experimental data.⁴ However, a higher number of dimensions would be even more difficult to interpret than the 2 condensed dimensions we present, and even a 5-dimensional fit would probably be a condensed version of the true amount of psychologically relevant dimensions in this agent space (which could hypothetically be even higher than the total number of agents in our sample).

A 2D solution allows for the easiest visualization of the inter-agent distances, an important motivation for using the MDS analysis in the first place. If interesting structure emerged only in higher-dimensional fits for these data, this might have justified using these MDS solutions. However, we actually found the clearest and most interesting structure within a 2D fit.

The most striking aspect of the space is its ring-like structure, similar to what one would observe in a 2D MDS plot of the color wheel (see Shepard, 1980). The significance of this ring structure was not immediately clear, in part because MDS dimensions are in general not self-explanatory

⁴While we examined a scree plot of the pooled data from Experiments 1 and 2, we do not display it here due to space considerations. This scree plot does not demonstrate a clear “elbow” favoring one particular number of dimensions over another.

Table 1: Correlations ($r[10]$) between programmed parameters (rows) and MDS dimensions (columns). Bold font represents $p < .01$

	MDS Dimension 1	MDS Dimension 2
Parameter 1	-.070	.384
Parameter 2	-.275	-.074
Parameter 3	.527	.199
Parameter 4	.411	-.375
Parameter 5	-.801	.093
Parameter 6	.459	.197

but rather pull out subjectively primitive parameters. Exp. 3, presented below, was designed to help clarify the nature of the parameter exhibited in this ring.

The goal of the present experiments was not, per se, to see how the somewhat arbitrary parameters with which we programmed the agents mapped to subjects’ percepts of the agents’ behaviors. Rather, we had aimed to infer the structure of the perceptual space itself. Nonetheless, relating these parameters to the MDS dimensions was a useful step in understanding the 2D MDS space.

Subjects’ perception of the agents’ behaviors arises from some complex interaction of its underlying programming and the chaotic interaction with other agents that arises during each unique simulation. This contributed to there being many individual differences between subjects’ results; few subjects’ distance matrices showed obvious correlation. However, one of the 6 parameters with which we programmed each agent was indeed strongly correlated with one of the MDS coordinates (see Table 1). This parameter controlled how an agent behaved when the nearest other agent was between 40 and 70 units (4.6 to 8.1 cm) away from it. This finding is addressed further in the Experiment 2 discussion.

Experiment 2

In Exp. 2, we adjusted the basic methodology of Exp. 1 in hopes of reducing the amount of noise in the data. The most significant change was to allow the subject to control one of the agents in each simulation via the mouse. The chance to interact with the simulated agents would, we expected, allow the subject to glean more information about the other agents’ behaviors during the short 15-second display time and thus promote stronger impressions of the agents’ “personalities” than was possible in Exp. 1.

Method

Subjects Seven students between the ages of 18 and 23 participated in an approximately one-hour experimental session in exchange for course credit.

Stimuli We presented scenes to subjects on an eMac with a 17 inch (16 inches viewable) monitor and a 1152 x 864 display. The monitor refresh rate was 80 Hz and the computer had a 1.25 GHz processor. The simulation environment it-

self measured 25.4 x 16.5 cm, and the viewing distance was approximately 45 cm.

Exp. 2's scenes were populated with triangular agents of the same size and programmed under the same scheme as in Exp. 1. We used the same pool of 12 agents from Exp. 1, each which had been created with 6 randomized parameters within the programming scheme.

Additionally, the subject controlled one agent with the mouse: a white circular agent 4 units in diameter. The automatic agents reacted to the subject-controlled agent in the same manner as any other triangular agent in the simulation.

Procedure In each 15 s scene, the subject observed 6 agents and controlled 1 agent. 2 agents were red, 2 were green, 2 were blue, and the subject-controlled agent was white. The reds would behave according to the same parameters as the other reds, the greens according to a different set of parameters, and the blues according to a third set of parameters. The agents were drawn from a larger 12 agent pool; thus, there were 220 possible triads of these 12 agent programs. For each scene, one of these 220 triads was selected at random, and then each of the three programs in the selected triad was randomly assigned to either red, green, or blue. Each subject saw 220 such scenes, exhausting the possible triads.

Subjects were openly encouraged to construe the triangular agents as animate, and were instructed that how agents of a certain color behaved during one trial would have nothing to do with how they behaved in subsequent trials. At the end of each scene, they were asked to determine which color of agent behaved *least* like the other two—that is, which was most different: red, green, or blue? They responded by key press, at which point the next trial began.

As in Exp. 1, we constructed a 12 x 12 symmetric distance matrix for each subject, to be fed into the individual differences multi-dimensional scaling (MDS) algorithm. For each trial, the two non-chosen agents in the odd-one-out procedure were made more similar within this distance matrix.

Results and Discussion

Parameter 5	-.310	-.619
Parameter 6	.249	.233

Once again, we derived a 2D MDS solution in order to visualize the space of agents that subjects (on average) perceived, and we once again observed a ring-like structure in the space (Fig. 3).

The MDS solutions for the two experiments—processed representations of subjects' raw similarity matrices—were correlated with each other. Dim. 1 of Experiment 1's MDS was strongly correlated with Dim. 2 of Experiment 2's MDS [$r(10) = .713, p < .01$]. Dim. 2 of Experiment 1's MDS was weakly (and negatively) correlated with Dim. 1 of Experiment 2's MDS [$r(10) = -.551, p = .063$]. (The direction of these correlations is arbitrary and unimportant, but helpful in relating the 2D MDS spaces presented in Figures 2 and 3.) These correlations provide some assurance of the robustness and psychological reality of the subjective mental spaces that we have uncovered.

As shown in Table 2, Dim. 2 in Experiment 2 correlated significantly with parameter 5 of the agents' programming. This is consistent with the results of Experiment 1, where Dim. 1 had been correlated with this same parameter. Apparently, how an automaton reacted to (i.e. accelerated toward or away from the direction of) the nearest other agent in the simulation when that agent was 40-70 units away (10 to 17.5 times the length of an agent) was a psychologically important variable.

We wondered if the prominence of this parameter in subjects' judgments was actually an artifact of the frequency with which interactions at this distance actually occurred in the displays. But the data do not bear this out. Because the entire displays were recorded (10 frames/second), we could assess the proportion of the time the inter-agent distance between any automaton and its nearest other agent was within each of the six intervals corresponding to the six underlying programmed parameters. The two most common distances between an automaton and its nearest other agent during a simulation were 0-5 units (0-1.25 agent lengths) and 20-40 units (5-10 agent lengths). 40-70 units (10-17.5 agent lengths) was only the fourth most common inter-agent distance. The pivotal role of this inter-agent distance is not an artifact, but rather reflects a genuine cognitive focus on behavioral interactions at this distance.

Experiment 3

The results of the first two experiments were qualitatively similar, and we therefore choose to pool data from all 15 subjects for the following analysis and discussion. The 2D MDS solution for these pooled subjects reveals an even cleaner ring structure (see Figure 4). But what does it mean as we travel around this ring?

In the combined MDS, Dim. 1 is connected to how an agent behaves when the closest other agent is between 10–17.5 agent lengths away (i.e. programmed parameter #5). Agents low on Dim. 1 all tend to accelerate away from the nearest other agent; agents high on Dim. 1 tend to accelerate toward the nearest other agent. The meaning behind Dim. 2 is less straightforward. While this dimension is clearly not independent from Dim. 1, it is uncorrelated with any of the programmed agent parameters. Hence we turn to further psychophysics to provide evidence about its meaning.

We hypothesize that a potential “friendly” versus “hostile” dimension emerges from the interaction of these two MDS dimensions. This hypothesized dimension would be neither orthogonal nor redundant with whether an agent accelerates toward or away from another agent at a certain distance—say, the distance with which programmed parameter #5 is concerned. When an agent moves in the direction of another, it may, for instance, appear to be aggressive or merely curious.

Method

Subjects Seven students between the ages of 18 and 24 participated in an approximately half-hour session in exchange for course credit.

Stimuli and Procedure We presented scenes to subjects under the same viewing conditions as Exp. 1. We again populated the simulations with the pool of 12 agents employed in Exps. 1 and 2. During each trial, the subject watched 7 agents interacting for 15 seconds. Six of the agents were colored red and behaved under programs randomly selected from the pool of 12. The seventh, critical agent was colored blue, and the subject was instructed to attend to it. At the end of each trial, the subject was asked, “On a scale of 1–5, 1 being most hostile, and 5 being most friendly, how do you rate the blue agent?” The subject indicated his response on the keyboard. Each of the 12 agents in the pool was assigned the blue color for 8 of the session’s trials, for a total of 96 trials presented in random order.

Results We first normalized each subject’s responses, then calculated each subject’s mean normalized response for each of the 12 agents observed over the experimental session. Then, averaging across subjects, we were able to get a sense of how friendly versus hostile subjects perceived each of the 12 autonomous agents. Figure 4 shows, on a gradient from red to green, what these perceptions were. The most hostile agents seem to be those which were high on MDS Dim. 1 and low on Dim. 2, while the friendlier agents tended to be low on Dim. 1 and high on Dim. 2. Agents low on both dimen-

Figure 4: Pooled 2-dimensional MDS from Experiments 1 and 2. The 2D space is rotated about the origin so that the cosine of the agent angle (relative to the horizontal) best predicts how subjects rated the agents along the “hostility” versus “friendliness” dimension. “Hostility” versus “friendliness” is represented for each agent here with a color gradient from red (most hostile) to green (most friendly), with yellow being neutral.

sions were quite neutral. Fig. 4 shows the space in a rotated coordinate frame so that the horizontal dimension optimally reflects the friendliness vs. hostility dimension. (All of the inter-agent distances and relationships have been preserved; only the “ring” has been rotated.) In the rotated space the projection of each agent’s position onto the horizontal (i.e. the cosine of its angle relative to the horizontal) reflects its position along the friendly/hostile dimension. We regressed the subjects’ mean friendliness rating against this variable and found a close fit ($r(10) = -.768, p < .01$, Figure 5). These data corroborate our hypothesis that the ring variable essentially reflects the degree of perceived friendliness or hostility each agent exhibited.

General Discussion and Conclusions

These experiments were designed to probe the underlying structure of the agent space perceived by subjects as they watched autonomously programmed agents interacting in a dynamic scene. In Experiments 1 and 2, the MDS approach succeeded in revealing certain aspects of this perceptual space: a ring-like structure, which—in Experiment 3—we attempted to connect to a dimension of perceived hostility versus friendliness in the agents. One of the low-level parameters controlling the behaviors of the agents contributed to this more abstract percept: that which controlled inter-agent reactive behavior at one critical distance. We conclude that this reflected one perceptually critical inter-agent zone upon which subjects based their interpretations of the agents’ intentional behavior.

From the results of Experiment 3, we further conclude that “hostility” versus “friendliness,” or something akin to this di-

Figure 5: Cosine of the agent's angle in MDS space (see Fig. 4), plotted against how subjects, on average, rated them (from hostile to friendly). Best linear fit is drawn in red.

chotomy, appears to produce an especially salient partition in subjects' perceptual space. In other words, after first surmising that an object in the world has intentions (i.e., is animate), a next step for the cognitive machinery might be an attempt to guess whether these intentions are bad or good.

This work represents one step in what we hope is a fruitful new direction. Programming agents autonomously, and asking how subjects' interpretations of these agents' behavior relates to the actual programs they are carrying out, allows one to pursue a true "psychophysics of intention," in which we explore the relationship between the perceived intention and the "actual" intention present in the agent's autonomous program. In future experiments, employing displays of potentially far more complex behavioral interactions, we hope to uncover correspondingly more complex structures in the intentionality percept.

Abstract

Empirically minded researchers have begun exploring the “folk” notion of intentional action, often with surprising results. In this paper, we extend these lines of research and present new evidence from a radically new paradigm in exploration of folk intuitions about intentional action. Our results suggest that in some circumstances people make strikingly different judgments about intentions and intentionality as a function of whether the person brings about or observes an event. Implications for action theory and the experimental study of folk intuitions are discussed.

Keywords: Experimental Philosophy; Intentional Action; Actor-Observer Differences; Side-Effect Effect

Determining whether a person's behavior was intended or intentional is crucial for a host of important judgments such as assigning blame and praise. This part of human experience has been of central concern for philosophers of action (Mele, 1992). Many of these philosophers take themselves to be exploring the everyday or “folk” concept of intentional action (Adams, 1986; McCann, 1986, 2005; Mele, 1992). Some philosophers even write that “a philosophical analysis of intentional action that is wholly unconstrained by that [folk] concept runs the risk of having nothing more than a philosophical fiction as its subject matter” (Mele, 2001, 27). Empirically minded researchers (e.g., experimental philosophers) have helped shed light on this folk notion of intentional action, often with surprising results. In this paper, we extend these lines of research and present evidence using a new paradigm to study folk intuitions about intentional action. Our results suggest that in some circumstances people make strikingly different judgments about intentions and intentionality partially as a function of whether a person brings about or observes an event. Implications for traditional action theory and the study of philosophically relevant folk intuitions are discussed.

Experimental Philosophy and Action Theory

Arguably the best known studies in the experimental investigation of intentional action intuitions are Knobe's (2003a)

harmful (underlined) and helpful (bracketed) chairman cases:

Harm/Help: The vice-president of the company went to the chairman of the board and said, “We are thinking of starting a new program. It will help us increase profits, but [and] it will also harm [help] the environment.” The chairman of the board answered, “I don't care at all about harming [helping] the environment. I just want to make as much profit as I can. Let's start the new program. They started the program. Sure enough, the environment was harmed [help]ed]. (191)

The only difference between the two cases is the moral valence of the consequence of the chairman's decision. Remarkably, this shift in the moral valence of the consequence drastically changed people's intentionality judgments about the consequence: 82% of participants judged that the chairman brought about the harm to the environment intentionally whereas only 23% judged the chairman brought about the help to the environment intentionally. This general effect (the side effect-effect or the Knobe effect) has been replicated using similar scenarios (Cushman and Mele, 2008; Knobe, 2003a, 2003b, 2004a, 2004b) across cultures (Knobe and Burra, 2006), as well as across ages (Leslie, Knobe, and Cohen, 2006).¹

Knobe-style cases feature *side effects*. If a consequence of an intended action is foreseen but not intended, then that consequence is a side effect of the intended action.² Side effects have been considered important test cases of some theories of intentional action. Just to take one example, Knobe-style cases have been argued to challenge a prominent view in intentional action—the Simple View (SV). According to the SV, if an agent intentionally performs an action *A* then the agent intends to *A*. Some philosophers have argued that the SV is supported by folk intuitions (Adams, 1986; McCann 1986, 2005). However, as judgments in Harm suggest, sometimes the folk make judgments that are contrary to the SV. If the harm to the environment is a side effect, then it is

¹See Feltz (2007b) for a more detailed overview.

²See Cushman & Mele (2008) for a detailed definition of a side effect.

not intended. But, most people think that the harm is brought about intentionally. Hence, in some circumstances, many have the intuition that one can harm the environment intentionally without intending to do so. This pattern of intuitions seemingly falsifies that the SV is supported by folk intuitions (Nadelhoffer, 2006).

In the next two sections, we suggest that folk intuitions surrounding intentional action may be much more complicated than originally thought and may be influenced by a variety of factors including one's perspective.

Actor-observer differences

Actor-observer differences refer to a common effect where people who engage in behaviors (actors) see things differently than those who watch behaviors (observers). The traditional conception of the actor-observer asymmetry posits that the "actor's view of his behavior emphasizes the role of environmental conditions at the moment of action. The observer's view emphasizes the causal role of stable dispositional properties of the actor" (Jones & Nisbett, 1972, 80). While it is debatable whether this traditional conception is completely accurate (Malle, Knobe, & Nelson, 2007), some actor-observer asymmetries have been revealed in decisions made in risky environments (Fernandez-Duque & Wifall, 2007), moral judgments (Nadelhoffer & Feltz, 2008), and action explanations (Malle & Knobe, 1997; Malle, Knobe, & Nelson, 2007). To illustrate, consider one case from Nadelhoffer and Feltz (2008) where an actor-observer asymmetry was found:

Trolley: A trolley is hurtling down the tracks. There are five workers on the track ahead of the trolley, and they will definitely be killed if the trolley continues going straight ahead since they won't have enough time to get out of harm's way. There is a spur of track leading off to the side where another person is working. The brakes of the trolley have failed and there is a switch which can be thrown to cause the trolley to go to the side track. Imagine that you are an innocent bystander who happens to be standing next to the switch. You realize that if you do nothing, five people will definitely die. On the other hand, you realize that if you throw the switch, you will definitely save the five workers. However, you are also aware that in doing so the worker on the side track will definitely be killed as the result of your actions.³

Observers received the same scenario except 'you' was replaced with 'John' (along with appropriate verb conjugations). Participants were asked if flipping the switch is morally permissible and rated how much control over the situation one has. People given the 'John' version were more likely than those given the 'you' version to judge (a) that flipping the switch was "morally permissible" and (b) that John had control over the events.⁴

³These scenarios modified cases used by Petrinovich and O'Neil (1996), but Trolley Problem cases are well known in the literature.

⁴Ninety percent in the 'John' version thought it was permissible versus 65% in the 'you' version. Also, the mean control rating in the 'John' version was 4.28 and 5.12 for the 'you' version (on a 7

point ascending scale). But why do actors and observers sometimes display this asymmetry? According to Malle, Knobe, & Nelson, one reason is that "we can expect that actors normally have better access to their own reasons than observers do and that they are normally more motivated to portray themselves as active, conscious, and rational agents" (2007, 508). Hence, because actors may be motivated to (a) portray themselves in a positive light and (b) have special access to their own reasons, they are prone to judge their own behaviors differently from others' behaviors. This explanation could account for the asymmetry in the Trolley example. Because actors are motivated to portray themselves in a positive light and flipping the switch results in the awful killing of a person, they are less likely to judge it permissible for them to flip the switch. However, because they are relatively less interested in portraying others in a positive light, they judge that it is permissible for others to flip the switch. But actors who realize that flipping the switch is the optimal decision even if it kills a person may excuse themselves by judging they had no control over the situation.

Given that there are actor-observer differences in a wide variety of contexts, we thought that similar actor-observer differences would be found in judgments about intentions and intentionality. In our first experiment, we used a new method in the study of folk intuitions about intentional action borrowed from experimental economics. We had participants engage in a real decision making process with real rewards and penalties. Because participants *actually* became actors, we hypothesized this methodology would have the greatest chance of revealing actor-observer differences in intentional action intuitions.

Experiment 1

We constructed a decision making environment where participants could (a) engage in helpful and harmful behaviors and (b) observe others' helpful and harmful behaviors. We call *Actors* those who generate a behavior. We call *Observers* those who watch a behavior. In the *Harm* condition, an actor generates a harm to one other person. In the *Help* condition, an actor generates a benefit to one other person. We hypothesized that actors would judge behaviors as (a) less intended and (b) less intentional than when they judge behaviors as observers.

Participants

Participants ($N = 40$) were recruited via email at a small southern university.⁵ Participants were tested in 6 groups consisting of no more than 12 participants and no fewer than 4. Participants received \$10 for attending. They also had the opportunity to earn an additional \$10 depending on their performance in the experiment (Range = \$16-\$20). Participants were told that they would be paid as a function how many Experimental Currency Units (ECUs) they earned in the experiment. The payoff function was not disclosed.

point ascending scale).

⁵The expense of the experiment necessitated a small sample size.

Each participant was an actor and an observer (counter-balanced for order). However, each participant was in only one of the Help or Harm conditions. Because we were interested in intuitions about actions, all participants who did not perform the desired action (contributing to Account A, see below) were excluded. Five participants were thereby excluded in Harm. For the purposes of analyzes, there were 20 participants in Help and 15 in Harm.

Methods and Materials

Participants completed the experiment on a computer programed using Z-Tree software (Fischbacher, 2007). Actors in the Harm condition were instructed to indicate how many of their 10 “tokens” they wished to invest in 'Account A'. They were told that for every token they invested in Account A, they would earn 12 ECUs. For every token they did not invest in Account A, they would earn 10 ECUs. However, for every token invested in Account A, they would generate a 3 ECU penalty to one other person in the experiment. Actors in Help were given the same instructions as Actors in Harm but instead of generating a 3 ECU penalty, the actor generated a 3 ECU bonus by contributing to Account A. Observers in Harm read a display indicating that somebody else had contributed 10 tokens to Account A generating a 30 ECU penalty to them. Observers in Help read a display stating that another participant contributed 10 tokens to Account A generating a 30 ECU bonus for them. There was one unpaid practice round followed by one paying round in each condition.

After each instance of acting or observing, participants were asked to rate on a 7 point scale (1=disagree, 7=agree) their level of agreement with the appropriate version of each of the following sentences: 1. You/the other participant intended to generate the penalty/bonus; 2. You/the other participant intentionally generated the penalty/bonus; 3. You/the other participant are/is blameworthy/praiseworthy for generating the penalty/bonus. Participants were also given the opportunity to explain their answers in a few sentences. So, each participant answered 3 actor questions and 3 observer questions in only one of Harm or Help conditions and had the opportunity to explain their answers in each condition.

Results and Discussion

To test our hypothesis, a mixed-model Analysis of Variance (ANOVA) was preformed with Harm/Help and observer order as between participants variables and answers to the Actor Intended and Observer Intended prompts as within participants variables.

Table 1: Actor/Observer

Actor Intended	$M = 3.3, SD = 2.08$
Actor Intentionally	$M = 3.5, SD = 2.17$
Observer Intended	$M = 4.0, SD = 2.8$
Observer Intentionally	$M = 4.11, SD = 2.15$

The predicted difference in actor/observer judgments was found for intention judgments, $F(1, 31) = 4.51, p = .04, \eta_p^2 = .13$. Neither order $F(1, 31) = 1.12, p = .29, \eta_p^2 = .04$ nor condition interacted with judgments $F < 1$. A similar mixed-model ANOVA found the predicted differences in intentionality judgments, $F(1, 31) = 4.14, p = .05, \eta_p^2 = .12$. Order did not interact with judgments, $F < 1$.

Theoretically, there should be differences in people's Harm and Help judgments (Knobe, 2003a) and a moderately sized non-significant trend toward an interaction for Harm/Help was observed, $F(1, 31) = 2.61, p = .12, \eta_p^2 = .08$. To help illuminate these possible differences, each condition (Harm or Help) was selected and four mixed-model ANOVAs were conducted with order as between participants factors and judgments about (1) Actor Intention/Observer Intention and (2) Actor Intentional/Observer Intentional as within participants factors.

In Harm, predicted differences were found for Intention judgments, $F(1, 13) = 5.63, p = .03, \eta_p^2 = .3$. Order did not interact with judgments $F(1, 13) = 1.05, p = .33, \eta_p^2 = .07$. Predicted differences were also found for Intentional judgments $F(1, 13) = 9.15, p = .01, \eta_p^2 = .41$. Order did not interact with judgments ($F < 1$). In Help, no actor-observer differences were detected (all F 's < 1).

Table 2: Harm Actor/Observer

Actor Intended	$M = 2.13, SD = 1.13$
Actor Intentionally	$M = 2.5, SD = 1.96$
Observer Intended	$M = 3.2, SD = 2.01$
Observer Intentionally	$M = 3.73, SD = 2.25$

This experiment also allowed us to explore some other possibly interesting actor-observer differences. We thought that actors would display a reversed side effect-effect while observers would display the traditional side effect-effect. As side effects can occur when a behavior is judged intentional but not intended, we selected only those participants who did not judge the behavior in the relevant condition to be intended. After excluding those who did not intend the behavior (responding 4 or less), 14 participants remained in Harm and 10 remained in Help. A univariate ANOVA indicated the predicted shift in judgments in Harm that trended toward significance: Harm $M = 2.35, SD = 1.2$, Help $M = 3.1, SD = 1.97, F(1, 23) = 2.46, p = .13, \eta_p^2 = .11$. However, order appeared to interact with judgments, $F(1, 23) = 2.46, p = .13, \eta_p^2 = .11$. To eliminate any possible order effect, only first responses were analyzed.⁶ After eliminating those who were in the actor condition second, did not contribute to Account A, and responded that they intended the bonus or penalty, a very large marginally significant dif-

⁶ Participants could not go back to the previous condition after they had entered their answers. Once participants gave their actor judgments, they could not go back and change them after they entered the observer condition.

ference was observed: Harm ($N = 7$, $M = 2.43$, $SD = 1.9$), Help ($N = 3$, $M = 5.0$, $SD = 1.0$), $F(1, 8) = 4.68$, $p = .06$, $\eta_p^2 = .37$.⁷ However, we did not find the predicted side effect-effect for observers (all F 's < 1).

Finally, previous research indicates that some intentional action intuitions are predictable by the global personality trait extraversion (Cokely & Feltz, 2009a). Extraversion is a member of the Big Five personality model and is represented in almost all modern personality models (John, 1999). The current experiment allowed us to test for possible actor-observer differences in relation to extraversion. To this effect, participants also completed the Brief Big Five Inventory at the end of the experiment (Gosling, Rentfrow, & Swan, 2003). Extraversion was negatively correlated with judgments in Harm for Actor Intention, $r(15) = -.64$, $p = .01$ and Actor Intentionally, $r(15) = -.55$, $p = .03$ but was not correlated with Observer Judgments $p < .05$. To illustrate the difference, a rough median split of extraverts was created. Those who were relatively more introverted (scoring 9 or less) were more likely than extraverts (scoring higher than 9) to respond that they intended (Introverted $M = 2.63$, $SD = 1.3$, Extraverted $M = 1.57$, $SD = .53$, $F(1, 14) = 3.92$, $p = .07$, $\eta_p^2 = .26$) or intentionally (Introverted $M = 3.5$, $SD = 2.2$, Extraverted $M = 1.29$, $SD = .49$, $F(1, 14) = 5.67$, $p = .04$, $\eta_p^2 = .34$) brought about the harmful behavior. Order did not interact with judgments (F 's < 1). Of note, there was a strong overall correlation of intention and intentionality judgments: Other Intention/Other Intentional $r(35) = .83$, $p < .001$, Self Intention/Self Intentional, $r(35) = .77$, $p < .001$.

Experiment 2

Experiment 1 suggested that providing the right environment could engender an Actor-Observer difference in judgments about intentions and intentionality. However, a question remains whether Actor-Observer differences can occur in traditional pencil-and-paper surveys where participants are asked to imagine themselves in the role of the chairman. To address this possible worry that the effect found in Experiment 1 is not the result of the testing environment but rather is a more general phenomenon, Experiment 2 was designed to suggest that Actor-Observer differences are not likely to be found when participants are merely asked to imagine that they are the chairman.

Participants

One hundred and one participants were recruited from Amazon's Mechanical Turk to complete the survey for a small reward (\$0.15). Participants were excluded if they reported that their first language was not English or if they failed the comprehension question. After excluding these participants, 95 remained.

⁷ The small sample size and unequal cells are problematic. The small sample size in Help was anticipated because it is unlikely that good behaviors would be judged unintended by actors. See Feltz (2007a) and Nadelhoffer (2007) for a discussion.

Methods and Materials

Participants were redirected from Amazon's Mechanical Turk to complete the surveys at SurveyMonkey.com. There were four different scenarios: 1. Harm Observer, 2. Harm Actor, 3. Help Observer, and 4. Help Actor. The following were the Help and Harm cases in the Actor condition:

Actor Harm/Help: Imagine that you are the chairman of the board. The vice-president of a company comes to you and says, "We are thinking of starting a new program. It will help us increase profits for this year's balance sheet, but in ten years it will start to [harm/help] the environment." Imagine that you answered, "I don't care at all about [harming/helping] the environment. I just want to make as much profit for this year's balance sheet as I can. Let's start the new program." The program was started. Sure enough, ten years later, the environment started to be [harmed/helped].

Immediately following the scenario, participants were asked to rate their level of agreement with the following sentences (1 = strongly disagree, 4 = neutral, 7 = strongly agree):

1. You intended to [harm/help] the environment;
2. You intentionally [harmed/helped] the environment;
3. You are [blameworthy/praiseworthy] for harming/helping the environment.

Participants were also asked the following comprehension question:

4. How long did it take before the [harm/help] began?

The following were Help and Harm in the Observer condition:

Observer Harm/Help: The vice-president of a company went to the chairman of the board and said, "We are thinking of starting a new program. It will help us increase profits for this year's balance sheet, but in ten years it will start to [harm/help] the environment." The chairman answered, "I don't care at all about [harming/helping] the environment. I just want to make as much profit for this year's balance sheet as I can. Let's start the new program." They started the new program. Sure enough, ten years later, the environment started to be [harmed/helped].

Immediately following the scenario, participants were asked to rate their level of agreement with the following sentences (1 = strongly disagree, 4 = neutral, 7 = strongly agree): 1. The chairman intended to [harm/help] the environment; 2. The chairman intentionally [harmed/helped] the environment; and 3. The chairman is [blameworthy/praiseworthy] for [harming/helping] the environment. Participants were also asked the following comprehension question: 4. How long did it take before the [harm/help] began?

Each participant was an Actor and an Observer in only one of the Harm ($N = 46$) or Help ($N = 49$) conditions. The order of presentation was counterbalanced. Once participants completed their responses to one condition, they could not go back and change their answers.

Results and Discussion

Univariate ANOVAs found a large Knobe-like effect for Actor judgments about intentions, $F(1, 93) = 231.92$, $p < .$

001, $\eta_p^2 = .71$. Order did not interact with judgments $p > .22$. A similar effect was found for Observer judgments about intentions, $F(1, 93) = 64.54, p < .001, \eta_p^2 = .41$. Order did not interact with judgments $F < 1$. A Knobe-like difference was also found for intentionality judgments for Actors, $F(1, 93) = 369.8, p < .001, \eta_p^2 = .80$ and Observers, $F(1, 93) = 122.29, p < .001, \eta_p^2 = .57$. Order did not reliably interact with judgments for Actors ($F < 1$) or Observers ($p > .09$).

A mixed-model repeated measures ANOVA with Actor-Observer judgments as within-participants variables and order as between participants factor did not reveal a reliable Actor-Observer in Harm, all F 's < 1 . However, a significant difference was found for judgments in Help Intention $F(1, 47) = 9.77, p = .003, \eta_p^2 = .17$ and Help Intentionally $F(1, 47) = 8.46, p = .006, \eta_p^2 = .15$.

Table 3: Means for Paper Survey

	Harm	Help
Actor Intend	$M = 4.94$ $SD = 1.65$	$M = 1.14$ $SD = 0.54$
Actor Intentionally	$M = 5.83$ $SD = 1.36$	$M = 1.35$ $SD = 0.88$
Observer Intend	$M = 4.94$ $SD = 1.65$	$M = 1.96$ $SD = 1.94$
Observer Intentionally	$M = 5.83$ $SD = 1.24$	$M = 2.04$ $SD = 1.99$

The results of Experiment 2 suggest that the Actor-Observer asymmetry produced in Experiment 1 is not likely to exist when participants are only encouraged to imagine they are the chairman.

General Discussion

Consistent with and extending previous research, our results suggest that in some circumstances people tended to judge their own behaviors differently than they judge the identical behavior of others. In addition, our evidence suggests that a well-known result in experimental philosophy—the traditional side effect-effect—can be reversed. Finally, replicating previous work (Cokely & Feltz, 2009a), extraversion was systemically and predictably related to some intention and intentionality judgments.

These results provide further evidence that impression management can play a key role in people's intention and intentionality judgments. An important clue for this interpretation comes from the results of the Harm case. Participants were much less likely to judge that they intended the Harm or intentionally brought it about compared to their judgments as observers. Presumably, participants did not want to be a “bad guy” by bringing about the bad side effect whereas they were relatively less interested in managing their impression of others. Hence, they were more motivated to re-

spond that they did not intend or intentionally bring about the Harm. In addition, extraverts were much more likely to respond this way in Harm. Because extraverts are socially minded individuals, they would be relatively more concerned with possible social aspects of their behavior. However, because the behavior in Help is beneficial, there is less motivation to mitigate possibly negative implications of that behavior. So in Help, the responses between actors and observers would be similar.

These data also provide some important insights into the side effect-effect. We found strong correlations between people's intention and intentionality judgments. Those who favor the SV may take these as supporting data. However, defenders of the SV should be cautious for two reasons. First, correlation indicates that there is *some* relation between intention and intentionality judgments. These correlations *do not* necessarily indicate that an intention to *A* is a *necessary* condition for *A-ing* intentionally. These results are equally consistent with intending to *A* is a *sufficient* condition for *A-ing* intentionally when one *A*'s—a condition that most theories of intentional action would endorse under normal conditions (e.g., no causal deviance). Second, we have some evidence that a new but equally problematic side effect-effect exists. For actors who did not think they intended to bring about the penalty or bonus, the moral valence of the consequence influenced their intentionality judgments. Specifically, participants were more likely to judge they brought about the beneficial consequence intentionally than the harmful consequence. These results suggest that at least some folk do not treat an intention to *A* as necessary for *A-ing* intentionally, contrary to the SV.

Third, our results reinforce the importance of individual differences in judgments about intentions and intentionality and provide more evidence that philosophically relevant intuitions are systematically fragmented (Feltz & Cokely, 2009; Cokely & Feltz, 2009b). Those who were extraverted were less likely to judge that they intended or intentionally brought about the penalty. Importantly, we were able to predict a priori who were likely to make those judgments. If there are predictable and systematic differences in intuitions regarding intentions and intentionality, then perhaps there is not a single folk concept of intentional action, but several (Cushman & Mele, 2008).

Finally, we would like to note one limitation of previous work in experimental philosophy that has relied on “pencil and paper” surveys. Rather than simply asking participants to respond to a scenario they read, we asked participants to perform an action and observe an action. We find that participants are less likely to think that a harm they actually bring about is intentional compared to a harm somebody else brings about to them. Hence, using this alternative method uncovered actor-observer differences in intuitions about intentions and intentionality, found an intriguing possible reversal of the side effect-effect, and provided additional evidence that folk intuitions about intentional action are predictably fragmented. We hope that the present experiments open up new methodological avenues for the experi-

mental investigation of folk intuitions about intentional action.

Abstract

A key characteristic of human cognition is the ability to learn from undesirable outcomes. This paper presents a computational account of learning from errors based on counterfactual reasoning, which we embed in ICARUS, a unified theory of the cognitive architecture. Our approach acquires new skills from single experiences that improve upon and mask those that initially produced the undesirable behavior. We demonstrate the operation of this model in a simulated urban driving environment. We also relate our approach to other research on error-driven learning and discuss possible improvements to the framework.

Keywords: cognitive architecture, learning from error, counterfactual reasoning, problem solving

Background and Motivation

The ability to acquire knowledge from experience is a fundamental component of human intelligence. There exist many accounts of learning from positive experiences, most often based on successful problem-solving attempts (Anzai & Simon, 1979; Laird, Rosenbloom, & Newell, 1986). In this paper, we focus instead on learning from undesirable outcomes, an ability that plays an important role in human cognition by providing a mechanism for avoiding past failures in the future. We provide a computational model for one type of error-driven learning that uses counterfactual reasoning to determine both the error's cause and the correct behavior.

Counterfactual reasoning is a strategy that considers what might have occurred if causal events were changed in some way. Psychological studies suggest that people employ counterfactual reasoning in a variety of situations (Roese, Hur, & Pennington, 1999). Byrne and McEleney (2000) also show that they tend to employ counterfactual reasoning mainly in response to negative outcomes, such as failure to achieve or maintain goals. Finally, Epstude and Roese (2008) make the connection to learning, based on their theory that the primary motivation for counterfactual reasoning is to improve future performance.

The work described here offers a computational account of the role of counterfactual reasoning in learning from failures. We embed this account within ICARUS (Langley & Choi, 2006), a unified theory of the human cognitive architecture that makes a commitment to hierarchical, composable knowledge structures. We claim that these structures, along with the mechanisms for

using and acquiring them, provide ICARUS with basic support for benefiting from undesirable outcomes. Our approach to learning from errors responds to a single negative experience, which distinguishes it from connectionist, reinforcement-based, and Bayesian techniques, which typically require many experiences.

We begin our discussion with a motivating task domain and a review of the ICARUS architecture. After this, we present our approach to learning from errors via counterfactual reasoning, including methods for determining the source of the error, acquiring new concepts and skills in response, and utilizing these structures in future behavior. We then describe the extended architecture's operation in the task domain, discuss connections to other work on error-driven learning, and consider directions for further research in this important area.

An Illustrative Domain: Urban Driving

In modern society, the task of operating a vehicle in an urban setting is both common and cognitively challenging. People perform a variety of tasks in this context, such as navigation, obstacle avoidance, and signal response, along with higher-level tasks such as package delivery. Successful performance relies on substantial domain expertise, making urban driving a useful domain in which to study embedded cognition and learning.

For this reason, we have developed a three-dimensional urban driving environment based on the Torque Game Engine produced by Garage Games.¹ The driving simulator provides the driver with control over the gas pedal, brake and steering, with objects obeying realistic laws of physics. The simulator also generates detailed perceptual information, in egocentric polar coordinates, about nearby entities, including road segments, intersections, lane lines, buildings, pedestrians, and other vehicles.

The driving task we examine here requires the agent to overtake a stalled vehicle, which it decides to pass on the left. However, in taking this step, the agent crosses a double yellow line, thereby violating the rules of driving and risking collision with oncoming traffic. The problem is not that the agent lacks knowledge about this constraint; the error occurs because it was focusing on a different goal that interacts with the one it violates. We

¹<http://www.garagegames.com>

maintain that learning to avoid such errors relies on a form of counterfactual reasoning, which we describe in detail later. Our analysis is not limited to urban driving, nor do we intend it to model how humans learn to operate a vehicle, but it provides a useful setting to illustrate our ideas. However, we must embed our account within some theoretical framework, to which we now turn.

A Review of the ICARUS Architecture

We have explored these issues within ICARUS, a theory of the cognitive architecture (Newell, 1990) that makes commitments to the representations, performance mechanisms, and learning processes that underlie intelligence. Like Soar (Laird et al., 1986) and ACT-R (Anderson, 1993), ICARUS encodes content as symbolic list structures, matches long-term structures against short-term ones in a recognize-act cycle, combines goal-driven with data-driven processing, and interleaves an incremental form of learning with performance. Key differences include separate memories for concepts and skills, the hierarchical organization of knowledge, and cascaded integration in which problem solving builds on skill execution, which in turn relies on conceptual inference. In this section, we review ICARUS' structures and processes, drawing brief examples from urban driving. Langley and Choi (2006) describe the framework in more detail.

The most basic process in ICARUS is inference, which matches the agent's perceptions against long-term conceptual structures to produce beliefs about the environment. On each cycle, the environment deposits descriptions of perceived objects into the *perceptual buffer*, with each percept giving the object type, a unique identifier, and (typically numeric) attribute-value pairs. ICARUS links these perceptions to long-term structures in its *conceptual memory*. Each concept describes a class of situations in logical form that includes the concept's name, its arguments, and the conditions under which the concept applies. Conditions may refer to percepts or to simpler concepts, thus creating a hierarchical organization on memory. For instance, the conceptual structure

```
((aligned-in-lane ?agent ?line1 ?line2)
:percepts ((self ?agent) (lane-line ?line1)
            (lane-line ?line2 angle ?angle))
:relations ((steering-straight ?agent)
            (in-lane ?agent ?line1 ?line2))
:tests      ((≥ ?angle -3) (≤ ?angle 3)))
```

states when one should infer that **?agent** is driving parallel to the lane lines on either side, with the conditions referring to percepts, numeric tests among perceived attributes, and other conceptual relations.

On each cognitive cycle, ICARUS matches these concepts against elements in its perceptual buffer to produce inferences that it deposits in a *belief memory*, which in turn produce higher-level inferences. These typically describe relations among objects in the environment,

with each belief being an instance of some defined concept. For example, the belief (**aligned-in-lane me line23 line24**), that the agent is aligned in a lane bounded by **line23** and **line24**, is an instance of the **aligned-in-lane** concept above. A recent extension of ICARUS includes time stamps on beliefs to indicate when the architecture inferred them and when they became false, with the symbol **now** indicating that a belief holds on the current cycle. These time-annotated beliefs serve as a simple episodic trace to which we will return later.

ICARUS includes a separate long-term memory for skills. These are similar in form to concepts but specify methods for achieving goals rather than conditions for recognizing their achievement. Each skill includes a generalized goal (which must refer to a defined concept), a set of perceptual and conceptual conditions that must hold for the skill to match, and ordered subgoals that, once satisfied, should achieve the parent goal. For instance, the skill clause

```
((driving-well-in-lane ?agent ?line1 ?line2)
:percepts ((self ?agent) (lane-line ?line1)
            (lane-line ?line2))
:start      ((in-lane ?agent ?line1 ?line2))
:subgoals   ((at-speed ?agent)
              (centered-in-lane ?agent ?line1 ?line2)
              (aligned-in-lane ?agent ?line1 ?line2)))
```

specifies three subgoals the agent should achieve, once it is in a lane, to be driving well in that lane. Primitive skills have the same structure but replace subgoals with a set of executable actions the agent should carry out.

The ICARUS execution process uses the beliefs produced during conceptual inference to determine which skills to select. This process begins by choosing an unsatisfied goal – a concept instance the agent wants to be true – stored in a separate *goal memory*. The architecture retrieves all skills indexed by this goal, then attempts to find an applicable path downward through the skill hierarchy. A skill path is applicable if, for each skill on the path, the associated goal is not satisfied and the associated conditions are met. Such a path must terminate in a primitive skill with executable actions that affect the environment. On each cycle, ICARUS selects the first such path through the skill hierarchy that it finds, incorporating a preference for continuing an activity it has initiated over starting new ones.

When ICARUS can find no applicable skill in memory to achieve its current goal, it resorts to a form of means-ends problem solving (Newell & Simon, 1961; Carbonell, Knoblock, & Minton, 1990) that attempts to dynamically compose known skills, which it executes as they become applicable. The process begins when the architecture cannot find an applicable path through the skill hierarchy, in which case it attempts to retrieve a skill that would achieve the goal, then creates subgoals for its unsatisfied preconditions. If ICARUS cannot find such

a skill, it instead retrieves the definition for the goal concept and creates subgoals for each of its unsatisfied conditions. This process continues recursively, chaining backward off subgoals, until it retrieves a relevant applicable skill, which it then executes in the environment. Upon achieving the current subgoal, the system turns its attention to others, continuing this activity until achieving the top-level goal that initiated problem solving.

This mechanism lets ICARUS overcome situations in which it lacks skills to achieve its goals, but it often requires substantial search. However, the architecture also includes a learning process that generalizes and stores solutions for future use in similar situations. Briefly, this creates a skill whenever problem solving achieves a goal or subgoal, with the new structure being indexed by that goal, including subgoals that it satisfied along the way, and having conditions that were present when it began working on the problem. The details differ depending on whether the problem solver chained off skills or concept definitions, but the results are similar for both cases. ICARUS can then apply the new skills in the same manner as the other, older skills during subsequent execution.

Learning from Undesirable Outcomes

We have used ICARUS to develop cognitive models in a number of complex domains, including urban driving (Langley & Choi, 2006) and American football (Li, Stracuzzi, Cleveland, et al., 2009). Nevertheless, the architecture lacks some important functionalities, including the ability to learn from undesirable outcomes. The work we report here has started to address this limitation by adding a mechanism for learning from errors. More specifically, we consider the case in which the agent manages to achieve a given goal, but in which this causes it to inadvertently violate another, higher-priority, goal, which it must then attempt to repair.

As we discuss in detail below, the extended ICARUS responds to such situations in three steps. First, it determines which goals conflicted and constructs a new concept that it uses to encode the combined goal. Next, the architecture employs counterfactual reasoning to identify the primitive skill that produced the error and to determine another sequence that achieves this goal. Note that the skill which led to the conflict may have been executed many cycles prior to the actual goal violation. Finally, ICARUS learns new skills that mask the original structures and achieve the joint goal in similar situations. These mechanisms are not completely new, in that they build upon many existing ICARUS processes, making them more elaborations of the architectural framework than separate modules.

Combining Interacting Goals

The first step toward learning from errors is to determine which goals conflicted to cause the failure. A conflict here refers to a case in which the system violates a

previously satisfied, higher-priority goal in the course of pursuing its current goal. For example, suppose a driving agent (*me*) has two goals, (*on-right-side me*) and (*at-speed me*). The agent first maneuvers the vehicle onto the right side of the road and then begins accelerating toward its desired speed. If another, slower-moving vehicle then enters the road in front of the agent, it may execute a skill for passing on the left. This violates the agent's first goal, and causes it to abandon the second goal in an effort to restore the first.

If the agent prefers to pass on the left when approaching a slow vehicle, it will never satisfy both goals in this situation. To address this stalemate, the architecture constructs a new goal by conjoining the two concepts that supported the original goals, then replacing the goals with one based on the new concept. Returning to the driving example above, ICARUS first creates a concept (*on-right-side-and-at-speed ?agent*) with relations (*on-right-side ?agent*) and (*at-speed ?agent*). Note that the new concept extends the current hierarchy by building on existing concepts. ICARUS then replaces the two original goals with (*on-right-side-and-at-speed me*), giving the agent a new goal for which it can learn more specific skills.

Assigning Blame and Finding Alternatives

After identifying which goals conflicted and creating a revised top-level goal, ICARUS attempts to understand the reasons for its failure and how it might have been avoided. To this end, it attempts to identify the most recently executed primitive skill that, if replaced by a better choice, would avoid violating the high-priority goal and achieve the newly constructed one. This constitutes a form of counterfactual reasoning. The system begins by considering each primitive skill executed in the episode in reverse chronological order. For a selected skill, it rolls back episodic belief memory to the cycle on which it first selected and executed the skill.² ICARUS does not consider non-primitive skills, as they could lead it to backtrack farther than necessary.

After rolling back the episodic trace, ICARUS invokes problem solving with the new, conjoined goal created earlier. Recall that the architecture normally interleaves problem solving with execution, but here the agent can only suppose what might have happened if it had taken another path. For this reason, we introduced a more traditional version of problem solving that uses mental simulation based on skills' effects. Each time the problem solver selects a skill for imaginary execution, it updates belief memory with the expected changes, then triggers inference, which updates belief memory as though it had received new percepts.

²Primitive skills may be durative, which means they may require several cycles to achieve their intended goals. Backtracking over such a skill may therefore involve jumping backward in time by several cognitive cycles.

If the problem solver fails to achieve the combined goal, then the system rolls back another step, past the preceding primitive skill in the original episodic trace. The process outlined above then begins again with a new round of problem solving. Note that this approach to error localization and counterfactual reasoning is well integrated with existing facets of the architecture, and it depends critically on results produced by the modules for inference and problem solving. This provides further evidence that ICARUS offers a unified theory of cognition.

Learning and Selecting New Skills

Having determined a sequence of primitive skills that would have achieved both of its original goals, the extended architecture must generalize these results and store them in skill memory for use in guiding future behavior. We want the acquired skills to apply in more constrained situations than those which produced the undesirable outcome, so they should mask the old skills to prevent their selection in these cases. For our driving example, the system should select the new skill only if it wants to achieve *both* (**on-right-side ?agent**) and (**at-speed ?agent**).

To learn skills from the results of counterfactual reasoning, ICARUS uses the same mechanism as during normal problem solving. As the agent works toward its top-level goal, it acquires a new skill as means-ends analysis achieves each subgoal. The use of counterfactual reasoning and mental simulation, rather than execution in the environment, has no effect on this process. However, to make effective use of this learned knowledge, we must modify ICARUS' execution module. The standard mechanism selects the unsatisfied goal with highest priority, then finds a path through the skill hierarchy that should achieve it. This scheme works well when there are no goal interactions, but, as we have seen, it can lead to problems when they exist.

In response, we modified the execution module to prefer skills that, other things being equal, would let the agent achieve multiple goals. For example, it selects a skill that addresses two goals with first and second priority over one that would achieve only the first goal. However, priority still plays a key role; the system prefers a skill that tackles a first priority goal over one that would achieve goals with second and third priority. This approach lets more specific skills acquired through counterfactual reasoning mask the original, more general skills that caused the undesired behavior, while letting the older skills remain available for situations in which only they apply.

Demonstration on Urban Driving

We tested this extension to ICARUS in the urban driving domain described earlier. Here we consider a single run at length to clarify the architecture's operation. Our aim is not to match human behavior in detail, but to

show that the new system exhibits an important capacity of human cognition that its predecessor lacked. In this run, we placed the ICARUS driving agent³ in the leftmost lane on the right side of the road heading east. Another vehicle in the same lane was stalled in the road ahead. The agent's initial goals were (**on-right-side me**) and (**avoid-obstacle me**). As the agent drives, it realizes that it is approaching the car ahead too rapidly and avoids colliding with it by swerving left. The agent swerves left rather than right simply because the associated skill happens to prefer that option, but this causes it to violate the high-priority goal, (**on-right-side me**), by crossing to the left side.

At this point the agent realizes that it had ignored this high-priority goal while focusing on another one. Drawing its counterfactual reasoning abilities, the system creates a concept,

```
((on-right-side-and-avoid-obstacles ?self)
:percepts ((self ?self))
:relations ((on-right-side ?self)(avoid-obstacles ?self)))
```

that can serve as a new conjoined goal to direct its analysis. Next, the reasoning system backtracks through the episodic trace to the previously executed primitive skill, (**throttle-special-value me**). Using time stamps on beliefs to reconstruct its mental state at that point, it invokes problem solving and mental simulation to search for another sequence of skills that achieves the goal (**avoid-obstacle me**) without violating the other one. In this case, the problem solver cannot find a solution that begins with this state, so the reasoner continues to backtrack through the earlier skill, (**crossing-into-left-lane me**), which also fails to solve the problem. Eventually, after returning mentally to the state before (**wheels-straight me**), problem solving finds a sequence of primitive skill instances,

```
(crossing-into-right-lane2 me), (wheels-straight me),
(on-right-side-lane2 me), (lane-aligned me),
(wheels-straight me)
```

that, if executed, would have achieved the conjoined goal (**on-right-side-and-avoid-obstacles me**). Analysis of this solution using the adapted means-end problem solver leads to creation of a single new skill

```
((on-right-side-and-avoid-obstacles ?self)
:percepts ((self ?self))
:start ((on-right-side-lane1 ?self)
(drone-ahead ?self ?drone ?dist ?angle))
:subgoals ((avoid-obstacles-by-right ?self)))
```

which is indexed by the new conjoined concept that, if satisfied, ensures that its component concepts are met.

On a subsequent run after learning with the same initial situation, the agent makes a different choice when

³The ICARUS agent for this task included 23 skill clauses and 48 conceptual clauses, both organized hierarchically.

it approaches the stalled vehicle, swerving into the right lane rather than crossing over to the left side. The reason is that the architecture prefers skills that are indexed by more specific goals, thus masking the original preference for veering left over right. The result is that the agent still avoids hitting the stalled car ahead of it, satisfying the goal (`avoid-obstacle me`), without violating the even higher-priority goal, (`on-right-side me`).

Discussion

Counterfactual reasoning has been implicated in humans as a mechanism for establishing the cause of particular events (Roese, 1997), for identifying errors of both omission and commission (Byrne & McEleney, 2000), and for learning from errors (Roese & Olson, 1995; Wells & Gavanski, 1989). Our work with ICARUS has focused on using counterfactuals to establish the cause of negative events (violations of maintenance goals) and to replace incorrect actions with proper ones. Although we have not yet shown that it can recover from errors of omission, we believe that the same mechanisms will support such learning.⁴ Our account of counterfactual reasoning makes clear contact with psychological literature on the topic and, although our model makes some implausible assumptions (e.g., about memory), its main features are consistent with key theories and empirical findings.

Few computational models have made use of counterfactuals in the context of learning. One example, Mueller and Dyer's (1985) DAYDREAMER, uses them more broadly than ICARUS but in a less directed manner. The system learns from both positive and negative experiences by postulating alternative actions and considering their consequences, but it proposes scenarios based on control goals, episodic memory contents, and emotional state. This strategy can produce a variety of outcomes, some substantially removed from reality, while ICARUS pursues a single goal until achieving it. Pearson's (1996) IMPROV also makes use of counterfactuals to improve procedural knowledge. Like ICARUS, it considers alternative action sequences starting from the last state before the error occurred, then working backward until it finds a solution. However, IMPROV focuses on revising skills that fail to achieve intended goals, while ICARUS specializes skills that violate other goals it achieved previously. In addition, IMPROV revises its knowledge by modifying skill preconditions, rather than learning new skills that achieve more specific goals.

Other research on learning from errors has also focused on detecting and resolving errors, most on ones that stem from overly general rules. For example, early versions of the SWALE system (Schank, 1986) adapt explanations to unanticipated situations when its expectations are violated. Similarly, Ohlsson (1996) shows how to correct

errors that stem from overly general rules by comparing the actual and intended outcomes of selected actions, while Holland et al. (1986) describe a mechanism for specializing rules using counterexamples. Langley (1987) also reports an approach which compares similar situations that produce positive and negative outcomes to improve upon overly general rules. Work on analytical learning typically focuses on learning from success, but a few efforts (Carbonell et al., 1990; Laird et al., 1986) address learning from failure. These share our concern with explaining reasons for errors, but they produce control rules that specify what to avoid, while our approach instead acquires skills that mask the undesired behavior.

In addition to testing the architectural extensions in other domains that involve goal interactions, we should also improve our account of counterfactual reasoning along other dimensions. One involves increasing its psychological plausibility by placing realistic limits on the contents of ICARUS' perceptual buffer and its episodic memory, which currently contain far more than their human analogs. We should also expand the generality of our counterfactual reasoning framework to learn from other types of errors, such as Ohlsson's constraint violations. In addition, we should extend the architecture's representation and its inferential abilities to let it reason about the goals and beliefs of other agents, since many of the most interesting errors that humans exhibit, and from which they are driven to learn, occur during their interpersonal interactions.

The main contribution of our work has been a computational account of skill learning through counterfactual reasoning. This involves three major steps: detecting that pursuit of one goal has violated another, reasoning backwards from the conflict to identify the choice that caused it and finding an alternative path that would have avoided it, and storing a specialized skill that produces the desired actions and masks the original behavior. Although we have embedded our account within ICARUS, one could also incorporate it into other architectures, although some details would certainly differ. And although we have illustrated these mechanisms in the context of urban driving, they seem relevant to any domain in which goal conflicts can arise. We will not claim that our account covers all forms of learning through counterfactual reasoning, which may also support revision of incorrect concepts, skills, and beliefs, but we believe it advances our understanding of this complex ability, and thus our grasp of human cognition.

Concluding Remarks

In this paper, we presented a set of interacting computational mechanisms that support learning from undesirable outcomes via counterfactual reasoning. We embedded this account within ICARUS, a theory of the cognitive architecture that placed strong constraints on our

⁴Ginsberg (1986) discusses the use of counterfactual reasoning in identifying subgoals during problem solving, which we have not addressed here.

approach to the problem. After reviewing the structures and processes that ICARUS assumes, we presented new mechanisms that identify the violation of previously satisfied goals, localize the cause of this event by inspecting an episodic trace, invoke problem solving to find alternative steps that would have avoided the error, and learn specialized skills from this analysis that generate the desired behavior in the future.

We demonstrated these interacting mechanisms in the context of a simulated urban driving environment, showing that they behave as intended in a complex scenario that requires multi-step reasoning. We also considered earlier work on error-driven learning that bears similarities to our own, but that has addressed different issues, and promising directions for extending our approach. It seems clear that counterfactual reasoning plays an important role in human learning and, although our current model explains only certain forms of such cognitive behavior, it nevertheless provides a novel account of the mechanisms that underlie support this complex ability.

Abstract

Knowledge representations are central to many cognitive processes, and how these representations change is a central issue in learning and cognitive development. Here we developed and implemented a Bayesian inferential procedure to detect and elucidate representational change in numerical estimation. The proposed procedure of an adaptive numerical experiment both infers a learner's representation and predicts the feedback that is likely to induce representational change. We provide an application of this procedure using simulated subjects and demonstrate its effectiveness in inferring representational state and inducing change.

Keywords: representational shift; numerical estimation; adaptive experiment; Bayesian inference.

Introduction

Knowledge representations play a large role in cognitive processes such as learning, memory, and problem-solving (Markman, 1999), and a central problem in cognitive development concerns how representations change with age and experience (Carey, 1985; Dixon & Bangert, 2002; Siegler & Opfer, 2003). A striking example of representational change occurs in developing numerical magnitude representations. These representational changes are apparent across a wide range of tasks where numbers are quantified along a range, whether by categorizing numbers by magnitude (Opfer & Thompson, 2008), estimating numerosity (Booth & Siegler, 2006), measurements (Booth & Siegler, 2006), or positions of numbers on number lines (Dehaene, Izard, Spelke, Pica 2008; Siegler & Opfer, 2003).

Studies on development of numerical representations typically find that young children initially estimate numerical magnitudes to increase logarithmically with actual value before later learning the decimal system (Siegler & Opfer 2003, Booth & Siegler 2004; Opfer & Thompson 2007). This change is interesting theoretically because the logarithmic representation is implicit in speeded magnitude comparisons (Moyer & Landauer, 1967) and generation of random numbers (Banks & Hill, 1974) despite explicit judgments of numerical magnitude. This shift is also widespread across cultures, occurring relatively early in cultures that emphasize children's mathematical education

(Siegler & Mu, 2008) and delayed in cultures that lack formal schooling (Dehaene, Izard, Spelke, & Pica, 2008). Recent evidence also suggests that this representational shift can be induced in situ by providing examples (Izard & Dehaene 2007; Opfer & Siegler, 2007). That is, feedback on a few key numbers that are highly discrepant between logarithmic and linear functions causes rapid and broad adoption of linear representations (Opfer & Siegler, 2007).

Ideally feedback should take into account a child's current and target representational states. To do so, one must first infer, from a few noisy examples, the model that best describes the child's perception of numerical magnitude. This inference may be viewed as a model selection problem in which candidate models are evaluated and compared for their ability to capture the regularities underlying the data (Pitt & Myung, 2002). With the underlying representation having been inferred, one is now in a position to determine feedback that is most likely to induce representational changes in learners. This latter perspective proposes hypotheses for the ideal training regimen; feedback given to a child will be the most effective when it maximally discriminates between a logarithmic and linear representation while tracking the learner's current representation. These ideas can be formalized in a statistical framework, which is described in detail in a later section. This formal approach should have benefits to the theoretical questions that motivate research on the shift in numerical estimation, i.e. what is the path and source of change in numerical estimation abilities? We will be able to measure more precisely what about a child's representation changes to and what types of feedback are most likely to elicit it. The fruits of this approach could lead to the introduction of more effective teaching and training regimens.

In the present paper we propose a procedure that both (1) adaptively infers a learner's most likely representation and (2) predicts the feedback that will most likely induce representational shifts through what we call a cognitive tutor. We will demonstrate how this procedure is performed using computer simulations with information drawn from previous experimental data. We will also show the advantages of this procedure over traditional training studies in efficiency and the likelihood of inducing change.

Given our present focus on simulations of the above procedure, the purpose of this simulation study is three-fold. First, before implementation in experimental settings, it is necessary to run simulations to check the performance and accuracy of the method. Second, simulations could demonstrate the advantages of the cognitive tutor over the traditional paradigm. Finally, we are able to generate hypothesis for later experiments from simulation results. We use the topic of numerical estimation as a running example, and then discuss the potential to transfer the technology to other domains.

Adaptive Numerical Experiment

For representational shift problems, specifically in the domain of numerical representation, we propose an adaptive numerical experiment which infers the representation and performs the role of cognitive tutor. The procedure takes a perspective of model selection and distinguishes between the following models:

$$y_i = ax_i + b + e_i \quad (i = 1, \dots, n) \quad (1)$$

$$y_i = a \log x_i + b + e_i \quad (i = 1, \dots, n) \quad (2)$$

where x denotes the presented stimuli, y denotes the perceived numerical magnitude, and e is a normally distributed error with mean 0 and standard deviation σ .

In the experiment, we follow the paradigm used in Opfer and Siegler (2007), which shows the importance of choosing feedback. The same Number-Line Task is used as the numerical estimation task in our experiment. In each experiment trial, the child is shown a number between 0-100 or 0-1000 and is asked to estimate its position on a line.

The experiment is split into three sessions, as illustrated in Figure 1, and mirrors previous number line studies. In the pre-test session (Session 1), the Number-Line Task is performed to infer the child's existing representation model; each trial children are shown a number and asked to estimate its corresponding position on a line. Next in the feedback session (Session 2), children respond as in pre-test, but after each response are shown the (correct) linear position of each number. The post-test session (Session 3) is similar to the pre-test session, which examines whether any shift occurred in the child's representation model, with no feedback provided.

The proposed adaptive numerical experiment applies the Adaptive Design Optimization (ADO) method and reorganizes the three sessions into two processes, the adaptive inference and the adaptive tutoring. In what follows we define the two processes and describe how ADO works and how it is incorporated into the processes.

Adaptive Inference Process

The adaptive inference process (AIP) takes place in the pre-test session and infers a child's most likely representation model (e.g. linear). It conducts a series of experiment trials and presents the numerical stimuli sequentially. Within each trial, the observed response is analyzed and the next stimulus is provided based on the

analysis. It is adaptive in that it tailors the test procedure to individual state from trial to trial. Consequently, it obtains sufficient evidence to make inference within the fewest possible trials.

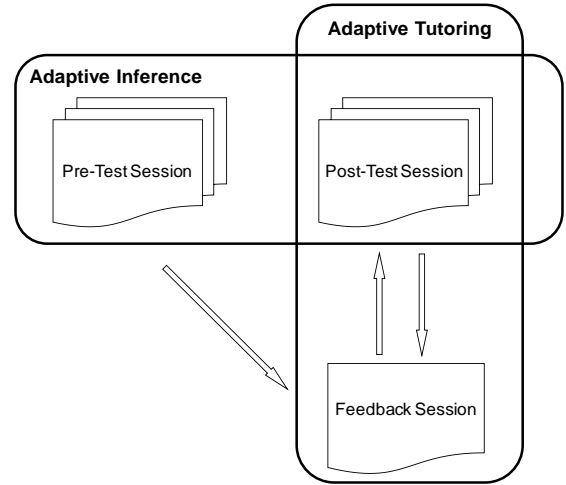

Figure 1: General structure of adaptive numerical experiment consisting of the adaptive inference and the adaptive tutoring processes.

Figure 2: Flowchart of ADO process including repeated sessions of design optimization (designs), data collection (experiment), and model updating (inferences).

Figure 3: A typical curve of model probability change in ADO experiments.

The adaptive choice of numerical stimuli is formally done via experiment design optimization methods, where the numerical stimuli are the designs of interest. The idea of design optimization in this task is to find a numerical stimulus that is the most informative in distinguishing among alternative representational formats (i.e., logarithmic vs. linear). This method of adaptive design optimization (ADO) is developed and performed in a Bayesian framework (Myung & Pitt, 2009). In ADO, design optimization (designs), data collection (experiment), and model updating (inferences) are repeatedly performed, as illustrated in the flowchart in Figure 2. In the process, x denotes the numeric value presented to the child and is the design variable to be optimized. The symbol y denotes the child's response, and s denotes the current inference about the child's underlying representation state, such as the relative likelihood of candidate models and their parameters, which are formally defined later. The numbers the child sees in the session are updated trial by trial along the experiment.

The ADO process is performed as follows. At the beginning, the experimenter has some prior information s_0 about the child's model, from which the initial number x_1 is drawn and the response y_1 is observed. With s_0 and y_1 , the posterior s_1 is obtained by Bayes theorem. For the next trial, s_1 serves as the prior and the above process is repeated. The process continues until the model information s_T after T trials meets certain stopping criterion. Such an adaptive approach bases the later designs upon previous experimental results and makes better use of individual data. Hence, it is more efficient compared to the traditional manner of using the same designs for every individual. Figure 3 shows a typical curve of model probability obtained from an ADO simulation. It indicates that the predicted model probability of the true underlying model reaches as high as .9 within four trials. To summarize, ADO-embedded adaptive inference process could find the optimal designs (i.e. numerical values to estimate) that tailor to individual state, thus could permit efficient inference from the results.

Adaptive Tutoring Process

After inferring the child's representation model through AIP, we may know that the child uses some undesired logarithmic or linear model. The next concern is to find appropriate feedback stimuli that will be most likely to induce representational shift. For this purpose, we combine the feedback session and the post-test session to form what we call the adaptive tutoring process (ATP). Design optimization methods are also applied in ATP. In the feedback session, the choice of the feedback stimuli is optimized in order to teach the child most effectively. For this purpose, we make the assumption that the effectiveness of the design is determined by the maximum discrepancy between the child's model and the target model (e.g., an accurate line $y_i = x_i$). After the optimal feedback stimulus is found and provided to the child, ATP moves to the post-test session. The post-test session infers the child's model again and checks if he has changed the model. If the child

retains a logarithmic model or changes to an undesired linear model (e.g. a linear model with slope smaller than .5), the feedback and post-test sessions are repeated until the child has acquired the target model. Generally speaking, adaptive inference is also performed within the adaptive tutoring process.

The adaptive tutoring process starts from the information s_T obtained at the end of the adaptive inference process. In determining the numbers to be used for teaching, our assumption is that the most informative feedback stimuli for the child lie in the region where the target model and the child's current representation model have the largest discrepancy. The target model is assumed as a fixed, correct model. Hence, we are not adapting to the child's representation states, but are optimizing to the difference between the child's current status and the target model. Formally, we are maximizing the informativeness of the feedback stimulus described as the discrepancy between its true value and its value in the child's representation. The child is tested with the optimal feedback and is corrected with the true position. Then the experimenter obtains the updated information about the child's numerical representation model using the same process as in AIP. The updated information can be used to find the next optimal feedback stimulus, if necessary. The process runs back and forth until the child has shown acquisition of the target model by giving accurate linear responses to the numerical stimuli. In all, the adaptive tutoring process tailors to the child's learning progress and provides a way to combine optimal teaching and progress verification.

Bayesian Framework of Design Optimization

In this section, we provide a brief description of the ADO framework implemented in this paper. For fuller technical details and applications, the reader is directed to Myung and Pitt (2009) and Cavagnaro, Myung, Pitt and Kujala (2010). In ADO, each experimental design is assigned a utility describing the value of a hypothetical experiment with that design. It is analogous to choosing among a set of gambles whose payoff is determined by the risks and rewards of each type of gamble. The set of all possible designs that could be used in a given experiment consist of the design space (Amzal, Bois, Parent, & Robert, 2006; Pitt & Myung, submitted). The goal of ADO is to search the entire design space and find the most informative design(s).

The problem of design optimization is formally expressed as finding an optimal design d^* over the design space, which maximizes the expected utility function $U(d)$. $U(d)$ typically takes into consideration of all unknown but possible conditions. If multiple models are plausible for describing the underlying process in an experiment, $U(d)$ could be defined as:

$$U(d) = \sum_{i=1}^K p(m_i) \iint u(d, m_i, \theta_{m_i}, y) p(y | \theta_{m_i}, d) p(\theta_{m_i}) dy d\theta_{m_i} \quad (3)$$

In the above equation, m_i ($i = \{1, \dots, K\}$) is one of K models under consideration, d is a design, y is the outcome of an experiment with design d under model m , θ_m is the

parameter of model m , and finally, $u(d, \theta_m, y)$ is the “local” utility function of design d , parameter θ_m and experimental outcome y . In general, $U(d)$ represents the expected value of local utility functions in which the expectation is taken over all possible models and their parameters and over all possible experimental observations given the models and parameters.

In *adaptive* design optimization, the optimization of $U(d)$ is repeated over a series of experimental stages. At each stage, the model and parameter priors, $p(m)$ and $p(\theta_m)$, are updated upon the specific outcome observed in an actual experiment carried out with the optimal design d^* . This updating is performed via Bayes rule and Bayes factor calculation (Gelman, Carlin, Stern & Rubin, 2004).

Simulations

Pre-test Simulations and Results

In this section, we describe the computer simulations that demonstrate the performance and advantages of the adaptive numeric estimation experiment. The purpose of conducting simulations is to guarantee that the processes work as expected, as well as to show the efficiency of the methodology.

Figure 4: Sample curves of linear (black solid lines) and logarithmic (red dashed curves) models randomly generated from the priors.

Figure 5: Prediction density scatter plot of linear and logarithmic model predictions at the end of the pre-test. The darkness of each dot indicates the probabilities of a response y given the presented number x . Black dots indicate the highest probabilities and the yellow dots indicate the lowest probabilities.

In order to run the simulations, we first chose the priors on the basis of previous experiment data and experts' beliefs, so that the priors covered a reasonable range of numerical representation models. Several data sets (e.g. Opfer & Siegler, 2007, Siegler & Opfer, 2003) were fitted and the parameter ranges of the models were obtained. Uniform priors over the parameter ranges were then used for intercept, slope, and error variance. Figure 4 shows a sample of possible models under the priors, in which the linear models and logarithmic models are mixed with each other. It also suggests the difficulty of depicting intuitive designs for distinguishing between the two sets of models.

The simulation first implemented the pre-test session with the above priors. The data-generating model, which was assumed to be the child's true model in the simulations, took the following logarithmic form:

$$y_i = 0.21 \cdot \log x_i + 0.75 + e_i, \quad e_i \sim N(0, 0.005^2)$$

Within each simulation, we ran 10 trials (number of trials fixed for convenience purposes) of the Number-Line Task in the pre-test session. Results showed that after 6 trials, we had already obtained sufficient evidence to conclude that the logarithmic model was over 90% likely to be the data-generating model. Meanwhile, we also narrowed down the range of model parameters as shown in the prediction density scatter plot in Figure 5. The darkness of each dot indicates the probabilities of a response y given the presented number x . Figure 5 shows that the predictions from possible linear models are more widely spread than the predictions from possible logarithmic models. It suggests that the predictions from the logarithmic model posteriors are highly concentrated and have higher probabilities, which provides strong evidence that the true model takes a logarithmic form.

Feedback and Post-test Simulations

After the pre-test session, we simulated the adaptive tutoring process. The first step was to choose an optimal feedback stimulus that maximized the discrepancy between the target model and what we knew about the child's existing model. Formally, the utility of the feedback design accounted for the prediction probabilities of both models, as well as the parameter range of both models. For the specific simulated learner, the optimal feedback design was found at $x = 0.354$. That is, the child would be most “surprised” for this stimulus when he sees the difference between his response and the correct answer. Figure 6 shows the location of the optimal feedback and its relationship with the child's model and the target model.

To simulate the post-test session, we needed to assume a learning mechanism that caused the representational shift and generated the post-test experiment results. An intuitive assumption was a conservative learning mechanism in which a child learner made the smallest change to accommodate the feedback. Suppose the child could change to any models within the range of the priors. Among these models, there were a subset of linear models and a subset of logarithmic models that were consistent with the learned

feedback. A conservative learner would estimate the amount of overall discrepancy between these candidate models and the current model and choose the one that has the smallest discrepancy. That is, the conservative learning mechanism assumed the child to be an ideal learner. To demonstrate another plausible mechanism, we also assumed a less ideal learner, the model-conservative learner. The model-conservative learning mechanism assumed that the child only considered a subset of logarithmic models that were consistent with the learned feedback and chose one that required the smallest change from the previous model. In both mechanisms, the winning model was used as the data-generating model for the post-test session. Figure 7 shows representational shifts of the two hypothesized learners. After learning the optimal feedback, the conservative learner changes to a linear model $y_i = 0.758 \cdot x_i + 0.086 + e_i$, and the model-conservative learner changes to another logarithmic model $y_i = 0.218 \cdot \log x_i + 0.580 + e_i$. The two models intersect at the point of optimal feedback because they both accommodate the feedback.

Figure 6: Optimal feedback for the simulated learner indicated by the square at $x = 0.354$. The prediction density scatter plot shows the inference of the child's representation at the end of the pre-test session. The dotted line shows the target model ($y_i = x_i$).

Figure 7: Predicted representational shift to the linear model (solid line) and the logarithmic model (dashed curve) caused by the two learning mechanisms. Both models intersect with the target model at the feedback (the square).

The post-test session simulation started from the same priors used for the pre-test session (shown in Figure 4). It was because the data-generating model had changed and the posterior information from the pre-test session was no longer valid. For convenience purpose, we simulated 5 trials of Number-Line Task in the post-test session. For the conservative learner, there was sufficient evidence to conclude that linear model was over 90% likely to be the data-generating model after 4 trials. For the model-conservative learner, it took 5 trials. The range of parameter estimates for the data-generating model was also narrowed down at the end of the post-test session. Hence, results from the post-test simulations showed that the post-test session made quick and reliable inferences about the new data-generating model.

In general, simulation results of the pre-test, feedback, and post-test sessions demonstrated the validity and the efficiency of the adaptive numerical experiment. We further discuss its practical applications and theoretical implications in the next section.

Discussion

Previous feedback studies have demonstrated that providing children with data that is incommensurate with their current numerical representation can promote a representational shift. In the current paper we improved upon this design using an adaptive design optimization procedure to perform an adaptive-inference, adaptive-tutoring process. This process infers the most likely dominant numerical representation and provides the optimal feedback to elicit a shift to an accurate linear representation. We simulated this process for a logarithmic learner using parameters from previous empirical experiments. Finally we predicted the learner's updated numerical representation based on two possible learning mechanisms.

We established the plausibility of the algorithm for the problem at hand. The adaptive design optimization procedure was able to infer the data generating function in each simulation by optimizing across the design space. The procedure was more efficient than traditional feedback studies in inferring the simulated child's representational state in a few trials. This efficiency in turn suggests that a shorter pre-test phase is less likely to reinforce the learner's initial representation. Shorter testing and feedback phases also provide obvious benefits to both experimentation and real world application for testing children; fewer trials reduce the overall attentional costs to children and thereby reduce the influence of attention-related noise in their responses.

The adaptive tutoring process also proved useful in determining optimal feedback. Feedback points have previously been chosen to maximize the discrepancy between an ideal logarithmic and linear function (Opfer & Siegler, 2007), while our cognitive tutor chooses personalized feedback based on the individual learner's most likely logarithmic or linear representation. This generates very informative results about the ideal feedback points.

The magnitudes chosen by the adaptive tutor are approximately 30% of the range for a simulated learner based on the parameters of children from previous studies. They are near to the previously chosen points (15% of the range), but are clearly not the same. These optimal feedback points may prove to vary widely in actual children, highlighting the need for the adaptive tutoring process to control for individual differences in representations.

The adaptive numeric estimation experiment clearly needs to be run on children to determine its external validity, which we plan to carry out. Nevertheless, we were able to use the adaptive experiment to accurately infer the representational state of a simulated learner. A byproduct of this process was the implementation of two potential learning mechanisms to test the end-state representation of the simulated learner. The conservative and model-conservative learning mechanisms were used to produce quantitative predictions. A conservative model that uses optimal feedback to adjust parameters and the model form with the least amount of change showed a shift to a more accurate linear function with parameters near to the ideal model. The model-conservative mechanism resulted in a preserved logarithmic function with an overall decrease in the model parameters.

If these results can be extended to children, they would support a perspective that learner will behave as a modeler and update his dominant representation with ideal feedback. We might then further test whether the child learner is engaging in Bayesian learning; specifically whether the different learning mechanisms can be seen as a variation in the learner's likelihood ratio. Conservative learning asserts equal likelihood to the representations, while model-conservative learning gives weight only to the dominant representation. These may be plausible mechanisms of cognitive change based on culture and the strength of each representation, with emphasis on mathematical education directly affecting the learner's likelihood ratio of a linear representation.

Adaptive inference of the probability that a learner is linear or logarithmic in representation and an adaptive tutor function that maximizes the effect of feedback are necessary to understand the learner's representation which might apply to many types of representations in diverse areas. The process could easily be extended to similar numerical estimation tasks that use a variety of presented numerical stimuli to determine perceived magnitude. It is possible to extend this design to other areas in which representational shifts are seen, whether to determine children's past tense verb use and predict errors in overgeneralization (Marcus, 1995) or function learning to predict attention to relevant cues (Kruschke 1996). The adaptive design optimization procedure is of obvious use as a means of better modeling the learner and refining training.

Abstract

Research suggests that educational games may be particularly useful for helping children learn STEM concepts; however, the mechanisms involved in game-based learning are not well understood. The present study tested the hypothesis that games are effective because they provide a supportive learning context that allows children to react adaptively to errors. Children (*M* age = 7 yrs, 6 mo) were given two half-hour learning sessions in which they solved nontraditional arithmetic problems (e.g., $__ = 3 + 4$) in game and formal contexts. In a third session, children were given a transfer test in which they solved mathematical equivalence problems (e.g., $1 + 5 = __ + 2$). Children who committed more of their learning errors in the game context solved a greater number of problems correctly on the transfer test than did children who made more of their errors in the formal context. Moreover, children reacted less negatively to errors made in the game context than in the formal context. These findings suggest that educational games may be an effective learning tool because they provide a supportive context that allows children to learn from errors.

Parents and teachers often use educational games (e.g., computer games, card games, board games, etc.) to help children learn important academic skills. This strategy is intuitively appealing because educational games are widely available, and they seem to make learning fun. The use of educational games is also backed by research in psychology and education. Indeed, many prominent researchers throughout history have suggested that games and other “play” activities facilitate children’s learning and cognitive development (Hirsh-Pasek & Golinkoff, 2003; Piaget, 1962; Ramani & Siegler, 2008; Schultz & Bonawitz, 2007; Vygotsky, 1967).

Research suggests that educational games may be particularly useful for helping children learn science, technology, engineering, and mathematics (STEM) concepts (Annetta, Minogue, Holmes, & Cheng, 2009; Barab, Thomas, Dodge, Carteaux, & Tuzun, 2005; Ke, 2008; Ramani & Siegler, 2008; Siegler & Ramani, 2008; Wilson,

Revkin, Cohen, Cohen, & Dehaene, 2006). For example, in a series of recent experiments, Siegler and Ramani (2008, 2009; Ramani & Siegler, 2008) demonstrated that the numerical knowledge of children from low-income backgrounds could be improved substantially by playing numerical board games with equal-sized spaces that are linearly arranged and consecutively numbered. Other studies have demonstrated that children who learn STEM concepts via computer games show more motivation, more engagement, and more positive attitudes toward learning than children who learn STEM concepts via formal instruction (Annetta et al., 2009; Collier & Scott, 2009; Ota & DuPaul, 2002). Taken together, the evidence suggests that educational games have the potential to promote learning and engagement in STEM domains.

Although it is widely acknowledged that educational games can be a useful tool for learning STEM concepts, the mechanisms involved in the benefits of game-based learning are not well understood. In the present study, we focused on one potential mechanism involved in the benefits of game-based learning. Specifically, we hypothesized that games promote learning, in part, because they provide a supportive learning context that allows children to react adaptively to and to learn from errors.

All children inevitably make errors when they are learning something new, and the way that they react to these errors has the potential to affect the learning process (Baker, D’Mello, Rodrigo, & Graesser, in press; Elliot & Dweck, 1988; Dweck, 2000). Specifically, negative reactions to errors such as frustration, anxiety, or helplessness are likely to hinder learning (Ashcraft & Kirk, 2001; Baker et al., in press; Dweck, 2000).

Importantly, research suggests that the nature of the learning context can influence how children react to their errors (Mueller & Dweck, 1998; Okolo, 1992). Some

learning contexts are more supportive than others. Supportive learning contexts are non-evaluative and deemphasize the association between errors and intelligence (Burhans & Dweck, 1995; Elliot & Dweck, 1988; Dweck, 2000). Such contexts buffer children from reacting negatively to errors and encourage children to persist longer in the face of errors (Okolo, 1992).

We propose that the benefits of games may derive, at least in part, from the supportive learning context they provide. Games are less evaluative than formal learning contexts. Children's performance is typically not graded during games, and failure during games can often be attributed to luck. Thus, games may help deemphasize the association between errors and intelligence. For these reasons, games should help children learn because they remove the evaluative factors that often cause children to lose motivation for learning. If children do not feel like they are being evaluated, then they may react more adaptively to their errors.

In contrast, formal contexts may make children feel more evaluated. When children err in a formal context, their sense of intelligence may be threatened, and they may respond with helpless behaviors. For example, children might stop trying to solve the problems correctly so that poor performance can be attributed to lack of effort rather than to low intelligence. If children's focus is on being evaluated instead of on learning, then they may react more negatively to their errors.

In the present study, we tested these ideas by studying a group of children who were learning to solve mathematics problems in the context of both games and formal flashcards. If games provide a supportive learning context for making errors, then children should be less likely to react negatively to the errors they make in a game context versus a formal context. Thus, we hypothesized that the proportion of errors that children reacted to negatively during the games would be lower than the proportion of errors that children reacted to negatively during the flashcards. Moreover, if games facilitate learning *because* they provide a supportive context for making errors, then children's learning should benefit from erring more in a game context relative to a formal context. Thus, we hypothesized that children who committed more of their errors during the games would learn more than children who committed more of their errors during the flashcards.

Method

Participants

This study used existing data from a larger study that tested how various ways of solving addition problems affect children's understanding of mathematical equivalence. The participants of interest were 37 children who participated in two sessions in which they learned to solve addition problems that were presented in a nontraditional format (e.g., $__ = 3 + 4$; $10 = 6 + __$). Children were recruited from a diverse range of public and private elementary schools in a mid-sized city in the midwestern United States. One child was excluded because he did not make any errors over the

course of the learning sessions. Thus, the sample contained 36 children (M age = 7 years, 6 months; 19 boys, 17 girls; 3% Asian, 3% Hispanic or Latino; 11% African-American or black; 83% white).

Procedure

Children participated individually in three half-hour sessions. During the first two sessions, children learned to solve nontraditional addition problems (e.g., $__ = 3 + 4$; $10 = 6 + __$) by playing games one-on-one with a tutor (i.e., game context) and by answering flashcards (i.e., formal context). All children participated in both the game and formal contexts in alternating order during both sessions. Each session started with games, continued onto flashcards, and then ended with more games. During a third session, children were introduced to a new experimenter who assessed their learning by giving them a transfer test. All three sessions were video recorded.

Learning sessions The learning sessions were designed to help children solve single-digit addition facts with two addends (e.g., $17 = 9 + 8$, $14 = 8 + 6$). All problems were presented in a nontraditional format with the operation on the right side of the equal sign. This format is considered to be "nontraditional" because arithmetic problems are traditionally presented with the operations on the left side of the equal sign. Children learned via two main types of activities: (a) two-player games involving cards, dice, or the computer, and (b) flashcards. Children received feedback about correctness throughout the sessions in both the game and formal contexts, and any errors were corrected.

Game context. Children played several two-player games over the course of the learning sessions with the experimenter. One game was a modified version of "Snakey Math" by Curry K. Software. In this computer game, an addition problem was presented at the bottom of the computer screen (e.g., $__ = 3 + 4$), and several possible numbers (e.g., 7, 1, 12, 8) were scattered in random locations on the screen. The child and the tutor each controlled an animated snake, and the goal was to be the first snake to "eat" the number that correctly solved the addition problem.

Another game was called "Smack it!" In this card game, the child and tutor each used a swatter with a suction cup at the end. At the beginning of the game, four addition problems were placed face-up on the table, and a pile of number cards were placed face down. To start each round, the tutor turned over one of the number cards to serve as the target number. The goal was to be the first player to "smack" the addition problem that should have the target number in the blank. Children also played other two-player games that were similar in content and scope. Most of the games were rigged so the child would win; however, some games involved luck, so the tutor occasionally won. Overall, children solved an average of 46.03 problems in the game context across the two learning sessions.

Formal context. The formal context consisted of flashcards presented in succession. Before completing the

flashcards, children received a brief demonstration on how to solve the flashcards. Children solved an average of 45.11 flashcards in total across the two learning sessions. Thus, there was not a significant difference in the number of problems that children solved in the game and formal contexts, $F(1, 35) = 0.21, p = 0.65$.

Transfer test Children solved four mathematical equivalence problems ($1 + 5 = _ + 2$, $7 + 2 + 4 = _ + 4$, $2 + 7 = 6 + _$, $3 + 5 + 6 = 3 + _$). Similar to the addition problems solved during the learning sessions, these problems do not correspond to the traditional “operations on left side” format, so they drew on the knowledge that children had gained from the learning sessions. However, they were much more difficult than the problems solved in the learning sessions because they have operations on both sides of the equal sign. Children never saw problems with operations on both sides of the equal sign during the learning sessions. Previous research has shown that most children in this age range in the U.S. have trouble solving mathematical equivalence problems correctly in the absence of special instruction (Alibali, 1999; Falkner, Levi, & Carpenter, 1999; McNeil & Alibali, 2005; Perry, Church, & Goldin-Meadow, 1988). We limited the transfer test to four problems for the sake of efficiency because previous research has shown similar performance on mathematical equivalence problems regardless of whether children solve three, four, or more than four problems (e.g., Alibali, 1999; Perry, 1991; Rittle-Johnson & Alibali, 1999; Siegler, 2002).

When each problem was presented, the tutor told the child to figure out what number to put in the blank to make the right side of the equal sign the same amount as the left side of the equal sign. If the child provided the correct number, the tutor gave positive feedback, such as “good job” and then moved on to the next problem. However, if the child provided an incorrect number, the tutor provided the feedback as follows: “No, that’s not the number that goes in the blank. The correct number is x because a plus b is equal to x plus y ” (the actual numbers in the problem were used in the place of a , b , x , and y).

Coding

Errors during the learning sessions Children’s errors during the learning sessions were tallied, and the total number of errors made in the game context was compared to the total number of errors made in the formal context.

Reactions to errors Children’s immediate reactions to hearing that they had made an error were coded as “negative” or “not negative.” Reactions were coded as “negative” if children said something negative (e.g., “this is hard,” “I’m getting really messed up,” “no fair”) or exhibited negative behaviors (e.g., whining, growling, huffing, rolling their eyes, or withdrawing). Reliability was established by having a second coder code the reactions of 20% of the children. Agreement between coders was 81.5%.

Transfer performance Children’s solutions on the transfer test were coded as correct or incorrect based on a system used in prior work (e.g., Alibali, 1999; Perry et al., 1988; McNeil & Alibali, 2004; Rittle-Johnson, 2006). Children were given a point for every correct solution. Scores ranged from 0-4.

Results

Performance during the learning sessions was highly variable across children. Collapsing across the game and formal contexts, children made an average of 13.70 ($SD = 11.01$) errors. To test if children made more errors in the game or formal context, we performed a repeated measures analysis of variance (ANOVA) with context (game or formal) as the independent variable and number of errors as the dependent variable. There was no statistical difference in the number of errors that children made in the game context ($M = 6.53, SD = 4.73$) versus the formal context ($M = 7.19, SD = 7.95$), $F(1, 35) = 0.32, p = .58$.

Although there were not general patterns in terms of which context elicited more errors, there were individual differences in which context elicited more errors. Some children made more of their errors in the game context ($n = 20$), whereas some children made more of their errors in the formal context ($n = 16$). We predicted that children who made more of their errors in the game context would learn more than and perform better on the transfer test than children who made more of their errors in the formal context.

To test our hypothesis, we performed a between-subjects ANOVA with error group (more errors in game context or more errors in formal context) as the independent variable and number correct on the transfer test (out of 4) as the dependent variable. Consistent with our predictions, there was a significant main effect of error group, $F(1, 34) = 5.99, p = .02, \eta^2 = .15$. Children who made more of their errors in the game context performed better on the transfer test ($M = 2.70, SD = 1.75$) than did children who made more of their errors in the formal context ($M = 1.13, SD = 1.62$). These results held even when controlling for the total number of errors made across contexts (total number of errors was not a statistically significant predictor of transfer performance, $F < 1$).

Results also held when the independent variable was treated as a continuous predictor and a regression analysis was performed. For the regression analysis, we calculated a difference score by subtracting the total number of errors each child made in the formal context from the total number of errors that child made in the game context. Thus, a positive difference score reflects more errors made in the game context relative to the formal context. This difference score was then used to predict number correct on the transfer test (out of 4). As predicted, the difference score was positively associated with performance on the transfer test, $b = 0.12, t(34) = 3.00, p = 0.005$. The greater the difference between the errors made in the game versus formal context, the greater the number of transfer problems solved correctly. More specifically, for every additional

error made in the game context versus the formal context, the number correct on the transfer test increased by 0.12 (out of 4). The effect was moderate, with the difference score accounting for 21% of the variance in transfer performance.

Finally, we hypothesized that it would be more beneficial for children to make their errors in the game context versus the formal context because games provide children with a more supportive context for making errors. According to this account, children should be less likely to react negatively after making an error in the game context than after making an error in the formal context. To test this prediction, we calculated the proportion of errors that children reacted to negatively in the game context and the proportion of errors that children reacted to negatively in the formal context. Five children were excluded from this analysis because they did not make at least one error in both contexts. We then performed a repeated measures ANOVA with context (game or formal) as the independent variable and proportion of errors that children reacted to negatively as the dependent variable. Consistent with predictions, there was a significant main effect of context, $F(1, 30) = 5.47, p = .03, \eta^2 = .15$. The proportion of errors that children reacted to negatively was lower in the game context ($M = .14, SD = .18$) than it was in the formal context ($M = .28, SD = .30$).

Discussion

Games are widely used to teach children STEM concepts because they are intuitively appealing, and they promote learning and motivation. The results of the present study suggest that games may be an effective instructional tool for learning mathematics concepts because they provide a supportive context for making errors. Children who made more of their errors in the game context learned more than did children who made more of their errors in the formal context. This was confirmed by superior performance on the transfer test. Moreover, children had fewer negative reactions to the errors they made in the game context than they did to the errors they made in the formal context. This suggests that games may provide children with a supportive context that allows children to react adaptively to errors, which promotes learning.

Errors are inevitable during the learning process, and how children react to these errors may have important implications for learning. When children react negatively to errors, they may exhibit frustration, anxiety, or helplessness. Such behaviors reduce the probability of learning (Baker et al., in press; Elliot & Dweck, 1988; Dweck, 2000). In contrast, when children do not react negatively to errors, they may be more likely to persist in the face of challenge and regard errors as an opportunity to learn (Dweck, 2000; Okolo, 1992). Such behaviors increase the probability of learning. The present results suggest that games may facilitate learning, in part, because they buffer children from reacting negatively to errors.

Although the results of this study supported our hypotheses, it is important to note that this study was not designed specifically to test the mechanisms by which

game contexts outperform formal contexts. The data were collected as part of a larger study that was designed for a different purpose, so future studies will be needed to corroborate the results and rule out alternative explanations. For example, it is possible that the difference between game and formal contexts could be due to an individual difference variable that leads children to perform worse in both the formal context and the transfer test. Specifically, children who have mathematics anxiety may have made more errors in the formal context and on the transfer test because both of these contexts resemble traditional school contexts, and thus, might have been viewed as an evaluative, anxiety-provoking situation.

Alternatively, it is possible that children who committed more errors in the game context (versus the formal context) performed better on the transfer test not because they were buffered from negative reactions in the game context, but because the specific act of playing a game made them more engaged in learning. If children learn to solve the problems correctly in the game context, then they will be more likely to win the game. Thus, it is possible that learning is more instrumental in the game context than in the formal context. Future research should control for this potential confound.

Future research should also examine whether the present results generalize to the classroom setting. In the present study, children learned in game and formal contexts while working one-on-one with a “tutor” who stuck to a meticulous script. More typical learning environments are often less structured and less conducive to one-on-one instruction. In order to determine the practical effectiveness of the game context on learning, future studies should investigate whether the results generalize to the types of game and formal contexts that are used in classroom environments.

Overall, the present results are consistent with prior research suggesting that educational games can be helpful for learning STEM concepts. Results suggest that games are helpful not just because they are fun and engaging, but also because they provide a supportive context for making errors. Future work should continue to investigate the benefits of educational games and other innovative contexts that facilitate children’s learning.

Collaborative Facilitation through Error-Detection: A Classroom Experiment

Abstract

Prior work has shown that individuals working in groups often perform worse than individuals working alone, a finding commonly referred to as collaborative inhibition. In the current work we examine whether engaging in error correction processes can mitigate or eliminate the collaborative inhibition effect and perhaps even facilitate collaborative facilitation. Participants engaged in a writing error-detection and revision task while working either with a partner or individually. On the error-detection task, dyads found more structural flaws in the text, whereas individuals found more surface flaws. Moreover, when comparing dyads nominal groups the dyads did not show the collaborative inhibition effect. A similar pattern of results was found on the revision task. The results are discussed in terms of the underlying cognitive and social processes that support successful collaboration.

Keywords: collaborative learning; error-detection; instruction.

Introduction

When does collaboration lead to robust performance and learning outcomes? A large amount of evidence from past research shows that when individuals collaborate with one or more partners, it leads to better performance outcomes when compared to the average individual (see Hill, 1982; Kerr & Tindale, 2004 for reviews). This result has been found in number different tasks and domains. It is hypothesized that groups are able to “pool” their resources and knowledge to perform better than the average individual whether brainstorming, memorizing lists of words, or solving puzzle problems.

Although groups tend to perform better than the average individual, individuals working in groups often do not perform up to their predicted potential. An extremely robust finding in the collaboration literature is that individuals working in groups actually perform worse than individuals working alone (Andersson & Ronnberg, 1995; Weldon & Bellinger, 1997). This has been referred to as “collaborative inhibition” or “process loss” (Steiner, 1972). It is often measured by comparing the dyad or group performance to nominal group performance. For example, when comparing dyads and individuals, a nominal dyad is formed by randomly pairing two individuals who did not collaborate, and their joint performance is considered, as if they were a collaborating dyad. In a simple list learning task, if a dyad recalled the following letters from a list (a, b, c, d, e, f, g) and two

individuals recalled the following: individual 1 (a, b, e, g, h) and individual 2 (c, d, e, f, i) the dyad performs better than the average individual (7 vs. 5) but worse than the nominal dyad (pooled performance: 7 vs. 9).

Much research has focused on trying to understand the causes of collaborative inhibition. Both cognitive and social factors have been advanced to explain it. Social factors include the free-rider effect or social loafing (Karau & Williams, 1993), evaluation anxiety (Collaros & Anderson, 1969; Mullen, 1983), and diffusion of responsibility. Cognitive factors include cognitive overhead of coordination during collaboration (Steiner, 1972) and disruption of retrieval strategy due to interference caused by the collaborators’ input (Basden, Basden, Bryner, & Thomas, 1997; Finlay, Hitch, & Meudel, 2000; Weldon, Blair, & Huebsch, 2000). Each of these factors has been shown to contribute to the collaborative inhibition effect.

In addition to identifying factors that increase or decrease collaborative inhibition a few studies have shown an elimination of the collaborative inhibition effect or even an advantage for collaborative groups over nominal groups. For example, Wright and Klumpp (2004) compared individuals and two collaborative group conditions during free recall: a “see” condition in which people in the pairs took turns recalling items from a previously studied list and showed each other the words as they were being recalled, and a “no see” condition, in which the participants again took turns recalling the previously seen list, but neither knew which items the other person had recalled. Thus, the “no see” condition was effectively the same as a nominal group, as the participants did not engage in any form of interaction while recalling the items. Not surprisingly, Wright and Klumpp found that the “no see” group performed significantly better than the “see” group, and equal to nominal groups.

In another demonstration of collaborative facilitation, Takahashi and Saito (2004) compared recall of studied story materials by nominal dyads and collaborators. When tested immediately, they found that nominal dyads performed better than collaborators, however, when tested after a one-week delay, collaborators recalled more than nominal dyads.

These findings suggest that there must be some aspect of the task structure in which collaborators engage that play a part in determining collaborative inhibition or

advantage. We propose that if the task structure facilitates the cognitive mechanisms hypothesized to underlie the collaborative advantage, we should be able to overcome the collaborative inhibition effect.

One of the primary mechanisms suggested to underlie successful collaboration is error-detection (Shaw, 1932; Sniezek & Henry, 1989). Groups are hypothesized to engage in a higher degree of error detection and correction compared to individuals. It has been widely documented that detecting your own errors is an important metacognitive skill, however, not many learners have such skills. Moreover, in order to detect an error, it is necessary to have the requisite domain knowledge, which an individual may not possess, but a collaborator may. This results in more errors being detected and corrected. Further, being in an interactive situation, dyads are more likely to engage in constructive processes such as explanation, and therefore more likely to detect errors when things don't compute. There is evidence that by scaffolding learners' interactions to encourage explanation, they were able to form more coherent representations of science concepts (Coleman, 1998).

If error-detection is indeed a mechanism underlying collaborative facilitation, then engaging in an error-detection task collaboratively should help mitigate the collaborative inhibition effect. In other words, the task of error-detection should lead to dyads performing at least as well as nominal dyads. Past studies have proposed error-detection as a mechanism, but not studied it as an aspect of the task structure. In the current experiment, we employed error-detection as the task in which participants would engage either collaboratively or individually.

We decided to test this hypothesis in a college classroom in the context of writing summaries of empirical articles. One reason for choosing this domain was that it provided an ideal open-ended task for students to work on in dyads or individually. Second, research in writing instruction has consistently shown how generating a coherent summary of read material is a challenging task for most students (e.g., Flower, 1979). In any college course with a substantial writing component, especially research reporting, students have the most difficulty summarizing related research succinctly and relating it to their own ideas. The errors that students make are due to imperfect understanding of what constitutes a good summary. It is not intuitive for students to understand the difference between a good summary and a bad one, without engaging in deliberate cognitive processing.

Most of the past work that has found a collaborative advantage has been with simple tasks such as list learning and tested with recall or recognition judgment tasks. We wanted to extend this further to a task involving higher order processing than simple recall.

Finally, testing this paradigm in a real classroom also gave us increased ecological validity. This paradigm has not yet been explored in a controlled experimental way in a real classroom. Investigations of collaborative learning

have been conducted either in a lab setting, where a degree of strict experimental control is possible or in educational settings where factors such as random assignment have been implemented due to various constraints of working in a classroom. Recent endeavors have taken findings from cognitive science and attempted to apply them in authentic learning situations (e.g., Nokes & VanLehn, 2008). We followed in this tradition, and explored this paradigm in a cognitive psychology lab classroom, without sacrificing experimental rigor.

We propose that by collaborating with a peer, students will be more likely to detect flaws in a given summary. Collaborating peers will bring different knowledge to bear on the issue, not all of which will be overlapping. As stated before, we hypothesized that working with a peer will be able to detect a greater number of errors than those working individually. Moreover, we expect that by collaboratively engaging in error-correction, collaborative dyads will outperform nominal dyads, or at least equal them on performance.

We also wanted to see whether the benefits of collaborative error-detection extend to a subsequent on the revision task. In the revision task, students were asked to revise the initial error-ridden summary with the same partner or individually. We hypothesized that because dyads will uncover a greater number of errors to begin with, they will be more likely than individuals to correct those errors, and will perform better than individuals.

Method

Participants

Fifty students from University of Pittsburgh (32 females and 18 males) participated in the study. These students were from three of the lab sections of the course Cognitive Psychology for Majors. Most of the students were upperclassmen (juniors or seniors).

Design

The design was between subjects and students were randomly assigned to either the individual condition or were randomly paired with a partner from the same section without considering gender or ability, and assigned to the collaborative condition. The two main dependent variables of interest were the performance on the error-detection task as measured by number of errors identified and performance on the revision task.

Materials and Procedure

The experiment was conducted over a three-week period, and comprised of homework assignments and in-class activities. The flowchart shown in Figure 1 describes the activities that students performed.

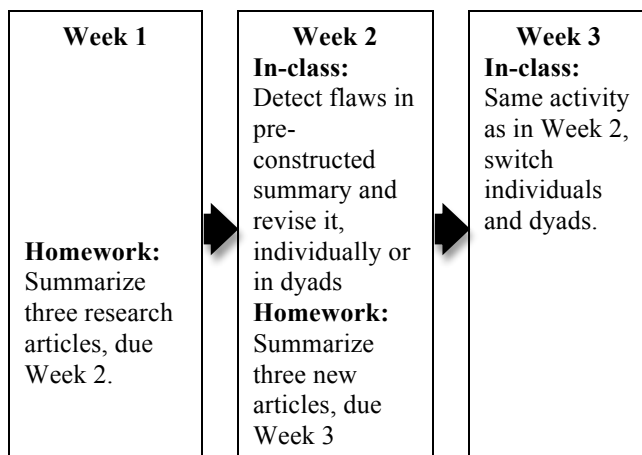

Figure 1: Flowchart of procedure

During week 1, students were asked to summarize three articles on a topic in cognitive psychology. They could choose out of six articles, but one of them was mandatory, because the in-class activity in the following week would be based on that article. The articles were abridged versions of published research articles and consisted of just the Abstract, Method, and Results section. Assigning the summarizing homework prior to the in-class activity ensured that participants were familiar with the task before they worked on it in class.

During the in-class activity in week 2, students were given a pre-constructed summary of the mandatory research article that they had read and summarized in their homework. This summary contained a number of errors. Students were given the same article they had summarized in their homework in order to cut down on time needed to read the article in order to summarize it. During the in-class activity, students were randomly assigned to either the individual or dyadic condition. Each person or dyad got the pre-constructed summary as well as the original abridged article. They were told that this summary was constructed by another student, and their job was to list the flaws in that summary and then rewrite the summary to revise it. At the end of the class, they were assigned a new homework activity in which they summarized three new articles. This homework was due on the class of week 3.

The experiment took place during a regular weekly lab as part of their normal instruction. Students were given 50 minutes to enlist the flaws in the summary and write a revised version. No other scaffolding was provided during the experiment.

A rubric was developed to score students' completed worksheets. First, students' list of flaws was examined to determine how many flaws they could correctly identify. This was compared with a list of all flaws in the document, which could be either structural level flaws or surface level flaws. Structural level flaws included flaws

such as "research question not stated" or "participant characteristics absent". Surface level flaws were stylistic flaws, for example, "summary was not indented" or "italicization in reporting of statistics was incorrect." There were a total of 11 structural level flaws and 6 surface level flaws in each summary. See appendix A for a list of flaws.

Next, a rubric was created to score the revised summaries that students had developed. There were 12 criteria that needed to be fulfilled in order to get full credit. See appendix A for a list of criteria.

Results

We will first describe the performance of dyads and individuals on the error detection task. We will then see whether there is a difference in performance when individuals are randomly paired with another individual to form nominal dyads. This will be followed by an analysis of the scores that dyads or individuals received on the revision task, and subsequently whether dyads and nominal dyads differed on the revision task. Finally, we will see whether the effects of the error-detection activity transferred to a new but related situation, by examining students' performance on the homework assignment immediately after the in-class activity.

As we had hypothesized, dyads performed better than individuals on the error detection task. That is, dyads could detect a higher number of structural-level flaws in the summaries compared to individuals. Dyads could detect 2/3 of the total number of flaws, whereas individuals could detect only 1/2 of them. See Figure 2 for means and standard errors. A 2 (collaboration: dyads versus individuals) \times 2 (error: structural versus surface) mixed ANOVA showed no effect of collaboration, $F(1, 33) = 2.33$, ns. However, there was a main effect of error type with structural errors being better identified than surface level errors. In addition, there was a significant interaction of collaboration by error type, such that dyads were better at detecting structural level flaws than individuals whereas there was no difference between them in detecting surface level flaws, $F(1, 34) = 10.83$, $p < .05$.

Next, we looked at dyads versus nominal dyads. We used Kelley and Wright's (2010) procedure to form nominal dyads¹, and looked at the unique number of

Most studies that have compared nominal dyads and collaborators in the past have randomly paired individuals to form nominal dyads. This introduces an unnecessary source of errors, and it is advisable to use all possible pairs of nominal dyads to reduce this error. However, with a sample size of 20, one would need to look at 2×10^{24} pairs of nominal dyads, which is computationally almost intractable. Kelley and Wright (2010) have written a program that randomly selects 10,000 pairs of nominal dyads and then generates a list of nominal dyads with a mean and standard deviation closest to the true mean.

errors identified by each nominal dyads. For example, if one member of the nominal dyad identified errors 1, 2, 3, 4, and 5 and the other identified 4, 5, 6, and 7, their total score was 7. The means and standard errors are shown in Figure 2.

Figure 2: Means and standard errors for individuals, dyads, and nominal groups.

A mixed ANOVA with follow-ups using the LSD procedure ($\alpha = .05$) was performed to examine the effects of collaboration on the number of structural and surface level errors detected. There was a significant main effect of error type such that participants found significantly more structural errors compared to surface errors, $F(1,23) = 83.64$, $p = 0.00$. There was also a significant main effect of condition such that nominal dyads detected a significantly more number of errors overall, compared to collaborators, $F(1,23) = 17.70$, $p = 0.048$. There was an marginally significant interaction between condition (nominal vs collaborative) and error-type (structural vs surface), $F(1,20) = 3.45$, $p = 0.076$. Follow-up tests using Fischer's LSD ($LSD = .15$) showed that the difference between nominal dyads and collaborators was significant only for surface level errors. The two groups were not different on structural level errors. However, both groups found a significantly larger number of structural level errors compared to surface level errors.

Thus, although dyads did not outperform nominal dyads in detecting structural level flaws, they were equally good in terms of their individual performance within the dyad. We found evidence for collaborative inhibition on the surface level flaws. This might be due to social pressure to identify only those flaws that the students' thought would be considered most important, such as structural-level flaws and that perhaps surface-

level flaws were not considered important or so obvious to be easily fixed.

Next, we looked at the performance of dyads and individuals on the revision task. The revised summaries were scored on a rubric where the maximum possible score was 20 points. The means and standard deviations for the revision score are displayed in the last column of Figure 2. A one-way ANOVA revealed that dyads significantly outperformed individuals on revising the summaries, $F(1, 34) = 6.57$, $p < .05$. Thus, the benefit of error detection activity extended to the actual revision of summaries, and reinforcing the collaborative advantage. We then compared scores on the revision task for nominal dyads and dyads. Similar to the error-detection task, we awarded one point for every criterion that either or both of the two partners got correct in a nominal dyad. A one-way ANOVA revealed that the dyads and nominal dyads were not significantly different from one another, $F(1, 23) = .03$, ns.

To understand how the in-class error-detection activity impacted students' performance on subsequent writing assignments, we looked at their scores on homework assignments immediately following the in-class session. This is a transfer task, because we expected students to apply what they had learned during the in-class activity (error-detection) to generating their own summary of an article.

We expected students who found a greater number of errors to score better on the homework assignment, because they would be less likely to commit the same errors while summarizing an article. We found a marginal correlation on the subsequent homework such that the score on the homework assignment correlated with the number of errors that they detected during the in-class activity $r(44) = .28$, $p = .058$. There was however no difference by condition, that is the scores of the collaborative participants and individual participants did not differ significantly, after controlling for their performance on the earlier homework, $F(1, 43) = .421$, ns.

Discussion

In the present study, we investigated whether by promoting the mechanisms underlying collaboration, we can overcome the collaborative inhibition effect reported widely in the literature. Our results from this experiment are very encouraging, and provide evidence that by structuring collaborative learning activities according to the cognitive processes underlying it, we can get collaborative learners to perform at least as well as nominal dyads.

We found that engaging in an error-detection task with a partner led to better performance on detecting structural level errors than doing so individually. Even more important is the finding that when the dyads were compared with nominal dyads, they did not do worse, than the nominal dyads unlike many past studies (e.g

Andersson & Ronnberg, 1995). However, individuals found a greater number of surface level errors. One of the possible explanations for this is that dyads focused on the structural level features and ran out of time before getting to the surface level features. Individuals on the other hand, because they could find only a certain number of structural errors, moved on to the surface level errors, and were able to detect more of them. However, as noted before, the overall rate of detection of surface level errors was low, indicating that both individuals and dyads focused more on the structural features.

The other important finding from this study was that dyads performed significantly better than individuals when they revised the flawed summaries. When comparing revision scores of collaborators and nominal dyads, we found no difference between the two. Thus, we have evidence that benefit of error-detection extended to the revision task as well.

We also tested the effects of collaborative error-correction on a measure of transfer when we looked at whether the students' performance on the error-detection task affected their performance on a subsequent homework, which involved generating their own summaries. We found that the number of errors detected during the in-class activity was correlated with their score on the homework assignment. Although we did not find a significant difference between scores of individuals and collaborators, the correlation indicates that students who detected more errors were more likely to perform better on the summarizing task, regardless of condition. There are some caveats to our findings. The first is that since this experiment was conducted in a classroom setting, we could not control all variables as strictly as we would have liked to, in a laboratory setting. We therefore aim to replicate this in a more stringently controlled environment, and understand collaborative error-correction at a more fine-grained level.

Next, we need to replicate this finding in a different domain, and find out whether the effects of collaborative error-detection are robust enough to be found across various domains, such as conceptual physics or mathematics problem solving.

Several issues still need to be addressed in understanding why error-detection leads to better collaborative outcomes. It is clear that error-detection encourages some kind of constructive activity in collaborators that causes them to perform better than individuals. Process data such as verbal protocols can help us better understand what these constructive activities are.

For example, the study by Okada and Simon (1997) found that dyads were more likely than individuals to generate explanations. It would be helpful to analyze process data from collaborative error-detection and understand whether collaborators are more likely to generate explanations for the errors they detected, which

in turn leads to benefits in learning and transfer, and not remain confined to performance alone.

In recent years, scripting of collaborative interaction had been found to be beneficial especially in computer-mediated settings. Understanding how to encourage constructive processes like explanation through collaboration can help create better scripts for collaborative learning.

It is also important to better understand the social dynamics of collaborative learning. For example, what is the role of grounding in collaboration? In our present study, the participants had the required in the task. However, will we find the same effects if less skilled participants are given the same task? What amount of shared knowledge is necessary for successful collaborative learning? All these are open questions that future work needs to address.

In conclusion, we found a robust effect of collaborative error-correction such that collaborators showed better performance compared on a subsequent revision task, and performed as well as nominal dyads. This can have strong educational implications, ranging from applications to classrooms to computer-mediated learning environments.

Acknowledgements

We would like to thank the lab teaching fellows—Daniel Belenky and Jooyoung Jang for their assistance in collecting data for this experiment. Also, thanks to Melissa Patchan for her insightful suggestions during conceptualizing this study and Linnea Warren for help scoring data.

A Double Causal Contrast Theory of Moral Intuitions in Trolley Dilemmas

Michael R. Waldmann (michael.waldmann@bio.uni-goettingen.de)

Alex Wiegmann (Alex.Wiegmann@psych.uni-goettingen.de)

Department of Psychology, University of Göttingen,
Gosslerstr. 14, 37073 Göttingen, Germany

Abstract

In trolley dilemmas a train is about to kill several victims who could be saved if instead a different victim is harmed. A number of theories have been proposed which assume that permissibility judgments in these harm-based moral dilemmas are mediated by an analysis of the underlying causal structure. For example, it has been postulated that it is permissible to harm people as a side effect but not as a means. We have developed a different causal theory which claims that moral judgments are influenced by two contrasts, the global contrast between the number of victims in the presence and absence of the act, and an additional local contrast that compares the fates of the morally relevant target (i.e., threats, victims) of the proposed intervention in the presence versus absence of the act. This double causal contrast theory explains intuitions in various types of trolley dilemmas better than its competitors.

Keywords: moral reasoning; trolley dilemmas; causal reasoning; doctrine of double effect

Introduction

Trolley dilemmas have become the *drosophila* for testing alternative philosophical and psychological theories of moral judgments in harm-based moral dilemmas (see Kamm, 2007). In the philosopher's Judith Thomson's (1986) version of the trolley dilemma, a situation is described in which a trolley whose brakes fail is about to run over five workmen who work on the tracks. However, the trolley could be redirected by a bystander on a side track where only one worker would be killed (bystander problem). Is it morally permissible for the bystander to throw the switch or is it better not to act and let fate run its course? Most people seem to have the intuition that throwing the switch is morally required or at least permissible. However, the intuitions change in another of Thomson's (1986) examples, in which the train could be stopped by throwing a fat person from a footbridge on the tracks, thus stopping the train with his body (footbridge dilemma). Most people find this act outrageous, even though again one person is sacrificed to save five. For philosophical theories these two intuitions present a puzzle. The intuitions in the bystander dilemma seem to be in line with utilitarian or consequentialist theories that focus on the favorable outcome of the act in contrast to not acting (1 vs. 5 dead people). However, the footbridge dilemma yields the same outcomes. The intuitions in this dilemma seem to be more consistent with non-consequentialist reasoning, which focuses on the impermissibility of the act of killing a person.

Not only in philosophy but also in psychology the trolley dilemmas have attracted interest as test cases for psycholog-

ical theories of moral intuitions. Some have derided this research as trolleyology because of the artificiality of the task. It is certainly true that most people never will be in a situation that mimics the trolley problem. However, we would like to defend this paradigm as a valuable tool to study the cognitive basis of moral intuitions. People care about how society should deal with violent death, severe illness, terrorism, or emergency, even though they may never be involved in a dilemma involving these events. Nevertheless, these intuitions influence how our society and law functions. Thus, it is important to understand the mechanisms that underlie people's moral intuitions.

Threat vs. Victim Interventions

From a psychological point of view, the philosophical comparisons between bystander and footbridge trolley versions are flawed because of the various confounds. The footbridge dilemma differs in a number of relevant features from the bystander problem, including the act (re-directing a train vs. pushing a person), the physical distance between agent and victim, the directness, and the saliency of the death, or the degree of intentionality (see also Greene et al., 2009; Waldmann & Dieterich, 2007, for evidence). Unfortunately, in the early research on trolley dilemmas psychologists have often adopted close variants of Thomson's (1986) versions, which makes it hard to interpret the results of these studies (Greene et al., 2001; Mikhail, 2007). In our own research we have therefore tried to create variants of trolley dilemmas, which are better controlled so that some of the already well known factors affecting moral intuitions (e.g., distance, violence of act) are kept constant (Waldmann & Dieterich, 2007). We will first present a new, better controlled experiment which highlights the structural differences between different variants of trolley dilemmas. This experiment will serve as the base example for presenting competing theories, which then will be tested in additional experiments.

General Procedure Unless otherwise noted all experiments were run in groups (including seminars and lectures) with students from the University of Göttingen, Germany. Participants came from various fields, but we excluded philosophy and economics to avoid prior exposure to relevant philosophical positions. Subjects were handed booklets in which they were told that they are going to read about a situation which mentions two options of an agent in the story. All dilemmas used a format in which a fictitious agent in a remote control room of a train company is presented with two alternatives with outcomes, which lie in the future. The outcomes were clearly stated and characterized as cer-

tain. In the instructions it was pointed out that participants should carefully read the stories and attempt to empathize with the situation of the agent. The story was presented in a brief story that described the moral dilemma and the future options. Additionally, images were shown that presented the two options (acting vs. non acting)(see figures for examples). Subsequently, a rating scale was presented. Generally participants were asked to rate whether the agent should act or not in the described situation. The scale ranged from 1 (“not at all”) to 6 (“definitely”) with separated numbered boxes.

Experiment 1

In Experiment 1 we compared two parallel versions in which we manipulated the locus of intervention, threat versus victim. In the threat intervention condition the threatening train is redirected, in the victim intervention condition the train in which the single alternative victim is sitting is targeted. In both variants of the trolley problems all trains are moving and can only be redirected by employees of the train company who are sitting in a remote control room. The workers on the trains did not have any control over the trains. In the threat intervention condition ($n=15$)(Condition I), which corresponds to the bystander problem, five track workers sit on train A and one on train B. The empty train C, which represents the threat, is, due to a signaling defect, running behind train A and cannot be stopped. Soon it would hit train A with the five workers. However, the control room could throw the switch and redirect the train on the parallel track where it would hit train B. In both cases the victims would be seriously hurt (see Fig 1, I).

Fig. 1. Illustrations of the consequences of the proposed interventions in the threat (I) versus victim (II) intervention conditions in Experiment 1. In Condition I the threatening train C has been redirected to the side track, in Condition II train B with the victim has been redirected to the main track where it stops train C.

In the victim intervention condition ($n=14$)(Condition II), the first part of the story is identical. However, here the option is to redirect train B by throwing the switch on the parallel track. This way train B would go up to the track where the other two trains are running and would end up in between train C and train A (see Fig. 1, II). Now train C would hit train B which would stop the threatening train C. This would seriously hurt the one worker in train B, but save the five in train A. Consistent with the findings about bystander and footbridge dilemmas, the threat intervention option was rated more acceptable ($M=4.93$, $SD=0.79$) than the victim intervention option ($M=2.57$, $SD=1.02$), $F(1, 27)=48.8$, $p=0.00$.

Causal Theories of Moral Intuitions

How can the different moral assessments of threat and victim interventions be explained? We kept various familiar factors constant so that some simple accounts are ruled out. In both conditions the distance between the intervention and harm is roughly the same, the initial act (re-directing a train via remote control) is identical; in both cases the act only indirectly affects the fate of the victim, and there is no physical closeness or personal force. Moreover, none of the passengers has control over the train so that there are no differences in responsibility. What are the structural differences that may account for the different intuitions? Given that moral judgments are primarily about evaluating the moral quality of acts or interventions which lead to outcomes, causal theories seem to be a prime candidate for an analysis of such differences.

All theories that can be described as causal include the contrast between the outcomes in the presence versus absence of the intervention, and predict that the size of the contrast influences moral permissibility judgments. However, different theories postulate different representations of the acts and focus on different causal features.

Consequentialism Consequentialism is primarily interested in the contrast between the outcomes. Thus, consequentialist approaches choose a fairly abstract level of describing the acts as acting versus not acting, which blurs the differences between threat and victim interventions. This level of representation in both conditions yields the global outcome contrast between one dead person when the agent acts and five dead people when she refrains from acting (i.e., 1:5). Therefore, this theory predicts generally high acceptability ratings for the act. This may be acceptable as a normative principle (see Unger, 1996), but fails as a psychological account. The theory correctly predicts the intuitions in the threat intervention condition but makes wrong predictions for the victim intervention condition.

Doctrine of Double Effect Traditional non-consequentialist or deontological theories focus on moral rules permitting or prohibiting acts. For example, harmful acts, such as killing, are prohibited. However, simply prohibiting such acts also does not explain the intuitions in trolley dilemmas because apparently people find killing in the threat intervention condition acceptable. A more promising variant of a non-consequentialist theory accounting for trolley intuitions is the doctrine of double effect (DDE), an old deontological rule that is based on a causal analysis and also includes contrasts. A number of psychologists have proposed this rule as a moral heuristic (Royzman & Baron, 2002), or part of an innate moral grammar (Hauser, 2006; Mikhail, 2007). According to the dominant reading of the DDE it is permitted to do a neutral or good act as a means to a greater good, although we foresee lesser harm as a side effect, assuming that there are no better alternatives. However, it is impermissible to bring about lesser harm as an end in itself or as a means to a greater good. Thus, the DDE contains two stages: First a global favorable contrast needs to be ascertained (“greater good”)(i.e., 1:5 in the trolley dilemmas). We know

already that this global contrast does not explain the effect, although it is certainly the case that the size of this contrast influences judgments (Nichols & Mallon, 2006). The main focus of the DDE is on the causal processes entailed by the proposed act. Here the doctrine distinguishes between two types of causal processes involving the single victim. If the victim is harmed as a side effect, as in the threat intervention condition, the act is permitted. However, if the victim is used as a means to save the five, as in the victim intervention condition, the act is prohibited. Thus, this rule explains the intuitions in the two conditions of Experiment 1. Importantly the DDE explains the different intuitions by analyzing the causal processes in the *presence* of the proposed intervention, whereas a contrast with events in the *absence* of the intervention does not play a role after the initial evaluation stage.

A Double Contrast Theory We are going to propose and test another variant of a causal contrast theory, our double contrast theory, which is an extension of Waldmann and Dieterich's (2007) proposal. Our main assumption is that subjects choose a level of abstraction of the act that brings out the specific causal characteristics of the proposed intervention. Contrasting the two interventions on the abstract level as presence or absence of acting or as killing and saving is too abstract because it does not reveal the differences between the scenarios. Using a very low-level description, such as button pressing on a remote control, also blurs the differences. We believe the most natural basic level description in the scenarios refers to the kind of intervention and the morally relevant target of the intervention. Morally relevant targets in trolley dilemmas are threats or victims, which can be stopped, redirected, derailed and so forth by the interventions. This is also the level of description that is used in the stories describing trolley dilemmas. For example, a natural description of the interventions in Experiment 1 might state that in Condition I the threatening train is redirected, whereas in Condition II the train with the single victim is set into motion towards the threatening train. Thus, in Condition I the threatening train is the target of intervention, whereas in Condition II the train with the single victim is the target of intervention.

Our main claim is that people will focus on the target of intervention and assess the harm directly caused by intervening in this target in contrast to the harm *the target* would cause in the absence of the intervention. This local contrast which focuses on the target of intervention rather than the global outcomes will, according to our theory, heavily influence the acceptability rating.

How does the double contrast theory explain the two standard dilemmas? In general, the morally relevant targets of intervention in our trolley dilemmas are either the trains which pose a threat, or the trains which house a potential victim. In the threat intervention condition (I) the proposed act can be summarized as re-directing the threat. Thus, the morally relevant target is the threatening trolley C. To assess the local contrast we need to focus on the direct harm caused by the target of intervention, train C, which is one

seriously harmed person. This outcome is contrasted with the direct harm caused by the target of intervention (i.e., train C) in the absence of the intervention, which in Condition I are five people who are harmed by train C in the absence of an intervention. Thus, the local and global contrasts are the same in this case (1:5), both favoring the proposed intervention.

In contrast, in the victim intervention condition (II) the proposed act can be described as re-directing train B with its potential victim towards the threatening train C. Thus, train B with its potential victim is the target of intervention, and the local contrast will therefore focus on train B with its single potential victim. Setting this train into motion will directly cause harm to this victim. The fact that five people are saved further in the future is an indirect, more remote consequence of the act and therefore not part of the local contrast. To compute the local contrast the harm caused by the target of intervention in the absence of the act also needs to be considered. Train B with its single passenger, the target of intervention, would safely stay on the side track so that its passenger would not be harmed. Thus, the local contrast focusing on train B would amount to 1:0 (1 harmed vs. 0 harmed). The local contrast implies that the act is harmful, which predicts the lowered acceptability ratings.

As in the other theories we also believe that the global contrast (1:5) additionally plays a role, which explains why the ratings are not at a minimum. However, we assume that these global contrasts are backgrounded. In this regard, the double contrast theory makes similar assumptions as the DDE. But whereas the DDE explains differences of intuitions by focusing on the causal structure entailed by the acts, the double contrast theory focuses on the *contrast* of the fate of the target of intervention. In sum, both the double contrast and the doctrine of double effect explain the patterns in the standard trolley cases (e.g., Experiment 1).

Evidence for the Double Contrast Theory

In order to test our double contrast theory against its competitors we started to look for alternative versions of the trolley problem that better distinguish between the theories. In previous trolley research the target of intervention and the location of the alternative victim were often confounded. Whereas threat interventions typically redirect empty trains, victim interventions more directly intervene in the alternative victim. Other variants of the trolley problem allow us to disentangle these and other confounds, and provide informative tests for the alternative theories.

Experiment 2

In Experiment 2 we ran four conditions with 20 participants in each condition. Condition I is a standard threat intervention condition in which an empty threatening train can be redirected away from five victims towards one. All victims are sitting in trains, as in Experiment 1. As usual, this condition yielded relatively high mean ratings ($M=4.6$, $SD=1.57$), which signals high acceptance for the act. Our theory predicts this pattern as a consequence of the 1:5 contrast (see

above). Condition II is new (see Fig. 2): Here a passenger is sitting in the threatening train C. According to the instructions this passenger has no control over the train. The train is about to kill the five on the main track if nothing is done. However, in our instructions we stated that the passenger on the threatening train will be able to jump off the train before it crashes into the train with the five, and save himself. Thus, in the absence of an intervention five people would die, as in Condition I. Alternatively the threatening train could be redirected. Unfortunately, the train needs to be redirected to a side track which traverses a bridge. This bridge prevents the passenger on the threatening train from jumping off so that he will be killed in the collision between train C and the empty train B, which is parked on the side track behind the bridge. This is a novel condition because the intervention targets a threatening train which also transports a potential victim. Thus, this is a case of both a threat and a victim intervention. Interestingly, this condition descriptively received slightly (although not significantly) higher acceptability ratings ($M=5.0$, $SD=1.3$) than Condition I, which means that most subjects opted for sacrificing the one. Although in this condition a train with a single victim is the direct target of a harmful intervention, this variant of victim intervention is not aversive.

How does our theory explain this finding? According to the double contrast theory subjects will compute a local contrast on the morally relevant target of intervention. In both Conditions I and II the target is the threatening train C, which in one condition is empty and in the other houses a potential victim. In both conditions, train C directly harms one person in the presence of the intervention but harms five people in the absence of the intervention. Thus, both Conditions I and II yield the same 1:5 local (and simultaneously global) contrast, which favors acting.

Fig. 2: Illustration of Condition II in Experiment 2 (see text for details).

We ran two more conditions. The most interesting condition of this experiment is Condition III. Here the threatening train C again carries a passenger who has no control over the train, and who is about to jump off (see Fig. 2). In the absence of the intervention, the five in train A at the end of the main track would be killed. On the side track an empty train B is parked, which could be directed upward toward the threatening train C. This empty train would stop the threatening train C on the main track but would kill its single passenger, who, according to the instructions, would not have sufficient time left to jump off. Note that killing the one with the empty train is on the causal path of preventing harm to the five. Thus, the train with its single passenger is

used as a means to prevent harm from the five. Harming people and using them as means against their will should, according to the DDE, be aversive (see Experiment 3 for further discussions of the concept of means). In contrast to the predictions of DDE, however, we got again high acceptability ratings ($M=4.7$, $SD=1.69$), which in fact are statistically equivalent to the ones in the standard threat intervention condition (I).

Condition IV is a standard victim intervention condition, which serves as a control. An empty threatening train C is heading toward a train (A) with five passengers. At the end of a side track, which leads over a bridge, a train (B) with a single passenger is parked. This train B with its passenger can be set in motion in the direction of the main track where it would arrive in time to stop the threatening train C, however with fatal consequences for the single passenger. This condition yielded the expected low ratings ($M=3.15$, $SD=2.01$). In fact, these ratings proved significantly lower than the ratings in the three other conditions, $F(1, 76)=16.2$, $p=0.00$, which were not significantly different from each other.

How does our double contrast theory explain the difference between Condition III and the superficially similar standard victim intervention, Condition IV? Note that in both conditions the train that is parked on the side track is set in motion, and directed towards the threatening train on the main track. Thus, at first sight one might conclude that this empty train is in both scenarios the target of intervention. However, this is wrong according to our theory. In the victim intervention condition (III) the morally relevant target of intervention is indeed the train on the side track with its potential victim, who would either be killed or would stay alive. Thus, the local contrast favors inaction (1:0). However, although the act seems superficially similar in Condition IV, in this condition the train that is being moved is empty. Thus, it neither represents a threat nor is a victim located inside the train. This train is therefore not a morally relevant target of the intervention; it rather plays the causal role of an instrument to stop the threatening train. In this regard the empty train is similar to other morally irrelevant instruments, such as the remote control or button presses. As a consequence, the threatening train C, not the empty train B is the morally relevant target of the intervention in Condition IV. Computing the local contrast over the harmful outcomes train C is causing in the presence versus absence of the intervention yields a 1:5 local (and global) contrast, which favors the intervention. In sum, the results of the experiment favor our double contrast theory over the DDE and related principles (Kamm, 2007).

Experiment 3

In Experiment 3 we ran different variants of some of the conditions in Experiment 2 along with new conditions. This experiment provides further tests of the DDE and our double contrast theory. Again we used the standard trolley instruction about a threatening train on a test site which, due to a brake failure, is about to hit a train with five track workers

at the end of the main track. These five workers would be killed. As in Experiment 1 there is also a parallel side track, which is connected to the main track via a connecting track (see Fig. 3). We ran four conditions. As in the other experiments the passengers inside the trains had no control over the trains and therefore were not responsible for the outcomes in all conditions. In both Conditions I and II we placed the single victim inside the threatening train B in a safe location in the rear of the train. Thus, unlike in the last experiment the passenger does not need to jump off the train to save himself. Doing nothing leads to the death of the five in train A at the end of the main track, but would spare the passenger in the safe location inside the threatening train B. In Condition I ($n=58$), the instructions propose as an alternative that the agents in the remote control station could redirect an empty train C located on the parallel side track up to the main track, thus hitting the threatening train in the rear section and thereby leading to the death of the single passenger (see Fig. 3). However, the threatening train B would be derailed saving the five. This scenario led to fairly high ratings ($M=4.4$, $SD=1.28$).

Fig. 3: Illustration of consequence of proposed act in Conditions I and II of Experiment 3 (see text for details).

Condition II was similar. However, to provide a clear cut case against the DDE, we made the role of the victim as a means more salient. Technically one could argue that in all our experiments the means of saving the five were the redirected trains, not the bodies of the passengers, whose deaths could be construed as side effects. However, such an argument would not save the DDE because then the difference between the threat and victim intervention in Experiment 1, for example, would be a puzzle. Moreover, we doubt that people would construe their harm as a side effect if they were sitting in a vehicle that is being used without their consent to save others (see also Kamm, 2007). Anyhow, in Condition II ($n=54$) we stated again that a single passenger in train C, who is unfamiliar with the steering and brake system, is sitting in the rear of the train in a safe location. Now employees in the control station, guided by a camera inside the train, notice that by hitting the train, the passenger would fortuitously be pushed against the brake system, which would lead to a derailment of the train. The passenger would be killed by this act but the five would be saved. In this instruction the body of the victim is clearly specified as a necessary means for the goal to derail the train and save the five. Interestingly, similarly high ratings as in Condition I were obtained ($M=4.81$, $SD=1.04$). In fact, descriptively these were the highest ratings in this experiment. Clearly participants were not sensitive to whether the body

of the victim was causally necessary for saving the five or not.

Both Conditions I and II refute the DDE as a theoretical account. Although in both conditions the single victim was used as a means to save the five, subjects found the intervention highly acceptable. This finding is explained by the double contrast theory. As in Condition III in Experiment 2, in Conditions I and II of Experiment 3 the empty train C plays the role of an instrument, the morally relevant target of intervention is train B, which both constitutes a threat and houses a potential victim. In the presence of the intervention train B, the target of intervention, is involved in the death of one victim while in the absence of the intervention the five passengers in train A die. Thus, this conditions leads to a 1:5 local and global contrast.

To ascertain that the high ratings in Conditions I and II are indeed different from predictably aversive conditions, we also ran Condition III as a control, which is the standard victim intervention condition ($n=49$). In this condition train C on the side track which transports a single passenger is redirected through the connecting track to the main track where the train would hit and derail the empty threatening train B, thus leading to the death of the one in train C, but saving the five in train A. As usual, this intervention was given fairly low ratings ($M=3.76$, $SD=1.64$), which is predicted by our theory as a result of the 1:0 local contrast.

Finally, in Condition IV ($n=51$), a fourth train D in which one worker is sitting was introduced which is parked on the connecting track, thus blocking the way to the main track. The proposed intervention was to send an empty train C located on the parallel side track up the connecting train, thus derailing train D on the connecting track, and thereby killing its passenger. After stating this fact, the instruction mentioned that this event will open up the way to the main track where train C from the side track could derail the empty threatening train B on the main track, thus saving the five in train A. This intervention also yields fairly low ratings ($M=3.88$, $SD=1.37$). How does our theory explain the finding in Condition IV? The initial morally relevant target of intervention in this condition is train D, which is parked with its potential victim on the connecting track. This victim dies in the presence but would be alive in the absence of the intervention, thus creating a 1:0 local contrast.

The general pattern is confirmed by an ANOVA: Conditions I and I, which are statistically equivalent, yielded significantly higher acceptability ratings than Conditions III and IV, $F(1, 208)=11.30$, $p<0.001$.

General Discussion

The goal of our studies was to test theories of moral acceptability in harm-based moral dilemmas. Certainly there are other types of moral problems which might require different theories (Haidt, 2007). Trolley dilemmas represent interesting test cases for cognitive theories because they show that our moral intuitions are influenced by structural factors which go beyond simple comparisons between outcomes (e.g., numbers of victims) or acts (e.g., killing, saving).

Despite identical outcomes and the identical conflict between saving and harming, our moral intuitions differ depending on various factors including the kind of act, distance, intention, contact, legal responsibility, personal force, or the framing of the outcomes (e.g., Greene et al., 2009; Rai & Holyoak, 2010). In our studies we tried to control for these already known factors in order to focus on the remaining structural causal differences between types of scenarios, which pose a puzzle for both psychologists and philosophers.

A number of moral theories focus on causal structures and are therefore candidates for explaining effects of such structural differences. These theories differ in the choice of the level of description and in the postulated relevant causal features. *Consequentialism* focuses on outcomes, and therefore uses abstract descriptions of acts. The moral analysis contrasts global outcomes in the presence and absence of the act. This theory fails as a psychological account.

A second causal account, the non-consequentialist *doctrine of double effect* also tests for a favorable global contrast first, but then focuses on the causal paths entailed by the act under consideration. Here the distinction between harming people as a means versus as a side effect carries most of the weight in explaining differences in intuitions in trolley dilemmas.

A third theory, our *double contrast theory*, also starts by considering the global contrast. But then a local contrast is computed using basic level descriptions of the interventions targeting threats or victims. For example, in the victim intervention conditions people represent the intervention as re-directing the victim, and consider what will happen to this victim in the presence versus absence of the proposed act.

Three experiments have shown that the double contrast theory wins over the doctrine of double effect. People clearly find it acceptable to use people as means without their consent when the local contrast favors the act.

Directions for Future Research

More research is needed on how people choose the level of description in moral dilemmas. It would be interesting to present subjects with still movies, and have them describe the scenarios in moral and non-moral settings.

Another interesting goal would be to further explore the factors influencing local contrasts. In our experiments we have chosen interventions in which the acts were morally innocuous (e.g., throwing a switch). In the contrast between re-directing a victim and not re-directing the victim, the morally relevant contrast is surely about what happens to the victim. However, if the intervention was shooting a victim versus not shooting her, the contrast between shooting and not shooting would certainly impact on the moral evaluation of the contrast. A clear example of this case is, for example, the famous *Jim and the Indians* dilemma, in which Jim is given the choice of watching twenty Indians be shot or shoot one of these twenty Indians himself, thus saving the rest (Williams, 1973). Although the local contrast for the Indian, Jim could shoot, would be 1:1 (he is dead regardless

of the act), the act is certainly aversive because of the shooting component of the contrast shooting the Indian vs. not shooting the Indian.

Finally it would be interesting to get a more quantitative assessment of the relative weight between global and local contrasts. Global contrasts surely affect moral assessments, as can easily be seen if we consider a 1:1.000.000 contrast in a disaster variant of a trolley problem (Nichols & Mallon, 2006). Note that none of the previous theories includes assumptions about how global contrasts quantitatively affect judgments because moral philosophers typically ask about permissibility, not about degree of permissibility. Our experiments clearly suggest that local contrasts dominate judgments but they do not allow us to answer the question how much weight these contrasts have relative to the global contrast.

Deconfounding Distance Effects in Moral Reasoning

Jonas Nagel (jnagel1@uni-goettingen.de)

Michael R. Waldmann (michael.waldmann@bio.uni-goettingen.de)

Department of Psychology, University of Göttingen, Germany

Abstract

A central question of moral philosophy and moral psychology is whether spatial distance is morally relevant (Kamm, 2007). Does spatial distance reduce our sense of obligation to help strangers in great need? One problem of assessing this question is that distance between agent and victim is typically confounded with other factors, such as saliency of the victim's need, costs for the agent, or location of the agent's means. The goal of our experiments is to find out whether spatial distance *per se* matters in people's intuitions. Whereas the first two experiments seem to indicate that spatial distance between the agent and the victim or between the agent's means and the victim affect subjects' intuitions, Experiment 3 and a closer look at Experiment 2 both reveal that the assumed distance effects disappear if the compared cases are properly deconfounded. Implications of these findings for theories of psychological distance are discussed.

Keywords: moral reasoning; moral intuitions; distance; obligation to help; human experimentation

Introduction

The present research aims at exploring the role of spatial distance in moral judgments: Does spatial distance reduce our sense of obligation to help strangers in great need? The normative relevance of this factor has been heavily disputed in philosophy. Thus, we will set out by first reviewing some of the philosophical debate about whether distance *ought* to matter morally. The aim of this section will not be to contribute to this normative issue, but instead to motivate our empirical investigation and to introduce the thought experiments on which our experimental materials are based. Unlike philosophers we do not want to address the question whether spatial distance ought to matter, but rather aim at finding out whether spatial distance *per se* is psychologically relevant in moral judgments. Alternatively, distance may only appear to be descriptively relevant due to factors with which it is typically confounded. After a brief discussion of relevant empirical work in psychology, we will report three experiments which explore whether our sense of obligation to help strangers is affected by distance *per se*. In the concluding section, we briefly discuss the implications of our findings for theories of psychological distance.

Distance and the Obligation to Help in Philosophy

In his famous article *Famine, Affluence, and Morality*, the philosopher Singer (1972) argues for an intuitive moral principle: "If it is in our power to prevent something bad from happening, without thereby sacrificing anything of comparable moral importance, we ought, morally, to do it"

(p. 231). In a case example supposed to illustrate this principle, a child is drowning in a shallow pond. Intuitively, a person walking past this pond has a strong obligation to rescue the child, even if this means that she will spoil her clothes. Singer then argues that there is no justification to mitigate this principle on the grounds of increased distance between the victim and the potential agent, for such reasoning would clash with "any principle of impartiality, universalizability, [or] equality" (p. 232). Therefore he believes that we are obligated to help distant strangers as much as physically close strangers, for example by donating a good proportion of our assets to the needy.

The philosopher Unger (1996) agrees with this conclusion, and similarly does not view distance as a normatively relevant factor. For him, physical proximity is merely a factor increasing the conspicuousness of a victim's needs to a potential agent. This conspicuousness, while responsible for our increased urge to help near as opposed to far strangers, is not itself given any moral weight by Unger. He supports this view by contrasting several versions of two cases, *The Vintage Sedan* and *The Envelope*. In *Sedan*, the agent refuses to pick up a man with a self-inflicted injury and to drive him to a hospital, because he fears that the victim's blood will spoil the leather-seating of his car, leading to a \$5000 damage. As a consequence, the victim loses a leg. In *Envelope*, the agent refuses to respond to a letter from UNICEF which informed him that 30 children could be saved from death if he sent in a check for \$100. As a consequence, 30 more children lose their lives than if the agent had donated the money. According to Unger, our intuitions tell us that the agent's behavior is severely wrong in *Sedan*, but not so much in *Envelope*, although there are many features suggesting that the *Envelope*'s behavior is actually much worse (e.g., more victims, each of them suffering a greater loss, smaller costs for the agent, etc.).

To show that the difference in our intuitions between these cases is not primarily grounded in physical proximity, Unger (1996) then discusses both a version of *Sedan* in which physical distance is increased (*The CB Radios*, in which the agent is informed via a radio in his car about the victim's bad condition while he is ten miles away from him), and a version of *Envelope* in which distance is decreased (*The Bungalow Compound*, in which the agent receives the UNICEF mail while he is on holiday, and the children are suffering in his immediate neighborhood). Unger's intuitions (which can in our view be debated) is that we condemn the agent's behavior in *CB Radios* as strongly as in *Sedan*, and that we judge his behavior in the *Bungalow* as leniently as in the *Envelope*. Therefore, our diverging intuitions toward *Sedan* and *Envelope* cannot be accounted

for by the difference of physical distance between agent and victim.

Recently, the philosopher Kamm (2007)¹, who in contrast to Singer and Unger endorses a nonconsequentialist ethical position, has presented a different view on these matters. Part of her argument against Unger's (1996) claims is as follows: If one wants to show that distance per se *never* matters morally, it does *not* suffice to provide a couple of sets of cases in which it does not matter morally, for there might be different equalized contexts in which it does. For example, in both the *Envelope* and the *Bungalow*, the children's bad condition is caused by a lack of basic social justice, and it might be that an individual's obligation to help in such cases is not tracked by distance. However, this does not imply that the same holds true for cases involving accidents, for example. On the flipside, Kamm argues, if one wants to show that distance per se *does* matter morally, it suffices to provide one single set of perfectly equalized cases in which it does. Her approximation of such a set of cases (with the contrast case in parentheses) is as follows:

Near [*Far*] Alone Case. I am walking past a pond in a foreign country that I am visiting. I alone see many children drowning in it, and I alone can save one of them. [*I alone know that in a distant part of a foreign country that I am visiting, many children are drowning, and I alone can save one of them.*] To save the one, I must put the \$500 I have in my pocket into a machine that then triggers (via electric current) rescue machinery that will certainly scoop him out. (p. 348)

Kamm's intuition is that she has a stronger obligation to the child in *Near Alone* than to the child in *Far Alone*. As she notes, in this set of cases most of the factors normally confounded with distance are held constant. Among them are, for example, the numbers of victims, the seriousness of their suffering and how it came about. Further factors are the costs for the agent and the way in which they arise, as well as the agent's means of helping and their probability of success. Moreover, the number of potential alternative helpers typically increases with distance. Because all these confounded factors are held constant, Kamm believes that spatial distance alone is responsible for the difference in our sense of moral obligation between *Near Alone* and *Far Alone*.

In summary, the question of whether we *ought* to help needy strangers who are near us more than those who are far is controversial among philosophers. In the current research we are more interested in the question whether spatial distance per se affects intuitive judgments of laypeople if, like in Kamm's cases, potentially confounded variables are controlled. Surely, the intuition that we have a greater responsibility to take care of what is going on near us rather than far from us is shared by most people. But why is this? Is this intuition entirely explainable in terms of distinct, confounded factors like conspicuousness of need, as Unger (1996) claims? Or does distance possess some moral weight of its own in our intuitive judgments, even if all confounding factors are controlled?

Distance and Obligation to Help in Psychology

Before we present our experiments, we want to take a look at previous relevant research in psychology. We are primarily interested in the determinants of moral intuitions rather than in what people actually do. Of course, there is an enormous amount of social psychological studies on determinants of actual (im)moral behavior, some of which also involve investigations of distance effects (e.g., Milgram, 1965). However, such behavior is obviously determined by many more factors than moral judgment alone (e.g., Latané & Darley, 1970).

To our knowledge, only a few studies have directly investigated the influence of distance on people's sense of obligation to help. One study is by Gillis and Hagan (1983), in which participants reported that they were more likely to intervene to prevent criminal behavior if the incident occurred close to their own home as opposed to a distant part of their hometown. In this case, distance refers to the proximity of a threat to the center of an agent's territory, whereas the distance between agent, threat, and victim at the time of the incident is constantly small. Hence, the results indicate that some types of spatial distance may influence people's sense of obligation.

Levine and Thompson (2004) presented a British sample of participants with two scenarios describing the aftermath of a natural disaster. One was about an earthquake in Eastern Europe, the other about a flood in South America. Additionally, the instructions highlighted for half of the participants their British identity, whereas for the other half their identity as Europeans was emphasized. Participants responded to be more likely to offer financial help as well as political engagement if the disaster happened in Europe rather than in America. However, this main effect was qualified by an interaction with the highlighted identity: The difference was greater when the European identity was salient, in which case the comparison between Eastern Europe and South America involved an ingroup/outgroup contrast. For this reason, Levine and Thompson (2004) argue that social categorization of the self relative to the victims rather than absolute geographical distance between them crucially affects whether people feel obligated to help. Note, however, that the distance between agent and victims, while differing in relative terms, is very large in both location conditions. Thus, these results do not rule out that distance effects could be found if the contrast involved one case in which the victim is near the agent in absolute terms and one case in which she is far. As Kamm argues, it might be really spatial *proximity* or absolute nearness which makes a moral difference, rather than any difference in relative distance.

Finally, Baron and Miller (2000) explored how people deal with the fact that, in principle, they have an unlimited amount of opportunities to help others in great need at little costs to themselves. They considered several factors that people might use to limit the scope of their positive duties, among them spatial distance. They found in both an American and an Indian sample that people find it more

¹ All following references to Kamm refer to this volume.

wrong that an agent does not donate bone marrow to a sick patient if this patient lives in the same town as opposed to on the other side of the world. Moreover, significantly more subjects feel that the agent has a responsibility to donate in the near rather than in the far condition. Whereas the contrast in this study contains a genuine difference of proximity between agent and victim, it is again confounded with a difference in shared group membership. In fact, Baron and Miller (2000) themselves explicitly make the ingroup/outgroup contrast accountable for the distance effect they found.

In sum, there is some evidence compatible with the hypothesis that spatial distance might play a role when people consider whether they ought to help needy others. However, there is no previous study that thoroughly deconfounded distance from other factors naturally varying with distance, such as group membership. Moreover, in all studies reviewed so far the distance factor was varied within subjects only. Since people had to compare cases that were otherwise very similar, the salience of the varied factor was probably artificially increased. Thus, demand characteristics may have distorted the results. While the within-subjects component is actually typical for the setting in which philosophers usually form their intuitions (see above), we believe a stronger empirical case for a true influence of spatial distance on laypersons' moral intuitions could be made if effects were found in a properly deconfounded between-subjects design.

Experiment 1

We take Kamm's *Near Alone* and *Far Alone* cases as a starting point for our investigation. As noted above, these cases are equalized in many important respects. Consequently, confounds contained in previous studies can largely be avoided. Moreover, past research (Miller, Bersoff, & Harwood, 1990) has shown that members of different cultures unanimously regard helping strangers in life-threatening situations as a genuine moral obligation rather than as a matter of social convention or personal choice. That is, helping in such cases is considered both as an "objective" duty (i.e., existing not just because of a law) and as legitimately regulated by society. This indicates that most subjects will evaluate the selected cases in moral terms. If a lack of mere spatial proximity between agent and victim *decreases* people's sense of obligation to help, subjects should judge the agent's obligation in *Far Alone* to be somewhat lower than in *Near Alone*. Experiment 1 tests this hypothesis. Note that, since both cases involve an action that is generally considered to be driven by a strong moral duty, a small effect size near the ceiling is to be expected if distance turns out to be relevant.

Method

Participants 62 Göttingen University students (48 women) with a mean age of 23 years participated voluntarily. The experiment was conducted either in a class room before a

lecture, or subjects were individually approached on campus.

Design, materials, and procedure Each participant individually filled out a questionnaire consisting of two pages. The first page contained general instructions explaining the task and asking the participant to try to empathize with the scenario's agent, even though, for methodological reasons, the scenario content would not be realistic. After turning the page, half of the participants ($n=31$) read a variant of *Near Alone*, the other half ($n=31$) a variant of *Far Alone*. The wording of both cases was kept as close as possible to Kamm's original formulation (see above), but we decided to include the description of a mechanism by which the agent could possibly have learned about the victims in *Far Alone*. The text of our Near [*Far*] case was as follows (translated from German):

You are on holiday in a foreign country. There, you take a walk past a pond. You alone see many children drowning in it [*While you take a walk there, you alone learn via an information service on your cell phone that many children are drowning in a pond situated in a distant part of the country*], and you alone can save one of them. To save the one, you must put the €500 you have in your pocket into a machine that accidentally is situated right next to you. This machine then triggers a remote-controlled rescue machine in the pond which will definitely pull one of the children out of the water and save her life. There is no other possibility to save one or more of the children.

This case description was followed by an assessment of the participants' sense of obligation to help. The wording of the question was: "How strongly do you feel obligated to put your €500 into the machine in order to save one of the children?," highlighting both consequences and costs of the action. Finally, participants were asked to indicate their judgment on a 6-point rating scale, labeled "not at all" at the left-hand end (1) and "very strongly" at the right-hand end (6).

Results

The mean rating for sense of obligation was 5.61 ($SD=.67$) in the Near condition, and 4.97 ($SD=1.22$) in the Far condition. This difference was statistically significant ($t(df_{\text{corr}}=46.37)=2.58$, one-tailed, $p<.01$, $d=.65$).²

Discussion

Our participants seem to share Kamm's intuitions regarding the *Near Alone* and *Far Alone* cases. Even though, as expected, ratings were very high in both conditions, participants reported a higher sense of obligation to rescue a child drowning near them rather than far from them. This effect cannot be accounted for by most confounds usually associated with spatial distance, such as social distance, number of potential saviors, urgency, probability of success, or type, and size of costs for the agent.

² In none of the experiments there was a significant effect of sex on sense of obligation to help. Therefore, this factor is excluded from all analyses.

This result encouraged us to test further factors proposed by Kamm. In particular, an important claim she makes is that not only proximity between agent and victim might be of moral importance, but also proximity between the victim and the agent's items that are efficacious in helping the victim. In other words, Kamm's intuition is that an agent is more strongly obligated to let his means be used if they are situated near the victim rather than if they are far, even if he is far from the victim himself in both cases. As an example she uses drowning scenarios in which the distance between agent and victim is kept constantly high, but the distance of the means of saving, a boat the agent owns, is either near or far the victim. Kamm's intuition is that this distance is morally relevant.

Experiment 2

In Experiment 2 we seek to test the hypothesis that proximity between an agent's means and the victim increases the agent's sense of obligation to help, even if the agent himself is constantly far away from the victim. We construed a scenario in which an agent has the opportunity to donate money in order to save sick children in Kenya from early death. His means to this end is money on a bank account which is either located close to him but far from the victims (in Göttingen, Germany) or close to the victims (in Kenya). Additionally, we anticipated that subjects might infer that they are in some way involved with Kenya from the fact that their money is there already. To control for this obvious confound, we decided to include previous personal involvement with Kenya as an additional independent variable.

Method

Participants 80 Göttingen University students (48 women) with a mean age of 24 years participated voluntarily after being approached individually on campus.

Design, materials, and procedure The two independent variables yielded a 2 (distance between victim and agent's means: Near vs. Far) \times 2 (involvement: High vs. Low) between-subjects design (each $n=20$). The questionnaires had the same format as in Experiment 1. The case vignette in the Near/High [Near/Low] condition read as follows (translated from German):

A couple of years ago, you have opened a bank account in Kenya while you spent your holidays there [*because you found out about the high interest rates there*]. Since then, you have returned there a couple of times. This is why you are still maintaining this account today. [*Since this proved of value, you are still maintaining this account today. Neither have you ever been to Kenya yourself, nor have you had any other connection to that country.*]

One day, while you are in Göttingen, you hear in the news that several children in Kenya have been infected with a rapidly progressing disease. If these children do not receive medical treatment, they will die within the next few days. However, there is a lack of money for the urgently needed treatment. You could effectively contribute to saving the children by transferring €30 via internet from your Kenyan bank account to a local donation account.

The respective Far conditions were identical, except that the agent's bank account was located in Göttingen. Sense of obligation was assessed using the same scale as in Experiment 1. The wording of the question was: "How strongly do you feel obligated to perform the proposed action?"

Results

The results are summarized in Figure 1. A two-way ANOVA revealed a main effect of involvement on sense of obligation to help ($F[1,76]=11.25$; $p<.01$; $\eta_p^2=.13$), indicating that stronger previous involvement with Kenya led participants to report that they feel more strongly obligated to donate the money. Moreover, there was a main effect of distance ($F[1,76]=4.31$; $p<.05$; $\eta_p^2=.05$), showing that participants reported feeling more strongly obligated to help if their bank account was in Kenya. The interaction between both independent variables was not significant ($F[1,76]=1.25$; $p=.27$).

Figure 1: Mean ratings of sense of obligation in Experiment 2. Error bars indicate SEM.

Discussion

As expected, previous personal involvement with the home country of the children in need heavily increased respondents' sense of obligation to help. More interestingly, we found an independent effect of the location of the bank account: Participants felt more obligated to help if the means by which they could do so were already located close to the victims, even in the case in which the agent had never visited the country and only had opened an account because of the favorable interest rate. The effect of the spatial distance of the means is especially interesting since the action required to help (i.e., instructing a transfer of funds via internet) is virtually identical in both conditions. Moreover, the location of the means is actually merely symbolic in this scenario, since the agent's money does not have real physical presence either in Kenya or in Göttingen prior to being withdrawn from a cash machine. Still, it seems that even under these conditions participants share Kamm's intuition that proximity of means increases obligation to help.

So far, Kamm's propositions about the impact of mere spatial distance on moral intuitions are mirrored in our

participants' judgments in both experiments. However, despite all the effort invested in making the cases maximally parallel, both experiments still contain remaining confounds. In particular, it cannot be ruled out that in the Near/Low condition in Experiment 2, the knowledge that the agent is somehow profiting from the Kenyan financial system is the source of increased obligation, even if all other personal involvement is explicitly ruled out. In fact, in informal discussions with participants who had completed this condition, quite a few of them spontaneously mentioned that such considerations had influenced their judgment. Moreover, even in the more tightly controlled and therefore more artificial cases of Experiment 1 there is a remaining potentially relevant confound (see also Kamm): In the Near case, the agent directly sees the drowning children with her own eyes, whereas in the Far case the information is mediated by an electronic device. Therefore, in Experiment 3, apart from trying to replicate the results from Experiment 1, we aim to go one step further and try to experimentally control for informational directness in order to find out whether an independent effect of spatial distance can still be found.

Experiment 3

Experiment 3 aims at replicating the results of Experiment 1 while controlling for the previously confounded factor of informational directness. Additionally, we seek to find out whether a distance effect can be found if there are no considerable costs to the agent. Kamm's intuition is that distance does not matter under such conditions of no cost: If all I need to do to save someone's life is to pull a switch, I ought to do so regardless of whether the victim is near me or not.

Method

Participants 240 Göttingen University students (133 women) with a mean age of 24 years participated voluntarily after being approached individually on campus.

Design, materials, and procedure We orthogonally manipulated three independent variables, yielding a 2 (distance between agent and victim: Near vs. Far) \times 2 (informational directness: Direct vs. Mediated) \times 2 (costs: Zero vs. High) between-subjects design (each $n=30$). The case vignettes were closely matched to Near and Far in Experiment 1, but to control for informational directness we made some changes. To be able to construe a case in which the agent has direct information despite large physical distance (by means of binoculars), we decided to move the victims somewhat closer to the agent, so that now the distance was about five kilometers in all Far conditions. In all Mediated cases, the information was again transmitted via cell phone in the form of a video (to keep the visual modality constant). In the Near/Mediated conditions, there was a high wall between agent and victims to avoid direct visual contact. Moreover, the pond was replaced by a thunderous river in all conditions to prevent participants in this condition from assuming that the agent could hear the

children screaming. In Near/Direct, we included a fence instead of a wall to make sure that participants in this condition would not believe the agent could simply jump into the river. Finally, in all Zero cost conditions, the action no longer consisted of putting money (in the costly case €300, being closer to Kamm's \$500 in terms of actual worth) into the machine, but rather of pulling a switch. Sense of obligation was assessed using the same scale and wording of question as in Experiment 2.

Results

The results are summarized in Figure 2. In order to test whether the results of Experiment 1 could be replicated, we first conducted a planned contrast between the conditions Near/Direct/High and Far/Mediated/High, which correspond to Near and Far in Experiment 1. This contrast was significant ($t[232]=2.41$, one-tailed, $p<.01$, $d=.62$)³ and the respective means were almost identical with those obtained in Experiment 1, thus neatly replicating its results.

Afterwards, we conducted a three-way ANOVA which revealed a main effect of costs on sense of obligation to help ($F[1,232]=15.77$; $p<.001$, $\eta_p^2=.06$), indicating that participants reported feeling more strongly obligated to help at zero costs than at high costs. Moreover, there was a main effect of informational directness ($F[1,232]=4.53$; $p<.05$; $\eta_p^2=.02$), showing that participants reported feeling more strongly obligated to help if they witnessed the incident with their own eyes. Crucially, there was no main effect of distance ($F[1,232]<1$), nor were any of the interactions between the three independent variables statistically significant.

Figure 2: Mean ratings of sense of obligation in Experiment 3. Error bars indicate SEM.

Discussion

The findings from this experiment indicate that the assumed distance effect from Experiment 1 can be attributed to an effect of informational directness. If directness is kept constant, distance does not have an effect anymore. The fact

³ This difference remains significant if the t-test is based exclusively on the two compared groups and corrected for their unequal variances ($t[df_{corr}=45.95]=1.88$, one-tailed, $p<.05$, $d=.48$).

that we were able to exactly replicate the mean ratings of Experiment 1 in the corresponding conditions of Experiment 3 makes it seem unlikely that any of the small changes we introduced to the material (e.g., slightly lower costs, video-mediated information, more abstract question wording) is responsible for the absence of a distance effect. Thus, we are confident that informational directness also caused the effect in Experiment 1.

The strongest effect we found was that our subjects' sense of obligation to help was lowered when there were substantial costs for the agent. None of our subjects may have actually believed that a child's life is not worth \$300. Rather, some of them may have felt that a shady machine taking \$300 to rescue a child is itself immoral. More interestingly, we did not find an interaction of costs and distance, as Kamm would have predicted. Distance indeed did not affect the ratings when there weren't any costs for the agent, but neither did it when there were.

General Discussion

Kamm supports her claim that distance per se matters morally with her intuitions regarding her sense of obligation to help needy strangers in well equalized scenarios. Experiment 1 showed that laypersons share her intuitions on one of her central set of cases. Experiment 2 indicated, as Kamm has proposed, that not only distance between agent and victim, but also distance between an agent's means and the victim may affect our moral intuitions. It seems likely, though, that distance effects here were mediated by assumptions about different amounts of social responsibility. The interpretation that distance effects may be generally reducible to other confounded factors is bolstered by Experiment 3, which additionally controlled for informational directness. This experiment revealed that the assumed distance effect from Experiment 1 disappears if the compared cases are properly deconfounded. Thus, while we find that our participants' responses to specific cases are largely in line with Kamm's intuitions, we also find, contrary to what Kamm argues, that these intuitions are informed by factors typically confounded with distance rather than by distance per se. In this sense, our data are more in line with Unger's (1996) behavioral predictions. Moreover, they align nicely with recent findings by Greene et al. (2009) who did not find spatial distance to influence judgments of moral dilemmas when this factor was carefully separated from related factors such as personal force or physical contact.

This pattern of results indicates that a purely spatial notion of distance does not seem to affect moral judgment of laypersons. That, of course, is not to say that what is commonly experienced as spatial distance in everyday life does not influence people's moral judgments. In fact, as Experiment 2 has shown, in naturalistic settings, people are sensitive even to very subtle manipulations of distance. However, psychologically relevant distance seems to be a broad concept naturally enriched with many covariates, such as informational directness or personal involvement. The

difficulty of isolating spatial distance from its typically associated dimensions becomes evident in the highly artificial scenarios that result from our attempts to hold the confounded variables constant.

Future research could aim at investigating psychological mediators of effects of (enriched) distance. Previous studies in the framework of Construal Level Theory (CLT) have demonstrated the impact of psychological distance on the intensity of moral judgments (Eyal, Liberman, & Trope, 2008). The present findings constitute an interesting anomaly from the perspective of CLT, which predicts the impact of abstract, high-level moral values (such as "it is good to help others in need") on the intensity of moral judgment to *increase* with increasing psychological distance. While this seems to be true for temporal distance (Eyal et al., 2008), our results indicate that sense of obligation is not affected by spatial distance per se, and that it, if anything, *decreases* with increasing enriched distance. This might indicate that, at least in the realm of morality, the processes through which different distance dimensions operate are not as similar as CLT commonly assumes.

Developing Notions of Free Will: Preschoolers' Understanding of How Intangible Constraints Bind Their Freedom of Choice

Abstract

Our folk psychology involves the ability to reason about free will. In a series of experiments, we looked at young children's ability to reason about their own freedom of choice, and contrast this with their ability to reason about situations that constrain it. We asked preschoolers (Range: 4 y; 1 mo. – 5 y; 7 mo.) whether they had the choice to *have done otherwise* when they did not have the necessary knowledge to do so (epistemic constraint), had the moral duty not to do so (moral constraint), preferred not to do so (preference constraint), were told not to do so (permissive constraint), or were told that everyone else did not do so (conformist constraint). Results suggest that while preschool children generally believe their actions are freely chosen, they also understand how psychological, social and moral considerations may constrain their actions. These results have implications for children's developing notions of free will and moral reasoning.

Keywords: preschoolers, freedom of choice, morality, epistemic states

Introduction

Free will has long been studied in the field of philosophy, social psychology, and more recently, cognitive neuroscience (Baer, Kaufman, & Baumeister, 2008; Kane, 2002; Soon, Brass, Heinze, & Haynes, 2008; Wegner, 2003). Recent work has also begun to investigate how this important intuition develops and takes form in young children's reasoning (Kushnir, Wellman, & Chernyak, 2009; Nichols, 2004; Seiver, Kushnir, & Gopnik, 2009).

For example, Nichols (2004) found that six-year-old children ascribe the choice to *have done otherwise* to an agent, but not an inanimate object. Therefore, Nichols (2004) posits an *agent-causal view* of free will in which children believe that agents have indeterminate choice which is unbound by outside forces. This is contrasted with children's beliefs about physical causation, namely that, unlike agents, inanimate objects are *not* free to choose their own course of action and are wholly governed by outside forces.

However, the distinction between agents and inanimate objects is only part of our adult intuitions about freedom of choice. More central to our mature understanding – and to the important role that intuitive notions of free will play in our social and moral reasoning – is the ability to contrast

situations in which agents are free to choose and situations in which agents are constrained in their choices. In other words, to adults, “free will can't really mean that at any moment a person's behavior is totally unpredictable (and therefore entirely unconstrained)” (p.4; Baer et al., 2008). Therefore, understanding free will implies understanding the complementary notion of *constraint*.

Kushnir et al. (2009) asked four- and five-year old children if they *could have done otherwise* in two situations. One in which they were free to draw a picture and one in which they were physically prevented from doing so (i.e., the experimenter held the child's hand so that it was stuck in one place). Children overwhelmingly responded that they had freedom of choice when they were physically unbounded, but responded that they did not have that freedom when they were physically constrained. Therefore, preschoolers may already know that their agency, and therefore their freedom of choice, is limited by the physical world.

However, the physical world is just one type of force that may constrain one's free will. One's freedom to choose may also be constrained, or at least limited, by non-physical phenomena, such as beliefs, knowledge states, desires, and social and moral obligations. Research on children's social cognition shows that preschoolers have a rather firm grasp of how constraints which come from the mind differ from those of the physical world (Inagaki & Hatano, 1999; Wellman, 1990). In the current investigation, we explore two related questions about such “intangible” constraints: First, do young children understand that these constraints bind their freedom of choice? Or alternatively, do they believe that their ability to *have done otherwise* is unbounded by psychological and social forces, and is subject only to the laws of the physical world? Second, can children distinguish between intangible constraints which fully determine behavior (and thus fully constrain free will) and those which only influence it (and thus do not fully constrain free will)?

Experiments 1 and 2 explored the first question by asking older and younger preschool children whether they believed they *had the choice to do otherwise* when they didn't have the necessary knowledge to do so. We chose this epistemic constraint – that seeing leads to knowing – because it is one

with which children are quite familiar (Wellman, 1990). Critically, this constraint fully limits one's free will, much like a physical constraint. Thus, we predict that, if children understand intangible (non-physical) constraints, the results should replicate Kushnir et al.'s (2009) findings.

Experiment 3 explored the second question by asking preschoolers about their freedom to act against constraints which, by adult intuitions may influence behavior, but do not fully constrain one's free will. Therefore, we asked children whether they believed they *had the choice to do otherwise* when bound by moral considerations, personal preference, permission, and conformity.

Experiment 1

In Experiment 1, a group of older preschoolers (4.5- 5-year-olds) were asked to reproduce two shapes from a modeled drawing. Across two trials, we varied when each child had the ability to see (thus, to know about) a modeled shape. In the *Constrained Drawing* trial, the modeled shape was hidden from the child's view behind an occluder. In the *Free Drawing* trial, the modeled shape was visible. After drawing, children were asked if they *could have done otherwise* – that is, if they could have drawn the shape they didn't see (and therefore didn't draw) in the Constrained Drawing trial, or if they could have drawn the shape that they did see (but didn't draw) in the Free Drawing trial. We also asked them to explain their responses. If children understand the epistemic constraint binding their free will, then their responses and explanations should differ across the two trials.

Method

Participants 22 four- and five-year-old children (Mean age = 4 y; 11 mo.; SD = 6 mo.) were recruited from preschools in Ithaca, NY.

Procedure Children were interviewed individually in a separate room in the preschool by a female experimenter. Four colored placemats (randomly chosen and ordered from a set of red, orange, green, yellow, blue, and brown), were used to distinguish between the individual trials. The occluder was a black piece of construction paper.

The set-up is shown in Figure 1. The experimenter began by first showing children a drawing of a dot (Shape B) and asking the child to label it. This was followed by the Free and Constrained Drawing trials, order counterbalanced. Each of these trials consisted of an action (drawing a shape), an outcome (the shape) and two critical questions (Alternate Choice Judgment and explanation).

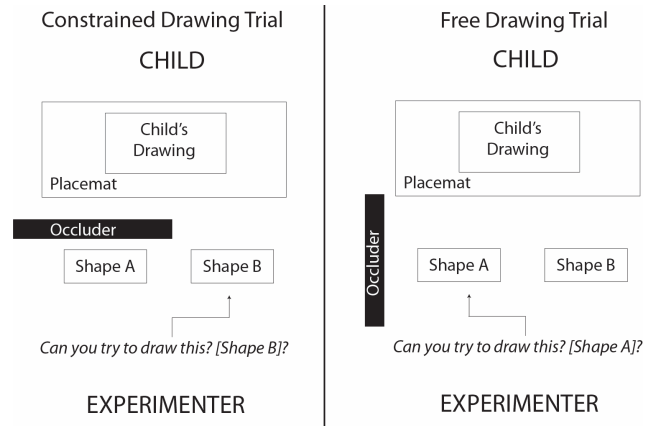

Figure 1: Set-up of Experiment 1.

Action: The experimenter drew Shape A, hidden by the occluder, saying “And now, I’m going to put the paper up like this and draw a different shape.” Shape A was either a line or a circle (randomly chosen).

Outcome: The Experimenter then asked the child to draw the hidden shape (“Can you try to draw this?”). If the child refused to draw, the experimenter encouraged them to draw Shape B. Ten children drew Shape B, and 12 drew something on their own.¹ After the child finished drawing, the experimenter revealed the hidden shape (“Now I’m going to show you what I drew!”)

Questions: The colored mat was then set aside and children were asked the *Alternate Choice Judgment*: “Last time, on the [blue] mat...could you have drawn the [line]?” The child was then asked to *explain* his/her response.

Coding Explanations were coded and classified into the following four categories: References to Epistemic Constraints (“because the paper was up and I couldn’t see it”; “because this time the paper wasn’t up”); Enactments (“by going like this”), Non-Explanations (“because there was a dot there”; “I don’t know”), and References to Other Constraints (“because you told me to draw this one.”).

Results and Discussion

Figure 2 shows that children’s responses to the Alternate Choice Judgment were marginally different between conditions. In the Free Drawing trial 12/22 (54.5%) children indicated that they could have drawn the other shape. In contrast, only 8/22 (36%) of the children said they could have drawn the hidden shape in the Constrained Drawing trial (McNemar’s $p = .07$, one-tailed).

¹ Analyses revealed no differences between these two groups

Figure 2: Percentage of children who said that they “could have drawn something else” in Experiment 1.

Figure 3 shows the same pattern in children’s explanations. The majority of explanations (54.5%; 12/22) in the Constrained Drawing trial appeal to the epistemic constraint imposed in the task. Epistemic explanations were provided more often than non-explanations, $\chi^2(1, N = 15) = 5.40, p < .05$, enactments, $\chi^2(1, N = 16) = 4.00, p < .05$, and other constraints, $\chi^2(1, N = 15) = 5.40, p < .05$. In contrast, in the Free Drawing trial children mostly provided enactments and non-explanations. In the Free Drawing trial, enactments were provided most often, significantly more often than references to epistemic constraints, $\chi^2(1, N = 11) = 4.46, p < .05$ and the proportion of enactments was not significantly different from the proportion of non-explanations and references to other constraints (all *ps* non-significant).

Like children’s judgments, children’s explanations differed significantly between trials. Children were significantly more likely to provide epistemic explanations in the Constrained Drawing trial than in the Free Drawing trial (McNemar’s $p = .001$, one-tailed). Similarly, a greater proportion of children in the Free Drawing trial explained their response by enactment (demonstrating the alternate action) (McNemar’s $p < .05$, one-tailed). The proportion of non-explanations and references to other constraints did not differ significantly between trials.

Figure 3: Proportion of Explanation Types within Each Trial in Experiment 1

Experiment 2

In Experiment 1, older preschoolers’ judgments and explanations revealed some ability to reason about epistemic constraints on free will. In Experiment 2, we replicated the task with a sample of younger preschoolers, and also made a few critical modifications to the procedure. First, we included a warm-up to prime children to think about knowledge states. Second, we eliminated the ambiguity in the Constrained Drawing trial of what the child was supposed to draw by doing away with Shape A (see Figure 4). Thus, the experimenter had only one drawing in front of her (hidden or visible, depending on the condition). Note also that, in this modified procedure, children were free to draw whatever they wanted to in both trials except, of course, the picture they could not see.

Figure 4: Set-up of Experiment 2

Method

Participants 26 four-year-old children ($M=4$ y; 6 mo; $SD=4.8$ mo) were recruited from preschools in Ithaca, NY, Cortland, NY, and New York, NY. The ages of these children was significantly lower than of those in Experiment 1, $t(46) = 3.58, p < .01$. All preschools were roughly matched for socioeconomic status and demographic population.

Procedure Knowledge Access Warm-Up: In order to prime children to think about knowledge states, we began with a knowledge access task (Wellman & Liu, 2004). In this procedure, children were shown a drawer with hidden contents, asked to guess the contents of the drawer, and then prompted to open the drawer, revealing a toy dog. The drawer was then closed and a doll ignorant to the contents of the drawer was introduced (“Now Polly has never ever seen inside this drawer. Here comes Polly!”). Children were then asked two questions pertaining to the doll’s knowledge state: “Does Polly *know* what’s in the drawer?” and “Has Polly *seen* inside the drawer?” 85% (22/26) of the children

answered both questions correctly. Corrective feedback was not provided.

The experiment then continued with the same two trials (Free Drawing and Constrained Drawing) as in experiment 1. As shown in Figure 4, the set-up was simplified to include only one drawing in front of the experimenter (either hidden or visible) and a blank sheet of paper in front of the child. The experimenter first drew her shape, then she asked the child “can you see it?” She then prompted the child to draw by saying, “Now it’s your turn to draw something different for me!” After both drawings, the experimenter revealed her shape (if hidden) and asked the Alternate Choice Judgment and explanation questions. Coding was the same as in Experiment 1.

Results and Discussion

The results replicate the findings of Experiment 1 with younger preschoolers. Figure 5 shows that children’s responses to the Alternate Choice Judgment were significantly different across conditions. In the Free Drawing trial, 17/26 (65%) of children answered that they could have drawn the other shape, whereas only 9/26 (35%) did so in the Constrained Drawing trial (McNemar’s $p < .05$, one-tailed).

Figure 5: Percentage of children who responded they “could have drawn something else” in Experiment 2

Though younger children provided fewer explanations overall, of the 54% (14/26) of children who provided explanations, 36% (5/14) referred to epistemic constraints in the Constrained Drawing trial, whereas no child referred to epistemic constraints in the Free Drawing trial (McNemar’s $p < .05$, one-tailed). This difference is consistent with the pattern of explanations provided by the older preschoolers in Experiment 1. The difference between the proportion of non-explanations, enactments, and references to other constraints in the Free and Constrained drawing trials were not significant.

Experiment 3

Experiments 1 and 2 revealed that 4- and 5-year-olds can reason about their own free will and epistemic constraints on their free will. These results provide initial evidence that young children may already understand that their freedom to act can be restricted by non-physical, intangible constraints.

Experiment 3 focused on other intangible constraints which influence, rather than fully limit, free will – moral considerations, personal preferences, permission, and conformity. Research has shown that even three-year-olds are sensitive to moral rules (e.g., Smetana, 1981) and the subjective nature of preferences (Wellman, 1990, Wellman & Woolley, 1990; Repacholi & Gopnik, 1997). Young children are further able to reason about how rules of permission (Kalish & Shiverick, 1995); and conformist considerations (Kalish, 1998; Racoczy, Warneken, & Tomasello, 2008) may determine one’s actions. Do children also believe that these factors constrain their freedom of choice? If so, do they consider these four influences to be equally constraining, or do they distinguish among them?

Participants Participants were 15 four- and five-year olds (Mean age = 4 y; 7 mo.; SD = 4.5 mo) recruited from preschools in Ithaca, NY, Cortland, NY, and New York, NY. Preschools were roughly matched for socioeconomic status and demographic population.

Procedure All children completed four trials (randomly ordered): Moral Trial, Preference Trial, Permissive Trial, and Conformist Trial. In each trial, children began by being shown two shapes (randomly chosen from a set of 8: a dot, a line, a circle, a square, a triangle, a squiggly line, an X, and a U). Each child was then given a white piece of paper on a colored mat and introduced to one of four puppets (a dog, a cat, a pig, or an elephant; randomly chosen).

In the *Moral Trial*, children were asked to act in accordance with a moral obligation: “This is [Doggie]. [Doggie] *hates* [triangles]. [Triangles] remind him of something *really* sad, and sometimes, when he sees them, he even cries! Can you draw the [circle (i.e, other shape)]?” In the *Preference Trial*, children were told: “This is [Piggy]. [Piggy] really likes to watch people draw! She wants you to draw whichever one of these shapes you like the best. Can you draw the one you like the best?” Children were then prompted to draw one of the two shapes they had just seen. In the *Permissive Trial*, the experimenter asked the child to act in accordance with a non-moral rule: “This is [Kitty]. [Kitty] says the rule is you *have* to draw a [squiggly]. She says that’s the rule and you have to do it. Can you draw a [squiggly]?” Finally, in the *Conformist Trial*, children were asked to do as everyone else has done: “This is [Ellie]. [Ellie] just played with lots of boys and girls and all of them drew a [line]. She says *every* one of them drew a [line]. Can you draw a [line]?”

After each trial, the colored placemat was set aside, and children were asked the Alternate Choice Judgment and explanation questions (as in Experiments 1 and 2).

Coding

Explanations were coded into the following six categories: references to Moral Constraints (“because it would make Doggie sad”), Preferences (“because I wanted to draw the square”), Permissive Constraints (“because Doggie said to draw the line”), Conformist Constraints (“because all of my friends did it”), Enactments (“by going like this”), and Non-Explanations (“because there was a dot there”; “I don’t know”).

Results and Discussion

The results show that, to a large extent, 4- and 5-year-old children believe their free will is constrained by all four contexts. Overall, 77% (46/60) responses to the Alternate Choice Judgment question were “no’s” and 67% (40/60) of the explanations refer to one of the coded constraints. However, there were also important differences between the four constraints in both judgments and explanations.

Figure 6 shows that a significant majority of children (87%; 13/15) indicated that they did not have the choice to act immorally (Binomial $p < .05$) or against conformity (87%; Binomial $p < .05$). A non-significant majority indicated that they could not act against permission (60%; 9/15), or their own preference (73%; 11/15).

Figure 6: Percentage of children who answered they “could not draw something else” in Experiment 3

Figure 7 shows the proportion of each type of explanation that children gave in each trial. In the Moral Constraint trial, the majority (87%; 13/15), of children appealed to moral considerations in their explanations. Also, moral constraints were most often referenced in the moral trial than each of the other three trials (all McNemar’s p ’s $< .01$, one-tailed).² In the Preference Constraints trial, approximately half (53%; 8/15) of children referred to preference considerations in

² Of those that referred to Moral Constraints in the other (non-moral) trials, all children experienced the Moral Trial before the trial in which they referenced the moral constraint, suggesting the presence of an order effect.

their explanations. Preference constraints were referenced more often in this trial than each of the other three (all McNemar’s p ’s $< .05$, one-tailed). In the permissive trial, only 33% (5/15) children referenced constraints of permission, and in the conformist trial, only 13% (2/15) referenced conformist constraints in their explanations. Moreover, the number of permissive and conformist explanations was low overall and did not significantly vary between trials. Enactments and non-explanations also did not significantly vary between trials.

Figure 7: Proportion of Explanation Types within Each Trial in Experiment 3

The results suggest that children responded quite differently to each type of constraint. These differences are further illuminated by analyzing the relationship between children’s judgments and their explanations. Only moral constraints were overwhelmingly judged and explained consistently and appropriately – 80% (12/15) of the children responded that they could not draw the other shape (“no” judgment) because it would make the puppet cry (Moral Constraint explanation). By the same analysis, preference constraints were also somewhat consistently evaluated – 47% (7/15) of the children said that they could not draw the other shape because they didn’t like it as much. On the other hand, children’s overwhelming “no” judgments in the Conformist trial were almost never followed by conformist constraint explanations – only 13% (2/15) of the children said they could not draw the other shape because no one else did. Also, only 20% (3/15) of the children said they could not draw it because those were the rules. Further research is needed to understand the reasons for these differences.

The most critical finding, then, is that children overwhelmingly said that they were not free to act to harm another person. One potential interpretation might be that

children felt “pressured” to state that they could not act immorally because a moral rule presented a “permissive” rule in some sense (Piaget, 1932/1997). However, children’s explanations reveal that this is not the case – children referenced moral considerations (“because it would make Doggie cry”) rather than permissive ones. Also, they were clearly less likely to say they were constrained by a simple rule (Permissive trial).

General Discussion

The results of these three studies show that by the time children are five years old they have an intuitive notion of free will that is sensitive to certain intangible constraints. Importantly, in contrast to the fact that children overinflate their own abilities (e.g., Stipek, 1984) preschool-aged children do not simply believe that their freedom to choose is limitless. Instead, preschool-aged children already appear to have notions of freedom of choice that are in-line with “compatibilist” (Hume, 1910) views (i.e., that some actions are fully or partially determined while others may be entirely unconstrained).

We also found that preschool children can reason about both wholly constraining (Experiments 1 and 2) and limiting (Experiment 3) influences on their past actions. Moreover, their responses indicate that they distinguish between different types of constraints. This is consistent with past work showing that young children understand the limiting nature of morality (Smetana, 1981; Yamada, 2008) and the nature of social norms (Kalish, 1998; Kalish & Shiverick, 1995). In adults, freedom of choice is linked to moral and normative behavior (Phillips & Knobe, in press; Vohs & Schooler, 2008). The current study suggests that this link is already present in very young children.

In the real world, social and psychological factors often come in conflict. For example, the desire to have your sister’s toy may conflict with the moral judgment that grabbing it from her would make her cry. Future work could study how preschoolers reason about freedom of choice when these social and psychological factors conflict.

Keywords: sequential decision making, computational modeling, cognitive neuroscience

The experimental study of decision making has historically focused on simple single-trial judgement or reasoning tasks. However, real world behavior often necessitates online decision making, planning, and sequentially organized behavior. The goal of the proposed symposium is to bring together researchers who are working to understand the cognitive processes underlying this kind of “dynamic decision making” (defined as tasks or contexts that are structured as a sequence of interdependent decisions).

A symposium on this topic is particularly timely since research in the area of dynamic decision making is having a tremendous impact on the field of psychology as a whole. First, researchers are converging on a set of novel computational modeling approaches that explain how decision makers plan sequences of multiple actions, take into account future contingencies, and react in real time to continually changing environmental dynamics. Second, many of the proposed algorithms and models are closely linked to neurobiological correlates (e.g., the recent explosion of research on neurobiology of reinforcement learning). Third, many of the tasks that are being developed for evaluating these models also appear to relate to important individual differences in real-world decision-making. The goal in the symposium is to 1) highlight some of the best work in this area, 2) to facilitate communication between researchers working on these problems from varying perspectives, and 3) to provide an excellent showcase of this area for members of the cognitive science community who may not yet be familiar with this work.

The speakers who agreed to participate are all accomplished researchers in this area but each approach the set of problems involved in sequential decision making and learning from a slightly different perspective. The key topics covered include 1) how people plan sequences

of actions to accomplish goals (Hotelling, Dimperio, & Busemeyer, Simon & Daw), 2) the underlying neurobiology of sequential decision making and planning (Simon & Daw), 3) how cognitive representations of the task or environment supporting planning and decision-making (Gureckis & Markant, Love & Otto, and Simon & Daw), and 4) how people balance exploration and exploitation in order to arrive at effective decision strategies in an unknown environment (Lee, Zhang, and Steyvers and Gureckis & Markant). In addition to these overlapping psychological themes, the researchers all share a core approach of applying sophisticated computational models to understand human behavior (including Bayesian approaches, reinforcement learning, and Markov Decision Processes).

Todd Gureckis & Douglas Markant (New York University)
Exploring to Exploit: Modeling the Process of Information Search and Planning

Effective learning often involves actively querying the environment for information that can be exploited at a later point in time. However, the space of observations available in any situation can vary greatly in potential “informativeness” and relative cost. How do people decide which observations to make at any point in time given their future goals? We describe a series of studies looking at how people plan sequences of information collection actions in a cognitive search task based on the children’s game Battleship. Participants made sequences of observations to disambiguate between a large number of potential game configurations subject to information-collection costs. Computational models are developed which predict which observations people will make on any given trial and when they should stop collecting information and exploit their current knowledge. In particular, the models measure the degree to which individuals take into account future consequences when planning immediate actions. In our second study, we explore how people generate hypotheses consistent with their prior

beliefs and how these hypotheses in turn influence search behavior.

Jared M. Hotelling, Eric Dimperio, & Jerome R. Busemeyer (Indiana University)

Cognitive Models of Planning Behavior in Multi-Stage Risky Decision Making

Much research into risky decision making has traditionally presented individuals with choice alternatives that provide an immediate reward or punishment based on the outcome of a random event. This allows researchers to understand how the values of choice alternatives and the probabilities associated with risk can influence an individual's choices. We present recent work that extends that research by manipulating the outcome probabilities and rewards involved in a multistage decision task where some rewards are only possible after a sequence of decisions. Our results show individual differences, with some participants being sensitive to possible future rewards and likelihoods, and others appearing not to plan ahead. A comparison of multiple competing models helps identify decision processes when planning ahead did occur.

Michael Lee, Shunan Zhang, & Mark Steyvers (Univ. of California, Irvine)

Human and optimal exploration and exploitation in sequential decision-making

In bandit problems, a decision-maker chooses repeatedly between a set of alternatives. They get feedback after every decision, either recording a reward or a failure. They also know that each alternative has some fixed unknown probability of providing a reward when it is chosen. The goal of the decision-maker is to obtain the maximum number of rewards over all the trials they complete. Bandit problems provide an interesting formal setting for studying the balance between exploration and exploitation in decision-making. In early trials, it makes sense to explore different alternatives, searching for those with the highest reward rates. In later trials, it makes sense to exploit those alternatives known to be good, by choosing them repeatedly. How exactly this balance between exploration and exploitation should be managed, and should be influenced by factors such as the distribution of reward rates, the total number of trials, and so on, raises basic questions about adaptation, planning, and learning in intelligent systems. In this talk, we present a series of models, both Bayesian and heuristic, aimed at understanding how people balance exploration and exploitation, and how their strategies relate to optimal decision-making.

You Don't Want To Know What You're Missing: When Information about Foregone Rewards Impedes Dynamic Decision Making

When learning to make decisions from experience, one reasonable intuition is that adding relevant information should improve performance. In contrast, we find that additional information about foregone rewards (i.e., what could have gained at each point by making a different choice) severely hinders participants' ability to repeatedly make choices that maximize long-term gains. We conclude that foregone reward information accentuates the local superiority of short-term options (e.g., consumption) and consequently bias choice away from productive long-term options (e.g., exercise). These conclusions are anticipated by a standard reinforcement learning mechanism that processes information about experienced and forgone rewards. In contrast to related contributions using delay-of-gratification paradigms, we do not posit separate top-down and emotion-driven systems to explain performance. We find that individual and group data are well characterized by a single reinforcement learning mechanism that combines information about experienced and foregone rewards. These findings will be situated within a broader research program that aims to characterize how people explore and exploit environments with unknown rewards and poorly understood states. Finally, interventions for improving human performance will be discussed.

Dylan Simon & Nathaniel Daw (New York University)
Neural correlates of decision evaluation by forward planning in sequential tasks

Theoretical models of reinforcement learning are commonly applied within neuroscience to explain the neural processes involved in learning and decision making. However, the approaches used are predominately "model-free," such as temporal difference learning which learns action values or policies directly from reinforcement without explicitly representing or utilizing any information about task structure. While these theories have shed light on observed neural activity in simple "bandit" tasks involving repeated choices rewarded independently and immediately, it is at odds with a long line of behavioral evidence from psychology and cognitive science for more flexible, goal-directed forward planning processes. We show how a different set of "model-based" reinforcement learning algorithms can be used to account for these phenomena, and test this framework in humans using a number of dynamic, continuous, sequential decision tasks. The models can account both for observed choice behavior and fMRI BOLD signals in decision-related brain areas. Consistent with cognitive theories, both behavior and neural activity show evidence of flexible learning and forward planning, indicating that existing neural models provide an incomplete picture of learning and decision making in dynamic tasks.

The Active Role of Partial Knowledge in Cross-Situational Word Learning

Daniel Yurovsky, Damian Fricker, Chen Yu, and Linda B. Smith

Abstract

A number of modern word learning theories posit statistical processes in which knowledge is accumulated across many exposures to a word and its potential referents. Accordingly, words do not go directly from unknown to known, but rather pass through intermediate stages of partial knowledge. This work presents empirical evidence for the existence of such partial knowledge, and further demonstrates its active driving role in cross-situational word learning. Subsequently, an incremental model which leverages its partial knowledge of word-object mappings from trial to trial is shown to account well for the data. In contrast, models which do not do so cannot explain the data. These results confirm crucial assumptions made by statistical word learning models and shed light on the representations underlying the acquisition of word meanings.

Keywords: word learning; language acquisition; computational modeling; statistical learning

Introduction

We have a tendency to characterize word learning as an all-or-none process: either a child knows a given word, or she has not yet learned it. This is apparent in our methodology (e.g. forced-choice tests, preferential looking), and assessment of vocabulary size via MCDI (Fenson, Dale, Reznick, Bates, Thal, & Pethick, 1994), as well as some theoretical claims. But this implicit all-or-none characterization may stymie our thinking about potential word-meaning representations.

For almost a century we have known that human learning and memory are not binary phenomena (Ebbinghaus, 1913). In learning lists of paired associates, for instance, a failure to recall the correct pair for a prompt does not imply no knowledge of the mapping. Evidence of this knowledge can be recovered using a different test paradigm (e.g. recognition or savings). The knowledge is not absent, but rather partial or sub-threshold. The central idea motivating this work is that such sub-threshold knowledge may play a profound role in the course of language acquisition.

Several recent theoretical and computational approaches to word learning have made explicit use of partial knowledge. For instance, McMurray (2007) modeled the learning of a word's meaning as the acquisition of partial meaning tokens. Yu and Smith (2007) argued that early word learning can be thought of as the accumulation of co-occurrence statistics between words and objects across multiple situations. These theories suggest that a word can be learned in bits rather than in a single perfect moment.

Other models make an even stronger claim: not only can one build lexical knowledge by accumulating parts; this

partial knowledge is an active driver of the learning system (Blythe, Smith, & Smith, in press, McMurray, Horst, Toscano, & Samuelson, in press, Fazly, Alishahi, & Stevenson, in press, Yu, 2008). These models have been tested predominantly on large corpora, reproducing qualitative patterns found in children's word learning. If they are correct about the presence and role of partial knowledge, however, then we should be able to find empirical evidence for the role of partial knowledge in human word learners.

Yurovsky and Yu (2008) presented indirect evidence of the active role of partial knowledge in cross-situational learning. They exposed participants to a series of individually ambiguous learning trials consisting of multiple words and multiple objects. At the end of each trial, participants were asked to indicate how sure they were (1-10) that they knew the correct label for each object. Yurovsky and Yu showed that a given object's rating could be predicted from the ratings given to the other objects on the same trial, even after the object's rating on its previous exposure was taken into account. Thus, participants seemed to be using partial knowledge of word-object mappings to reduce the set of candidates for other labels.

This analysis, while promising, was performed on participants' subjective knowledge ratings. In the present work, we propose to offer stronger and more direct evidence that partial knowledge plays an active role in word learning. To this end, we expose participants to two consecutive blocks of cross-situational learning. Crucially, half of the words and objects in the second block are those which participants failed to learn in the first block. Comparing the results of block 2 to those of several control conditions, we can determine the role of partial knowledge in cross-situational learning. First, we can ask whether partial knowledge exists in the system, whether learners are really accumulating bits of sub-threshold knowledge.

At a deeper level, we pursue a more interesting question: does partial knowledge of *individual* word-referent pairs – interacting in a *system* with partial knowledge of other word-referent pairs – facilitate the acquisition of new words. To answer this question, a set of computational models are fit to the data to understand the underlying learning mechanisms which give rise to the empirical results. We compare a *simple associative model*, a *biased associative model* which increments associations in proportion to their current strength, and a *competitive associative model* which adds within-trial competition. In the simple associative model, partial knowledge is not used in learning. In the biased associative model, partial knowledge of a word-

referent pair drives learning of that individual pair. Finally, in the competitive associative model, partial-knowledge of multiple word-referent pairs interacts and, by so doing, facilitates the learning of other pairs and thus the whole system of words and referents.

Experiment 1

To demonstrate the role of partial knowledge in word learning, we used the cross-situational word learning paradigm (Yu & Smith, 2007). In this task, participants are exposed to a series of individually ambiguous learning trials, each of which contains multiple co-occurring words and potential referents. While each trial is individually unambiguous, words always co-occur with their correct referent, and thus participants who correctly track co-occurrence between words and objects across trials can learn the correct pairings.

In Experiment 1, participants were exposed to two consecutive blocks of cross-situational word learning. At the end of block 1, participants were asked to select the correct referent for each of the trained words. For participants in the *unlearned* condition, half of the stimuli in block 2 were word-object pairs from block 1 for which they selected incorrect referents. For participants in the *new* condition, all stimuli in the second block were new.

If participants encoded nothing about words for which they selected incorrect referents in block 1, participants in the *unlearned* and *new* conditions should learn equally well in block 2. Alternatively, since no feedback is provided at test, if participants who selected incorrect referents did so as the result of binary hypotheses, and carried these wrong hypotheses to block 2, we might expect participants in the *unlearned* condition to underperform those in the *new* condition. However, if participants who selected incorrectly possess sub-threshold knowledge of the correct referent, we would expect participants in the *unlearned* condition to perform better than *new* participants in block 2. Most interesting would be if sub-threshold knowledge of one pair interacted with sub-threshold knowledge of other word-referent pairs to facilitate learning new pairs in block 2.

Method

Participants. Ninety-two Indiana University undergraduates participated in exchange for course credit; 50 in the *unlearned* condition and 42 in the *new* condition. However, to ensure a fair comparison across conditions, data from only a subset were analyzed (criteria explained in procedure). The final analysis was conducted on 23 participants in the *unlearned* condition, and 10 participants in the *new* condition.

Stimuli. Referents were represented by pictures of unusual objects which were easy to distinguish from each other, but difficult to name. Words were 1-2 syllable synthesized nonsense words constructed to be phonotactically probable in English. All words and objects have been used in previous cross-situational learning experiments (Yu &

Smith, 2007, Yurovsky & Yu, 2008). Forty-two unique words and objects were used in total – 24 in block 1 and 18 in block 2.

Training slides for block 1 presented two pictures – one on each side of the screen – and played two labels, following Yu and Smith's (2007) 2x2 condition. Training slides for block 2 presented four objects – one in each corner of the screen – and played four labels, following Yu and Smith's (2007) 4x4 condition. Test slides for each block displayed all of the objects from that block (24 for block 1, 18 for block 2) in random positions and played one label.

Procedure. Each participant was exposed to two blocks of cross-situational learning – first a 2x2 block and then a 4x4 block. Each block consisted of a training phase followed by a test phase. The training phases consisted of a series of trials each displaying a set of objects and playing an equal number of words. Screen position and word order were randomized, such that they provided no information about which word labeled which object.

Following training, participants were given a series of alternative forced choice tests in which they were asked to select the correct referent for each label. Each word was tested once, and all objects from a block were presented on each test trial, so the content of test trials was uninformative as to correct mappings.

Block 1 contained 24 novel words, each of which occurred 5 times with its correct referent and less often with other objects. This resulted in 60 2x2 trials in total. Block 2 contained 18 words, each of which occurred with its correct referent 4 times and less often with other objects. This resulted in 18 4x4 trials. Word-object pairings and trial orders were selected randomly for each participant.

Block 1 was identical for participants in both the *new* and *unlearned* groups. The stimuli for block 2 differed across conditions. In the *new* condition, block 2 consisted entirely of novel stimuli – 18 words and their associated objects. For participants in the *unlearned* condition, however, 9 of the words and objects in the second block were those for which they had selected the incorrect response at test in block 1 (see Figure 1). Thus, for participants in the *unlearned* group, half of the stimuli in block 2 were words and objects for which they had not successfully learned correct associations. We will refer to the words and referents carried over from block 1 as old and those which are seen for the first time in block 2 as new.

Since participants could complete block 2 of the *unlearned* condition only if they had selected incorrect referents for at least 9 words in block 1, we could analyze participants who learned at most 15 of the 24 possible mappings. However, this could produce a skewed measure of average learning performance in block 2 since we would be rejecting data from those who learned “too much” in block 1. To help compensate, we also excluded participants who learned less than 9 correct pairings. Thus, only participants who learned between 9 and 15 correct pairings in block 1 continued on to block 2 of either condition.

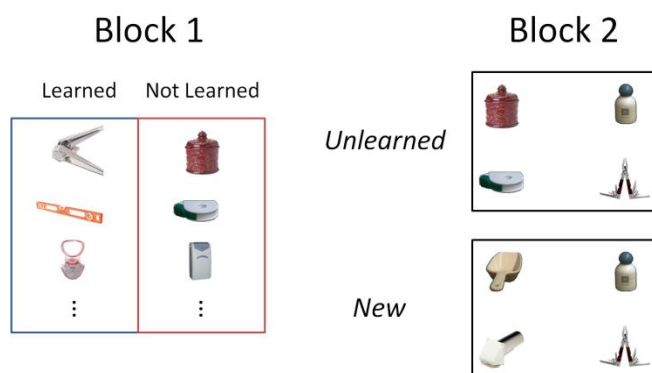

Figure 1: Selection of stimuli for block 2. In the *unlearned* condition, half of the items on each trial of block 2 were those for which the participant had given the incorrect response in block 1. The other half were new. In the *new* condition, all stimuli were new.

Results and Discussion

As described above, only a subset of the participants run in block 1 of either condition proceeded on to block 2. Importantly, the proportion of words learned in block 1 did not differ between the selected subset and the set of all participants in the *unlearned* condition ($M_s = .51$, $M_a = .50$, $t = .234$, *n.s.*) nor in the *new* condition ($M_s = .47$, $M_a = .43$, $t = .470$, *n.s.*). Neither was there a significant difference between the proportion of words learned in block 1 by the selected participants in the *unlearned* vs. the *new* condition ($M_u = .51$, $M_n = .47$, $t = 1.62$, *n.s.*). This is to be expected given that block 1 was identical across conditions. Thus, all further analysis will be performed on selected participants.

In the second block, participants in both the *unlearned* and *new* conditions learned a significant proportion of word-object pairings ($M_u = .56$, $t_u = 9.74$, $p < .001$, $M_n = .27$, $t_n = 6.62$, $p < .001$, *chance* = .056). However, as shown in Figure 2, participants in the *unlearned* condition successfully mapped more than twice as many words to their correct referents as those in the *new* condition ($t = 3.63$, $p = .01$). Further, this benefit was not only for the 9 old pairings carried over from block 1 ($M_u = .6$, $M_n = .26$, $t = 3.69$, $p < .001$), but for the 9 new pairings as well ($M_u = .51$, $M_n = .27$, $t = 2.48$, $p < .05$).

Thus, partial knowledge of word-object pairings in block 1 allowed participants in the *unlearned* condition to learn significantly more mappings in block 2 than participants in the *new* condition. Further, the benefit was not just for the pairings for which participants had partial knowledge, but for novel pairings as well. This suggests that partial knowledge plays an active role in organizing cross-situational learning. Even though knowledge of word-object pairings was below threshold in block 1, it was sufficient to drive learning of novel pairings in block 2.

These findings provide initial support for the idea that sub-threshold knowledge of word-object mappings drives

cross-situational learning. Partial knowledge of some pairs may influence the learning of other pairs on a trial-to-trial basis by constraining the pairs that are associated within a trial. An alternative explanation, however, is that participants in this experiment are benefitting from knowledge of which of the stimuli in block 2 had been seen previously in block 1. This could allow participants in block 2 of the *unlearned* condition to actively reduce the ambiguity of each training trial by mapping old words to old objects and new words to new objects. Some evidence for this second hypothesis comes from the errors made by participants in block 2 of the *unlearned* condition. When participants made errors in selecting referents for new words, they selected new referents at a probability significantly different from chance ($M = .70$, $t = 3.73$, $p < .01$, *chance* = .44). To provide further insights into the nature of the partial knowledge and its role in learning novel items, we constructed a new condition that was designed to assess the influence of sub-threshold mappings over and above possible knowledge of old/new.

Experiment 2

In Experiment 1 we tested the role of partial knowledge in word-referent mapping by exposing participants to two consecutive trials of cross-situational learning. Crucially, half of the pairings in block 2 were pairings for which participants failed to learn correct mappings in block 1. Learning results in block 2 showed that partial knowledge of these word-object pairings allowed participants to perform more than twice as well as participants exposed to a second block consisting of all new pairings. One possibility is that this benefit is entirely due to participants preferentially mapping old words to old objects and new words to new objects because they categorized them into two groups by mere exposure.

Figure 2: Proportion of word-referent pairings learned by participants in each condition across Blocks 1 and 2. Dotted lines indicate chance levels.

To establish a more stringent baseline for comparison, in Experiment 2 we constructed a *control* condition in which participants were exposed to the same word and object stimuli as participants in the *unlearned* condition, but without any opportunity to learn their associations. These same stimuli then appeared again in block 2. The *control* condition allows us to determine a second baseline – the effect of mere exposure to the stimuli of block 1.

Method

Participants. Ten Indiana University undergraduates participated in exchange for course credit. None had previously participated in Experiment 1.

Stimuli. Stimuli for Experiment 2 were identical to those for Experiment 1.

Procedure. The procedure for the *control* condition was similar to that used in the *unlearned* condition of Experiment 1. The crucial difference, however, was in the co-occurrence statistics of the words and objects of block 1. Whereas all words co-occurred with their correct referents 5 times in Experiment 1, in Experiment 2 half of the words occurred at most one time with each possible referent. Thus, there was essentially no correct referent for these 12 words. These unlearnable words and objects were matched for frequency of occurrence with those in block 1 – only co-occurrence statistics changed.

After the test phase of block 1, participants were exposed to a second cross-situational learning task as before. This time, however, 9 of the words and objects in block 2 were drawn randomly from the set of 12 unlearnable words and objects of block 1. In the second block these words each occurred 4 times with a single correct referent just like the 9 novel words. Thus, participants could distinguish the old words from the new words by their appearance in block 1, but they could not use potential partial knowledge of word-referent mappings to bootstrap their learning in block 2.

Results and Discussion

Because half of the words in block 1 of the *control* condition were unlearnable, it is unsurprising that these participants learned less words in block 1 than those in Experiment 1 ($M_1 = .5$, $M_2 = .28$, $t_u = 7.21$, $p < .001$). However, when only those words for which there was a correct answer in both Experiments are considered, participants performed equally well in both Experiment 1 and 2 ($M_1 = .49$, $M_2 = .48$, $t = 0.19$, $n.s.$). It is thus reasonable to compare block 2 performance across conditions.

In Experiment 2, we test the hypothesis that the benefit experienced due to participants in the *unlearned* condition of Experiment 1 was due not to partial knowledge, but to the ability to partition stimuli into two sets: old and new. If this is the case, mere exposure to the stimuli of block 1 – without the underlying co-occurrence statistics – should have been sufficient to reproduce this benefit. This is

Figure 3: Proportion of word-referent pairings learned by participants in each condition. Old words are those which have been carried over to block 2 from block 1. In the *new* condition there are no old words, so the old words are those which fill the same slots in the training trials as the old words in the *unlearned* and *control* conditions. Dotted lines indicate chance.

precisely the condition experienced by participants in the *control* condition. However, counter to this hypothesis, participants in the control condition did not outperform those in the *new* condition ($M_c = .27$, $M_n = .26$, $t = .16$, $n.s.$). They did, however, significantly underperform those in the *unlearned* condition ($M_c = .27$, $M_u = .56$, $t = -3.22$, $p < .01$). This difference was separately significant for old ($M_c = .2$, $M_u = .6$, $t = -4.06$, $p < .001$) and trending in the right direction for new ($M_c = .34$, $M_u = .51$, $t = -1.55$, $p = .13$) words. Figure 3 shows these results. This weighs against the hypothesis of mere exposure and lends credence to the hypothesis that partial knowledge is an active driver of cross-situational learning.

Computational Models

To more fully analyze the role of partial knowledge of word-referent mappings in driving cross-situational learning, we implemented three incremental associative models that were exposed to simulated trials identical to those seen by experimental participants. The three models allow us to explicitly test hypotheses about how partial knowledge is used.

The first model – the *simple associative model* – maintains a word x object co-occurrence matrix and simply increments the cell corresponding to a word-object association each time the pair appears on a trial. This model thus learns the pure frequency of each of the possible word-object pairs.

The second model – the *biased associative model* – similarly maintains a word x object co-occurrence matrix. However, instead of incrementing the association strength

between a word and object by one whenever they co-occur, it increments their association by the strength of the current association. Whereas the *simple* model produces linear growth, the *biased* model produces geometric growth. This rich-get-richer scheme capitalizes on partial knowledge of a pairing in order to learn that pairing.

The final model – the *normalized associative model* – adds a competitive process to the *biased* model. On each trial, the increase in association between words and objects are computed as in the *biased* model, but the increment for a given word-object pair is normalized by the sum of all increments made for that object on that trial. This implements competition between all of the words in one trial. Intuitively, as one word accounts better for the presence of an object, the association between other words and that object are depressed. This mechanism is similar to the alignment mechanism used by Fazly et al.’s (in press) iterative version of the IBM Machine Translation Model (Brown, Pietra, Pietra, & Mercer, 1994).

The models are each tested for their knowledge of word-object associations in the same way as experimental participants. At the end of training, they are exposed to a series of alternative-forced choice tests and make their selections using the Shepard-Luce Choice Rule (Luce, 1959, Shepard, 1957). The simulated participant selects each alternative with a probability proportional to the exponential function of the strength of its association with the tested word.

Each model has only one parameter: a sensitivity parameter (λ) which weights each of the exponentiated probabilities in the Shepard-Luce Choice rule. Higher values of λ indicate that participants are more sensitive to differences in associative strengths between alternatives. To simulate Experiments 1 and 2, we exposed simulated participants to exactly the same stimuli as real participants. For instance, simulated participants in the *unlearned* condition were exposed to all of the training trials of the first block one at a time. Then, each simulated participant made selections at test using the Shepard-Luce Choice Rule. Nine of the items for which the model gave the wrong answer were then carried over to block 2, which were once again presented to the participant one trial at a time. Finally, the same decision rule was used to select a referent for each tested word. One thousand simulated participants were run in each of the three conditions using each model.

As can be seen in Figure 4, all of the models make essentially the same predictions for block 1. However, they make differing predictions for block 2 – the block during which partial knowledge may play a role. Figure 5 shows that the *simple associative* model is unable to produce the trend found in the data at even a qualitative level. It predicts that participants in the *unlearned* condition should underperform those in the *control* and *new* conditions. The other two models produce qualitatively similar trends. The *competitive* model, however, performs quantitatively better than the *biased* model ($SSE_c = .0071$, $SSE_b = .0191$, Bayes Factor = 2.69). As both have an equal number of

Figure 4: Proportion of word-referent pairs learned in block 1 by experimental participants and each of the three models across all experimental conditions.

Figure 5: Proportion of word-referent pairs learned in Block 2 by experimental participants and each of the three models across all experimental conditions.

parameters, we can conclude that the *competitive model* is the better model for this empirical data. This supports the hypothesis that partial knowledge plays an active role in cross-situational learning, with partial-knowledge of multiple word-object associations interacting to support the acquisition of new word-object associations.

General Discussion

Whereas many methods for measuring word learning treat it as if it were binary – either the correct referent of a word is known or it is not – recent theoretical and computational models have argued that it is a gradual, accumulative process. Rather than learning a word's referent from a single perfect moment, learners may hone in on the correct referent through exposure to environmental statistics.

Empirical work has demonstrated that co-occurrence statistics alone are sufficient for learning word-object pairings (Yu & Smith, 2007). Furthermore, Vouloumanos (2008) showed evidence that learners are not only sensitive to the most frequently associated object for a given word, but also show deep knowledge of the statistical structure. Still, these results probed statistically acquired word-object knowledge only in its final state – producing a binary learned/unlearned data point for each potential pairing. Empirical evidence of graded states of partial knowledge has been indirect at best (Yurovsky & Yu, 2008).

The present work provides direct empirical evidence of not only the presence of such partial knowledge, but also its active role in driving word learning from exposure to exposure. The compared incremental models of statistical word learning show that partial knowledge may be leveraged on a trial-to-trial basis to bootstrap learning. Crucially, the better quantitative fits of the *competitive* model suggest that partial knowledge of a word-object association does not merely facilitate learning of that one association, but also combines with partial knowledge of other word-referent pairs to bootstrap learning of the whole system of words and referents. When words are learned as an interacting system, partial knowledge of one component gives a learner a leg up on acquiring others (Landauer & Dumais, 1997).

While there is no denying the importance of word learning models at the computational level (Frank, Goodman, & Tenenbaum, 2009, Xu & Tenenbaum, 2007, Yu, 2008), this work again underscores our need to understand the continuous interaction of knowledge and learning on a moment-to-moment basis. Word learning is a constructive process, with initial successes cascading on themselves to empower even more successful learning (Smith, 1999). By digging deeper into word learning – understanding the latent representations that drive the system – we can hope to come to terms with its incredible complexity.

Abstract

Higher frequency has been shown to have a positive effect on the acquisition of words and other linguistic items in children. An important question that needs to be answered then is how children learn low frequency items. In this study, we investigate the acquisition of meanings for low frequency words through computational modeling. We suggest that for such words, the familiarity of the context they appear in has an important effect on their acquisition. We note that context familiarity is confounded with another factor, namely the age of exposure to a word, and hence examine the independent role of each of the two factors on word learning.

Cross-situational Word Learning

Learning the meaning of words is a challenging task for young children, especially given that most words are learned from noisy and ambiguous contexts. Many specific word learning biases and constraints, as well as general learning mechanisms, have been suggested to be at work in the course of child lexical development. In particular, the learning of word–meaning mappings has been suggested to be based on cross-situational observation (Quine, 1960; Pinker, 1989) — that is, the meaning of a word can be learned by detecting the common set of meaning elements across all situations in which the word occurs. Psychological experiments on adults and children show that they are capable of learning word–referent mappings from their co-occurrences over time, even when each single occurrence of a word–referent pairing is ambiguous (Yu & Smith, 2007; Smith & Yu, 2007). The learning process seems to be sensitive to the statistical properties of the input, such as word frequency, the degree of ambiguity of presentation (i.e., how many words appear together), and the familiarity of the context. However, the relevant properties and their precise impact on learning word meanings are not well understood.

For example, higher frequency has been shown to have a positive effect on learning many linguistic constructions (Huttenlocher et al., 1991; Naigles & Hoff-Ginsberg, 1998). But frequency must be investigated carefully, since in many learning situations — including word learning — it may be confounded with other factors, such as the diversity of the context that a word can appear in (see, e.g., Kachergis, Yu, & Shiffrin, 2009). Moreover, many experimental studies have shown that children can acquire the meaning of a novel word with only one or a few exposures (i.e., when the word has very low frequency), especially if it is presented in a familiar context, a phenomenon known as *fast mapping* (Carey & Bartlett, 1978; Gershkoff-Stowe & Hahn, 2007; Alishahi et

al., 2008). These observations about the interactions of various factors with frequency are especially important given that words in the input children receive have a Zipfian distribution (Zipf, 1949) — that is, a large proportion of words have a very low frequency of occurrence, yet generally they are successfully learned. Therefore, the relevant statistical features of the input data and their independent effect on learning need to be carefully investigated.

The experimental study of Kachergis et al. (2009) on adult subjects is one such attempt to identify and study the role of some of the important statistical properties of input on word learning. By varying the frequency of co-occurrence of different word–referent pairs, Kachergis et al. examine the independent and differential role of frequency, contextual diversity (i.e., diversity in the co-occurring words across usages of a target word), and within-trial ambiguity (i.e., the number of co-occurring words in each sentence) in cross-situational word learning. In particular, Kachergis et al. suggest that high contextual diversity and low within-trial ambiguity can boost the acquisition of low frequency words. However, some of the experimental results in their study cannot be explained by the factors they propose. Also, contextual diversity cannot explain children’s ability to easily learn the referent of a novel word from a single exposure to that word, since it captures a property of the input across multiple exposures to a word. These observations suggest that other factors may be at play, especially for the acquisition of low frequency words.

Our goal is to investigate what other factors may have an effect on learning the meanings of words in general, and on the acquisition of low frequency words in particular. We use an existing computational model of cross-situational word learning to simulate the experiments of Kachergis et al. (2009), and to examine the effect of two additional factors in word learning: the familiarity of the context that a word appears in (i.e., how well the model/learner knows the other words in the sentence), and the age of exposure to a word. The computational simulations of our model show a matching behavioural pattern with that of adult word learners in the experiments of Kachergis et al. Moreover, our results suggest that for low frequency words, it is not the contextual diversity that helps learn their meaning, but the degree of familiarity of their context. We further test this claim by applying our model to a large corpus of child-directed speech, and examine the role of the proposed factors in the learning performance of the model.

Statistical Properties of the Input

Contextual Diversity and Within-trial Ambiguity

Kachergis et al. (2009) report a series of studies on adult subjects learning word–referent mappings from ambiguous utterance–scene pairs, where the utterance contains a bag of words, and the scene is the set of their referents. They investigate the effect of frequency by having some words and referents appear more often than others. They also investigate the interaction between word–referent frequencies and the diversity of the contexts that a word appears in, to examine the independent effect of each of the two factors on word learning. In these experiments, contextual diversity is varied by manipulating either the overall rate of co-occurrence among words, or the number of co-occurring words within a trial. More precisely, Kachergis et al. study the interactions among the following three factors:

- Word frequency:
 $F(w)$ = total #occurrences of w in the input
- Contextual diversity:
 $CD(w)$ = total #words co-occurring with w across all usages of w in the input
- Within-trial ambiguity:
 $WA(w)$ = mean #words co-occurring with w in each utterance

Their results show that a higher F often leads to better learning of a word, and to boosting the learning of other words. However, F is usually confounded with CD , which can be seen as an alternative explanation for learning facilitation. When F is controlled for, a higher CD improves learning (i.e., more word–meaning pairs are learned), whereas a higher WA harms learning. Similarly when CD is controlled for, a higher F improves learning. Most interestingly, when a higher CD is achieved by interleaving high frequency words in the presentation of low frequency words, the learning of the low frequency words is improved.

Age of Exposure and Context Familiarity

As described in the previous section, the results of Kachergis et al. (2009) suggest that contextual diversity (CD) is particularly important for the acquisition of low frequency words. However, some of their results show a boost in the acquisition of low frequency words where there is no notable difference in CD . In an attempt to explain these results, and inspired by the well-studied fast mapping effect (Carey & Bartlett, 1978), we study two additional statistical factors that might play a role in cross-situational learning:

- Age of exposure:
 $AE(w)$ = time at which w first appears in the input
 - Context familiarity:
 $CF(w)$ = mean *familiarity* of words co-occurring with w , averaged across all usages of w in the input
- where *familiarity* of a word is determined by its frequency of occurrence prior to its current appearance.

Computational Analysis

We investigate the role of each of the above factors in cross-situational learning through two sets of experiments. First, we replicate the results of Kachergis et al. (2009) using the computational model of Fazly et al. (2008) (briefly explained in the next section), and examine the impact of our proposed factors as well as the ones proposed by Kachergis et al. on learning. Second, we apply our model on a larger corpus of actual child-directed speech to better understand how the model learns the meaning of low frequency words in a more naturalistic situation, and to study the impact of the statistical factors and their interaction during the course of learning.

Overview of the Computational Model

We use an incremental probabilistic word learning algorithm, explained in full detail in Fazly et al. (n.d.). Here we repeat a brief explanation of how the model works.

Utterance and Meaning Representations

The input to our word learning model consists of a set of utterance–scene pairs that link an observed scene (what the child perceives) to the utterance that describes it (what the child hears). We represent each utterance as a set of words, and the corresponding scene as a set of meaning symbols.

Utterance: { *Joe, rolled, the, ball* }

Scene: { *joe, roll, the, ball* }

Given a corpus of such utterance–scene pairs, our model learns the meaning of each word w as a probability distribution, $p(.|w)$, over the semantic symbols appearing in the corpus. In this representation, $p(m|w)$ is the probability of a symbol m being the meaning of a word w . We assume that in the absence of any prior knowledge, all symbols are equally likely to be the meaning of a word. Hence, prior to receiving any usages of a given word, the model assumes a uniform distribution over all semantic symbols as its meaning.

Meaning Probabilities

Our model combines probabilistic interpretations of cross-situational learning (Quine, 1960) and a variation of the principle of contrast (Clark, 1990), through an interaction between two types of probabilistic knowledge acquired and refined over time. Given an utterance–scene pair received at time t , i.e., $(U^{(t)}, S^{(t)})$, the model first calculates an alignment probability a for each $w \in U^{(t)}$ and each $m \in S^{(t)}$, using the meaning probabilities $p(.|w)$ of all the words in the utterance prior to this time (Step 1 below). The model then revises the meaning of the words in $U^{(t)}$ by incorporating the alignment probabilities for the current input pair (Step 2). This process is repeated for all the input pairs, one at a time.

Step 1: Calculating the alignment probabilities. We estimate the alignment probabilities of words and meaning symbols based on a localized version of the principle of contrast: that a meaning symbol in a scene is likely to be highly associated with only one of the words in the corresponding utterance. For a symbol $m \in S^{(t)}$ and a word $w \in U^{(t)}$, the

higher the probability of m being the meaning of w (according to $p(m|w)$), the more likely it is that m is aligned with w in the current input. In other words, $a(w|m, U^{(t)}, S^{(t)})$ is proportional to $p^{(t-1)}(m|w)$. In addition, if there is strong evidence that m is the meaning of another word in $U^{(t)}$ — i.e., if $p^{(t-1)}(m|w')$ is high for some $w' \in U^{(t)}$ other than w — the likelihood of aligning m to w should decrease. Combining these two requirements:

$$a(w|m, U^{(t)}, S^{(t)}) = \frac{p^{(t-1)}(m|w)}{\sum_{w' \in U^{(t)}} p^{(t-1)}(m|w')} \quad (1)$$

Step 2: Updating the word meanings. We need to update the probabilities $p(\cdot|w)$ for all words $w \in U^{(t)}$, based on the evidence from the current input pair reflected in the alignment probabilities. We thus add the current alignment probabilities for w and the symbols $m \in S^{(t)}$ to the accumulated evidence from prior co-occurrences of w and m . We summarize this cross-situational evidence in the form of an association score, which is updated incrementally:

$$\text{assoc}^{(t)}(w, m) = \text{assoc}^{(t-1)}(w, m) + a(w|m, U^{(t)}, S^{(t)}) \quad (2)$$

where $\text{assoc}^{(t-1)}(w, m)$ is zero if w and m have not co-occurred before. The association score of a word and a symbol is basically a weighted sum of their co-occurrence counts.

The model then uses these association scores to update the meaning of the words in the current input:

$$p^{(t)}(m|w) = \frac{\text{assoc}^{(t)}(m, w)}{\sum_{m_j \in \mathcal{M}} \text{assoc}^{(t)}(m_j, w)} \quad (3)$$

where \mathcal{M} is the set of all symbols encountered prior to or at time t . We use a smoothed version of the above formula, as described in (Fazly et al., n.d.).

Word Comprehension Score

Our model updates the meaning of a word every time it is heard in an utterance. The strength of learning of a word at time t is reflected in $p^{(t)}(m = m_w|w)$, where m_w is the “correct” meaning of w according to a gold-standard lexicon. We refer to $p^{(t)}(m_w|w)$ as the comprehension score (Comp) of word w at time t . Ideally, a word is accurately learned when the probability distribution $p(\cdot|w)$ is highly skewed towards the correct meaning m_w . In our experiments reported in the following sections, we first train our model on a number of utterance–scene pairs, and then examine the comprehension scores of words as an indirect way of measuring the performance of our model in selecting referents of words.

Analysis of Artificial Word Learning Data

Here we report the results of our simulations on artificially-generated data similar to that of Kachergis et al. (2009). Their (human) experiments examine the effect of three factors on word learning: frequency (F), contextual diversity (CD), and within-trial ambiguity (WA), as defined on page 2. The artificial input data set used in our simulations is explained next, and then the results of the experiments are presented.

Input Data

The artificial data set consists of randomly-generated sequences of utterances in the form of an unordered bag of novel words, each paired with a set of novel meaning symbols. In the artificial data, one of the three factors under study is changed while the other factors are kept constant, in order to better understand the role each plays in learning, as well as the interactions among the different factors. We use nine sets of artificial data (each containing 18 word–meaning pairs), one set for each experimental condition of Kachergis et al. (2009). The first experiment investigates the role of F: one condition divides words into two frequency groups (F=3,9), the other into three frequency groups (F=3,6,9). The second experiment examines the role of context by manipulating either CD or WA, while keeping F constant. One condition manipulates CD by dividing words into two unequal-sized groups (with 6 and 12 words, respectively), and allowing words in each group to co-occur only with other words from the same group. In two other conditions, a word appears with either 2 or 3 other words in each trial (WA=3 and WA=4, respectively). The third experiment studies the interaction between F and CD by controlling the co-occurrence among words from three frequency groups (F=3,6,9), resulting in four conditions: In Low CD condition, words from each frequency group co-occur only with other words from the same group. In Med CD conditions, low frequency words (F=3) are allowed to either co-occur with words in F=6 (Med CD-3&6), or with those in F=9 (Med CD-3&9). In High CD condition, there is no restriction on the co-occurrence of words from different frequency groups. For each experimental condition, we randomly generate 30 different artificial input. Results presented here are averages over 30 different simulations, each using a different input.

Modeling Effects of Frequency and CD

Figures 1 to 3 present the performance of our model on the artificially-generated input in three experiments analogous to those of Kachergis et al. (2009).

Our findings in Experiment 1 (Figure 1) are generally in line with those of Kachergis et al. (2009): that higher frequency does not seem to have a consistently positive effect on word learning. As noted by Kachergis et al., frequency might be conflated with other factors, and thus we cannot make a decisive conclusion only on the basis of this experiment.

Figure 2 (left half) shows that contextual diversity (CD) has a significant positive effect on word learning ($p \ll .001$).¹ Figure 2 (right half) shows that an increased WA has an adverse effect on word learning, even though it also increases CD (difference is significant; $p \ll .001$).

Recall that in Experiment 3 the interaction between CD and F is examined by looking at the learning performance of low (F=3), medium (F=6), and high (F=9) frequency words in

¹All statistical significance tests reported in this paper are for paired t -tests with a 95% confidence interval, and are performed using the R statistics package (<http://www.r-project.org>).

Figure 2: Average Comp scores for words with different contextual diversity (CD), or within-trial ambiguity (WA) (Experiment 2).

conditions with varying degrees of CD. The overall pattern of our results across the four conditions of this experiment, presented in Figure 3, matches those reported by Kachergis et al. for humans. Specifically, we note that, as for human subjects, the overall learning is significantly greater for our model in the High CD condition ($p \ll .001$). Moreover, we observe that, similar to human behaviour, the acquisition of low frequency words in our model is better when they are allowed to co-occur with higher frequency words (Conditions: High CD, Med CD-3&6, and Med CD-3&9); differences between each of these three conditions and the Low CD condition are statistically significant ($p \ll .001$). Whereas Kachergis et al. attribute this behaviour to an increased CD, we suggest that there is another factor (namely context familiarity), which is responsible for this boost of performance in the acquisition of low frequency words.

Context Familiarity as the Explanatory Factor

As discussed above, Kachergis et al. (2009) suggest that contextual diversity is especially important for the acquisition of low frequency words. However, there are cases (in our experiments and in those of Kachergis et al.) where we see a boost in the acquisition of low frequency words, with no notable difference in CD. Instead, as we show now, differences in context familiarity (CF) can explain the pattern of results.

Consider again the results of Experiment 3 shown in Figure 3. We also summarize some properties of the input in the four conditions of that experiment in Figure 4. For each condition we select one simulation such that the overall pattern of results (e.g., with respect to the learning of low frequency words) for these simulations match that of the average performance given in Figure 3. For each input used in the selected simulations, we then calculate the average CD and CF values for words in each of three frequency groups (i.e., $F=3,6,9$). To

Figure 3: Average Comp scores for low, medium, and high frequency words (left to right bars) within each of the four conditions of contextual diversity (Experiment 3).

calculate CF for a word in an utterance, we set the familiarity of each co-occurring word to its frequency of occurrence prior to the current appearance.

Figure 3 shows that the highest performance in learning of low frequency words is achieved when these words are allowed to co-occur with words with $F=9$ (Condition: Med CD-3&9). Kachergis et al. attribute this high learning performance to an increased CD. There is indeed *overall* a higher CD value for the High and Med CD conditions. However, when they are separated by the frequency of the items as in Figure 4(a), we observe that the CD values for the low frequency words do not substantially change across the four conditions. (The overall pattern of CD values in Figure 4(a) match very closely those presented in Table 3 on page 5 of Kachergis et al. CD values range from 4 to 5.6 in our experiments, and from 4 to 5.5 in those of Kachergis et al.)

Interestingly, however, if we look at the pattern of the CF values in Figure 4(b), we see that it conforms to the learning performance of our model (and those of humans) on low frequency words (compare the lightest bars in each of the two figures across the four conditions). We can explain this effect of CF in the learning of our model as follows: When low frequency words are allowed to co-occur with words with $F=9$, we expect the contexts of the low frequency words to be, on average, more familiar than in other conditions. Since our model is expected to have learned something about the possible meanings of a familiar word, this in turn decreases the degree of ambiguity in an utterance–scene pair, making the acquisition of a novel low frequency word easier. This result is a direct consequence of the interactions between the two sets of probabilities accumulated over time in our model, namely the alignment and the meaning probabilities. When aligning a word in an utterance to a referent/meaning in the corresponding scene, our model uses its acquired knowledge about the meaning of the co-occurring words (according to the meaning probabilities). The more familiar the co-occurring words are, the more reliable the meaning probabilities for these words will be, and this in turn makes it easier for the model to align the target word to its correct referent.

For higher frequency words ($F=6$ and $F=9$), we can see a

(a) Average CD for different frequency ranges across different conditions

Figure 4: Average CD and CF values for low, medium, and high frequency words (left to right bars) within each of the four conditions of contextual diversity (Experiment 3).

clear effect of CD (compare darkest bars in Figure 3 and Figure 4(a)). These results together suggest that CD positively affects the learning of medium and high frequency words (as also noted by Kachergis et al.), but for low frequency words it is the familiarity of the context that is the key factor in their acquisition (in contrast to the suggestion of Kachergis et al.).

Analysis of Naturalistic Child-directed Speech

As noted previously, children are exposed to a great number of low frequency words in the input they receive (due to the Zipfian distribution of words in a language). We thus further investigate the effects of context familiarity (CF) on the acquisition of low frequency words in a more naturalistic setting, by performing experiments on a large corpus of actual child-directed speech. The child-directed corpus and the details of the experiments are explained below.

Input Data

The child-directed corpus consists of 10,000 utterance-meaning pairs, where the utterances are taken from the Manchester corpus (Theakston et al., 2001) in the CHILDES database (MacWhinney, 2000), and the corresponding meanings are artificially generated by including a distinct meaning symbol for each word in the utterance. Our focus in the

Table 1: Average frequency (F), CD, Comp, CF, and AE values for two groups of low frequency words: High Comp vs. Low Comp. Number of words in each group is given in parenthesis.

	High Comp Comp ≥ 0.9 (877)	Low Comp Comp < 0.9 (258)
F	1.50 ± 0.73	1.49 ± 0.73
CD	6.61 ± 2.82	6.70 ± 2.77
CF	4.64 ± 0.40	3.58 ± 0.62
AE	9.39 ± 5.55	6.36 ± 6.19
Comp	0.93 ± 0.02	0.52 ± 0.15

following experiments is on F, CD, CF, and another factor usually confounded with CF, namely age of exposure to a word or AE. We control for the effect of within-trial ambiguity (WA) in our experiments by considering only those utterances whose length is between 5 and 7 (inclusive).

We measure the factors CD, CF and AE for each word according to the definitions on page 2. Here we measure the *familiarity* of a word slightly differently from on the artificial data. Since the frequency of words in the child-directed corpus is on a different scale and varies a lot, we set familiarity of a word to a value between 0 and 5 according to the frequency range it belongs to. The mappings between familiarity values and frequency ranges are: 0 (0), 1 (1), 2 (2–4), 3 (5–9), 4 (10–29), and 5 (≥ 30), where the numbers in parentheses specify frequency ranges. Similarly, we re-scale AE for a word to be the sequence number of the utterance in which the word is encountered for the first time, divided by 500 (e.g., all words in utterances 1 to 499 will have an AE of 0).

Modeling Effects of Context Familiarity

AE has been identified as an important factor in word learning (Carey & Bartlett, 1978; Gershkoff-Stowe & Hahn, 2007). However, it is usually confounded with CF since a later AE entails that there are generally more familiar words in the input. It is thus important to examine the independent role of CF and AE on word learning, as we see below.

After training our model on the 10,000 utterances in our child-directed corpus, we divide low frequency words (those with $F < 4$) into two groups according to how well they are learned: one group with a high comprehension score (Comp ≥ 0.9), and another group with a lower comprehension score (Comp < 0.9). Table 1 summarizes the averages of the different factors for the two groups. Interestingly, although F and CD are similar for both groups, we observe a substantial difference in the average Comp scores (0.93 vs. 0.52), suggesting that a factor other than F and CD must be responsible for this difference in learning. Looking at CF and AE, we can see an effect for both: words that have a high Comp score also tend to have higher CF and AE. That is, the words that are learned more confidently are those that have occurred in contexts with greater familiarity and that are first seen at a later age (i.e., when more words have been learned).

We now examine the independent effects of CF and AE on the acquisition of low frequency words, by holding one fac-

Table 2: Average AE, CF, and Comp for two groups of low frequency words: High CF vs. Low CF when AE is held constant (top part); and High AE vs. Low AE, when CF is held constant (bottom part). Number of words in each group is given in parenthesis.

	High CF CF ≥ 4.5 (313)	Low CF CF < 4.5 (160)
AE	9.90 \pm 2.60	9.68 \pm 2.49
CF	4.84 \pm 0.17	3.98 \pm 0.38
Comp	0.93 \pm 0.02	0.77 \pm 0.22
	High AE AE ≥ 9 (78)	Low AE AE < 9 (143)
CF	3.50 \pm 0.38	3.43 \pm 0.41
AE	13.62 \pm 2.95	2.15 \pm 2.22
Comp	0.60 \pm 0.20	0.62 \pm 0.21

tor constant (fixed within a range), and looking at the effect of the other factor. First, we consider low frequency words with AE values within a fixed range (here $5 < \text{AE} < 15$), and divide them into two groups based on their CF (Table 2: top part). Second, we hold CF constant within a fixed range ($2 < \text{CF} < 4$), and divide words into two groups with high and low AE (Table 2: bottom part). (Note that F and CD are the same for the two groups in both conditions.) We find that words that have occurred with differing CF values (top of Table 2) show an effect on their Comp score, with much better learning when the context familiarity is higher. On the other hand, words that have occurred with differing AE values (but with similar CF; bottom of Table 2) show no difference in learning at the different ages of exposure. These results show that CF has an independent and positive effect on the acquisition of low frequency words, whereas AE does not. We suggest that the effect we previously observed for AE (Table 1) is mostly through its effect on CF: since the model/learner learns more and more words over time, words encountered later (with higher AE) are in general more likely to appear with other familiar words, and thus to have a higher CF.

Conclusions

We have used an incremental probabilistic model of cross-situational word learning to study the effects of various statistical properties of the input on the acquisition of low frequency words. This is especially important since a large proportion of words in the input children receive have a very low frequency of occurrence. Replicating the results of a set of psychological experiments on artificial word learning (Kachergis et al., 2009), we argue that different factors affect the acquisition of high and low frequency words. These results and our findings through further experiments on natural child-directed utterances suggest that, for medium and high frequency words, the diversity in the context has a positive effect on learning (as also noted by Kachergis et al.), whereas for low frequency words it is the familiarity of the context that greatly impacts their acquisition.

These effects can be explained as a natural consequence of the interactions between two sets of probabilities that our

model acquires over time. Through these interactions, our model draws on its own acquired knowledge of word meanings to boost the learning of other (novel) words. Thus, the acquisition of a set of high frequency words helps learn low frequency words by increasing their context familiarity. Generally, our model learns word meanings by drawing on the statistical regularities found in the input, and without incorporating any specific word learning biases or constraints, thus making the model appropriate for conducting studies on the relation between input properties and word learning.

Object and Word Familiarization Differentially Boost Retention in Fast-Mapping

Abstract

Recent research demonstrated that although twenty-four month-old infants do well on the initial pairing of a novel word and novel object in fast-mapping tasks, they are unable to retain the mapping after a five-minute break. The current study examines the role of familiarity with the objects and words on children's retention in fast-mapping tasks. Twenty-four month-old infants were familiarized with either a series of novel objects or a series of novel names prior to the referent selection portion of a fast-mapping task. Infants retained the novel mapping after a delay when familiarized with the novel objects, but did not demonstrate retention when familiarized with the novel words. The results suggest familiarity with the object or word-form lead to differential encoding of the name-object link and altered subsequent word learning.

Keywords: language acquisition; fast-mapping; word learning

Introduction

Fast-mapping, or the ability to quickly link a novel word to a novel referent is perhaps the canonical example of young children's word learning prowess. In Carey's (1978) original demonstration of this phenomenon, preschoolers correctly determined that the novel word "chromium" referred to a novel olive-green colored tray rather than a familiar blue-colored tray. This result has been replicated and extended many times (see, for instance, Golinkoff, Hirsch-Pasek, Bailey, & Wenger, 1992; Mervis & Bertrand, 1994; Wilkinson, Ross, & Diamond, 2003). Fast-mapping has been demonstrated in infants as young as 17 months (Halberda, 2003), and 30-month-olds have been shown to fast-map as many as six novel items in a single session (Golinkoff et al, 1992). On the basis of such results, there has been a general tendency in the literature to equate fast-mapping and word learning and to see fast-mapping as the basis for children's rapid word learning (see Horst & Samuelson, 2008 for discussion). However, retention has only rarely been examined in fast-mapping paradigms, and recent work suggests that children do not retain the links between a novel name and object formed in these tasks.

Horst and Samuelson (2008) examined retention of name-object links presented in a fast-mapping context with 24-month-old infants. Their fast-mapping paradigm included both referent selection and retention trials. On referent selection trials, infants were presented with two known objects ("get the block"); on other trials, infants were asked

for the novel object ("get the roke"). On retention trials, which followed five minutes after referent selection, infants were presented with two objects that had been fast-mapped in the referent selection trials, and a third, previously seen but not named object. During these trials, infants were asked to get one of the previously fast-mapped objects by name. Because all three objects presented on retention trials were equally novel, Horst and Samuelson's task is very stringent. In this carefully controlled environment, infants performed well in the referent selection trials – choosing the known object 73% of the time when requested, and the novel object 69% of the time it was requested. However, retention of the fast-mapped name-object link was no higher than chance after the 5-minute delay (Horst & Samuelson, 2008; Experiment 1A).

The fact that the children in Horst and Samuelson's (2008) study did not retain the newly fast-mapped words contradicts some prior findings of retention following fast mapping. For example, Carey & Bartlett (1978) examined children's memory for "chromium" a week after the original presentation and found that the majority of children retained the link between the word "chromium" and some form of the color green. Likewise, Markson and Bloom (1997) demonstrated retention of novel fast-mapped words in 3-4 year-old children. However, as Horst and Samuelson (2008) point out, many of these prior studies did not use as stringent a measure of retention. For example, Carey and Bartlett (1978) presented the novel name and referent during a very familiar sequence of events (setting up for snack time), thus allowing for many possible contextual supports for retention. Other work demonstrating retention has isolated the target so that it is the only object named during test (Markson & Bloom, 1997) or used ostensive naming in conjunction with fast-mapping (Mervis & Bertrand, 1994), thus failing to provide a stringent test of retention.

Furthermore, Horst and Samuelson's data does fit with Carey's (1978) original proposal of a slow-mapping process that follows the initial fast-mapping of a word to an object. In particular, Carey proposed that after children initially map the novel object and name (fast-mapping), further experience and exposure is required to fully learn the new word and referent (slow-mapping). Subsequent studies have examined this slow-mapping process, demonstrating that depth of semantic representation (Capone & McGregor, 2005), lexical practice (Gershkoff-Stowe, 2002; Gershkoff-Stowe & Hahn, 2007), and word segmentation (Graf Estes,

Evans, Alibali, & Saffran, 2007) all play a role in successful word retention and retrieval. The current study follows this line of work, examining the role of prior familiarity with the components of the mapping on retention of newly fast-mapped words.

It seems like familiarity with the components to be mapped may aid children's formation of a lasting association between a novel word and object by aiding in the creation a fairly robust, stable representation of each component. Horst, Samuelson, and McMurray (under review), have recently demonstrated that visual familiarity influences the process of referent selection. Likewise, Capone and McGregor (2005) demonstrated that ostensibly highlighting the visual properties of objects (i.e. cueing shape) boosts infants' fast-mapping of object labels and their referents, whereas Graf Estes et al. (2007) demonstrated that statistical segmentation of auditory word forms can play a role in subsequent referent selection.

In the present experiments we used a stringent version of the standard forced-choice referent selection and retention task, modeled after Horst and Samuelson (2008), but added a minimal familiarization period prior to the referent selection task. We used the 3-trial version of Horst and Samuelson's task (2008, Experiment 1C) to reduce the chance of fatigue that might be caused by the time added by the familiarization period. Using this procedure, Horst and Samuelson (2008) found that only 60% of infants in their 3-trial experiment succeeded in the initial mapping of the name and object during referent selection. While this was a statistically significant level of mapping, it means that retention could only be tested in 12 infants. We found similar levels of mapping in pilot testing. Thus, in an effort to boost the number of infants who initially map the novel word to the novel object, we used the same three known items throughout the warm-up and referent selection trials (rather than using different known objects on each of the referent selection trials).

In Experiment 1 we examined the role of minimal familiarity with the objects or word-forms in infants' retention of fast-mapped words. Half the infants were given the novel objects to explore freely for two minutes prior to the referent selection task. The other half of the infants heard the novel word multiple times prior to the referent selection trials. As in Horst and Samuelson (2008), there was a five minute delay between the referent selection and retention trials. Only infants familiarized with the objects demonstrated significant retention. Experiments 2 and 3 serve as controls to ensure our findings were not due to our use of the same known objects on all referent

selection trials (Experiment 2), or the use of a highly salient favorite novel item as the target (Experiment 3). Taken together, then, these experiments probe the degree to which prior encoding of either the word or object boosts the retention of fast-mapped words.

Experiment 1: Object and Word Familiarization

Methods

Participants Forty 24-month-old-infants (20 girls, $M = 24$ months, 26 days; range = 24 months, 10 days – 25 months, 13 days) with a mean vocabulary of 303 words (range = 21–672) participated. All infants were recruited through county birth records and were native English speakers. Participant's parents provided informed consent prior to the start of the study. Participants received a small toy for participation.

Stimuli Each infant saw a random selection of three out of sixteen possible known items and three or six of eight possible novel items over the course of the experiment (see Figure 1). Parents confirmed the status of each object as known or novel prior to the experiment. Substitute items were used if the infant was unfamiliar with any of the known items or familiar with any of the novel items. During the session, stimuli were presented on a 24x45cm white tray divided into three equal sections. Up to six possible novel non-words (Horst & Samuelson, 2008) were randomly selection for use with each child.

Procedure During the study, infants were seated across a white table from the experimenter in a booster seat next to their parents or in their parent's lab. Parents completed the MacArthur-Bates Communicative Development Inventory: Words and Sentences (MCDI; Fenson et al, 1994) during the session and were instructed to avoid interacting with their child, only offering encouragement if necessary.

Pre-familiarization. Half the children began the session with a one minute familiarization period with six novel objects. The experimenter drew the infant's attention to each object by picking it up or by pointing to it and saying "Look." Once the infant had explored each object, the experimenter lined all six items along the middle of the table and asked the infant to pick their favorite item. The favorite item was then given back to the infant to explore briefly. This was repeated twice more and the remaining three non-favorites were then removed from the table. The three favorite items were then used as the novel objects in the experiment with the favorite item selected first being the target during the novel referent selection trial.

The other half of the children began the session with a familiarization period in which they were exposed to six possible novel non-words. A 19-inch, 1280x1024 pixel touch screen computer was presented on the table approximately 24 cm in front of the child. The computer screen showed six 241x241 pixel basic shapes (i.e. circle, triangle, diamond, cross, square, octagon) in six different

Figure 1: Known (A) and Novel (B) objects used during test

basic colors (i.e. red, purple, orange, green, yellow, blue) in a 2x3 matrix with each item roughly 130 pixels away from each other. The trial began when the buttons appeared on the screen. The experimenter directed the infant's attention to the screen saying "Look! You can push the buttons!" and then randomly touched a button, producing one of six possible novel words. This was repeated until all buttons had been pushed and thus all six of the novel words were produced one time each. The experimenter then directed the infant to push the buttons by asking "Can you push the buttons?" If the infant did not respond, the experimenter again demonstrated by randomly pushing each button once. If the infant again did not respond, the experimenter demonstrated the buttons a third time and encouraged the infant to try themselves. At this point, if the infant refused to push the buttons themselves, the experimenter then randomly chose a button and pushed it multiple times to familiarize the infant with one of the six novel names. There were eight possible examples of each novel word varying in intonation, pitch, and frequency, which were randomly selected from at each button press. All words were spoken by the same female experimenter who was running the experimental session. After two minutes of familiarization with the sounds, the computer was removed and the experiment continued with the warm-up trials. The novel name that was produced the most during the familiarization period was used as the target name during the novel referent selection trial.

Warm-up trials. For each infant, three known objects were randomly chosen for use throughout the warm-up trials. The experiment placed each of the items in a slot on the tray, keeping the tray out of sight of the infant. The trial began with the experimenter placing the tray on the table and allowing the infant to examine the objects for three seconds. The experimenter then asked the infant to get an object ("Can you get the block") and slid the tray forward. Infants were prompted up to three times until a response was given. Responses on these warm-up trials were corrected or praised heavily as necessary. Infants were asked for a different object in a different location across the three warm-up trials.

Referent Mapping Trials. The referent selection trials immediately followed the warm-up trials, proceeding in the same manner except that no corrections or praise was given. Each infant was presented with three sets of objects, each of which included two known objects and one novel object. The same three known objects used during warm-up were used. On the first and third trials, infants were asked to get a known object. On the second trial, infants were asked to get a novel object (i.e. "Can you get the roke?"). Location of the target item was counterbalanced across trials and randomized across infants.

Delay Period. A five-minute delay followed the referent selection trials. During the delay, the infant was allowed to play in the waiting room. None of the items used during the experiment were present during the delay.

Retention Trial. The delay period was immediately followed

by a single warm-up trial that proceeded in the same manner as the previous warm-up trials and used the same three known objects. Praise was given and infants were corrected as needed. The warm-up trial was immediately followed by the retention trial in which the infant was presented with the three novel objects present during the referent mapping trials, one of which had been named in the second trial and two of which were distracters present when the experimenter had asked for a known objects on trials one and three. The position of items was randomized across infants with the target item never being in the same location it had been during the referent selection trial.

Results

Infants chose the target significantly more than would be expected by chance on novel referent selection trials in both conditions, as seen in Table 1. In particular, 13 out of 19 infants familiarized with the novel object selected it when asked during referent selection as did 18 out of 20 familiarized with the word form; exact binomial, $p < .01$ and $p < .001$ respectively, see Table 1. These results are similar to those of Horst and Samuelson (2008; see also Mervis & Bertrand, 1994; Wilkinson et al, 2003). In contrast to Horst and Samuelson (2008), however, infants familiarized with the object prior to referent selection chose the target object at levels significantly greater than chance on the retention trials (10 out of 13, exact binomial, $p < .01$, note that only data from the infants who correctly mapped in the novel referent selection trials were included in this analysis). Infants familiarized with the word prior to referent selection, in contrast, performed at chance levels on retention trials (6 out of 18, exact binomial, p ns).

To directly examine the difference between conditions, we performed X^2 tests of homogeneity of proportions. These revealed no differences in referent selection performance across conditions, X^2 (1, $N=39$), *ns*, however, performance in retention did differ significantly between conditions, X^2 (1, $N=31$) $<.05$. Thus, it appears that familiarization with the novel object, but not the novel word, prior to the formation of a novel word-object mapping boosts retention of that mapping.

However, before accepting this conclusion we examine the possible role differences between our task and that of prior studies, as well as differences between our conditions, may have had on our findings.

Experiment 2: No Familiarization

One difference between our current procedure and that of Horst and Samuelson (2008) was our use of the same three known objects during warm-up and test. Pilot testing demonstrated that with both a familiarization period and different known objects on every trial, infants could not succeed in referent selection and thus, retention could not be analyzed. Thus, in Experiment 1 we had used the same known objects on each trial in an effort to direct children's attention to the novel object even more, thereby boosting infants' initial mapping during referent selection. However, it is possible that our repeated use of the same known objects on every trial also served to boost retention. We examine this possibility by testing retention in our procedure without the familiarization period, thus demonstrating that using the same three known items serves to boost referent selection but not retention.

Method

Participants Twenty 24-month-old infants (9 girls, $M = 24$ months, 19 days; range = 23 months, 20 days – 25 months, 4 days) with a mean vocabulary of 342 words (range = 134–536) participated. All infants were recruited through county birth records and were native English speakers. Participant's parents provided informed consent prior to the start of the study. Participants received a small toy for participation. Data for one additional infant was not included due to a recording error.

Stimuli The same novel objects and novel names from Experiment 1 were used (see Figure 1).

Procedure The procedure was identical to that of Experiment 1, with the exception that there was no pre-familiarization period.

Results

Infants chose the target significantly more than would be expected by chance on novel referent selection trials (18 out of 20, exact binomial, $p < .001$, see Table 1). In contrast to infants in Experiment 1 who were familiarized with the object prior to referent selection, infants in this experiment did not retain the novel object-word mapping over the delay; they selected the target object at chance levels during the

retention test (8 out of 18, *ns*, note that again, only data from infants who correctly mapped in the novel referent selection trials were included in this analysis). Chi-square tests of homogeneity of proportions revealed that while there was a difference in referent selection performance between infants in Horst and Samuelson (2008) and infants here, X^2 (1, $N=40$), $<.05$, there was no significant difference in retention between the two groups, X^2 (1, $N=28$), *ns*. With respect to Experiment 1, then, these results indicate that easing the task by using the same known stimuli throughout did boost children's mapping ability during initial referent selection, but it was likely not responsible for the boost in retention seen when infants were familiarized with the novel objects.

Experiment 3: Non-Favorite Novel Target

One possible explanation for the difference in retention performance seen for children familiarized with the objects versus the words in Experiment 1 has to do with our use of the child's favorite object as the novel target. Recall that during familiarization we asked children for their three favorite items from the set of six novel objects, using these as the novel items present during referent selection. When then asked to find the target item during the retention trial when all three were present, children would be scored as correct if they chose their overall favorite item, even if they did not recall its link to the novel name. To test this possibility, we re-ran the object familiarization condition of Experiment 1, but instead used the non-favorite items as the novel items during referent selection.

Method

Participants Twenty 24-month-old infants (11 girls; $M = 24$ months, 22 days; range = 23 months, 21 days–25 months, 3 days) with a mean vocabulary of 272 words (18–567) participated. All infants were recruited through county birth records and were native English speakers. Participant's parents provided informed consent prior to the start of the study. Participants received a small toy for participation.

Stimuli The same novel objects and novel names from Experiment 1 were used (see Figure 1).

Procedure The procedure was identical to the visual condition in Experiment 1, with the exception that when asked to pick their favorite novel item during familiarization, that item was then removed from the table. This was repeated until three non-favorite items were remaining. These three remaining items were then used as the novel referents during the experiment.

Results

Infants chose the target significantly more than would be expected by chance on novel referent selection trials (14 out of 20, exact binomial, $p < .001$, see Table 1). Like infants in Experiment 1 who were familiarized with the object prior to referent selection, infants in this experiment also retained the novel word-object mapping over the delay, selecting the target object the majority of the time (10 out of 14, exact

binomial, $p < .01$, note that again, only data from infants who correctly mapped in the novel referent selection trials were included in this analysis). Chi-square tests of homogeneity of proportions revealed that there was no significant difference in referent selection, $X^2(1, N=39)$, *ns*, or retention $X^2(1, N=27)$, *ns*, between infants familiarized with the object in Experiment 1 and infants here. These results then indicate that the use of the infant's favorite novel object as the target during referent selection did not alter the infant's ability to retain the word-object link after a delay.

General Discussion

Despite the complexity of word learning, young children are remarkable at quickly mapping a novel word to a novel object. However, recent work has suggested that this mapping may not be as robust as previously thought, and thus, not the basis of children's rapid acquisition of new words. The goal of the present set of experiments was to probe how prior familiarity with the parts of a novel name-object mapping may help children retain novel name-object links. The results indicate that children given prior familiarity with the novel object to be mapped retained the mapping between the object and a novel word following a delay. In contrast, children given prior familiarity with the word-form mapped the novel word to a novel object during referent selection, but did not retain this mapping over a delay. Even when repetition of known objects and novel item preference were controlled for, children still demonstrated retention of a word-object mapping when familiarized with the object prior to test. Thus, our results indicate an important difference in the word-learning boost given by familiarity with the objects versus familiarity with the words in a fast-mapping task.

Importantly, the results of Experiments 1 and 3 support previous suggestions that a slow-mapping process (Carey, 1978; Carey & Bartlett, 1978) is needed for a robust mapping between a word and object. Notably, however, the results also demonstrate that prior familiarity with the object, but not the word, to be mapped helps this process. A similar idea has been presented in a recent model of word learning proposed by Mayor and Plunkett (2010). In this model, fast-mapping is facilitated by a well-developed representation of the object category prior to the actual name-object mapping. Likewise, our findings are also consistent with previous work by Smith and Yu (2008) suggesting that multiple exposures to a novel name and object are necessary for learning (see also McMurray, Horst & Samuelson, in prep; and Horst, McMurray, & Samuelson, 2006). It is clear from the literature that with more experience or information, children's ability to make specific word-object mappings is heightened (see also, Horst, 2007; and McMurray, Horst & Samuelson, in prep; Horst, Samuelson, & McMurray, 2010). One implication of the current study is the suggestion that across multiple exposures, visual and auditory components may not have been encoded equivalently. The literature presents several interesting suggestions as to why this might be the case.

One possible interpretation of the differential effects of word and object familiarization in our results comes from Sloutsky and colleagues' proposal of auditory dominance (Robinson & Sloutsky, 2004; Robinson & Sloutsky, 2007; Robinson & Sloutsky, 2008; Sloutsky & Napolitano, 2003; Sloutsky & Robinson, 2008). This is the suggestion that when both auditory and visual information are given to infants simultaneously, the auditory information receives preferential processing. Support for this idea comes from studies in which infants were trained that a particular combination of auditory and visual stimuli indicated the location of a prize. When presented with either the trained auditory or visual cue paired with a competing auditory or visual cue, infants relied more on the auditory modality to anticipate the location of the prize (Robinson & Sloutsky, 2004; Robinson & Sloutsky, 2007). This theory would suggest that in Horst & Samuelson's (2008) referent selection task when infants were only given a single exposure to the novel object and name, they preferentially processed the auditory information and thus, only encoded half of the mapping – the novel name, not the physical referent. In the current study, the theory of auditory dominance would suggest that the familiarization period had a differential effect on infant's processing of novel names and objects at the point of referent selection. If infants come to the task with an auditory processing bias and are given additional familiarity with the visual component prior to test, when the word and object were presented during referent selection, both components could be processed at equivalent levels, allowing both the word and object to be encoded robustly. On the other hand, when infants were pre-familiarized with the word-form, the auditory processing was boosted even further, thus overshadowing the encoding of the visual object during referent selection.

It is also possible, however, that the apparent difference in visual and auditory familiarization stems more from task demands than differential processing of each component. That is, perhaps the use of a comprehension task to test retention creates the appearance of processing differences. In the traditional fast-mapping task, the experimenter provides the word during testing. When the infants are pre-familiarized with the objects and the experimenter provides the word during the retention task, children would then have both components necessary to demonstrate robust retention of the word-object link. On the other hand, when infants are pre-familiarized with the words and again given the word at test, the infants only have a rich encoding of the auditory component and do not demonstrate retention of the link. By this view then, the object familiarization condition did provide a boost to word learning, not because infants are biased to process the word form, but rather, because the task privileged the modality in which the children would subsequently use to find the referent.

It may be possible to discriminate between these explanations by examining the strength of the representations of the word and object following the initial referent selection trials without a pre-familiarization period.

Sloutsky's auditory dominance proposal would suggest that in a recognition test following referent selection, infants should show recognition of the words, but not the objects. In contrast, if the differences in results in our experiment are due to task effects, infants should show no encoding of the auditory information following referent selection. These results would also give insight to the extent to which familiarization might boost the representation of the category, as Mayor and Plunkett (2010) predict in their model. We are currently examining this possibility.

While further research is required to elucidate the exact depth to which object and word forms are processed by infants in a fast-mapping task, the current study makes it clear that the novel words and objects presented for mapping play different roles in the establishment of that mapping and in its retention. Thus, our finding that infants retain novel word-object mappings when familiarized with the objects but not the words reinforces Horst & Samuelson's (2008) and Carey's (1978) point that fast mapping is not equivalent to word learning. Our results also point to the importance of further work into the incremental process by which representations of words, objects and their mappings are created on the way to word learning.

Abstract

There has been increasing interest in the role of early attention in the context of word learning. There has also been growing interest in attentional differences between bilinguals and monolinguals. The present study examined the relationship between mutual exclusivity and attentional control by comparing bilingual children whose attentional control is relatively advanced to age-matched monolingual children. The novel adjective learning paradigm was the word-learning measure and the Attention Network Test was the measure of attentional control. Three-year-old monolingual and bilingual children with similar vocabulary development participated. The results replicate earlier work on advanced attentional control among bilingual children and suggest that better performances in novel adjective learning by bilingual children might be due to attentional control. These findings support the importance of attention in early word mapping. The results add to a growing body of literature on the potential relevance of bilingualism in early word learning.

Keywords: Attentional learning; early word learning; adjective learning paradigm; mutual exclusivity; selective attention

Attentional Shifting and Word Learning

A growing body of experimental literature (mostly concerning adults) indicates that effective attentional control optimizes learning, especially in complex scenes (e.g., Cowan, Fristoe, Elliot, Brunner, & Sauls, 2006). In the developmental literature, there has been interest in the role of effective attention shifting in learning, particularly in the domain of word learning. Because different kinds of words refer to different kinds of properties (e.g., nouns to shapes or whole objects, adjectives to properties such as color or texture), being able to shift attention seems an important aspect of word learning (Au, 1990). Indeed, a number of studies have documented that by the time children are 2 years old, they shift attention to different kinds of properties for different kinds of entities and in the context of different kinds of words (Graham, Williams, & Huber,

1999; Landau, Smith, & Jones, 1988, 1998; Soja, 1992; Soja Carey, & Spelke, 1991; Yoshida & Smith, 2003, 2005).

Some accounts of this effective attentional shifting refer to mapping principles for learning words (e.g., Bloom, 2000; Carey, 1978; Markman, 1989). One such principle is mutual exclusivity (Markman & Wachtel, 1988): In the context of a known word and referent, a novel word shifts attention to a novel referent. Mutual exclusivity is pervasive in early word learning, helping the learning of new nouns, but it has also been suggested as a reason why young word learners have difficulty learning adjectives (e.g., Carey, 1978; Markman, 1989; Regier, 1996). For example, young learners who know that a horse is called “horse” might reject the label “brown” being applied to it. This one label–one object constraint has long been considered a positive constraint on early word learning that promotes the learning of nouns. Also, it may help more advanced word learners learn adjectives. Older children, when challenged with two labels for a single object, will effectively shift attention to a nonshape property (if “horse” means HORSE, then “brown” must mean something about the horse; see Waxman, 2001; Waxman & Klibanof, 2000). Although the earlier view saw these constraints as lexically specific and possibly innate (Markman, 1989), more recent work suggests that the effect is related to learning through competitive attentional processes (Halberda, 2009; Hollich, Hirsh-Pasek, Tucker, & Golinkoff, 2000; Plunkett, 1998; Smith, 2000; Yoshida & Hanania, 2007).

If mutual exclusivity emerges because of competitive processes among words and referents that arise in on-line comprehension, then these processes—and their relation to effective attentional control in word learning—should be related to the learner’s history of experiences in resolving competitions among words and referents. This, in turn, suggests that the development of mutual exclusivity may benefit from bilingualism and attentional control more generally.

Executive Control

Bilingual children have been characterized as developing cognitive flexibility earlier than monolingual children and demonstrating more robust self-control, including attentional control, throughout their lives (e.g., Bialystok, 1992, 1999; Bialystok & Martin, 2004; Bialystok & Senman 2004; Carlson & Meltzoff, 2008). Such positive effects are seen most profoundly in what are known as executive-function (or self-control) tasks. These are tasks that require the individual to inhibit preferred or prepotent patterns of responding (e.g., not jump up when one should be sitting, not take the candy when told not to, do a task in a new way not an old way; see Beaver & Wright, 2007; Kochanska, Murray, & Harlan, 2000; Luria, 1966; Luria, Pribram, & Homskaya, 1964; Mischel, Shoda, & Rodriguez, 1989; Zelazo & Frye, 1998). A number of recent studies have shown that these effects are also evident in executive function relevant to controlling attention and in the suppression and separation of languages to avoid interference. Indeed, the current consensus is that the bilingual advantage in executive control derives from the history of switching between languages (i.e., Costa, Hernandez, & Sebastian-Galles, 2008; Martin & Bialystok, 2003; Mezzacappa, 2004).

The idea that bilinguals are able to control the choice of their speech via well-developed processes of executive control is supported by their better performance in attentional tasks such as the Attention Network Test (ANT), which was developed by Fan, McCandliss, Sommer, Raz, and Posner (2002). This test was designed to measure the functionality of the attentional network: alerting, orienting, and executive control. Children are asked to find a fish facing a certain direction among other fishes on a computer screen. The direction the fish faces does not change throughout the task, but the facing direction of other fish does change and thus the task requires effective attention control. The response time for searching is often used to measure the attentional control. Costa et al. (2008) reported that bilinguals performed this task faster and more efficiently than monolinguals. Furthermore, when the task was broken down into the attentional network components, bilinguals performed significantly better in the alerting and executive control components. The bilingual advantage has also been reported in studies of bilingual children who have significantly lower English proficiency than the group of comparison English monolinguals (using ANT; Yang, 2004). This is an intriguing finding with a potentially widespread impact: Children who speak more than one language seem to show developmentally advanced attentional control.

What is not known is the extent of the advantage in attentional control or the role it plays in language

learning. If this advantage emerges in young bilingual children as a consequence of learning two languages, then it seems its core function might be to support language learning itself. The experiment reported here seeks to link differences in attentional control between monolingual and bilingual children to attention shifting in word learning, and more specifically to mutual exclusivity in the context of learning a novel adjective.

Experiment

Method

Participants

Participants were 20 monolingual English learners with a mean age of 36.66 months (range: 29.47 to 43.16) and 20 bilingual learners (e.g., English–Spanish, English–Bengali, English–Chinese, English–Russian, English–Urdu, English–Vietnamese) with a mean age of 38.86 months (range: 30 to 45.53). The criteria of bilingual status was determined by a demographic questionnaire. A bilingual questionnaire was used to ensure that the language spoken at home was primarily not English.

Stimulus Materials

Vocabulary Assessment (MCDI) Eight sections from the MacArthur–Bates Communicative Development Inventories (MCDI) were selected and used to measure productive vocabulary. For English monolingual children, the English version was used, and for bilingual learners, their dominant language (if reported by their parents) was measured. We also used the Spanish MCDI. Adaptations of the MCDI in Chinese and Vietnamese were used when possible. Monolingual children's total vocabulary was measured as the number of words parents reported in their productive vocabulary in English; bilingual children's total vocabulary was measured as the number of words parents reported in their dominant language (i.e., the language used most often by parent report).

MacArthur Socioeconomic Status Parents were asked to fill out a demographic questionnaire to control for the influence of socioeconomic status (SES) in bilingual and monolingual participants. All participants were matched and came from the same SES background.

Novel Adjective Learning Task Each of the eight trials in this task used three objects (one exemplar, two test objects); the objects in each trial were unique. All were instances of familiar animate objects (e.g., ducks) and inanimate objects (e.g., trucks) with distinctive colors. As shown in Figure 1, each exemplar was presented with a property that was highly novel (*sticky*). The two test objects for each trial had the same shape as the exemplar, but different colors. One test object presented

a target property match of the novel texture (e.g., red *sticky* duck), and one presented a non-property-matching texture (e.g., red *bumpy* duck). Within all trials, all objects—exemplars and test objects (property matching and non-property-matching)—had the same shape.

Familiar Adjective Learning Task The same three-dimensional object form was used for exemplars and test objects (e.g., ducks, trucks). The properties, familiar and likely to be receptively known by the children (e.g., bumpy, spotted, shiny, holey), can be seen in Figure 2. Two types of test objects were presented: one with a property match of a familiar/known texture (e.g., red *bumpy* duck), and one with a nonmatching property where texture did not match the exemplar (e.g., red *shiny* duck).

All objects were approximately 10 cm³. Textures—the intended target property—were chosen to be highly novel and included a stringy pattern, a wire pipe-cleaner surface, a sponge-like surface, and a Velcro surface. These properties were named by novel labels such as *blickish*, *dakish*, *talish*, and *wuggish*, respectively. For familiar textures, stimuli were *holey*, *shiny*, *bumpy*, and *spotted*.

Attention Network Test (ANT) We used the original "child version" of Dr. Jin Fan's ANT (<http://www.sacklerinstitute.org/users/jin.fan/>). The children were asked to watch a computer screen where five fish lined up horizontally. The task was to point to the mouth of the "hungry fish," which was defined as the fish always in the middle. The direction the hungry fish faced changed throughout the task, but the facing direction of other fishes changed. Children were required to shift their attention effectively to detect the direction of the hungry fish's mouth. We used a touch-screen laptop to measure accuracy in this task.

Procedure

All children participated in the Novel Adjective Learning Task, Familiar Adjective Learning Task (control), and the ANT (in randomized order) in their dominant language; the task order was counterbalanced. Caregivers were asked to fill out the SES and MCDI forms. Parents of bilingual children were asked to fill out two MCDI forms, one in English and one in their second language. Parents were asked to go through the list and specify all the words they had heard their children use. The Novel Adjective Learning Task, Familiar Adjective Learning Task, and ANT trials were administered in a quiet, controlled room (both at the laboratory and at daycare centers) by trained research assistants fluent in the child's dominant language.

Novel Adjective Learning Task Participants were presented with an exemplar and told the name along

with a novel adjective (e.g., "See this? This is a *blickish* duck!"). After the exemplar was removed from view, the participants were then presented with two test objects. They were asked to give the experimenter the one to which the novel adjective could apply (e.g., "Now, can you give me a duck that is *blickish*?"). The order of the trials was randomized and the children's selection of the test object—whether a property-matching object or a non-property-matching object—was recorded for all trials for later analysis.

Familiar Adjective Learning Task The same procedure was administered, only now the adjectives presented were familiar/known and not novel (e.g., "See this? This is a *bumpy* duck!" "Now, can you give me a duck that is *bumpy*?").

Attention Network Test (ANT) The ANT trials were administered using E-Prime software on a 15" touch-screen laptop computer. The children sat at a comfortable distance from the screen and used their index finger to touch the fish displayed on the screen. The children were instructed to help feed the hungry (target) fish as fast as they could by touching the mouth of the fish on the screen, according to which direction the hungry fish was oriented. They were told that sometimes the fish would appear alone, and other times it would swim together with other fish. In all cases, they were instructed to concentrate on the one fish in the middle—the hungry fish. They were also asked to keep their eyes on the fixation point during the task. The completion time was approximately 10 min. Their accuracy (percent correct) and reaction times (RTs) were recorded for later analysis.

Results

All bilingual and monolingual participants came from the same SES background (i.e., middle class) and were matched on vocabulary production through parental reports. Table 1 shows vocabulary size, dominant language, and age.

Novel Adjective Learning Task

As can be seen in Figure 3, bilingual children performed better than monolingual children, $t(19)=3.92$, $p<.05$, in the Novel Adjective Learning Task, selecting property-matching objects with high accuracy, whereas the monolingual children performed at chance.

Familiar Adjective Learning Task

In terms of overall accuracy on the Familiar Adjective Learning Task, bilingual and monolingual children performed similarly and above chance, $t(19)=2.75$, $p<.05$, and $t(19)=3.18$, $p<.05$, in selecting property-matching objects (see Figure 3). These results indicate

that the participants were able to comprehend the task at hand and that bilinguals had no special advantage in this task. Thus the advantage observed in the Novel Adjective Learning Task must be due to mapping novel adjectives to the novel properties of known things.

Attention Network Test

Bilingual children performed better than monolingual children on the ANT, $t(19)=3.74$, $p<.05$, (Figure 4). More critically for the present hypothesis, children’s success in the Novel Adjective Learning Task was significantly correlated with scores from attentional control ($r=.480$, $p<.05$).

General Discussion

These results replicate the bilingual advantage in attentional control tasks that has been reported by others and tie this effect to attentional strategies in word learning. The findings promise new insights about the cognitive consequences of learning and speaking two languages and the role of attention in using and learning language. Attention is a process that changes itself through its own activity, a fact that has far-reaching importance for understanding the learning of words and referents by both monolingual and bilingual children.

The Consequences of Bilingualism

The default assumption in the study of bilingual children has been that their cognitive systems are no different than those of monolingual children, and thus speaking two languages has often been viewed as a source of developmental delays (e.g., Doyle, Champagne, & Segalowitz, 1978). However, we now know there are significant positive consequences that extend beyond language itself and appear to involve executive control processes across many domains—from not taking candy, to sitting still when one should, to—in the present study—shifting attention to novel words and properties of well-known objects. In this way the present study connects the bilingual advantage in executive control to language learning—the context in which that advantage emerged in the first place.

Attention in Word Learning

By tying the bilingual advantage in executive control to attention shifting in the learning of novel adjectives, the results also suggest that the competitive and attentional processes that are studied in early word learning (in monolinguals as well as bilinguals) may be fundamentally linked to general processes of executive and attentional control. There is a large body of literature in this domain (Diamond, 1990) showing—in monolingual children—incremental advances from late infancy to the school-age years in the ability to switch attention and inhibit prepotent but irrelevant

information. The present results highlight the importance of studying the codevelopment of these processes with word-referent learning in both monolingual and bilingual children. In brief, we may be able to mechanistically ground word-learning strategies in more general attentional processes.

There are certainly intriguing indications that there is still much to be learned from taking this approach. For example, whereas the present task asked children to learn a property label for a known category—and bilingual children showed an advantage—other studies have asked whether bilingual and monolingual children differ in their ability to learn two different names for the same thing. Depending on how one conceptualizes the task, bilingual children either show an advantage at learning two names or exhibit weaker mutual exclusivity constraint in this context (Au & Glusman, 1990; Davidson, Jergovic, Imami, & Theodos, 1997; Davidson & Tell, 2005; Merriman & Kutlesic, 1993). Much of the previous work on this “two names for one thing” task used labels from different languages with different phonological properties. This provides a potentially useful way to understand the microprocesses and context cues that elicit and resolve competitions within and across languages.

In sum, the present work supports the importance of attention in word learning and its link to general processes of attentional switching and executive control. Systematic comparisons of monolingual and bilingual children in both word learning and attentional control tasks offer a new window on these fundamental processes, their development, and their relation to word learning.

Table 1: Productive vocabulary of dominant language based on the MCD.

group	age	noun	verb	adjective	Total
monolingual	36.7	177.9	81.6	48.5	308.0
bilingual	38.9	178.6	83.7	45.9	308.2

A Bayesian Nonparametric Approach to Multisensory Perception

İlker Yıldırım (iyildirim@bcs.rochester.edu)

Robert A. Jacobs (robbie@bcs.rochester.edu)

Department of Brain & Cognitive Sciences, University of Rochester, Rochester, NY 14627, USA

Abstract

We propose a Bayesian nonparametric model of multisensory perception based upon the Indian buffet process. The model includes a set of latent variables that learn multisensory features from unisensory data. The model is highly flexible because it makes few statistical assumptions. In particular, the number of latent multisensory features is not fixed a priori. Instead, this number is estimated from the observed data. We applied the model to a real-world visual-auditory data set obtained when people spoke English digits. Our results are consistent with several hypotheses about multisensory perception from the cognitive neuroscience literature. We found that the model obtained the statistical advantages provided by sensory integration. We also found that the model acquired multisensory representations that were relatively sensory invariant. Lastly, we found that the model was able to associate unisensory representations based on different modalities.

Keywords: multisensory perception; Bayesian modeling; rational analysis; Indian buffet process

Introduction

We learn about our environments from many different senses. Objects can be seen, heard, touched, tasted, and smelled. How are our mental representations based on these different sensory modalities structured, combined, and coordinated?

Cognitive neuroscientists have recently studied three important hypotheses about multisensory perception. First, researchers have conjectured that multisensory representations are advantageous because sensory integration ameliorates the effects of bias and noise contained in representations based on single modalities. Multisensory representations are, therefore, able to convey more accurate and reliable information than the unisensory representations from which they are derived. Consider an observer that sees and touches a surface slanted in depth. Suppose that the observer's slant estimates based on the visual cue and on the haptic cue are each corrupted by sensory noise with some variance. It is easily shown that the maximum likelihood estimate of surface slant obtained by combining information from both cues has a lower variance, and is thus more reliable, than estimates based on either cue alone. Evidence that the brain is able to combine sensory information in such a manner was obtained by Ernst and Banks (2002), for example, who found that people's estimates of object height based on both visual and haptic information was more reliable than their estimates based on either visual or haptic information alone.

Second, researchers have hypothesized that our neural representations of objects are often sensory invariant, meaning they are the same (or at least similar) regardless of the sensory modalities through which we perceive those objects. Evidence consistent with this hypothesis was obtained by Amedi et al. (2001). They showed that a neural region known as the

lateral occipital complex (LOC) shows similar patterns of activation regardless of whether an object is seen or touched.

Third, researchers have speculated that representations based on different modalities are associated with each other. Suppose that an observer sees, but does not hear, an object. A visual representation of that object will be active in the observer's brain, and this representation will often predict or activate an auditory representation of the object even though the object is not heard. Evidence consistent with this hypothesis was obtained by Calvert et al. (1997). They found that viewing facial movements associated with speech (lipreading) leads to activation of auditory cortex in the absence of auditory speech sounds.

Here, we propose a model of multisensory perception that learns about its multisensory environment in an unsupervised manner. In unsupervised learning, the data provided to a learner are unlabeled. The goal of the learner is to discover patterns and structure within the data set. There is a dichotomy in the cognitive science and machine learning literatures between parametric and nonparametric unsupervised learning methods. A parametric method uses a fixed representation that does not grow structurally as more data are observed. Examples include factor analysis, where the number of latent variables is fixed a priori, and cluster analysis, where the number of clusters is fixed a priori. In contrast, a nonparametric method uses representations that are allowed to grow structurally as more data are observed. These methods are often used when the goal is to impose as few assumptions as possible and to "let the data speak for themselves" (Blei, Griffiths, & Jordan, 2010). Examples include Dirichlet process mixture models (or Chinese restaurant processes) and Indian buffet processes.

The proposed model of multisensory perception is an instance of a Bayesian nonparametric model. It "explains" the unisensory representations arising from different modalities through the use of a set of latent or hidden variables that learn multisensory representations. The number of latent variables is not fixed. Instead, this number is treated as a random variable whose probability distribution is estimated based on the unisensory data. Because the size of the latent multisensory representations are estimated from the observed unisensory data, nonparametric statistical methods are required for inference. We use a Bayesian nonparametric framework developed by Griffiths and Ghahramani (2005, 2006) known as the Indian buffet process. Due to its Bayesian foundations, the proposed model can be regarded as an ideal observer model inferring optimal features of its multisensory environment (Austerweil & Griffiths, 2009).

We applied the proposed model to a visual-auditory data set obtained when people spoke different digits. Our results are consistent with the three hypotheses from the cognitive neuroscience literature described above. It was found that the model obtained the statistical advantages provided by sensory integration: categorization of objects was more accurate based on its latent multisensory representations than on the latent features of unisensory models. In addition, the model’s latent or multisensory representations were relatively sensory invariant. That is, similar representations of an object were formed regardless of whether an object was seen or heard. Lastly, the model was able to associate representations based on different modalities. In other words, it could use one type of unisensory representation to predict or activate another type of unisensory representation.

Visual-Auditory Data Set

The multisensory perception model was applied to a visual-auditory data set known as the Tulips1 data set (Movellan, 1995). Twelve people (9 adult males, 3 adult females) were videotaped while uttering the first four digits of English twice.

In each video frame, the image of a speaker’s mouth was processed to extract 6 visual features: the width and height of the outer corners of the mouth, the width and height of the inner corners of the mouth, and the heights of the upper and lower lips. The auditory signal corresponding to a frame was processed to extract 26 features: 12 cepstral coefficients¹, 1 log-power, 12 cepstral coefficient derivatives, and 1 log-power derivative. Because speech utterances had different durations, we sampled 6 frames for each utterance spanning the entire duration of the utterance in a uniform manner. In summary, each data item contained values for 36 visual features (6 frames \times 6 visual features per frame) and 156 auditory features (6 frames \times 26 auditory features per frame).

Training and test sets were created as follows. For the first eight speakers, one utterance of each digit was used for training and the other utterance was used for testing. For the remaining speakers, both utterances were used for training. Thus, the training set contained 16 data items for each digit, and the test set contained 8 data items for each digit.

Multisensory Perception Model

We describe the proposed model in the context of a visual-auditory environment, though we note that the model is equally applicable to other sensory modalities and to any number of modalities. A coarse schematic of the model is illustrated in Figure 1. It contains three sets of nodes or variables corresponding to visual features, auditory features, and multisensory features. The visual and auditory features are statistically dependent. However, they are conditionally independent given values for the multisensory features. The values of the visual features are observed when an object is viewed. When an object is not viewed, the visual features are latent,

Figure 1: A coarse schematic of the multisensory perception model.

and their distributions can be inferred. Similarly, the values of the auditory features are observed when an object is heard. Otherwise, the auditory features are latent, and their distributions can be inferred. The multisensory features are always latent variables. Whereas the numbers of visual and auditory features are fixed, the number of multisensory features is not. Consistent with the nonparametric approach, this number is a random variable whose distribution is inferred from the data.

Formally, the model is a straightforward extension of the Indian buffet process (Griffiths & Ghahramani, 2005, 2006). A detailed graphical representation of the model is shown in Figure 2. An important goal of the model is to find a set of latent multisensory features, denoted Z , “explaining” a set of observed visual and auditory features, denoted X_V and X_A , respectively. Assume that a learner both sees and hears a number of objects. Let Z be a binary multisensory feature ownership matrix, where $Z_{ij} = 1$ indicates that object i possesses multisensory feature j . Let X_V and X_A be real-valued visual and auditory feature matrices, respectively (e.g., X_{Vij} is the value of visual feature j for object i). The problem of inferring Z from X_V and X_A can be solved via Bayes’ rule:

$$p(Z|X_V, X_A) = \frac{p(X_V|Z) p(X_A|Z) p(Z)}{\sum_{Z'} p(X_V|Z') p(X_A|Z') p(Z')}$$

where $p(Z)$ is the prior probability of the multisensory feature ownership matrix, and $p(X_V|Z)$ and $p(X_A|Z)$ are the likelihoods of the observed visual and auditory feature matrices, respectively, given the multisensory features. We now describe the prior and likelihood distributions.

The multisensory feature ownership matrix is assigned a Bayesian nonparametric prior distribution known as the Indian buffet process (Griffiths & Ghahramani, 2005, 2006). It can be interpreted as a probability distribution over feature ownership matrices with an unbounded (infinite) number of features. The distribution is written as:

$$p(Z) = \frac{\alpha^K}{\prod_{h=1}^{2^N-1} k_h!} \exp\{-\alpha H_N\} \prod_{k=1}^K \frac{(N - m_k)!(m_k - 1)!}{N!}$$

where N is the number of objects, K is the number of multisensory features, K_h is the number of features with history h (the history of a feature is the matrix column for that feature interpreted as a binary number), H_N is the N^{th} harmonic

¹Cepstral coefficients are the coefficients of the Fourier transform representation of the log magnitude spectrum.

Figure 2: A Bayesian network representation of the multisensory perception model.

number, m_k is the number of objects with feature k , and α is a variable influencing the number of features.

The visual and auditory likelihoods are each based on a linear-Gaussian model. Let z_i be the multisensory feature values for object i , and let $x_{i\beta}$ be the feature values for object i where β is set to either V or A depending on whether we are referring to visual or auditory features. Then $x_{i\beta}$ is drawn from a Gaussian distribution whose mean is a linear function of the multisensory features, $z_i W_\beta$, and whose covariance matrix equals $\sigma_{x_\beta}^2 I$, where W_β is a weight matrix (the weight matrices themselves are drawn from zero-mean Gaussian distributions with covariance $\sigma_{w_\beta}^2 I$). Given these assumptions, the likelihood for a feature matrix is:

$$p(X_\beta | Z, W_\beta, \sigma_{x_\beta}^2) = \frac{1}{(2\pi\sigma_{x_\beta}^2)^{ND_\beta/2}} \times \exp\left\{-\frac{1}{2\sigma_{x_\beta}^2} \text{tr}((X_\beta - ZW_\beta)^T (X_\beta - ZW_\beta))\right\}$$

where D_β is the dimensionality of X_β , and $\text{tr}(\cdot)$ denotes the trace operator.

Simulation Results

The multisensory perception model was applied to the visual-auditory data set. To better understand its performances, we also consider the performances of two other models. The vision-only model is identical to the multisensory model except that it contains only two sets of variables corresponding to visual and latent features. When applied to the visual-auditory data set, it received only the visual features. Similarly, the auditory-only model contains only two sets of variables corresponding to auditory and latent features. It received only the auditory features from the data set.

Because exact inference in the models is computationally intractable, approximate inference using Markov chain Monte Carlo (MCMC) sampling methods (e.g., Gelman et al., 1995) was performed based upon the training data following Griffiths and Ghahramani (2005). A single chain of each model was simulated. Each chain was run for 5000 iterations. The

first 3000 iterations were discarded as burn-in. To reduce correlations among variables at nearby iterations, the remaining iterations were thinned to every 10th iteration (i.e., only variable values at every 10th iteration were retained). Thus, the results below are based on 200 iterations.

Posterior distributions over latent features

Recall that the number of latent features in each model is not fixed a priori. Instead, it is a random variable whose distribution is inferred from the training data. The three graphs in Figure 3 show the distributions of the numbers of latent features in the visual-only, auditory-only, and multisensory models. The visual-only model used relatively few latent features, the auditory-only model used more latent features, and the multisensory model used the most latent features. This result confirms that the models are highly flexible. Their non-parametric nature allows them to adapt their representational capacities based on the complexities of their data sets.

Categorization performances

We evaluated each model's ability to categorize the speech utterances as instances of one of the first four digits in English based upon its latent feature representations. At each iteration of an MCMC chain, a model sampled a latent feature representation for each data item in the training set. Using these representations, we performed k-means clustering with four cluster centers. We then performed an exhaustive search of assignments of clusters to English digits (e.g., cluster $A \rightarrow$ digit 3, cluster $B \rightarrow$ digit 1, etc.) to find the assignment producing the best categorization performance. Performances were averaged across iterations of a chain.

The results are shown in the leftmost graph of Figure 4. The horizontal axis gives the model, and the vertical axis plots the percent of data items in the training set that were correctly classified (error bars indicate the standard deviations of these percents across iterations of an MCMC chain). As expected, the vision-only model showed the worst performance, the auditory-only model showed better performance, and the multisensory model showed the best performance.

It's possible that the multisensory model showed the best performance solely due to the fact that it received both visual and auditory features and, thus, received a richer set of inputs than either the visual-only or auditory-only models. To evaluate this possibility, we simulated a model, referred to as a 'mixed' model, that resembled the multisensory model in the sense that it received both visual and auditory features. However, for the mixed model, these features were not segregated into separate input streams. Instead, the mixed model contained a set of latent features that received inputs from a set of undifferentiated perceptual features, namely a concatenation of the visual and auditory features. The results for the mixed model on the training set are also shown in the leftmost graph of Figure 4. The mixed model showed significantly poorer performance than the multisensory model, thus suggesting the statistical advantages of segregating perceptual inputs into separate streams.

Figure 3: The distributions of the numbers of latent features in the visual-only (left), auditory-only (middle), and multisensory (right) perception models.

This analysis was repeated using the data items in the test set. Performing the analysis on test items presents unique challenges. Although it is reasonable to sample variables' values, and thus estimate variables' distributions, on the basis of training items, models are not meant to learn from test items. Consequently, we could not run our MCMC sampler on a model using the test items to evaluate the model's categorization performance. Doing so would erase the distinction between training and test data items.

Instead, we proceeded as follows. For a given model, consider the latent feature representations obtained on iteration i of the MCMC sampler when the model was trained on the training data. There is one such representation for each training item. These are the latent representations with non-zero probability based solely on iteration i . Let \mathcal{L}_i denote this set of representations. For each data item in the test set, we searched \mathcal{L}_i to find a latent representation that was most probable given the item. This was repeated for every item in the test set. Using these representations, the analysis of the test set is identical to the analysis of the training set described above: latent representations were clustered using k-means clustering, and an exhaustive search of assignments of clusters to digits was performed to find the assignment producing the best categorization performance. Performances were averaged across iterations.

The results are shown in the rightmost graph of Figure 4. Again, the multisensory model showed the best performance.

In summary, the multisensory perception model showed the best categorization performance on both training and test data sets. We conclude that its superior performance is due to both its rich set of inputs (it receives both visual and auditory features) and due to its internal structure (visual and auditory features are segregated perceptual streams). Clearly, this model received the statistical benefits of sensory integration.

Sensory invariance

As discussed above, neural representations of objects are often sensory invariant. That is, the same (or at least similar) neural representations arise regardless of the modality through which an object is sensed. Does the multisensory perception model show this same property?

We investigated this question as follows. As above, let \mathcal{L}_i denote the set of multisensory feature representations obtained on iteration i of the MCMC sampler when the model was trained on the training data. Recall that these are the latent or multisensory representations with non-zero probability based solely on iteration i . For each data item in the training set, we calculated the probability distribution of the multisensory representation given an item's visual features, and the distribution of the multisensory representation given an item's auditory features where \mathcal{L}_i was the set of possible multisensory representations. When all training items are taken into account, these distributions are denoted $p(Z|X_V)$ and $p(Z|X_A)$, respectively. We then calculated the Battacharyya distance between $p(Z|X_V)$ and $p(Z|X_A)$.² On every iteration, this distance was zero.

We repeated this analysis using the data items in the test set. Again, we computed $p(Z|X_V)$ and $p(Z|X_A)$ where X_V and X_A refer to the visual and auditory features of test items, and where \mathcal{L}_i is the set of possible multisensory representations. The Battacharyya distances between $p(Z|X_V)$ and $p(Z|X_A)$ are always small values—the distribution of these distances has values of 1.51, 1.55, and 1.68 as its 25th, 50th, and 75th percentiles, respectively. By way of comparison, we also computed the distance between $p(Z|X_A)$ and a uniform distribution over multisensory representations. The distribu-

²We also considered the Kullback-Leibler distance but use of this metric led to numerical instabilities.

Figure 4: Categorization performances of the vision-only, auditory-only, multisensory, and mixed models on the training set (left) and on the test set (right). The horizontal axis of each graph gives the model, and the vertical axis plots the percent of data items correctly classified (error bars indicate the standard deviations of these percents across iterations of an MCMC chain).

tion of these distances has values of 3.49, 7.83, and 19.04 as its 25th, 50th, and 75th percentiles.

In summary, both training and test sets suggest that the multisensory perception model did indeed acquire sensory invariant representations. Its latent multisensory features had the same or similar distributions regardless of whether a speech utterance was seen or heard.

Predicting sensory representations in missing modalities

Above, we reviewed evidence of activity in people’s auditory cortices when they viewed speech utterances but did not hear those utterances (Calvert et al., 1997). This result is consistent with the hypothesis that sensory representations in one modality can predict or activate representations in other modalities. Does the multisensory perception model show this behavior?

This question was studied using the data items in the test set. Let \mathcal{V} and \mathcal{A} denote the sets of visual and auditory feature representations for the data items in the training set. Once again, let \mathcal{L}_i denote the set of multisensory representations obtained on iteration i of the MCMC sampler when the model was trained on the training data. For each test item, we computed the probability distribution of an auditory representation given a test item’s visual features. This was accomplished by first calculating a conditional joint distribution over both multisensory and auditory representations, and then by marginalizing over the multisensory representations where the set of possible auditory and multisensory representations were given by \mathcal{A} and \mathcal{L}_i . Analogous computations were carried out to compute the distribution of a visual representation given an item’s auditory features.

Representative results are shown in Figure 6. Four test items (items 1, 12, 24, and 28) were selected at random with the constraint that one item corresponded to each spoken digit.

The four graphs in the top row of the figure show the distributions of the visual representations given the auditory features of the test items. More precisely, the graphs show that when presented with the auditory features corresponding to one of the digits, the model’s distribution of visual representations was tightly peaked at a representation corresponding to the same digit. The four graphs in the bottom row show analogous results for distributions of auditory representations given test items’ visual features.

In summary, the multisensory perception model learns to associate unisensory representations from different modalities. It successfully predicts representations from missing modalities based on features from observed modalities.

Conclusions

Bayesian nonparametric approaches to modeling are becoming increasingly popular in the cognitive science and machine learning literatures. We regard this approach as an important advance over conventional parametric approaches in which a researcher sets the number of latent variables by hand, often in an ad hoc or unprincipled manner. How can a researcher be sure that the number of latent features should, for example, be exactly 10? Shouldn’t the number of latent features be determined by the structure of the task or data set? The Bayesian nonparametric approach is also an advance over modeling approaches that define a set of models, each with a different number of latent features, and perform “model comparison” to select the best model. Typical model comparison techniques are computationally expensive and, thus, only practical for comparing small numbers of models. How should a researcher pick a small number of models to consider? The Bayesian nonparametric approach eliminates (or at least ameliorates) the problems associated with model comparison.

We have proposed a Bayesian nonparametric model of multisensory perception. The model includes a set of latent vari-

Figure 5: Graphs in the top row demonstrate that when presented with auditory features of a test item corresponding to one of the digits, the multisensory perception model’s distribution of visual representations was tightly peaked at a representation corresponding to the same digit. Graphs in the bottom row show analogous results for distributions of auditory representations given test items’ visual features.

ables that learn multisensory features from unisensory data. The model is highly flexible because it makes few statistical assumptions. In particular, the number of multisensory features is not fixed a priori. Instead, this number is estimated from the data.

We applied the model to a real-world visual-auditory data set obtained when people spoke English digits. Our results are consistent with several hypotheses about multisensory perception from the cognitive neuroscience literature. We found that the model obtained the statistical advantages provided by sensory integration. We also found that the model acquired multisensory representations that were relatively sensory invariant. Lastly, we found that the model was able to associate unisensory representations based on different modalities.

Because the multisensory perception model is based on Bayesian statistics, it can be regarded as an ideal observer inferring optimal multisensory features from unisensory data (Austerweil & Griffiths, 2009). As such, it provides a basis for a rational analysis of multisensory perception. This analysis suggests that the acquisition of latent multisensory representations that are sensory invariant and more statistically robust than latent features from unisensory models is a rational response of an agent attempting to learn the structure of its multisensory environment. It also suggests the rationality of acquiring associations among unisensory representations.

Abstract

The study of cross-modal processing has generated two seemingly contradictory sets of findings. Studies examining cross-modal processing in infants often find evidence that auditory input interferes with visual processing, whereas studies with adults often find evidence for visual input interfering with auditory processing. However, in the absence of amodal measures of auditory processing, it is possible that visual input also interferes with auditory processing in young infants. The primary goal of the current study was to examine this issue by focusing on Heart Rate (HR) to assess discrimination of unimodal auditory stimuli (Experiment 1), and to examine how visual stimuli affect auditory discrimination (Experiment 2). The results indicate that the presence of visual stimuli facilitated, rather than interfered with, auditory processing.

Keywords: Cognitive Development, Attention, Heart Rate, Psychology, Human Experimentation.

Introduction

There are many tasks that require people to integrate information across sensory modalities (e.g., associating words with objects and categories, learning the sounds that objects make, etc.). While simultaneously presenting information to different sensory modalities can sometimes facilitate learning, there are also many occasions when presenting stimuli to one modality interfere with learning in a different modality (i.e., modality dominance). Interestingly, the study of modality dominance has generated seemingly inconsistent findings.

On the one hand, there is more than 30 years of research on the Colavita effect in adults (Colavita, 1974; Colavita & Weisberg, 1979; Klein, 1977; Posner, Nissen, & Klein, 1976, see Sinnett, Spence, & Soto-Faraco, 2007 for a review). The main finding of these studies is that visual information often interferes with the detection of auditory input, hence the “visual dominance effect”. On the other hand, studies with infants and young children often demonstrate the opposite finding: auditory input often interferes with visual processing, hence the “auditory

dominance effect” (Lewkowicz, 1988a; 1988b; Robinson & Sloutsky, 2004; 2007; 2010; Sloutsky & Napolitano, 2003; Sloutsky & Robinson, 2008).

Although the asymmetry between infant and adult literatures may reflect genuine developmental differences, it is also possible that the asymmetry stems from a lack of appropriate measure of auditory processing. In particular, most infant studies use visual fixations to examine auditory and cross-modal processing. For example, infants in many of the studies reported above were familiarized or habituated to an auditory stimulus, visual stimulus, or to a cross-modal stimulus. Infants in the cross-modal condition often failed to increase looking to a novel visual stimulus when it was paired with an old sound, suggesting that they did not discriminate the visual stimuli. This finding is noteworthy given that infants ably discriminated the same visual stimuli when they were presented unimodally.

In contrast, there were no costs of cross-modal presentation on auditory processing: infants equally discriminated auditory stimuli when presented unimodally and cross-modally. However, auditory processing was never measured independently of visual processing (i.e., auditory processing was assessed by examining infants’ visual fixations). In the absence of a true measure of auditory processing, it is possible that visual dominance was missed, with visual input interfering more with auditory input than the reverse. The goal of the present research was to address this issue.

The achievement of this goal requires an amodal measure of auditory processing. While sucking procedures and ERP tasks can provide modality-independent measures of auditory processing (e.g., Eimas, Siqueland, Jusczyk, & Vigorito, 1971; Nelson & deRegnier, 1992), sucking procedures are not appropriate for older infants and children and ERP tasks often require a large amount of trials. The present study uses infants’ Heart Rate (HR) to

measure auditory and cross-modal processing. HR has provided researchers with a powerful tool for examining the dynamics of visual attention. The gist is that HR decelerates while participants are actively processing visual input, and combining HR and visual fixations can delineate various stages of visual attention (Colombo, et. al., 2004; Courage, Reynolds, & Richards, 2006; Richards & Casey, 1992). Panneton and Richards (2002) used HR to assess how 4- to 6-month-old infants attend to auditory, visual, and cross-modal stimuli. This study demonstrated that HR decelerates more to dynamic and cross-modal stimuli than to static and unimodal stimuli. The current study expands on this research by using HR to examine the effects of visual input on auditory processing. In Experiment 1, we presented participants with unimodal auditory stimuli and measured auditory oddball detection. In Experiment 2, we examined how visual input affected the detection of auditory oddballs.

Experiment 1

Method

Participants Twenty-four 10-month-olds (16 boys and 8 girls, $M = 301$ days, $SD = 49.94$ days) participated in this experiment. A majority of infants were Caucasian and none of the infants had auditory or visual deficits, as reported by parents. No infants were excluded from the final sample.

Apparatus Infants sat on parents' laps 100 cm away from a 52" Sony LCD television. Two Boston Acoustics 380 speakers were 76 cm apart from each other and mounted in the wall (concealed by black felt). A pan-tilt-zoom camera was mounted above the television to capture a video stream of the infant, and a Sony DCR-TRV40 camcorder was located behind the infant to capture the AV stimulus presentation. These two video streams were overlaid using a Kramer PIP 200 picture and picture mixer, and videos were saved as mpg video files on a Dell Optiplex 755 computer.

In an adjacent room, a Dell Optiplex 745 computer with *E-prime* software was used to present stimuli to the infants, and a Dell Optiplex 755 computer with Mindware software was used to record electrocardiograms. Two Ag-AgCl electrodes were placed on the infants' right collar bone and left, lower rib, and a reference electrode was placed on the infants' right, lower rib. Electrocardiograms were collected using a BioNex acquisition unit with a BioNex Impedance Cardiograph and GSC amplifier. Electrocardiograms were time-locked with stimulus presentation and saved on the Dell Optiplex 755 computer.

Stimuli Auditory stimuli were seven nonsense words (e.g., vika, leru, kuna, etc.) that were recorded by a female speaker using infant-directed speech. Each nonsense word was edited in CoolEdit 2000 and saved as a 44.1 kHz, 16-

bit stereo wav file. Nonsense words were each 1 s in duration and were presented to infants at approximately 68-70 dB. One nonsense word served as the standard (presented 60% of the time) and the remaining nonsense words served as oddballs. While infrequent stimuli were presented for the remaining 40% of the experiment, six different oddballs were presented throughout the experiment. Thus, across the entire experiment the same standard was presented for approximately 60 s, whereas each individual oddball was only presented for 7 s.

Figure 1: Overview of stimulus presentation in Experiments 1 and 2. Standards were presented five times in a row, followed by four oddballs. Note: "*" denotes an example of oddball in both experiments.

Procedure Infants sat on parents' lap in a quiet, dimly lit room. A picture of a baby playing with toys was presented on the LCD television while the experimenter attached the electrodes to the infant. The experimenter left the room and started the experiment by pressing the spacebar on the Dell Dimension 8200 computer. At this point, the picture of the baby and toys disappeared and a white screen was presented throughout the entire experiment. Infants were presented with alternating standards and oddballs until the infant either became fussy or until all of the stimuli were presented (approximately 1.5 minutes). Stimuli were presented in Trials (i.e., Trial 1 = five presentations of standard → four presentations of oddball 1, Trial 2 = five presentations of standard → four presentations of oddball 2, etc.), such that the same standard was presented throughout the entire experiment and the oddballs changed on every trial. Auditory stimuli were presented for 1 s with a 0.75 s ISI. Thus, within each Trial, the standard was presented for 8.75 s (5 x 1.75 s) and then the oddball was presented for 7 s (4

x 1.75 ms). E-prime sent a pulse to BioNex every time the stimulus changed. For example, E-prime sent a pulse at the onset of the first standard presented in Trial 1. The next pulse was sent at the onset of the first oddball presented in Trial 1, etc. The experiment was not contingent on infants' looking, thus, auditory stimuli were presented as long as the infant was not fussy or interacting with the parent.

Results and Discussion

Analyses focused on changes in infants' HR to standards and oddballs across time. Artifacts were corrected using Mindware software, and HR data were transformed to Inter-Beat-Interval (IBI). IBI is inversely related to HR. In particular, as HR slows down, the time between heart beats (distance between R waves) increases. Thus, longer IBIs correspond with slower HR. IBIs were computed by averaging IBIs within a one second bin and baseline corrected. For example, to determine how HR changed 1 s after stimulus onset, we subtracted baseline IBI (IBI 1 s pre-stimulus) from IBI at 1 s post stimulus. To examine how HR changed 2 s after stimulus onset, we subtracted baseline IBI from IBI at 2 s post stimulus. Thus, values greater than zero denote that HR slowed down after stimulus onset and values less than zero denote that HR sped up after stimulus onset.

To examine discrimination of standards and oddballs, we compared IBIs to standards and oddballs averaged across Trials 1-3 (Figure 2a) and averaged across Trials 4-6 (Figure 2b). Paired-sample *t* tests were conducted comparing IBIs to standards and oddballs at each point in time. Reliable differences between standards and oddballs are denoted with a "*" on the x axis. For example, Figure 2a shows that IBIs to standards and oddballs only differed 3 s after stimulus onset, $p < .05$. However, as can be seen in Figure 2b, these differences became more pronounced in Trials 4-6. Furthermore, examination of Figure 2b also shows that the difference between standards and oddballs was not solely driven by greater deceleration to oddballs. Rather, HR also accelerated to standards. Examination of video streams suggests that this acceleration may be related to increased infant fidgeting rather than from auditory stimuli startling infants.

To examine how quickly oddballs engaged attention we identified the point for each infant when two consecutive IBIs exceeded baseline (zero). Eight of the 24 infants did not meet this criterion. Averaged across the remaining infants, it took approximately 2.3 s for HR to decelerate. Finally, we examined dwell time of attention to the oddballs (i.e., how long did the oddball hold infants' attention). For example, one of the infants' first of two consecutive IBIs exceeded zero 1 s after stimulus onset and returned to zero 6 s after stimulus onset. Thus, this infants' dwell time of attention was 5 s (HR was decelerated from 1 s – 5 s). On average infants' HRs were decelerated to oddballs for 5 s. However, it is important to

note that many of infants' HRs were still decelerated at the end of the trial. Thus, the value of 5 s underestimates how long the oddballs actually held infants' attention.

In summary, the findings from Experiment 1 demonstrate that HR can serve as a modality-independent measure of attention to assess auditory discrimination in a relatively short period of time, and these discriminations appeared to develop gradually across the experiment. In addition to providing time course information across trials, changes in HR can also provide a measure of speed of engagement and dwell time of attention within trials.

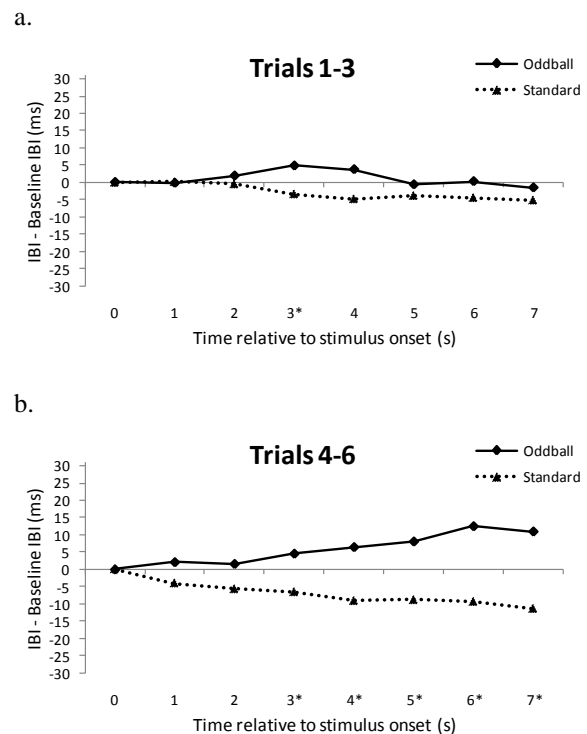

Figure 2: Change in IBI to standards and oddballs in Trials 1-3 (a) and Trials 4-6 (b). Note: "*" on the x axis denote means at that point in time were reliably different, $ps < .05$ (one-tailed).

Experiment 2

The goal of Experiment 2 was to examine how visual input affects discrimination of the auditory stimuli presented in Experiment 1. More specifically, we examined how pairing an old visual stimulus with a novel auditory oddball would affect discrimination, speed of engagement, and dwell time of attention.

Method

Participants Eight 10-month-olds (3 boys and 5 girls, $M = 309$ days, $SE = 56$ days) participated in this experiment. Demographics were identical to Experiment 1. Five infants were tested but were not included in the final sample due to fussiness ($n=3$) and experimenter error ($n = 2$).

Stimuli and Procedure The auditory stimuli were identical to Experiment 1, however, in the current experiment, auditory stimuli were paired with a visual stimulus (see Figure 1). The visual stimulus consisted of a novel creature that was created in PowerPoint and saved as a 400 x 400 pixel jpg. The visual stimulus was presented on the 52" Sony LCD and pulsed at the same rate as the auditory stimulus (1 s stimulus duration with a 0.75 s ISI). The procedure also differed from Experiment 1 in one important way. In the current experiment, the procedure paused and the screen darkened when infants looked away. The experiment started back up again when the infant looked to the darkened screen. This manipulation was important because we were interested in how the presence of an old visual stimulus affected auditory processing. Therefore, we only examined discrimination of auditory stimuli on those trials where the infants were looking to the visual stimulus. Trials where the infant looked away were discarded.

Results and Discussion

As in Experiment 1, we examined discrimination of standards and oddballs in Trials 1-3 (Figure 3a) and in Trials 4-6 (Figure 3b). Paired-sample t tests (one-tailed) were conducted to compare discrimination of standards and oddballs at each point in time. In contrast to Experiment 1, infants reliably discriminated auditory standards and oddballs in Trials 1-3 (see asterisks on the x axis to determine which means reliably differed from each other). This suggests that the presence of the visual stimulus actually facilitated auditory discrimination, with infants discriminating oddballs and standards early in the course of processing. Discrimination was also robust in the last three trials of the experiment (see Figure 3b).

As in Experiment 1, we also examined how quickly oddballs engaged attention and how long oddballs held attention. Two of the 8 infants never had two consecutive IBIs exceed zero. Averaged across the remaining infants, it took approximately 1.1 s for the oddballs to engage attention. Recall that infants in Experiment 1 took approximately 2.3 seconds. Therefore, the old visual stimulus did not appear to slow down the detection of the auditory oddballs. Furthermore, infants' HR in the current experiment was decelerated to oddballs for approximately 5.8 s, which was slightly longer than in Experiment 1. However, as in Experiment 1, many infants' HRs were still decelerated at the end of the trial. Therefore, it is

unclear if differences between Experiments 1 and 2 would have emerged if infants would have been given more time for HR to return to baseline levels.

In summary, Experiment 2 demonstrates that visual stimuli did not attenuate discrimination of auditory input or slow down the speed in which auditory oddballs engaged attention. Rather, cross-modal presentation in the current experiment actually facilitated auditory processing. Recall that infants in the current experiment (but not in Experiment 1) reliably discriminated standards from oddballs in Trials 1-3. Furthermore, these effects were much stronger in Experiment 2, with reliable discrimination occurring with a sample size of only eight infants. Finally, it is worth noting that all data reported in Experiment 2 came from trials when infants were looking throughout the entire trial. Therefore, analysis of looking data would suggest no discrimination of standards and oddballs, whereas HR data clearly demonstrate that infants discriminated these stimuli.

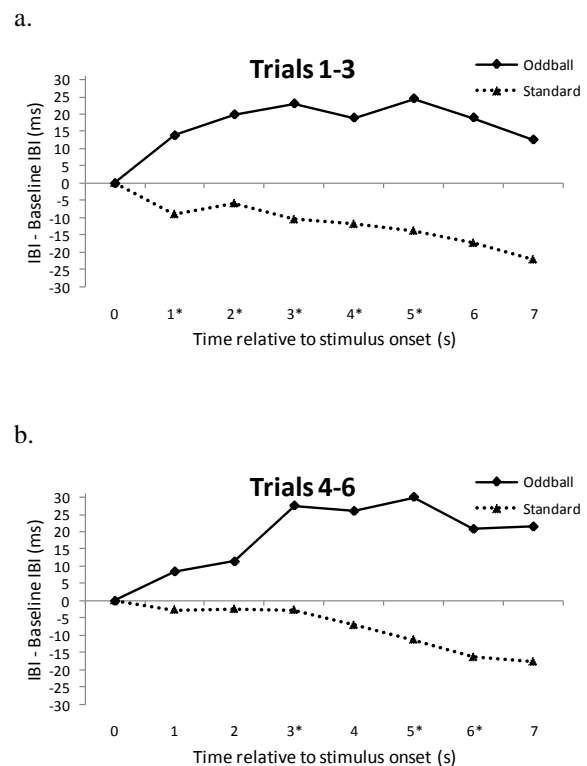

Figure 3: Change in IBI to standards and oddballs in Trials 1-3 (a) and Trials 4-6 (b). Note: "*" on the x axis denotes mean at that point in time were reliably different, $ps < .05$ (one-tailed).

General Discussion

The current study reveals several important findings. First, Experiment 1 demonstrates that HR can provide a powerful tool for examining auditory processing. In particular, changes in HR to frequent and infrequent stimuli can provide a measure of auditory discrimination. Furthermore, speed of engagement and dwell time of attention can also be estimated by examining when HR decelerates compared to pre-stimulus levels and by examining how long HR remains decelerated. More importantly, Experiment 2 demonstrates that visual input facilitated, rather than interfered with, auditory processing.

These findings suggest that the differences in modality dominance between infants and adults do not stem from an underestimation of visual interference with auditory processing in infants. Rather, these findings suggest that the difference may actually reflect a real developmental phenomenon, with allocation of attention to multimodal stimuli changing in the course of development.

Abstract

Simultaneous presentation of auditory and visual input can often lead to visual dominance. Most studies supporting visual dominance often require participants to make an explicit response, therefore, it is unclear if visual input disrupt encoding/discrimination of auditory input or results in a response bias. The current study begins to address this issue by examining how multimodal presentation affects discrimination of auditory and visual stimuli, while using a passive oddball task that does not require an explicit response. Participants in the current study ably discriminated auditory and visual stimuli in all unimodal and multimodal conditions. Furthermore, there was no evidence that visual stimuli attenuated auditory processing. Rather, multimodal presentation sped up auditory processing (shorter latency of P300) and slowed down visual processing (longer latency of P300). These findings are consistent with research examining modality dominance in young children and suggest that visual dominance effects may be restricted to tasks that require an explicit response.

Keywords: Attention, Cross-modal Processing, Electroencephalograph (EEG), Neurophysiology, Psychology.

Introduction

Most of our experiences are multimodal in nature. The objects and events that we encounter in the environment can be seen, touched, heard, and smelled. The fact that the brain can integrate this knowledge into a coherent experience is amazing given that each modality simultaneously receives different types of input, and this information is processed, at least in the early stages of processing, by dedicated sensory systems.

While multimodal presentation can sometimes facilitate learning, there are many occasions when presenting

information to one sensory modality interferes with learning in a second modality. These modality dominance effects can occur on detection tasks and on more complex discrimination tasks, with auditory input often attenuating visual processing in young children (Sloutsky & Napolitano, 2003; Robinson & Sloutsky, 2004) and visual input often attenuating auditory processing in adults (Colavita, 1974; Colavita & Weisberg, 1979).

Support for visual dominance in adults comes from a long history of research examining how multimodal stimuli affect the detection of auditory and visual input (Colavita, 1974; Colavita & Weisberg, 1979; Klein, 1977; Posner, Nissen, & Klein, 1976; see also Sinnett, Spence, & Soto-Faraco, 2007; Spence, Shore, & Klein, 2001, for reviews). For example, in a classic study Colavita (1974) presented adults with a tone, a light, or the tone and light paired together. Participants had to press one button when they heard the tone and a different button when they saw the light. While participants were accurate when the tone and light were presented unimodally, they often responded to the visual stimulus when the stimuli were paired together, with many adults failing to detect the auditory stimulus. This finding has been replicated using a variety of stimuli and procedures, with little evidence demonstrating that auditory input attenuates visual processing in adults (see Sinnett, Spence, & Soto-Faraco, 2007 for a review).

There appears to be an attentional component underlying visual dominance (Posner, Nissen, & Klein, 1976). In particular, the underlying idea is that the auditory and visual modalities share the same pool of attentional resources. While auditory stimuli

automatically engage attention, visual stimuli often have poor alerting abilities. To compensate for the poor alerting ability of visual input, adults endogenously direct attention to visual stimuli. This increased attention to the visual modality comes with a cost – attenuated auditory processing.

While there is much support for visual dominance, it is important to note that this support primarily comes from studies examining response latencies and response accuracies. Therefore, it is possible that visual input have no effect on encoding or discrimination of auditory stimuli. Rather, these effects may stem solely from visual input dominating the response. The current study begins to address this issue by examining processing of auditory, visual, and multimodal stimuli in a task that does not require an explicit response.

Participants in the current study were presented with a passive oddball task where they were presented with auditory, visual, or multimodal stimuli. Event Related Potentials (ERPs) were recorded as adults passively attended to frequent stimuli (standard) and infrequent stimuli (oddballs). The signature pattern of discrimination is a P300. P300 is a positive component with a peak latency occurring between 300-800 ms after stimulus onset and is strongest over the temporal, parietal, and fronto-central regions (see Polich & Criado, 2006 for a review). The amplitude of P300 is larger for novel or infrequent stimuli (Sutton, Braren, Zubin, & John, 1965), and the latency of P300 can be used as a measure of processing time (Kutas, McCarthy, & Donchin, 1977). In particular, experimental manipulations that affect the processing leading up to classification and responding should affect the latency of P300. The same underlying idea is guiding the current research: multimodal facilitation and interference should manifest themselves by affecting the latency (and possibly amplitude) of P300.

Previous studies have used oddball tasks to examine unimodal and multimodal processing and to examine effects of response on ERP components. However, these procedures differed from the ones reported here in several important ways. First, ERP studies that have directly compared unimodal and multimodal conditions either focused on early ERP components associated with stimulus detection or they required participants to make a response to oddballs (e.g., Brown, Clarke, & Barry, 2007; Fort, Delpuech, Pernier, & Giard, 2002; Giard & Peronnet, 1999; Vidal, Giard, Roux, Barthelemy, & Bruneau, 2008). In contrast, the current study focused exclusively on discrimination of standards and oddballs (P300), and participants did not make an explicit response to these stimuli. Second, the studies that have examined the effects of explicit response on oddball tasks were not interested in modality dominance, thus, they did not examine discrimination of the same auditory and visual stimuli when presented unimodally and multimodally

(Mertens & Polich, 1997; Wronka, Kaiser, & Coenen, 2008).

Thus, to the best of our knowledge this is the first study to use a passive oddball task to examine how multimodal presentation affects auditory and visual processing. If visual stimuli interfere with the encoding and/or discrimination of auditory stimuli, then the latency of P300 should occur later in the multimodal condition than in the unimodal condition. However, if visual stimuli only affect the response, then no effects should be found or auditory input may attenuate visual processing (auditory dominance).

Methods

Participants

Thirty-nine undergraduate students from The Ohio State University (23 men and 16 women, $M = 19.5$ years, $SD = 3.9$ years) participated in this experiment for course credit. Prior to the experiment all participants gave informed consent and provided basic personal information (handedness, age, medical history). All participants had normal hearing and normal (or corrected to normal) vision.

Stimuli

The stimuli and cover story were designed for young children. The visual stimuli consisted of six novel creatures that were created in PowerPoint and exported as 400 x 400 pixel jpeg images (see Figure 1 for examples).

Figure 1: Example of stimuli and overview of the visual, auditory, and multimodal conditions. Note: “*” denotes visual oddball and “**” denotes auditory oddball.

Visual stimuli were presented centrally on a Dell 17” LCD monitor for 480 ms. The interstimulus interval (ISI) randomly varied from 1000 ms - 1520 ms. Auditory stimuli were also 480 ms in duration, with a 1000 ms - 1520 ms ISI. The auditory stimuli

were dynamic sounds that changed in pitch and amplitude across time. The sounds were created in CoolEdit 2000 by using preset functions (e.g., DTMF signal, out of control, etc.). Stimuli in the multimodal condition were constructed by pairing the auditory and visual stimuli together (see Figure 1 and Table 1). Thus, the same stimuli were used in the unimodal and multimodal conditions, therefore, any differences found between these conditions cannot be accounted for by properties of the unimodal stimuli.

Procedure

Three different oddball tasks were used (see Figure 1 and Table 1), and task order was pseudo-randomized for each participant. Approximately half of the participants were presented with the unimodal oddball tasks (order of auditory and visual was randomized for each participant), and then they participated in the multimodal task. The remaining participants were presented with the multimodal task, followed by the two unimodal tasks (order randomized for each participant). The multimodal task took approximately 40 minutes, and each unimodal task took approximately 20 minutes.

As can be seen in Table 1, each task consisted of one standard (presented approximately 80% of the time), four oddballs (each presented approximately 4% of the time), and one novel (presented approximately 4% of the time). Participants were instructed to press a button every time they saw/heard the novel, and to not respond to the standards and oddballs (see cover story). The novel trials were presented to keep participants engaged, and ERPs from these trials were discarded. Four oddballs were used to keep the task interesting for participants and to maintain a low probability of oddballs (each oddball was only presented 4% of the time). In each of the unimodal conditions there were four oddballs, and in the multimodal condition, there were eight oddballs (four auditory and four visual). To examine how multimodal stimuli affect auditory processing, we compared auditory oddballs in the silent condition (e.g., A2, A3, etc.) with the same auditory oddballs in the multimodal condition (e.g., A2V1, A3V1, etc.). To examine how multimodal stimuli affect visual processing, we compared visual oddballs in the silent condition (e.g., V2, V3, etc.) with the same visual oddballs in the multimodal condition (e.g., A1V2, A1V3, etc.).

Prior to each task participants were told a short cover story. For example, in the unimodal visual task, participants were told: *You are going to see creatures from a far away place. Most of the creatures that you will see eat vegetables. However sometimes you will see this creature (novel was presented). This creature eats cookies. In this game you have to press a button every time you see this creature that eats cookies (novel was presented). Do not press any buttons when you see any of*

the other creatures. In the auditory condition they were told that they would hear the sounds of creatures eating vegetables and cookies, and in the multimodal condition they were told that they would see creatures and hear the sounds that they make while eating vegetables and cookies.

	Unimodal Auditory	Unimodal Visual	Multimodal
Standard	A1 (280)	V1 (280)	A1V1 (560)
Oddballs (A)	A2 (16)		A2V1 (16)
	A3 (16)		A3V1 (16)
	A4 (16)		A4V1 (16)
	A5 (16)		A5V1 (16)
Oddballs (V)		V2 (16)	A1V2 (16)
		V3 (16)	A1V3 (16)
		V4 (16)	A1V4 (16)
		V5 (16)	A1V5 (16)
Novel	A6 (16)	V6 (16)	A6V6 (16)

Table 1. Overview of stimuli and tasks (frequency of each stimulus).

Participants were presented with a warm up task where they were given 10 standards and 3 novels. ERPs from the warm up task were not included in the final data. Feedback was provided throughout the entire experiment. Feedback was provided if participants: (a) responded to a standard or oddball or (b) failed to respond to a novel. All data were recorded with eyes open and participants in the unimodal auditory condition were asked to fixate on a square taped to the top of the LCD monitor.

Recording Conditions and Data Acquisition

Experiments were conducted in a sound-attenuated, illuminated, and well-ventilated presentation chamber which housed a Dell 17" monitor, two Polk PLKRC65I wall mount speakers, and a response pad. In the experimenter room, a Dell Optiplex 755 computer with E-prime software v.2.0.8.22 was used to present stimuli to participants, and a Harman Kardon AVR-154 receiver was used to amplify the sounds. Timing tests were conducted to ensure that auditory and visual stimuli were presented simultaneously. Offsets between trigger registration and stimuli presentation were measured for unimodal and multimodal conditions and were adjusted during analysis. A PowerPC G5 Mac with Netstation software was used to record and store ERP data.

Electroencephalography (EEG) brain activity was recorded using a 128-channel HydroCel Geodesic Sensor Net (Electrical Geodesics, Inc., Eugene, OR). Scalp-electrode impedances were kept below 50 kOhms. All channels were referenced to Cz during

acquisition. EEG was recorded using a 0.1 to 100 Hz band-pass filter (3 dB attenuation), amplified at a gain of 1000, sampled at a rate of 250 Hz, and digitized with a 24-bit A/D converter.

Data analysis

Participants ably discriminated novels in all of the conditions (proportion of hits to novels – proportion of false alarms to standards + oddballs > .99). Because auditory and visual components both changed on novel trials and participants made a response, it is unclear if ERP waveforms reflect auditory discrimination, visual discrimination, or the response. Therefore, data from novel trials were not included in any of the analyses.

ERPs to standards and oddballs were processed using Netstation waveform tool. EEGs were band-passed between 0.1 Hz and 30 Hz and segmented between 100 ms pre-stimulus onset and 1000ms post stimulus onset. ERPs were referenced with respect to the average of all channels after correcting for bad trials using neighboring channels. Trials were then baseline corrected with respect to the 100 ms pre-stimulus and then exported to Matlab.

Initially, we looked at 8 different scalp regions, each comprising of 6 or 7 channels from the 10/20 system representing: F3, F4, P3, P4, T3, T4, Pz, and Oz. However, in the current study we focused exclusively on Pz; the region that provided the best measure of discrimination in all conditions (see Figure 2). In each of the unimodal conditions, participants provided two ERP waveforms (one for the standard and one for the oddball). To equate the number of standards and oddballs, we randomly picked and averaged 64 of the 280 standards and we averaged across the four different oddballs. In the multimodal condition, adults provided a waveform for the standard, a waveform for auditory oddballs, and a waveform for visual oddballs (see Table 1).

Results and Discussion

A reliable P300 was found at Pz, P3, and P4, however, as mentioned above, discrimination was most pronounced at Pz. Thus, analyses reported below focus on Pz between 250-650 ms after stimulus onset. Waveforms for the unimodal conditions are presented on the left side of Figure 2 and waveforms for the multimodal conditions are presented on the right side of Figure 2. As can be seen in Figure 2, participants ably discriminated auditory and visual stimuli when presented unimodally and multimodally. Mean averages were computed for each participant. For example, to assess discrimination of the auditory stimuli in the unimodal auditory condition, we computed a mean average for the standard (between 250-650 ms) and a mean average for the oddball (between 250-650 ms) for each participant. These means were then submitted to a one-way ANOVA with trial type

(standards vs. oddball) as a repeated measure. The same analyses were conducted in the four conditions (i.e., Unimodal Auditory, Unimodal Visual, Multimodal Auditory, and Multimodal Visual). All ANOVAs were significant, $F_s > 20$, $p_s < .0001$.

Figure 2. ERP waveforms for Standards and Oddballs across conditions. Solid line represents difference waves (Oddball – Standard).

To examine the effects of visual input on auditory discrimination, we compared the auditory difference waveform in the multimodal condition to the auditory difference waveform in the unimodal condition (see Figure 3a). A one-way AVOVA revealed that mean amplitude between 250-650 ms did not differ between the unimodal and multimodal conditions. We also examined how the presence of auditory input affected visual discrimination by comparing the visual difference waveform in the multimodal condition to the visual difference waveform in the unimodal condition (see Figure 3b). As in the auditory conditions, mean amplitude did not differ between the unimodal and multimodal conditions.

To statistically find and quantify any significant displacement of P300 between unimodal and multimodal conditions, we computed the fractional area latency. In particular, for a predefined window, we measured the area under the curve, and then we found the latency that divided that area into two equal parts (see Hansen & Hillyard, 1980). Using this measure for a window between 250 ms and 650 ms, we found that multimodal presentation sped up auditory discrimination by 26ms and slowed down visual discrimination by 12 ms.

However, as can be seen in Figure 3a, there are multiple peaks in both auditory conditions that could be the result of multiple underlying components. Therefore, we ran sliding windows of 200 ms, 300 ms, and 400 ms for each participant's data covering the whole time range of interest (250ms to 650ms). That is, for each window length, centered at a time sample, we computed the 50% area latency for both

the multimodal difference waveform and for the unimodal difference waveform. We then calculated a difference wave (Difference Multimodal – Difference Unimodal) to denote the displacement. We kept doing this while sliding the window at 4ms increments. Figure 4a – 4c plot the displacement waveforms for the 200 ms, 300 ms, and 400 ms windows, respectively. Values greater than zero denote that multimodal presentation increased the latency of P300 and values less than zero denote that multimodal presentation shortened the latency of P300.

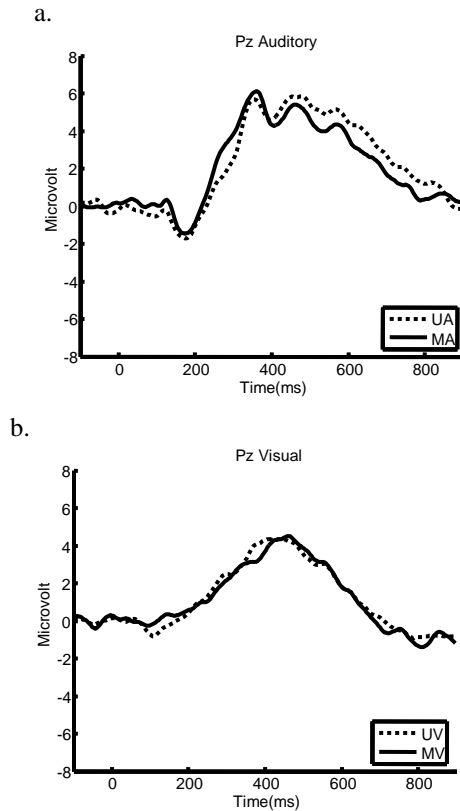

Figure 3. (a) Difference waves for Unimodal Auditory (UA) and Multimodal Auditory (MA), (b) Difference waves for Unimodal Visual (UV) and Multimodal Visual (MV). All data are averaged across participants.

As can be seen in Figures 4a-4c, across all windows, multimodal presentation sped up auditory processing and slowed down visual processing. ANOVAs were conducted for each window at every 4 ms increment. Using a window size of 200 ms, auditory and visual displacement waves differed from 370 ms to 514 ms, $p < .05$. Using a window size of 300 ms, auditory and visual displacement waves differed from 362 ms to 534 ms, $p < .05$. Finally, using a window size of 400 ms, auditory and visual displacement waves differed from 370 ms to 554 ms, $p < .05$. These findings suggest the multimodal presentation had different effects on auditory and visual processing, with multimodal presentation increasing the

latency of the visual P300 and shortening the latency of the auditory P300.

Figure 4. Displacement for (a) 200 ms window, (b) 300 ms window, (c) 400 ms window.

General Discussion

The current study used a passive oddball task to examine the time course of auditory and visual processing when stimuli were presented unimodally and multimodally. As can be seen in Figures 2, 3a, and 4a-4c, there was no evidence that visual input attenuated discrimination of auditory stimuli. Rather,

multimodal presentation appeared to speed up auditory processing and slow down visual processing. These findings have important implications for understanding the underlying mechanisms and time course of modality dominance. In particular, the current findings suggest that some of the effects of visual dominance may stem from visual input dominating the response. However, future research will need to make direct comparisons on tasks that do and do not require explicit responses before any strong conclusions can be drawn.

The novelty of the current research is that we examined the time course of auditory and visual processing on a task that did not require an explicit response. The results replicate auditory dominance effects found in young children, with multimodal presentation attenuating visual processing, and having no effect or facilitating auditory processing (see Robinson & Sloutsky, 2010 for a review). This interaction suggests that effects cannot solely stem from increased task demands, otherwise processing in both modalities would have been delayed. Rather, we believe this interaction stems from the dynamics of cross-modal processing. According to this account (Robinson & Sloutsky, 2010), auditory stimuli quickly engage attention and processing of the details of a visual stimulus does not begin until the auditory modality releases attention. While this account has received some support in young children, the finding that auditory input can also slow down visual processing in adults is novel.

Abstract

This study investigated the use of schema-specific diagrams in probability problem solving. Graduate students enrolled in an introductory probability and statistics course solved four probability problems, with and without instructor-provided diagram hints. Participants' solutions were examined and coded for correctness, use of provided diagrams, and use of student-generated external visual representations. Results show that provided diagram hints helped low-ability students on all but the most difficult problem, while high-ability students were aided by diagrams on the most difficult problem. Implications for the use of diagrams in the development of problem solving proficiency are discussed.

Keywords: probability problem solving; diagrams; visual representations; trees; Venn diagrams; contingency tables

Introduction

Learning probability concepts and solving probability problems can be challenging for students (Garfield & Ahlgren, 1988; Konold, 1989; O'Connell, 1999). Successful probability problem solving requires that students understand complex concepts, and also that they master how and when to use specific formulas and procedures that are particular to this domain. External visual representations are commonly used in many types of mathematical problems solving, including probability problem solving (PPS). These representations may promote solution success and student comprehension in several ways: by making abstract concepts visible and manipulable, or by organizing the subparts of a problem in a format that can be tied to solution procedures. Using structured visual representations may help problem solvers invent, retrieve, or apply formal solution schemas, increasing the rate of successful solution.

Why are external visual representations useful in the problem solving process?

Tversky (2001) suggests that external visual representations can serve many purposes, including recording information, relieving working memory, communicating to others, and facilitating inference and discovery. Drawing a diagram can reveal implicit information that is not readily available in a written description and make some pieces of information more explicit. It can also give a problem solver unique insight

into the problem's structure or schema. Van Essen & Hamaker (1990) report that the "construction of a drawing might increase the chance that the problem situation is recognized and that the correct schemata is identified among other competing schemata" (p. 311). Other researchers (e.g., Larkin & Simon, 1987; Koedinger & Anderson, 1990) propose that problems solvers possess stronger schemas for diagrams than for words that contain the same information. These diagrammatic schemas may thus have an advantage in problem solving over verbal solution methods. Diagrams may also contribute to a fuller understanding through the use of multiple representations when they are used in conjunction with mental images. Several researchers have suggested that multiple representations may lead to increased "depth" of processing (e.g. Logie & Baddeley, 1990; Mayer & Gallini, 1990; Ainsworth, 2007).

However, a diagram may not help every student at every stage of expertise. Lowrie & Kay (2001) suggest that for students who already have schemas in long-term memory, using a diagram may not be particularly helpful; instead these students are able to generate their own representations. Problem difficulty may also play a role in when students choose to create external visual representations. In their study, Lowrie & Kay (2001) found that elementary age students tended to create external visual representations for especially difficult problems. Since problem difficulty is relative to student ability level, this suggests that individual differences may play a role in diagram use.

Furthermore, the types of external visualizations used in scientific reasoning and problem solving may differ, and be used in different ways (e.g., Edens & Potter, 2008; Van Meter & Garner, 2005). Some representations are relatively abstract, and are commonly used to represent schematic or abstract aspects of the problem. These diagrammatic or schematic representations include tree diagrams, and Venn diagrams used to represent part-whole relationships. These general-purpose diagrams should be distinguished from problem-specific representations that include concrete components of the problem itself.

Other external visual representations may be iconic rather than schematic, including pictures that represent the problem context and sketches that display and/or reorganize the information presented in the problem. The type of

external visual representations used may be influenced by the problem goals and other specific problems features. The evidence above shows that spontaneous student use of diagrams is associated with higher rates of solution success. But the causal direction is not entirely clear.

Use of external visual representations in probability problem solving (PPS)

In the specific area of probability problem solving, Zahner and Corter (2010) provide evidence that particular types of external visual representations are more often used in particular stages in the problem solving process. Some representations, such as reorganizing the problem information or drawing sketches are more often used early in the solution process when a problem solver is trying to build a mental model of the problem text. Schematic diagrams, such as an outcome tree, can facilitate abstraction of the text, building a mathematical representation of the problem, and planning of the solution process. In general, different external visual representations may come into play in different stages of the problem solving process because of their specific structures and particular functions. The Present Study

While probability problems can be solved using formulas, we hypothesize that using external visuals may help students overcome comprehension difficulties and may lead to greater problem solving success. From an educational standpoint, we would like to better understand the positive correlation between use of diagrams and problem-solving success. The question is whether drawing correct diagrams leads to better understanding, which facilitates problem solution, or if better understanding enables both the creation of correct diagram and problem solving success. Previous work in this area has shown that a major barrier to success in PPS is problem comprehension and representation. Choosing an appropriate representation is a significant factor in problem solving success, and should be viewed as a skill unto itself (Novick & Hmelo, 1994; Edens & Potter, 2007; Uesaka, Manalo, & Ichikawa, 2007). We hypothesize that cuing or providing diagram “hints” appropriate to the problem type may aid students in the problem comprehension phase because the diagram provides a structure upon which problem components can be mapped. They may also help students recognize the structure of the problem.

Quite often, the external inscriptions created by students solving probability problems provide evidence of correct diagram and problem solving success. Previous spontaneously created diagrams and other visual representations. Three types of external visual representations often depicted in textbooks and used in PPS are Venn diagrams, outcome trees, and contingency tables. The structure of these diagrams allows for elements of the problem to be represented externally in an organized way. In an outcome tree, for example, each branch can be used to represent individual probabilities of events. The combination of events can be calculated by multiplying the values assigned to each branch. A Venn diagram is used to organize problem information, typically with overlapping circles to show the union and intersection of events. The contingency table is a matrix structure that shows the frequencies or probabilities of events, to show combinations of events. In particular, we are interested in the use of schematic specific external visual representations (distinguished from other representations, such as drawing a picture and reorganizing the given information), because we believe they have a special role in PPS. Thus, three common diagrams used in PPS were selected for use in the study: outcome trees, contingency tables, and Venn diagrams. The study attempted to investigate the role of correct external visual representations by providing appropriate but “generic” diagrams (“diagram hints”) directly to students. Each problem was chosen as a prototype of a specific problem topic/type and matched to diagram hints that are commonly used in probability curricula. The problems in this study were typical of those presented in the curricula and students had prior exposure to using specific diagrams for specific problem topics. For example, problem 4 is associated with higher rates of solution correctness for some conditional probability problem, for which outcome trees are an appropriate representation. We have three main research questions:

Previous studies have pointed to the use of specific visual representations appropriate to specific problem types. Russell (2000) found that use of outcome trees was correlated with improved performance specifically on contingency tables, outcome trees, and Venn diagrams. The conditional probability problems. He also found that students in a probability course used outcome trees more often than contingency tables or Venn diagrams. Interestingly, instructing students to draw an outcome tree did not affect performance. However, students who did draw outcome trees outperformed students who did not. Zahner & Corter (2010) found that particular external visual representations were associated with specific probability topics, and that particular representations were associated with higher rates of solution correctness for some conditional probability problem, for which outcome trees are an appropriate representation. We have three main research questions:

1. Do instructor-provided diagram hints (e.g. a correct but unlabeled Venn diagram) increase the probability of problem solving success on specific problems?

challenge (Novick 1990; 2001, Novick & Hmelo, 1994).

2. Do students actually use the diagram “hints,” or are they ignored, or are different external visual representations spontaneously created by students?

3. Does student ability mediate the effectiveness of the use of diagrams as a solution strategy?

Method

Participants. Participants were 129 students recruited from introductory probability and statistics classes at Teachers College, Columbia University. Participants were graduate students in education and social sciences, with a broad range of experience in mathematics.

Materials. Each participant was given four probability problems to solve as a problem set (Figure 1). Half of the participants received blank diagrams for problems 1 and 2 (Version A, $n=64$); the other half of the participants received diagrams for problems 3 and 4 (Version B, $n=65$). The diagrams were an outcome tree for problem 1, a contingency table for problem 2, a Venn diagram for problem 3, and an outcome tree for problem 4.

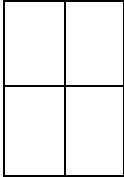

1. A bag of candy contains a mix of jelly beans that includes lime, cherry, and orange flavors. Five jelly beans are cherry, three are orange, and two are lime. Two jelly beans are randomly selected from the bag. What is the probability that the two selected jelly beans include exactly one cherry and one orange?	
2. A survey is conducted on attitudes towards handgun control. 42% of respondents to the survey are urban residents and the rest are rural residents. The results show that 33% of survey respondents are urban residents who support strict handgun controls, while 30% of survey respondents are rural residents who support strict handgun controls. What is the probability that a randomly chosen respondent is a rural resident, given that they support strict handgun control?	
3. A and B are mutually exclusive events. The probability of event A is .3, and the probability of event B is .25. What is $P(A \cap B)$?	
4. The weather forecast says that the probability of having good weather tomorrow is .60. If the weather is good, the probability that Eva will go out biking is .80. If it is not good weather, the probability is .20 that she will go out biking. What is the probability that Eva goes out biking tomorrow?	

Figure 1: Probability problems and provided diagrams

Procedure Participants were allowed to use their class notes to solve the problems, which is standard practice in the course for completing homework assignments and exams.

They were given approximately 20 minutes to solve the problems. This time limit was based on a pilot study and was imposed to discourage participants from either quickly scanning the problems or taking an inordinate amount of time.

Coding of participant solutions Written solutions were coded for several features. First, we coded whether or not the participant gave a correct answer to the problem. Problems were given a score of “0” if incorrect, and a score of “1” if correct. We also totaled student scores for the four problems. Second, we coded whether or not the participant used the instructor-provided diagram hint. Next, we coded for any other type of external visual representation created by the student. The following categories, developed through previous research in our lab, were used to code for the different types of external visual representations: pictures, outcome listings, outcome trees, contingency tables, Venn diagrams, reorganization of given information in the problem, and novel schematic representations (Corter & Zahner, 2007; Zahner & Corter, 2010).

Results

An initial analysis found that over 80% of the participants made use of the instructor-provided diagram for each of the four problems. Analyzing student responses found that the four problems varied in difficulty. Comparing student performance on Version A and Version B allowed us to examine the effect of a diagram hint on the proportion of participants who correctly solved each problem. Table 1 shows the means and standard deviations of participants who correctly solved each problem. Any differences in performance between problems with and without a provided diagram are not statistically significant.

Table 1: Means and standard deviations of correct responses

Problem	Total		Diagram		No Diagram	
	M	SD	M	SD	M	SD
1	0.539	0.500	0.619	0.489	0.462	0.502
2	0.398	0.492	0.339	0.477	0.460	0.502
3	0.305	0.462	0.365	0.502	0.246	0.434
4	0.773	0.420	0.769	0.425	0.778	0.419

We also examined participant self-generated external visual representations, since we were interested in whether the specific diagram hint we chose to provide was also spontaneously used by students who were not provided with a diagram hint. The problems in this study were typical of those presented in the curricula and students had prior exposure to using specific diagrams for specific problem topics. For example, problem 4 is a conditional probability problem, for which outcome trees are an appropriate representation. Table 2 shows that for all four problems, participants reorganized the given problem information

Table 2: Percentage of participants generating each type of external visual representation for each problem. Dashed lines indicate a cell with fewer than 3 participant uses.

Representation	Problem 1		Problem 2		Problem 3		Problem 4	
	Diagram	No Diagram	Diagram	No Diagram	Diagram	No Diagram	Diagram	No Diagram
Reorganization	43.8	38.4	18.5	75.0	43.8	18.5	35.4	53.1
Pictures	18.8	32.3	--	--	--	--	--	--
Outcome Trees	--	18.5	7.69	6.25	--	--	3.07	45.3
Contingency Tables	--	--	3.07	78.1	--	--	4.61	7.19
Venn diagrams	--	--	--	--	--	--	--	--
Outcome Listings	15.6	15.4	--	--	--	--	--	--
Novel schematic	--	--	--	--	--	--	--	--

more often than any other representation. For problem 1, the provided diagram hint was an outcome tree. Although 18.5% of participants without the diagram also created an outcome tree, 15% of participants given each version also generated outcome listings. For problem 2, the provided diagram was a contingency table, and 78.1% of participants not provided with this diagram chose to create one in solving the problem. A Venn diagram was provided for problem 3; although only 2 participants spontaneously created one, no other representations were used. Finally, problem 4 was accompanied by an outcome tree. 45.3% of students not given an outcome tree created their own in solving the problem.

In order to investigate the role of student ability / problem difficulty on diagram use, we performed a median split on participants' total scores on the four problems, defining two groups of students, low-ability and high-ability. An ANOVA analyzing the effect of provided diagrams showed different effects for these two groups. We hypothesized that the diagram hints might show a facilitative effect only for problems that are hard, but not too hard. Indeed, the pattern of results shows that for both the low-ability and high-ability groups, problems of moderate difficulty were aided by diagrams (Figure 2). "Moderate difficulty" was defined operationally as any diagram showing an overall proportion correct between .3 and .7 for a given ability group. For the below-median group, the problems of moderate difficulty were problems 1 and 4. As seen in Figure 2, problem solving was aided by provided diagrams in these problems but not for problems 2 and 3. A different pattern emerged for the above-median group. For this group of participants, a facilitative effect is shown for only problem 3, the most difficult problem. An interesting finding is shown for problem 1 in the above-median group. For this problem, providing a diagram (outcome tree) resulted in lower performance than not. It is possible that the outcome tree was not recognized by participants as an appropriate diagram for this problem; indeed outcome listings were spontaneously generated by students, both in the presence and absence of an outcome tree.

Figure 2. Dotted line shows results for Form A (diagram hints given for Problems 1 and 3); solid line for Form B (diagram hints for Problems 2 and 4).

Discussion

Successful problem solving in mathematics, and especially in PPS, depends on the construction of appropriate representations. External visual representations, including diagrams, are often used to aid in the comprehension and representation of problem information. Diagrams and other external visual devices that are used to comprehend and solve problems are commonplace in the field of

mathematics (e.g. Mayer, 1992). Previous research has conceptualized correctly" (309). Clearly, the nature of revealed that using these schema-specific diagrams can instruction contributes significantly to how students use facilitate successful probability problem solving (Russell, 2000; Zahner & Corter, 2010). In this study, we investigated whether the presentation of a diagram was related to problem solving success for each problem.

The participants in this study were novice probability problem solvers; they had only received instruction in PPS for a portion of the semester. We hypothesized that providing them with a schema-specific diagram would influence their success with the comprehension and a post-test improved significantly.

representation phases of problem solving. The vast majority of participants interacted with the provided diagram in some way. Some participants made marks on the diagram, and some participants drew a diagram of their own. A majority of the filled in the diagram with appropriate numbers and calculations. Many of the students used the diagram to organize and rewrite information. However, the students that used the diagram did not necessarily progress to the solution. We do not have sufficient evidence to conclude that providing a device particular to solving the problem is necessarily an aid to students at all ability levels. Overall, our results show that providing diagrams does not necessarily help students solve a problem successfully.

Our results show that provided diagrams are able to help low-ability and high-ability students differently (cf. Lowrie & Kay, 2001; Uesaka et al., 2007). High-ability participants may not have been helped by a diagram hint because they already possessed a schematic understanding of the problem. They may have generated their own diagram or used a mathematical formula to solve the problem. Low-ability participants, on the other hand, were helped on the less difficult problems only. We posit that providing a diagram hint helped them form a more complete schematic understanding of the problem and helped them achieve a correct solution. For problems beyond the grasp, however, providing a diagram hint did not help students. Future studies examining one type of diagram at a time could help provide information about the properties of the diagrams that make them more or less useful for schema appropriate for the problem. We interpret these results in the context of Vygotsky's zone of proximal development (Vygotsky, 1978). Providing a diagram hint on problems of moderate difficulty may be sufficient in helping students relate their current schematic understanding of specific types of probability problems to a solution schema while more assistance may be needed on problems of greater difficulty.

Abstract

A common misconception regarding evolutionary history is that the tree of life depicts the progression of species over time from least complex to most complex, ending with our own species at the pinnacle of evolution. The current study examined the diagrammatic factors that may impact the effect this misunderstanding has on students' ability to correctly interpret evolutionary trees. Students with weaker and stronger backgrounds in biology were presented with two cladograms, each featuring a different focal taxon (human or honeybee). The evolutionary relationships among the taxa were presented in four diagrammatic formats. Students reasoned in qualitatively different ways when asked about the human species as opposed to the honeybee, with specific diagrammatic formats facilitating anthropomorphic views, particularly among weaker background students.

Keywords: spatial cognition, teleological explanations, evolutionary diagrams, evolutionary misconceptions, cladograms, macroevolution

Introduction

There is a wealth of evidence that indicates students have great difficulty acquiring evolutionary concepts, particularly concepts regarding macroevolution and the origin of species. These studies have demonstrated that misconceptions are prevalent even among students with substantial training in the biological sciences (Ferrari & Chi, 1998; Greene, 1990; Samarapungavan & Weirs, 1997). A pertinent question is whether the tools that scientists use to study macroevolution are cognitively accessible and transparent to students of varying abilities, and whether there are perceptual or diagrammatic factors that potentially impede students' understanding of these tools in the absence of explicit instruction.

Tree thinking is a tool that professional biologists use to describe and classify species according to patterns of *most recent* common ancestry and to make inferences in the

absence of data (e.g., Angielczyk, 2009). Evolutionary trees, or cladograms, are based on hypotheses regarding the distribution of derived characters among a set of taxa; they provide biologists with a conceptual framework for understanding the historical processes that promote and maintain the biodiversity of our planet. Although intensive instruction on macroevolution and tree thinking is largely absent from high school and college biology classes (Catley, 2006), a recent analysis of textbooks indicates that biology students at both levels are exposed to cladograms (Catley & Novick, 2008). This poses a potential problem if students reason incorrectly about the evolutionary relationships depicted in those diagrams.

Researchers have only recently begun to examine what information students are able to extract from these diagrams, both in the absence of explicit instruction as well as after instruction. This research has focused on assessing tree-thinking skills when cladograms are drawn in the familiar hierarchical tree format or in an alternative ladder format (Catley, Novick, & Funk, accepted; Meir, Perry, Herron, & Kingsolver, 2007; Novick & Catley, 2010; Sandvik, 2008). The results indicate that students, regardless of instruction, find the tree format much easier to understand.

The current study builds upon this prior research by examining how the particular taxa depicted in the cladograms, and especially students' knowledge and/or beliefs about those taxa, affects tree thinking (i.e., cladogram interpretation). We used the simpler-to-understand tree format and manipulated how the cladograms were oriented and how the taxa were arranged (keeping the underlying structure—evolutionary relationships—constant across cladogram versions). In particular, this study explores the misconception that the tree of life depicts the progression of the evolution of taxa over time from least complex to most complex. If students reason incorrectly about the evolutionary relationships among taxa, they may

state that the most cognitively complex taxon (i.e., the human) is the most highly evolved. Feeding into this misconception is the widely held belief that humans are not subject to the same evolutionary pressures as other organisms because we were created intentionally by an outside agent (Evans, 2001; Greene, 1990) or created intentionally to fulfill a purpose (Kelemen, 1999; Kelemen & Rosset, 2008).

These considerations raise several questions: In the absence of explicit instruction, are students likely to perceive the evolution of specific taxa, such as the human, in teleological, or goal-directed, terms? Do students' responses differ depending on their biology background? Additionally, are students more likely to provide teleological responses when the focal taxon is located at the end of the cladogram versus when it is located in the center position? How does the vertical or horizontal orientation of the cladogram influence students' judgments?

Study Overview

The data presented here are part of a larger study that was designed to assess college students' reasoning about evolutionary history among several different subsets of taxa from the tree of life. The questions assessed, in several different ways, students' understanding of the evolutionary relationships among hierarchically nested sets of taxa. We limit our presentation here to one question that examined whether students' misinterpreted the information depicted in the cladograms by stating that the focal taxon was the most highly evolved. This question was asked about two cladograms, which differed in the focal taxon highlighted for subjects (human or honeybee).

The cladograms were drawn in four different ways: The cladogram itself was oriented either horizontally or vertically, and the focal taxon was situated either at one end of the cladogram (top or right) or in the center position among the set of nine taxa. Given students' teleological beliefs and misconception that humans are evolutionarily special, we predicted that students would be more likely to state that the focal taxon was the most highly evolved taxon when it was the human rather than the honeybee (see Figures 1 and 2). We also predicted that students would be more likely to make this claim when the focal taxon occupied the end (top or far right) rather than the middle position because a teleological construal would lead one to expect the most complex taxon to be at the end. Finally, because Franklin and Tversky (1990) have found that the vertical dimension is the most salient of the three spatial dimensions, we predicted that responses indicating that the human is the most highly evolved taxon would be most prevalent for the vertical orientation when human was situated at the top.

The main study included a sample of college students with weaker and stronger backgrounds in biology. In a follow-up study, a subset of the stronger background students received two days of instruction on phylogenetics

(i.e., understanding evolutionary trees). They were tested before and after instruction.

Method

Subjects

The subjects in the main study were 112 Vanderbilt University undergraduates. Most students (34 females, 33 males, 2 unknown sex) were recruited from a paid subject pool in the psychology department. The remaining students (23 females, 20 males) were currently enrolled in the evolution class at Vanderbilt (taught by the fourth author).

We divided the subjects into two groups based on their background in biology: Students who had completed at least the two-semester introductory biology sequence for biology majors and pre-med students were assigned to the stronger background group; the remaining subjects were assigned to the weaker background group. The 52 stronger background students (28 females, 24 males) completed an average of 3.09 semesters of biology classes that were chosen from a list of classes presented on a background questionnaire. The 60 weaker background students (29 females, 29 males, 2 unknown sex) had completed an average of only 0.40 semesters of such coursework. This is nearly an 8:1 difference in coursework between the groups.

Materials and Procedure

All students received a 4-page booklet that included one cladogram and two to three questions about the information in that cladogram on each page. The presentation order of the cladograms was counterbalanced. Students completed this booklet, as well as several other booklets, in one session that took approximately 50-75 min.

Each cladogram included nine taxa. One taxon was the focal taxon, so named because the first question for each cladogram asked students what the diagram shows about the evolution of that taxon. (Subjects provided a written response to that question.) We limit our discussion here to the third question that was asked about the two cladograms for which human and honeybee were the focal taxa. This question asked students which taxon/taxa was/were the most highly evolved. (The second question asked students to evaluate the relative evolutionary distance between pairs of taxa. This question did not reference the focal taxon and did not bear on the present results).

Design

We examined three factors in the present study. One factor was weaker versus stronger biology background. We were interested in whether a year-long introductory class (and perhaps subsequent biology coursework) would countervail stronger background students of a teleological perspective on evolution.

The remaining two factors pertained to the visual presentation of the cladograms. The first of these factors was the orientation of the cladogram, which was

manipulated between subjects. The terminal branches were either located at the right side of the cladogram (vertical orientation, Figure 1) or at the top of the cladogram (horizontal orientation, Figure 2). The second factor was the rotation of the branches of the cladogram. The branches were rotated, without altering the depicted relationships (i.e., the underlying topology), so that the focal taxon was located either at the end (far right or top, depending on the orientation; see Figure 1) or at the center position (see Figure 2). In Rotation Set 1, human was located at the end position whereas the honeybee was in the middle. In Rotation Set 2, the human was in the middle and honeybee was at the end. Rotation set was manipulated between subjects. We fully counterbalanced the orientation and rotation of the cladograms (see Figures 1 and 2 for two of the four possible combinations).

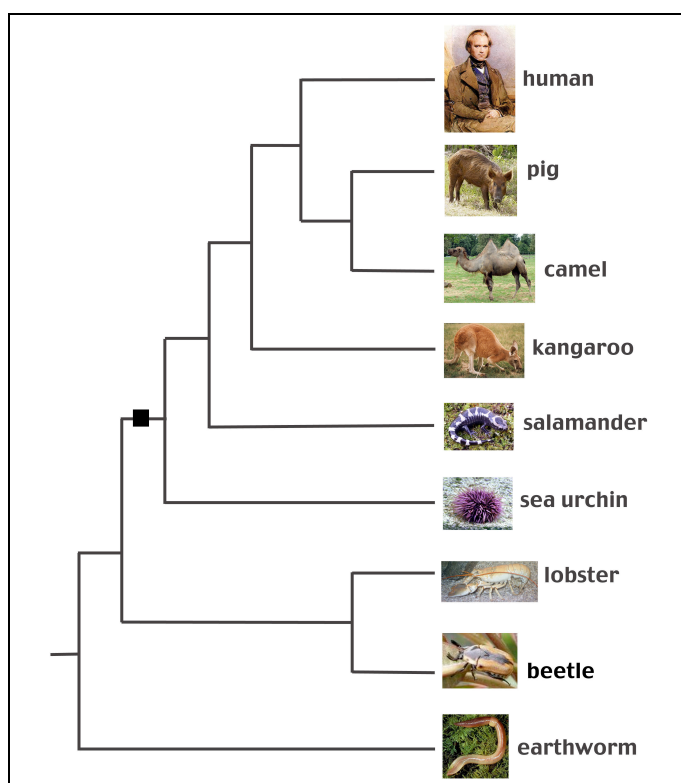

Figure 1: Human cladogram—vertical orientation, focal taxon at the end.

Follow-Up Study

We also examined whether students' evolutionary concepts were amenable to instruction by providing a subset of the students in the stronger biology background group ($N = 42$) with two days of instruction in phylogenetics (i.e., understanding cladograms). These students were recruited from their evolutionary biology course and completed the cladogram booklets at mid-semester (Time 1) and again 4.5–5 weeks later (Time 2). Students received the same booklet at both times.

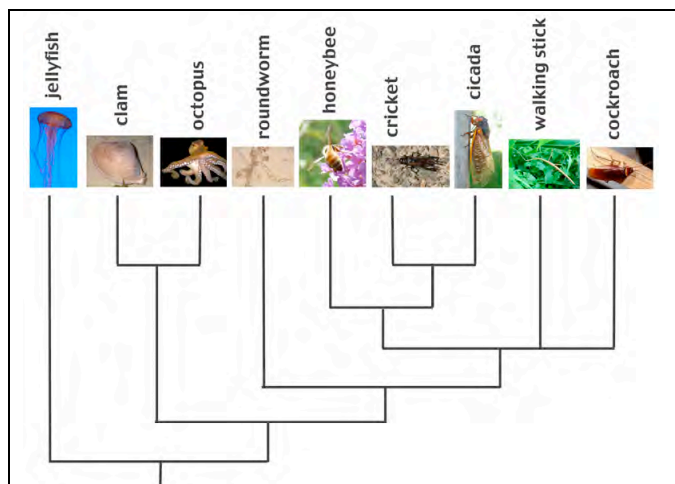

Figure 2: Honeybee cladogram—horizontal orientation, focal taxon in the middle.

Results

Are Humans Most Highly Evolved?

Students received a score of 1 if they indicated that the focal taxon (i.e., human or honeybee) was the most highly evolved species or a score of 0 for any other response. Overall, only 6% of students (all stronger background) responded correctly that the human cladogram did not reveal that any taxon was more highly evolved than any other taxon. In comparison, 5% of students (all stronger background) provided a correct response to this question regarding the honeybee.

As discussed earlier, we expected more responses that the focal taxon was most highly evolved when that taxon was the human as opposed to the honeybee. The results support this prediction, with 35% of students providing this response for the human cladogram, compared with only 2% (2 students, both from weaker backgrounds) for the honeybee cladogram, ($\chi^2 = 42.32$, $p < .001$). Because students essentially never said that the honeybee was the most highly evolved taxon, we restricted our analysis of the effects of the diagrammatic factors on these responses to the human cladogram.

We conducted a 2 (biology background; between) \times 2 (orientation; between) \times 2 (rotation set = human at the end vs. in the middle; between) analysis of variance (ANOVA) on the responses that the human was the most highly evolved taxon. The main effect of biology background, $F(1, 104) = 17.20$, $p < .001$, $MSE = 0.17$, partial $\eta^2 = .14$, indicated that weaker background students were more likely to make this incorrect claim than were stronger background students ($M = 0.50$ vs. $M = 0.19$, respectively). The main effect of focal taxon location (rotation set), $F(1, 104) = 20.17$, $p < .001$, partial $\eta^2 = .16$, indicated that a higher proportion of students made this claim when the human was

positioned at the end of the array than at the center ($M = 0.52$ vs. $M = 0.20$, respectively).

There was also a biology background \times orientation interaction, $F(1, 104) = 6.55$, $p < .05$, partial $\eta^2 = .06$. This interaction was subsumed by a three-way interaction between biology background, focal taxon location, and orientation, $F(1, 104) = 4.02$, $p < .05$, partial $\eta^2 = .04$ (see Figure 3). When the human was located in the middle of the cladogram, weaker background students said humans are most highly evolved 35% of the time, compared with 0% of the time for stronger background students. Cladogram orientation had little effect. When the human was located at the end, however, both groups of students said that the human was most highly evolved, with such responses being especially prevalent for weaker background students who received the vertical orientation. Indeed, 92% of these students said that humans were most highly evolved, compared with only 40% for the other three groups combined.

Figure 3: Proportion of students who claimed the human was the most highly evolved taxon as a function of biology background, focal taxon location, and cladogram orientation.

To examine the effects of instruction on students' phylogenetic conceptions, we conducted a 2 (orientation; between) \times 2 (rotation set = human at the end vs. in the middle; between) \times 2 (test: Time 1 vs. Time 2; within) mixed ANOVA on the responses that the human is the most highly evolved taxon. These students comprised a subset of the stronger background students from the main study. The analysis revealed a main effect of time of test, $F(1, 38) = 6.18$, $p < .05$, $MSE = 0.05$, partial $\eta^2 = .14$. Students were less likely to claim that the human is the most highly evolved taxon after having received two days of instruction on phylogenetics ($M = 0.17$ vs. $M = 0.05$, respectively, for before vs. after instruction). There was also a time of test \times focal taxon location interaction, $F(1, 38) = 6.18$, $p < .05$, $MSE = 0.05$, partial $\eta^2 = .14$. Students only claimed that the

human was the most highly evolved taxon when it was presented at the end (top or right) of the cladogram. Under these conditions, students were less likely to state that the human was the most highly evolved taxon after instruction ($M = 0.10$) than before ($M = 0.33$). Students never responded that the human was the most highly evolved taxon when it was presented in the middle position.

Students' Justifications

After indicating which taxon was most highly evolved, students were asked to provide an explanation for their response. We are in the process of devising a coding scheme to examine these qualitative data. In the following paragraphs, we provide a subset of the responses students wrote for the explanation question for illustrative purposes.

Consistent with our hypotheses, students who indicated that the human was the most evolved taxon frequently stated that a) the cladogram presented the progression of evolution across species and time, and b) presented an array of organisms, from least complex to most complex. For example, students provided statements such as, "The general assumption is that with every further deviation from the evolutionary chain, organisms develop more complete biological systems (esp. nervous systems)", "We have complex language & highly developed social systems", or "we are the only sentient beings on earth." Students also made comparative statements such as "I'm arrogant [*sic*] enough to believe [that] I'm more evolved than livestock" or "they are the last animal in the chart. I am, as a person, more evolved than a pig."

Students also provided evidence that they were reasoning about phylogenetic concepts, albeit incorrectly: "humans have diverged from the most basic common ancestor the most times out of all the animals shown", "humans are at the top of the diagram and they display the most specified method of evolution in the diagram", or "humans are the organism which most recently evolved." Interestingly, sometimes students provided conflictive statements such as, "from the chart I would say pig & camel, but I'm biased to say human" or "humans have to be the most highly evolved (regardless of the structure of the diagram)." Additional analyses will examine whether stronger and weaker background students provided different types of justifications for incorrect responses.

The aforementioned statements were qualitatively different from those that students provided for correct responses. For example, students who indicated that no taxon was more highly evolved than any other taxa made statements such as, "the diagram only shows the evolutionary relationships not how much each species has changed over time" or "these trees just show genetic similarity and hypothetical common ancestors. All the organisms have radiated into different niches, from the labeled hypothetical common ancestor." As stated previously, only a very small minority of students with stronger backgrounds in biology provided correct responses.

Discussion

The current study provides critical information regarding the use of cladograms for educational purposes. In the absence of instruction, both students with weaker and stronger backgrounds in biology misinterpreted the information depicted in cladograms when asked to evaluate which taxon was the most highly evolved. An important finding is that the cladograms had different effects on students' reasoning depending on the format in which they were presented and the biology background of the students.

As expected, students provided more teleological responses and explanations for the human cladogram than the honeybee cladogram. In fact, students essentially never stated that the honeybee was the most highly evolved taxon despite the fact that the two taxa occupied identical locations in their respective cladograms. Students provided justifications that indicated that they perceived the human as the most complex organism in the array, and therefore the most highly evolved.

Previous research has found that college students endorse scientifically unwarranted explanations for the occurrence of natural phenomena (e.g., "Finches diversified in order to survive"), especially when placed under a high cognitive load (Kelemen & Rosset, 2009). These studies indicate that adults, like children (see Carey, 1985; Keil, 1994; Kelemen, 1999), ascribe to teleological explanations for the existence of biological natural kinds and prefer these explanations to physical-causal explanations. These beliefs are suppressed under certain conditions, such as when students are provided with alternative explanations and are provided with ample time to think about the phenomena in question. However, under cognitively demanding circumstances, these unwarranted scientifically beliefs prevail.

Our results are consistent with these earlier studies and provide new information concerning the perceptual or diagrammatic factors that either promote or lessen students' appeal to teleological interpretations of evolutionary diagrams. We reasoned that students who conceived of evolutionary processes as goal-directed would expect the most complex taxon to occupy an end position. As predicted, students were more likely to state that the human was the most evolved taxon when it occupied the end position rather than the center position. Students with stronger backgrounds in biology only said that the human is the most highly evolved taxon when it was depicted at the end of the set of taxa. Instruction in phylogenetics reduced such responding to only 10% of students.

Teleological responses were most prevalent for weaker background students when interpreting the vertically oriented cladogram with the human located in the top position. One possible interpretation of these results is that students used spatial location to evaluate evolutionary relatedness; that is, they inferred the taxon at the highest vertical point was the most complex. These results are consistent with the embodied cognition perspective that states that individuals orient themselves vertically in

reference to elements of the environment, such as the sky and ground (Franklin and Tversky, 1990).

Given that high school and college students in the United States are currently exposed to cladograms in their biology textbooks, and perhaps from their instructors in class as well, our results indicate that it is essential that textbook illustrators and instructors consider the perceptual or diagrammatic factors that impact students' understanding of evolutionary processes. In particular, our results indicate that the horizontal cladogram format is preferable to the vertical format. Moreover, because cladogram branches can be rotated without changing the underlying structure (i.e., the evolutionary relationships depicted; just as the turning branches of a mobile in the wind do not change the structure of the mobile), when cladograms include taxa that may play into students' teleological misconception of evolution, it is critically important to present those taxa in a horizontal order that suppresses activation of this misconception. For example, more complex taxa should be located in the middle rather than the end, and there should be little or no correlation between the linear ordering of the taxa across the terminal branches of the cladogram and students' conceptions of complexity.

Abstract

Many planning tasks involve complex reasoning about time: what must happen in sequence and what may happen in parallel. One hundred ten online participants were provided with a simple planning scenario (to design a calling tree) and asked to manipulate different diagrammatic representations of the problem. More important than the initial representation was the participants' transformed representations: if time was encoded in the lengths of tree links then inference was more accurate. This finding suggests that diagram transformation may be a useful way to elicit representation strategies, and that such transformations from different starting conditions may be useful as diagnostics and as design aids.

Keywords: diagram understanding, design, topological diagrams, representation of time, distributed computing

Introduction

To solve problems or to simply organize information, people often make diagrams. Diagrams can aid problem solving and information organization by spatializing the essential concepts and relations among them. One of the most abstract kinds of diagrams is a network, where nodes are concepts and links are relations. Because of their generality, network diagrams appear in many diverse domains.

The advantage of networks, their ability to represent so many different relations, is also a disadvantage, because they may not make problem constraints apparent. Often, problems and information have more constraints than the

simple binary relations used in networks, constraints that would allow inferences, for example, asymmetric relations. Certain variants of networks can represent such constraints. Trees, for example, are commonly used to represent asymmetric or hierarchical relations, notably for structural relations such as organization charts or phylogenetic relations. They are also used to represent temporal relations, as in decision trees or flow diagrams. For structure, the links indicate an asymmetric structural relation, such as control in corporations or *kind of* in phylogenies. For time, the links indicate asymmetric temporal relations, at an ordinal level: this, then this, then this.

However, there are situations where representing both structural and temporal relations is desired, for example, in coordination situations where a set of agents carry out a temporally constrained set of actions. Representing both structural and temporal organizations simultaneously presents a challenge. The structure – who contacts whom – needs to be represented. Also the timing – the temporal ordering of contacts – must be shown. Links can be used for the structural information, but some other aspect of the diagram needs to be used for the temporal. Representing both structure and time simultaneously can be all the more challenging when *metric* properties of time are important because links in networks are typically used to indicate a relationship, but not the degree of a relationship.

These problems of representation are, more broadly, problems of cognition: as the data will show, reasoning

about coordination is difficult. Given the high cost of coordination failure in a number of different fields, and the everyday importance of coordination in computational fields, the problem deserves attention. Previously, studies have been performed on the way network diagrams convey information. For example, it has been shown that distance along network links is used to evaluate content similarity (Fabrikant, Montello, Ruocco, & Middleton, 2004). That study focused on the way distance and topology map to similarity; here we focus on the way distance and topology map to structure and time.

We turned to users to see how they would represent space and time simultaneously. Often, users turn out to be good designers, inventing clever devices to represent abstract information (e. g., Kessell and Tversky, 2008; Tversky, in press). Furthermore, their visualizations of thought are a window to thought (e. g., Tversky and Lee, 1999). The other side of successful design is comprehension. We have begun exploring how people design and comprehend diagrams and solutions for a class of problems that requires representing both structure and time (see Figure 1).

The paradigm we have been using is based on a distribution tree. Because the problem is a general one of transmission of something from one party to many, it applies to many situations when information or goods are distributed. For example, a telephone tree can be used to distribute information about a school closing due to weather conditions. For speed of transmission, it is better to distribute the callers; for reliability, it is better to minimize the number of callers. Solutions, then, depend both on structure and on time. Although some forms of trees, such as decision trees and flow diagrams, are used to represent time, they only represent temporal *order*. In contrast, optimizing a distribution tree depends on *metric* properties of time as well. Thus, diagramming a distribution tree solution not only requires representing both structure and time, it also requires representing time metrically. An added difficulty for designers and for users in producing or interpreting designs for distribution trees is that several calls can happen at the same time. That is, both sequence and parallelism need to be represented and understood.

In extensive pilot work, we have found that people spontaneously create trees to solve these problems, but that their trees usually represent structure, that is, who contacts whom, and rarely represent time. In fact, representing or grasping structure from diagrams is easier and more straight-forward than representing or grasping changes in structure, such as changes in time (e. g., Suwa & Tversky, 1997; Tversky, Heiser, Lozano, Mackenzie, & Morrison, 2008). More generally, space seems to serve as a metaphor for time more readily than time for space (Boroditsky, 2000).

For the telephone tree problem, structure is ordinal, but time is metric. There are several ways to superimpose time onto a network representing structure. Telephone trees are tricky because a single agent can make only one call at a time, but several agents can call simultaneously. One way to

represent time, illustrated in Figure 2, is to use length of link, as in additive similarity trees (Sattath & A. Tversky, 1977; Corter, 1996). In this representation, the lengths of the links emanating from any one agent indicate the sequence of that caller's calls. For large trees, this can be visually confusing. Another method to represent time is a combination of using levels of a tree to distinguish when a caller is first notified, and within levels, showing the sequence of calls made by a caller using a left-to-right first-to-last convention; this is visually more organized but requires keeping track of two spatial mappings to assess time. Both methods have been invented by our participants. Here, we investigate solution success when time is or is not represented by length of line.

As noted, users can be effective designers of visualizations of problems. Does the very process of designing visualizations facilitate using them? Architects and other designers sketch designs, study their sketches, get new insights, and revise them, a positive, productive cycle that has been likened to a conversation (Schon, 1983). Creating and revising visualizations of a range of complex concepts, for example, scientific ones, has been shown to increase depth of understanding (e. g., diSessa, Hammer, Sherin, & Kolpakowski, 1991; Schwartz, 1995).

The present experiment examines the dual roles of kind of design and act of designing for solving telephone tree problems. Participants were given a problem analogous to the guard problem and then asked to provide an optimal diagram and to compute the amount of time it should take to notify everyone. They were given an initial diagram, one they could alter, to create a diagram they regarded as optimal. For some participants, the initial diagram represented structure but not time. For others, the initial diagram represented time using proportional length of line. For a third group, the initial diagram varied in line length but not proportionally to time; thus this diagram provides a hint that line length might be helpful, but not how.

This design allows asking a set of questions. We can ask whether representing time explicitly in a visualization makes for a more effective diagram that better helps users to solve a telephone tree problem. We can ask whether time is more likely to be explicitly represented in user diagrams when the starting diagram provided to them uses variable line lengths, either compatible with time or incompatible with time.

Method

One hundred ten participants accepted and completed an assigned task in return for payment on Amazon's crowdsourcing marketplace. The participants in Amazon's pool have been characterized extensively in several previous studies: the pool is 55% female with a mean age of 31 (Kittur, Chi, & Su, 2008; Ross, Irani, Silberman, Zaldivar, & Tomlinson, 2010). Participants were presented with the following textual description:

Please read the following question and then make changes to the diagram.

Hart has the job of notifying 4 other parents in the event that school is called off due to weather conditions. Hart has created a plan for a sequence of phone calls:

Hart calls Dean and then Lane. Dean calls Boyd and then Ward.

Assuming that each phone call lasts one minute, please go to the website below to make changes to the diagram to meet the plan description.

Once they had saved the diagram, they were asked:

Assuming that each call lasts one minute, how many minutes will elapse before all parents know about the school cancellation?

Participants were randomly assigned one of the following three diagrams shown in Figures 1, 2 and 3. Figure 1 is a typical tree structure. The connections indicate who calls whom, using uniform line lengths. In a pilot study, most participants drew such a diagram.

Figure 1: A uniform tree with no time encoding

Figure 2: A time-encoded tree with edge lengths consistent with the problem description

In Figure 2, time has been encoded into the lengths of the connections between nodes. That is, after one minute, Hart has managed to talk to Dean. After two minutes, Hart has also managed to talk to Lane, and Dean has talked to Boyd.

The lengths of the connections reflect the constraint of the problem, that a person can only have one phone conversation, and so time has elapsed after each conversation. We found in a paper and pencil pilot study that some participants invented or at least used this representation. It is similar to diagrams used in transportation systems called space-time networks, in which nodes are lined up according to elapsed time (e.g., Pallottino & Scutella, 1998).

In Figure 3, variable edge lengths are used, but the vertical position of a node is not consistent with elapsed time in the problem. For example, in the problem statement, Dean calls Boyd before calling Ward, and the vertical arrangement of Figure 3 implies the opposite order. Thus, the diagram may cue individuals to the possibility of using connection length to represent time, but is not useful in representing the problem (and may even be misleading) unless it is transformed.

Figure 3: A time-encoded tree with edges inconsistent with the problem description

After being randomly assigned one of the three diagrams above, participants were provided instructions on how to use a customized web-delivered vector-based drawing tool to move nodes, thereby manipulating spacing in the diagram. In the tool, the connections between the nodes are preserved as the nodes are moved. The participants' mouse movements were recorded. Thus, the experiment allows us to study the effect of the initial diagram provided, the cuing representation. In addition, the participants' transformed diagrams can be classified, and the relationship between these produced diagrams and the accuracy of problem solving shown.

Results

A total of 32 participants were cued with the uniform tree of Figure 1, 38 with the consistent time tree of Figure 2, and 40 with the inconsistent time tree of Figure 3. The overall accuracy of their answer to the time question as a function of cuing diagram is shown in Figure 4 as a proportion. The consistent time tree was associated with the highest accuracy (.66), and the inconsistent time tree with lowest accuracy (.48); the uniform tree produced an intermediate level of accuracy (.53). In a logistic regression model comparing accuracy for these three conditions, cuing with the time tree yielded marginally higher accuracy than the uniform tree (Wald = 2.618, $.05 < p < .10$, one-tailed) and cuing with an inconsistent time tree produced marginally lower accuracy than the other two trees (Wald = 1.983, $.05 < p < .10$, one-tailed).

Figure 4: Accuracy of the answer depending upon the randomly provided starting diagram

The final tree diagrams produced by the participants were then classified into three sets: Uniform Trees, Time Trees, and Wrong Trees. Wrong trees could only result if participants used the drawing tool to change the topology of the graphs by adding or subtracting nodes. For example, one participant directly linked Dean to Lane, as in Figure 5.

Figure 5: A topologically incorrect tree (Wrong Tree)

The rest of the participants created two kinds of topologically valid trees. Those producing Uniform Trees

showed no attempt to encode time through distance, while those producing Time Trees did. Classifying the trees was straightforward, because the uniform trees tended to have uniform distances, and in particular equal distances between parents and direct descendants. We checked inter-rater reliability of the coding of the produced graphs by training two raters on 15 graphs and then testing on 43 graphs: Cronbach's alpha = .99. Figure 6 shows examples of the produced trees.

Figure 6: On the left, a produced uniform tree transformed from a given consistent time tree, and on the right, a consistent time tree transformed from a uniform tree.

Figure 7 shows accuracy, as a proportion of participants' time estimates by type of produced diagrams. For example, the left-most blue and tan bars show that 73% of those who produced time trees when provided with uniform trees calculated the correct answer, whereas 50% of those who produced a uniform tree in that same condition calculated the correct answer.

Figure 7: Accuracy of the answer depending upon the diagram produced by the participant, grouped by the starting diagram.

The number of participants in each category can be found in Table 1, which lists the accuracy for each category, the number of participants in each category, and the totals. The

accuracy of those who produced Time Trees was significantly greater than those who produced Uniform Trees, $\chi^2(1) = 7.58, p < .01$.

Table 1: Mean accuracy (and frequency) for combinations of given and produced trees

		Starting diagram			
		Uniform Tree	Consistent Time Tree	Inconsistent Time Tree	Overall (Total)
Produced diagram	Uniform Tree	.50 (18)	.46 (13)	.29 (17)	.42 (48)
	Consistent Time Tree	.73 (11)	.76 (21)	.85 (13)	.78 (45)
	Inconsistent Time Tree	-- (0)	-- (0)	.00 (4)	.00 (4)
	Wrong Tree	.00 (3)	.75 (4)	.50 (6)	.46 (13)
	Overall (Total)	.53 (32)	.66 (38)	.48 (40)	

Even when presented with a consistent time tree, six participants altered the tree into a uniform tree. That is, some participants went out of their way to reconfigure the most effective diagram type to a simpler type. On the other hand, eleven participants changed the inconsistent time tree to a consistent time tree, and these participants achieved the highest accuracy shown in the table: 85% got the problem right.

Starting from the inconsistent time tree condition, four subjects produced inconsistent time trees. An example is shown in Figure 8: The tree is inconsistent because Boyd is called before Ward, yet Boyd is placed farther away from Dean than is Ward. These inconsistent trees occurred in no other condition. More broadly, from an examination of the drawing logs, we found that participants will sometimes just modify a diagram slightly, as opposed to drastically or not at all.

Figure 8: An inconsistent time tree, transformed from an inconsistent time tree.

Discussion

One hundred and ten participants were asked to diagram and solve a telephone tree problem, that is, determine the structure of a call tree that would notify everyone the fastest, and then to use the call tree to compute the total time to call everyone. The implicit challenge was to design a diagram that simultaneously represented both the structure of the telephone tree and the time to accomplish the plan. To

assess the effects of cuing, participants were given one of three starting diagrams representing the structure of the plan: one that did not represent time; one that represented time with line lengths proportional to time; one that represented time with line lengths inversely proportional to time. There were two critical questions. Would diagrams that represent time lead to better solutions? Would cuing with a time diagram improve designs and solutions?

Those participants who created a diagram that represented time with line length were far more successful at computing the total time to call all agents than those who produced diagrams that did not represent time. Although diagrams not representing time and even some that represented time in a confusing way could be used to compute the correct solution, explicitly representing time led to large increases in correct solutions. Thus, using a diagram that directly represents all the information needed to compute the answer facilitates computation and performance.

Cuing participants with starting diagrams that did or did not represent time in a compatible way, that is, using line length proportional to time, had effects, if small, on successful solution, mediated by the final diagram participants produced.

The results show that reasoning about parallel and sequential events is difficult. Presented with a simple example involving a small number of nodes, participants in the study failed to infer the total time of a process about half the time. Presenting a diagrammatic representation that encodes time helped some, as did manipulating a diagram into a representation that encoded time.

There are implications for diagram design as well as diagram use. First, people do not always design diagrams that capture all the essential components of a situation or a problem. The present project elucidates one reason for the failure: some features of situations or problems are more readily spatialized than others. Importantly, space and structure, static relations, are more likely to be represented in diagrams and more likely to be interpreted correctly than more abstract features such as time. Representing structure and time simultaneously is especially difficult, all the more so because independently, each would select the same diagrammatic feature, lines linking nodes to nodes. Finding a second diagrammatic feature to represent the second variable, in this case time, is a challenge if only because time is unidimensional, best represented as a single line. Producing the right diagram, just like producing the right mental representation, facilitates problem solving.

Constructing internal diagrammatic proofs from external logic diagrams

Yuri Sato, Koji Mineshima, and Ryo Takemura

Department of Philosophy, Keio University
 {sato, minesima, takemura}@abelard.flet.keio.ac.jp

Abstract

Internal syntactic operations on diagrams play a key role in accounting for efficacy of diagram use in reasoning. However, it is often held that in the case of complex deductive reasoning, diagrams can serve merely as an auxiliary source of information in interpreting sentences or constructing models. Based on experiments comparing subjects' performances in syllogism solving where logic diagrams of several different forms are used, we argue that internal manipulations of diagrams, or what we call internal constructions of diagrammatic proofs, actually exist, and that such constructions are naturally triggered even for users without explicit prior knowledge of their inference rules or strategies.

Keywords: External representation; Diagrammatic reasoning; Logic diagram; Deductive reasoning

Introduction

People have tried to enhance reasoning abilities by the use of artificial devices since ancient times. In particular, symbol manipulation is a distinctive tool-use of human beings. Certainly, symbolic logic may be considered to be a tool for deductive reasoning. However, it should be noted that symbolic logic (e.g., first-order logic) is not always a usable system for untrained people. By contrast, visual-spatial representations are considered to be much more intuitive and effective for novices' actual reasoning. Consequently, over the past few decades, many researchers have shown an interest in the efficacy of diagrammatic reasoning (e.g. Allwein & Barwise, 1996; Glasgow, Narayanan, & Chandrasekaran, 1995).

An important assumption in the study of diagrammatic reasoning is that diagrams are syntactic objects to be manipulated in certain ways; we make an inference about a diagram itself, transforming it into another form or combining it with other diagrams. Such syntactic manipulations of diagrams play a crucial role in accounting for their efficacy in deductive problem solving. For example, consider the following process of checking the validity of a syllogism using Euler diagrams.

Figure 1: A diagrammatic proof of syllogism *All A are B, No C are B; therefore No C are A* with Euler diagrams.

The premise *All A are B* is represented by D_1 , and the premise *No C are B* by D_2 . By unifying D_1 with D_2 , we can obtain diagram D_3 . Here the exclusion relation holds between circles A and C, from which we can extract the correct conclusion

“No C are A”. In what follows, we call such a syntactic manipulation of diagrams to derive a conclusion of deductive reasoning a *construction of a diagrammatic proof*. The point here is that by unifying two diagrams in premises and observing the topological relationship between the circles, one can *automatically read off* the correct conclusion. Shimojima (1996) calls this a “free ride” property, and shows that it can be seen to exist in other kinds of diagram use in reasoning and problem solving.

In general, a deductive reasoning task would be easy if it could be replaced with a task of constructing a concrete diagrammatic proof. Typically, such a construction is supposed to be triggered by external diagrams and carried out internally, without actual drawing or movement of physical objects. However, the existence of such internal manipulations of diagrams has been the subject of controversy (see, e.g. Schwartz, 1995). Indeed, it is widely held that diagrams can serve merely as a memory-aid or an auxiliary source of information in deductive problem solving. Thus, Larkin and Simon (1987) argue that reasoning is largely independent of ways of representing information, hence diagrams are less beneficial in reasoning. Bauer and Johnson-Laird (1993) discuss efficacy of diagrams in deductive reasoning with double disjunction and argue that diagrams are used to keep track of alternative models, as postulated in mental model theory. Also in many logic textbooks, diagrams are used to depict models and aid understanding of logical representations, rather than as objects of syntactic manipulations.

In view of this situation, it is of central importance to investigate whether internal manipulations of diagrams really exist in actual reasoning with diagrams. Trafton and Trickett (2001) argue that there are mental processes of “spatial transformations” to extract information from graphs or visualization, based on an analysis of how expert scientists collect data in their researches. Shimojima and Fukaya (2003) and Shimojima and Katagiri (2008) argue for the existence of “inference by hypothetical drawing”, internal transformations of external diagrams, based on eye-tracking data of subjects working with position diagrams in transitive inferential tasks. In this paper, we focus on more complex deductive reasoning tasks, namely, syllogistic reasoning tasks, and on the effects of logic diagrams externally given therein. We present evidence for the existence of internal constructions of diagrammatic proofs, on the basis of experiments comparing subjects' performances in syllogism solving where logic diagrams of several different forms are given. Our claim is consistent with the influential view in the study of external representations in general, namely, that (a) external representations can be used without being interpreted, and that (b) they can change

the nature of tasks, namely, tasks with and without external representations are completely different from users' point of view (see Zhang & Norman, 1994; Scaife & Rogers, 1996).

The efficacy of logic diagrams has been investigated in the context of the studies of logic teaching method (Stenning, 1999; 2002; Dobson, 1999). In these studies, subjects are provided with substantial training in ways of manipulating diagrams. In contrast to this, our interest is in the question whether diagrams can be useful for those who are not trained in rules or strategies of diagrammatic deductive reasoning. This question is important because, in contrast to logical formulas in symbolic logic, logic diagrams in general have been expected to be much more intuitive and effective for novices' reasoning, not for experts' nor for machine reasoning. In view of the complexities of solving processes of deductive reasoning (e.g. Levesque, 1988), it is interesting to ask whether logic diagrams can have this surprising property.

Logic diagrams have also been studied in the field of formal diagrammatic logic since the 1990s (e.g. Shin, 1994; Howse, Stapleton & Taylor, 2005), and inference systems for various diagrams such as Euler and Venn diagrams have been developed. Currently, however, there are few empirical researches to investigate their cognitive foundations. Our study is also intended to provide a bridge between logical and cognitive studies of diagrammatic reasoning.

Cognitive model for reasoning with diagrams

Typical examples of deductive reasoning problems with external logic diagrams are shown in Figure 2.

Figure 2: Examples of syllogistic reasoning tasks with diagrams

Here a syllogism is presented with logic diagrams (Euler and Venn diagrams). How can such diagrams contribute to checking the validity of a deductive argument? Let us first hypothesize a cognitive model of deductive problem solving with diagrams. The model is shown in Figure 3. This model highlights two roles of diagrams in deductive reasoning.

Regarding sentential reasoning, we assume a standard two-staged framework in natural language semantics (see, e.g. Blackburn & Bos, 2005), according to which sentences are first associated with semantic information, and then the validity of the argument is checked using some inferential mechanisms (such as model-theoretical or proof-theoretical ones). The details and precise nature of such linguistic comprehension and inference are not our concern here.

Diagrams are also associated with semantic information, but at the same time they are syntactic objects to be manipulated in reasoning processes. We distinguish two ways in which diagrams can be effective in deductive reasoning.

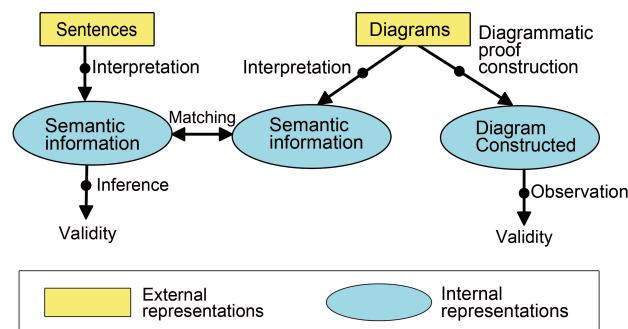

Figure 3: Cognitive model for diagrammatic reasoning

Interpretational efficacy Firstly, diagrams can help fix the correct interpretations of sentences and thereby avoid deductive reasoning errors due to misinterpretation. For example, a sentence “All A are B” is sometimes misinterpreted as equivalent to “All B are A”. This is known as *illicit conversion error* in the literature (e.g. Newstead & Griggs, 1983). Subjects presented with diagrams such as the ones in Figure 2 could immediately see that the diagrams corresponding to these two sentences are topologically different, and hence deliver different semantic information. In our model, such processes are formulated as processes of matching the semantic information obtained from diagrams with the one obtained from sentences. In this case, the validity of an argument is checked based on the same kind of process as the one in linguistic reasoning. Here diagrams are used in a static way, merely as a record of information (Barwise & Etchemendy, 1991).

Inferential efficacy Secondly, and more importantly, diagrams can play a crucial role in reasoning processes themselves. More specifically, the solving processes of deductive reasoning tasks can be replaced with internal manipulations of diagrams. In other words, one can check the validity of a deductive argument by means of constructions of diagrammatic proofs. The above model assumes that such constructions are conducted through a proof-theoretical component of diagrammatic reasoning. If a task of constructing diagrammatic proofs consists of simple and intuitive steps, it is expected to be more tractable than usual linguistic inferences.

It seems to be generally agreed that logic diagrams have interpretational efficacy. For example, Stenning (2002) argues that (a)symmetry of diagrams can aid processing of the meaning of quantified sentences in syllogisms. Mineshima, Okada, Sato, and Takemura (2008) presented experimental evidence for such interpretational effects, based on a comparison of the performances of syllogistic solving tasks with and without Euler diagrams. In what follows, we assume that logic diagrams can have interpretational efficacy, and investigate whether they can have inferential efficacy as well.

General Hypothesis

Based on the above model, we propose the following general hypothesis: (1) logic diagrams can have inferential efficacy, that is, internal constructions of diagrammatic proofs occurs

in deductive reasoning with external logic diagrams, and (2) certain diagrams would naturally trigger such constructions so that even users without explicit prior knowledge of inference rules or strategies could correctly manipulate diagrams.

One way to test our hypothesis is to compare performances of deductive problem solving with several distinct diagrams which are equivalent in semantic information but are of different forms, namely, ones that have a form suitable for diagrammatic proof constructions and ones that do not. A basic assumption here is that the existence of internal constructions depends on the forms of diagrams given, and on the simplicity or naturalness of the required diagrammatic proofs. If subjects' performance with diagrams of a form suitable for diagrammatic proof constructions would be significantly better, it could count as evidence for the existence of such constructions in subjects' reasoning.

To test the claim in (2), subjects in our experiments were presented with instructions on the meaning of categorical sentences and diagrams used, but not with any instruction on rules or strategies of constructing diagrammatic proofs. We expect that if certain diagrams have inferential efficacy, it would be exploitable based on their natural properties or constraints, rather than extra conventions. In other words, processes of constructing diagrammatic proofs as postulated in our cognitive model could be conducted without explicit knowledge of the underlying rule or strategies; such internal constructions could be naturally triggered based on the correct understanding of the meaning of diagrams.

Task Analysis

Conventional devices in Euler and Venn diagrams

In our experiment, we use the following three types of diagrams: Euler diagrams, Venn diagrams having two circles, which we call "2-Venn diagrams", and Venn diagrams having three circles, which we call "3-Venn diagrams". Typical examples are shown in Figure 4.

Figure 4: Representations of *All A are B* in Euler diagram (D_1), 2-Venn diagram (D_2), and 3-Venn diagram (D_3).

Euler diagrams used in our experiment are the ones introduced in Mineshima et al. (2008). Our system has the following features: (i) it uses a named *point* 'x' to indicate the existence of objects; (ii) it adopts a convention of *crossing*, according to which two circles which are indeterminate with respect of their relationship are put to partially overlap each other. Consequently, a single categorical statement can be represented by just a single diagram (see D_7 in Figure 5). This contrasts with another version of Euler system, which requires more than one diagrams to represent some categorical sentences, and hence has the well-known problem of combinatorial complexities (see chapter 4 of Johnson-Laird, 1983).

Figure 5: The diagrams corresponding to "Some A are not B" in traditional Euler system (D_4 , D_5 and D_6) and the one in our Euler representation system (D_7)

In Venn diagrams, every circle partially overlaps each other, as in D_2 and D_3 in Figure 4 and D_5 in Figure 5. Such diagrams do not convey any specific information about circles, hence are subject to the convention of crossing. Meaningful relations among circles are then expressed using a novel device, *shading*, by the convention that a shaded region denotes an empty set. For example, the statement "All A are B" is represented as D_2 or D_3 in Figure 4. Note that the same information can also be conveyed by the Euler diagram D_1 . Furthermore, 3-Venn diagrams use a link to connect points, which represent the disjunctive information about a point (see D_4^v and D_5^v in Figure 7 below).

Constructions of diagrammatic proofs

We compare syllogism solving tasks using these three types of diagrams in terms of difficulties in constructing the corresponding diagrammatic proofs. Deductive reasoning generally requires combining information in premises. Such a task could naturally be replaced by a task of combining presented diagrams. We expect that an inference process of combining diagrams is relatively easy to access, and accordingly, that an internal construction of a diagrammatic proof is naturally triggered if it consists only of such combining processes.

Reasoning with Euler diagrams As an illustration, consider a syllogism *All B are A*, *Some C are B*; therefore *Some C are A*. A solving process of this syllogism using Euler diagrams is shown in Figure 6.

Figure 6: A proof of syllogism using Euler diagrams.

Figure 7: A proof of syllogism using Venn diagrams.

In general, a diagrammatic proof of a syllogism with Euler diagrams consists of a step of combining premise diagrams, which we call a *unification* step. It is expected that unification steps are relatively easy to access, so that such constructions of diagrammatic proofs are naturally triggered.

Reasoning with 2-Venn diagrams A solving process in 2-Venn diagrams is illustrated in Figure 7, where the premise *All B are A* is represented by D_1^v , and the premise *Some C are B* by D_2^v . Since these two diagrams contain a different circle, in order to combining them while preserving the syntax of Venn diagrams, one needs to accommodate their circles. In this case, circle *C* is added to D_1^v , and *A* to D_2^v . Then, by superposing the shaded region of D_3^v on D_4^v , one obtains diagram D_5^v , from which the conclusion “Some *C* are *A*” can correctly be read off. Here we can see that a solving process in 2-Venn diagrams consists of two steps, which we call *addition* and *superposition*. Note that a process of combining Euler diagrams, namely *unification*, can exploit the movements of circles as in Figure 6, whereas a process of combining Venn diagrams, namely *superposition*, operates on premise diagrams with the same number of circles, and hence does not involve any movement of circles.

Reasoning with 3-Venn diagrams If we start the proof with the 3-Venn diagrams D_3^v and D_4^v in Figure 7, we can skip the steps of adding a circle as required in the case of 2-Venn diagrams. The only step needed is the *superposition* step, which is expected to be relatively easy to access.

Predictions

Intuitively, 2-Venn diagrams seem to be relatively difficult to handle in solving syllogisms. For in order to construct diagrammatic proofs from 2-Venn diagrams, one has to know the relevant inference rules and strategies in advance. More specifically one has to know the successive processes of adding a circle and superposing two diagrams, as indicated in Figure 7. We expect that those who are ignorant of such a solving strategy could not appeal to concrete manipulations of the diagrams. They seem to have to draw a conclusion solely based on usual linguistic inference, with the help of semantic information obtained from 2-Venn diagrams.

To test this point, we introduce set-theoretical expressions corresponding to Venn diagrams, such as $A \cap \bar{B} = \emptyset$ for “All *A* are *B*” and $A \cap B \neq \emptyset$ for “Some *A* are *B*”, as a control condition. We assume that they could only contribute to interpreting premises of syllogisms. Thus, they are used to check whether the effects of Euler, 3-Venn, and 2-Venn diagrams are interpretational or not.

In contrast to 2-Venn diagrams, both Euler diagrams and 3-Venn diagrams seem to be relatively easy to handle even for those users who are not trained to manipulate them in syllogism solving. The essential steps involved are unification and superposition steps. Given the fact that deductive reasoning generally requires combining the information in premises, these processes seem to be natural enough so that they would be immediately accessible to users. We expect that users could exploit natural constraints of diagrams and extract the right rules to draw a conclusion from Euler diagrams and 3-Venn diagrams themselves.

We will say that diagrammatic representations are *self-guiding* if the constructions of diagrammatic proofs are au-

tomatically triggered even for subjects without explicit prior knowledge of inferential rules or strategies. Then, our hypothesis amounts to saying that in syllogistic reasoning tasks, Euler diagrams and 3-Venn diagrams are self-guiding, whereas 2-Venn diagrams are not.

Based on these considerations, we predict that the performance in syllogism solving would be better when subjects use Euler diagrams or 3-Venn diagrams than when they use symbolic (set-theoretical) representations. We also predict that there would be little difference between the performance with 2-Venn diagrams and with the symbolic representations.

Method

Subjects are provided with instructions on the meanings of diagrams and then required to solve syllogistic reasoning tasks with diagrams. We conducted a pretest to check whether subjects understood the instructions correctly. The pretest was designed mainly to see whether subjects correctly understood the conventional devices of each diagram, in particular, the convention of crossing in both Euler and Venn diagrams and shading and linking in Venn diagrams.

Participants

365 undergraduates (mean age 19.78 ± 2.69 SD) in six introductory philosophy classes took part in the experiments. They gave a consent to their cooperation in the experiments, and were given small reward after the experiments. The subjects were native speakers of Japanese. The sentences and instructions were given in Japanese. The subjects were divided into four groups: Symbolic, 2-Venn, 3-Venn, and Euler groups. The four groups in this order consisted of 90, 95, 114, and 66 students, respectively. From each we excluded 26, 27, 35, 3 students (those who gave up before the end), respectively. It is notable that fewer students in the Euler group gave up compared to the other three groups.

Materials

The experiment was conducted in the booklet form.

Pretest The subjects of all groups were presented with ten representations (ten diagrams or ten set-theoretical expressions). They were asked to choose, from a list of five possibilities, all sentences which correspond to a given representation. The highest possible score on the pretest of the Symbolic group was ten and the cutoff point was set to be five. The highest possible score on the pretests of the 2-Venn, 3-Venn, and Euler groups was twelve, because there were two correct answers in two of the ten problems. Their cutoff point was set to be eight. These cutoff points were chosen carefully, based upon the results of our pilot experiments. The total time in Symbolic, 2-Venn and Euler groups was 5 minutes. The total time in the 3-Venn group was 6 minutes, since the instruction was longer than those of the other three groups. Before the pretest, the subjects in each group were presented with three examples.

Syllogistic reasoning tasks The subjects in the Symbolic group were given syllogisms with set-theoretical representations (such as the one in Figure 8). The subjects in the 2-Venn group were given syllogisms with Venn diagrams having two circles in premises (such as the one in Figure 9). The subjects in the 3-Venn group were given syllogisms with Venn diagrams having three circles in premises (such as the one in Figure 10). The subjects in the Euler group were given syllogisms with Euler diagrams (such as the one in Figure 11). We gave 31 syllogisms in total, out of which 14 syllogisms had a valid conclusion and 17 syllogisms had no valid conclusion. The subjects were presented with two premises and were asked to choose, from a list of five possibilities, a sentence corresponding to the valid conclusion. The list consists of *All*-, *No*-, *Some*-, *Some-not*, and *NoValid*. The subject-predicate order of each conclusion was CA. The test was a 20-minute power test, and each task was presented in random order (10 patterns were prepared). Before the test, the examples in Figure 8, 9, 10, and 11 were presented to each group.

All B are A. $B \cap \bar{A} = \emptyset$

All C are B. $C \cap \bar{B} = \emptyset$

1. All C are A.
2. No C are A.
3. Some C are A.
4. Some C are not A.
5. None of them.

Correct answer: 1

5. None of them.

Correct answer: 1

Figure 11: Example of reasoning task of Euler group

Procedure

All four groups were first given 1 minute 30 seconds to read one page instructions on the meaning of categorical sentences. In addition, the Symbolic group was given 2 minutes to read two pages instructions on the meaning of set-theoretical representations. The 2-Venn and Euler groups were given 2 minutes to read two pages instructions on the meaning of diagrams. The 3-Venn group was given 3 minutes to read two pages instructions on the meaning of diagrams. Before the pretest, all groups were given 1 minute 30 seconds to read two pages instructions on the pretest. Finally, before the syllogistic reasoning test, all four groups were given 1

minute 30 seconds to read two pages instructions, in which the subjects were warned to choose only one sentence as answer and not to take a note. These time limits were set based upon the results of our pilot experiments.

Results and Discussion

Pretest

In the Symbolic group, 39 students scored less than 5 on the pretest. In the 2-Venn group, 38 students scored less than 8 on the pretest. In the 3-Venn group, 41 students scored less than 8 on the pretest. In the Euler group, 18 students scored less than 8 on the pretest. These students are excluded from the following analysis.

Syllogistic reasoning tasks

Figure 12 shows the average accuracy rates of the total 31 syllogisms in each group. The rate for the Euler group was 85.2%, the rate for the 3-Venn group was 75.2%, the rate for the Venn group was 66.6%, and the rate for the Symbolic group was 58.7%.

Figure 12: The average accuracy rates of 31 total syllogisms in the Symbolic, 2-Venn, 3-Venn, and Euler groups (error-bar refers to SD).

These data were subjected to a one-way Analysis of Variance (ANOVA). There was a significant main effect, $F(3, 134) = 13.680$, $p < .001$. Multiple comparison tests by Ryan's procedure yield the following results: (i) There was a significant difference between the Symbolic group and the Euler group, $F(1, 68) = 5.935$, $p < .001$. (ii) There was a significant difference between the Symbolic group and the 3-Venn group, $F(1, 61) = 3.578$, $p < .005$. (iii) There was no significant difference between the Symbolic group and the 2-Venn group. (iv) There was a significant difference between the 2-Venn group and the Euler group, $F(1, 68) = 4.397$, $p < .001$. (v) There was no significant difference between the 2-Venn group and the 3-Venn group. (vi) There was a significant difference between the 3-Venn group and the Euler group, $F(1, 81) = 2.537$, $p < .05$. It should be noted that if we include those subjects who failed the pretest, we still obtain similar results in each comparison: for (i), (iv) and (v), there were significant differences, $p < .001$; for (ii), there was a significant difference, $p < .01$; for (iii) and (vi), there were no significant differences.

The results show that the performances of the Euler group and the 3-Venn group were better than that of the Symbolic group. This provides evidence for our hypothesis that Euler and 3-Venn diagrams have inferential efficacy and are self-guiding in the sense specified above. This means that as far as these diagrams are concerned, the internal constructions of diagrammatic proofs exist, and they can be naturally triggered for subjects without prior knowledge of inference rules or strategies. By contrast, there was little difference between the performance of the 2-Venn group and that of the Symbolic group. This suggests that 2-Venn diagrams have only interpretational efficacy, and are not self-guiding in our sense.

The results shown in Figure 12 indicate that the performance of Euler group was better than that of 3-Venn group. In particular, there was a significant difference with respect to a particular type of syllogism, namely, invalid syllogisms having an existential sentence as one of their premises. The data was subjected to a 4×2 ANOVA. As a main result, (i) there was a significant difference between this type of syllogisms in the 3-Venn group (57.8%) and the other types in the same group (83.4%), $F(1, 134) = 29.434$, $p < .001$. (ii) there was a significant difference between this type of syllogism in the 3-Venn group (57.8%) and that in the Euler group (84.2%), $F(1, 81) = 4.926$, $p < .005$. (iii) there was no significant difference between this type of syllogisms in the 3-Venn group (57.8%) and that in the Symbolic group (48.8%).

The relative difficulty in syllogism solving with 3-Venn diagrams could seem to be attributed to the difficulty in the process of drawing a conclusion from an internally constructed diagram. Such a process of extracting information may be formulated as a process of *deletion*. A deletion step in an Euler diagrammatic proof (as illustrated to the left in Figure 13) is simple in that it only requires to remove a circle without adjusting any other part of the diagram.

Figure 13: Deletion steps in Euler and Venn diagrams.

By contrast, deletion steps in 3-Venn diagrammatic proofs are somewhat complicated. Especially, in the step from D_5 to D_6 in Figure 13, which is an instance of invalid syllogisms having an existential sentence as one of its premise, one has to remove a circle and shading and to leave a linking point at the same region. Such complexities in deletion steps seem to reflect complexities of the processes of observing conclusions, and hence cause the difficulty in this type of syllogisms.

If our analysis is correct, the complexity of diagrams could make difficult the processes of *extracting* information. On the other hand, our results of the total 31 syllogisms suggest that 3-Venn diagrams have inferential efficacy, while 2-Venn diagrams do not. This in turn suggests that conventional devices

such as shading and linking points could facilitate the processes of *combining* information by means of superposition of two diagrams. Thus, we could say that the availability of the process of combining information in diagrams depends on the complexity of the inference processes involved, whereas the availability of the process of extracting information in diagrams depends on the complexity of the conventional devices involved. Stenning and Oberlander (1995) point out that efficacy of diagrams can be ascribed to “specificity” of diagrammatic representations, and argue that diagrams could be effective because of their limited expressive power, in particular of the inability to express indeterminate or disjunctive information. In view of this, our findings are particularly interesting since they show that conventional devices to deal with indeterminacy sometimes facilitate internal manipulations of diagrams, hence contribute to their efficacy.

Learning verb alternations in a usage-based Bayesian model

Christopher Parisien and Suzanne Stevenson

Department of Computer Science, University of Toronto

Toronto, ON, Canada

{chris, suzanne}@cs.toronto.edu

Abstract

One of the key debates in language acquisition involves the degree to which children's early linguistic knowledge employs abstract representations. While usage-based accounts that focus on input-driven learning have gained prominence, it remains an open question how such an approach can explain the evidence for children's apparent use of abstract syntactic generalizations. We develop a novel hierarchical Bayesian model that demonstrates how abstract knowledge can be generalized from usage-based input. We demonstrate the model on the learning of verb alternations, showing that such a usage-based model must allow for the inference of verb class structure, not simply the inference of individual constructions, in order to account for the acquisition of alternations.

Keywords: Verb learning; language acquisition; Bayesian modelling; computational modelling.

Introduction

An important debate in language acquisition concerns the nature of children's early syntax. On one side of the debate lies a claim that children develop their syntactic knowledge in an item-based manner. This claim of usage-based learning argues that very young children associate verb argument structure with specific lexical items, only gradually abstracting syntactic knowledge after four years of age (*e.g.*, Tomasello, 2003). An alternative claim suggests that young children do indeed possess abstract syntactic representations—*i.e.*, generalizations about the structure of their language that are not necessarily tied to lexical items (*e.g.*, Fisher, 2002).

Syntactic alternation structure is often considered to be a central phenomenon in this debate. Consider the following example of the English dative alternation:

- (1) I gave a toy to my dog.
- (2) I gave my dog a toy.

These sentences mean roughly the same thing, but are expressed in different ways. The first, a *prepositional dative*, expresses the theme (*a toy*) as an object and the recipient (*my dog*) in a prepositional phrase. The second, a *double-object dative*, expresses both the theme and recipient as objects and reverses their order.

Verbs that allow similar alternations often have similar semantics (Levin, 1993), which suggests that alternations reflect much of our cognitive representations of verbs. Furthermore, these regularities appear to influence our language use. In word learning experiments, children as young as three years of age appear to use abstract representations of the dative alternation (Conwell & Demuth, 2007). While this is evidence of abstract syntax at a very young age, it does not necessarily invalidate the usage-based hypothesis, since the abstractions may originate from item-specific representations.

One way to bring these opposing positions together is to demonstrate, using naturalistic data, how to connect a usage-based representation of language with abstract syntactic generalizations. We argue that alternation structure can be acquired and generalized from usage patterns in the input, without a priori expectations of which alternations may or may not be acceptable in the language. We support this claim using a hierarchical Bayesian model (HBM) which is capable of making inferences about verb argument structure at multiple levels of abstraction simultaneously. We show that the information relevant to verb alternations can be acquired from observations of how verbs occur with individual arguments in the input. In this sense, we present a *competency* model showing what can be acquired, but we do not make claims regarding the specific processing mechanisms involved.

From a corpus of child-directed speech, our model acquires a wide variety of argument structure constructions over hundreds of verbs. Moreover, by forming classes of verbs with similar usage patterns, the model can generalize knowledge of alternation patterns to novel verbs. This stands in contrast to earlier models which have focused on either the acquisition of the constructions themselves, or the formation of classes over given constructions. The integration in our model of these two important aspects of verb learning has implications for current theories of language acquisition, by showing how abstract syntactic knowledge can be acquired and generalized from usage-level input.

Related work

Previous computational approaches to language acquisition have used HBMs to represent the abstract structure of verb use. Alishahi and Stevenson (2008) used an incremental Bayesian model to cluster individual verb usages (or *tokens*), simulating the acquisition of verb argument structure constructions. Using naturalistic input, the authors showed how a probabilistic representation of constructions can explain children's recovery from overgeneralization errors. In another Bayesian model of verb learning, Perfors et al. (2010) cluster verb *types* by comparing the variability of constructions for each of the verbs. The model can distinguish alternating from non-alternating dative verbs and can make appropriate generalizations when learning novel verbs.

Both of the above models show realistic patterns of generalization, but they operate at complementary levels of abstraction. The model of Alishahi and Stevenson does not capture the alternation patterns of verbs, while Perfors et al. assume that the individual constructions participating in the alternation have already been learned. Furthermore, Perfors et

al. limit their model to only consider two possible constructions (the prepositional and double-object dative), and only the verbs that participate in those constructions.

In this work, we address both levels of abstraction of the above models. We cluster individual verb usages to learn argument structure constructions and their patterns of use across many verbs, and we also cluster verb types to learn alternation behaviour, generalizing that behaviour to novel verbs. Moreover, we use representative corpora of child-directed speech to model the acquisition of verb alternation behaviour in the context of many constructions, verbs, and alternations.

Vlachos et al. (2009) used a Dirichlet Process mixture model to cluster verb types by their subcategorization preferences, but did not address learning the argument structures themselves. Other work has modelled different aspects of the dative alternation, such as how discourse features affect the expression of dative constructions (de Marneffe et al., submitted), yet did not consider how these preferences are learned.

Model description

We discuss the feature representation of a verb usage and develop two contrasting models to show how alternation classes contribute to generalization in verb learning. Model 1 is an adaptation of an existing probabilistic topic model, the Hierarchical Dirichlet Process (HDP; Teh et al., 2006), to the problem of learning verb argument structure. Model 2, a novel extension to the HDP, addresses the limitations of Model 1 by learning verb alternation classes, allowing regularities in construction use to be transferred to novel verbs.

Verb features

Following from existing approaches (as in Joanis, Stevenson, and James (2008)), we use syntactic “slot” features to encode basic argument information about a verb usage. Table 1 presents the 14 features used in our representation. The first 12 (up through “PP”) are binary features denoting the presence or absence of the stated syntactic slot, such as an object (OBJ) or a prepositional phrase (PP); the slots are indicated by labels used by the CHILDES dependency parser (Sagae et al., 2007).¹ When a PP is present, the nominal feature PREP denotes the preposition used. Such syntactic slot features are easier to extract than full subcategorization frames. We make the assumption that children at this developmental stage can distinguish various syntactic arguments in the input, but may not yet recognize recurring patterns such as transitive and double-object constructions. The following examples show this representation used with a double-object dative and a prepositional dative, respectively:

- (3) I sent my mother a letter.
 $\langle \text{OBJ, OBJ2, PREP} = \text{null, NSLOTS} = 2 \rangle$
- (4) I sent a letter to my mother.
 $\langle \text{OBJ, PP, PREP} = \text{to, NSLOTS} = 2 \rangle$

¹We consider only the slots internal to the verb phrase, for now ignoring syntactic subjects. We also do not attempt to distinguish true arguments from adjuncts, a very difficult distinction to make.

Features	Description
OBJ, OBJ2	Objects
COMP, XCOMP	Clausal complements
PRED, CPRED, XPRED	Predicate complements
LOC	Locatives
JCT, CJCT, XJCT	Adjuncts
PP	Prepositional phrases
PREP	Preposition (nominal value)
NSLOTS	Number of slots used

Table 1: Slot features.

Model 1: Argument structure constructions

Like other topic models, the HDP (Teh et al., 2006) is essentially a model of category learning: the model clusters similar items in the input to discover structure. Adopting a usage-based approach to language (e.g., Goldberg, 2006), we view the acquisition of verb argument structure as a category-learning problem. In this view, structured verb knowledge translates well to the hierarchical nature of the model.

Model 1 is a straightforward adaptation of the HDP to verb argument structure, which we will use as a point of comparison for an extended model. Figure 1(a) provides an intuitive description of the hierarchical levels of inference in Model 1. At level 1, the lowest level of abstraction, individual verb usages y_i are represented by sets of features as described above.

At level 2, the model clusters similar usages together to form argument structure constructions, where a construction is represented by a set of multinomial distributions, one for each feature. Since the clustering mechanism is *nonparametric*, we need not specify the total number of constructions to learn. Each of these constructions, denoted by its multinomial parameters θ , probabilistically represents a pattern such as a simple transitive or a prepositional dative. While a construction here encodes only syntactic information, with no semantic elements, the model can be generalized to a combined syntactic/semantic input representation.

At level 3, a multinomial distribution for each verb (π) represents the range of constructions that tend to occur with the verb. For example, in Figure 1(a), *give* (π_2) would have a high probability for the double-object dative and prepositional dative constructions (θ_2 and θ_3 , respectively), but a low probability for the transitive construction, θ_1 . Let y_{ij} denote feature j of usage i . Levels 1 through 3 are given by the following:

$$\begin{aligned}
 \pi_v &\sim \text{Dirichlet}(\alpha \cdot \beta) \\
 z_i &\sim \text{Multinomial}(\pi_v) \\
 \theta_{jz_i} &\sim \text{Dirichlet}(1) \\
 y_{ij} &\sim \text{Multinomial}(\theta_{jz_i})
 \end{aligned}$$

The indicator variable z_i selects a cluster (i.e., a construction, one of the θ) for usage i . Given a verb v , this is drawn from a multinomial distribution which includes a small probability of creating a new construction.

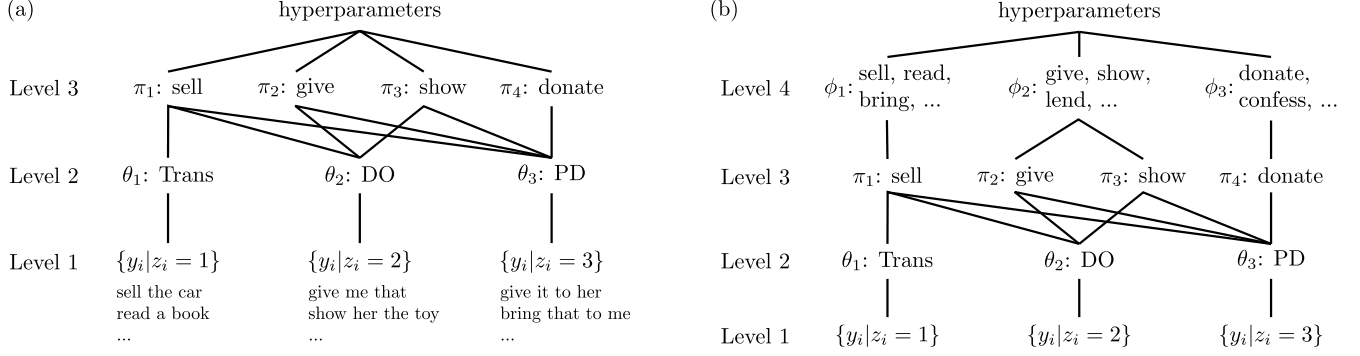

Figure 1: (a) Model 1, a Hierarchical Dirichlet Process applied to learning verb argument structure constructions. (b) Model 2, an extension of Model 1 to learn verb alternation classes.

The verb-specific distributions π_v depend on hyperparameters which encode expectations about constructions in general, across all verbs. They represent acquired knowledge about the likely total number of constructions, which constructions are more likely to occur overall, and so on:

$$\begin{aligned}\gamma &\sim \text{Exponential}(1) \\ \alpha &\sim \text{Exponential}(1) \\ \beta &\sim \text{Stick}(\gamma)\end{aligned}$$

As with lower-level parameters, these are influenced by observed structure in the input. β , drawn from a stick-breaking process (Stick), encodes how many constructions will be used and which constructions are more likely overall. α affects the variability of π_v . Large values of α push π_v closer to β , the global distribution over constructions, while smaller values encourage more variation among verbs. γ affects the total number of constructions; small values of γ correspond to fewer constructions. By drawing α and γ from an exponential distribution, we give a weak preference for verb-specific behaviour and for solutions with fewer constructions. These preferences are effectively designed into the model; they may be informed by general human category-learning behaviour. For further details of this model, see Teh et al. (2006).

Model 2: Alternation classes

Model 1 acquires argument structure constructions from individual verb usages, and learns how those constructions are used by individual verbs, but it is unable to recognize that certain *kinds* of verbs behave differently than others. Competent language speakers regularly use this kind of information. For example, if a verb occurs in a double-object dative construction, then we should infer that it is also likely to occur in a prepositional dative. We develop a novel extension of the above model to capture this phenomenon by learning clusters of similar verbs.

Recall that we represent a verb by a probability distribution over the constructions in which it may occur. In the example shown in Figure 1(a), *give* and *show* both tend to occur with a double-object dative and a prepositional dative, but

are less likely to occur as simple transitives. By recognizing the similarity of π_2 and π_3 , we can create a cluster containing *give*, *show*, and other similar verbs. Figure 1(b) presents this intuition in Model 2. We extend Model 1 by introducing a fourth level of abstraction, where we represent clusters of similar verbs. For each verb cluster c , we use ϕ_c to represent the range of constructions that tend to occur with any of the verbs in that cluster. By serving as a prior on the verb-level parameters π_v , ϕ_c directly influences each verb in the cluster.

The lower levels of this model are the same as in Model 1. In addition, the verb representations, π_v , depend on the alternation classes in level 4:

$$\begin{aligned}\phi_{c_v} &\sim \text{Dirichlet}(\alpha_0 \cdot \beta_0) \\ \pi_v &\sim \text{Dirichlet}(\alpha_1 \cdot \phi_{c_v}) \\ z_i &\sim \text{Multinomial}(\pi_v) \\ \theta_{jz_i} &\sim \text{Dirichlet}(1) \\ y_{ij} &\sim \text{Multinomial}(\theta_{jz_i})\end{aligned}$$

Each verb v belongs to a cluster of verbs, denoted c_v . Now, π_v depends on ϕ_{c_v} , which gives a distribution over constructions for all the verbs in the same cluster.

As before, these parameters themselves depend on top-level hyperparameters:

$$\begin{aligned}\gamma_0 &\sim \text{Exponential}(1) \\ \alpha_{0,1} &\sim \text{Exponential}(1) \\ \beta_0 &\sim \text{Stick}(\gamma_0)\end{aligned}$$

These hyperparameters serve similar roles to those in Model 1. β_0 gives a global distribution over all the constructions in use. γ_0 affects the total number of constructions overall. α_1 affects the variability of a verb compared with its class, and α_0 affects the variability of verb classes.

To group verbs into alternation classes, we use a mechanism similar to the way we group individual verb usages into constructions. Recall that c_v acts as an indicator variable, selecting a class for verb v from the available classes in level 4. This is drawn from a multinomial distribution σ which includes a small probability of creating a new verb class:

$$\begin{aligned}\gamma_1 &\sim \text{Exponential}(1) \\ \sigma &\sim \text{Stick}(\gamma_1) \\ c_v &\sim \text{Multinomial}(\sigma)\end{aligned}$$

As with earlier uses of the stick-breaking construction, γ_1 affects the expected total number of verb classes. This method of clustering verb types is similar to Wallach (2008).

Parameter estimation

Models 1 and 2, as written, each specify a prior distribution over the complete set of possible parameters to the models (*i.e.*, all possible values for θ , \mathbf{z} , ϕ , and so on). We update these distributions using the observed verb usage data, thus obtaining posterior distributions over parameters.

We estimate the posterior distributions using Gibbs sampling, a Markov Chain Monte Carlo (MCMC) method (Teh et al., 2006). Model parameters are initially set randomly, then iteratively adjusted according to the observed data. We randomly set each z_i to one of 10 initial constructions, and each c_v to one of 10 verb classes (if applicable). We set the remaining parameters to random values drawn from the distributions specified in the model descriptions. We then iteratively update each model parameter *individually* by drawing it from a posterior distribution conditioned on the data and all the *other* parameters in the model. As we iterate through the parameters many times, we collect samples of their values. Over time, this set of samples converges on the posterior distribution—*i.e.*, the model parameters given the observed data. In the experiments, we average over this set of samples to estimate what each model has learned about the input.

Experimental set-up

We use child-directed speech from the Manchester corpus (Theakston et al., 2001), part of the CHILDES database (MacWhinney, 2000). The corpus covers 12 British English-speaking children between the ages of approximately 2 and 3 years. Using CLAN, we extract all child-directed utterances containing at least one verb. We parse the utterances with the MEGRAPSP dependency parser (Sagae et al., 2007), then reserve every second usage for an evaluation dataset, using the remainder for development. As described above, we extract 14 slot features for each verb usage. The datasets corresponding to each child contain between 4,400 and 10,700 usages and between 239 and 479 verb types. All reported results are obtained using the evaluation data.

Due to flaws in the automatic part-of-speech tagging and parsing, the data contains many errors, particularly in ditransitive constructions. We manually correct the portion of the input related to the dative alternation. For each verb in the development set that occurs with at least one prepositional or double-object dative (as given by the automatic parsing), we draw a sample of up to 50 usages. We repair any cases of incorrectly parsed dative constructions, then duplicate the corrected samples as necessary. Since manual annotation is so labour-intensive, we use this same sample to correct the data for corresponding verbs in the evaluation set. We assume that

the proportions of various usages are identical for these verbs across the development and evaluation sets.

We implement both learning models using an adaptation of the NPBayes package (Release 1).² For each of the 12 children in the input, we run 10 randomly initialized simulations. The parameters appear to converge within 3,000 iterations, so we run each simulation for 5,800 iterations, discarding the first 3,300 as burn-in. We record a sample of the model parameters on every 25th iteration after the burn-in, giving 100 samples per simulation, 1,000 per child. By averaging over these samples, we can examine the models' behaviour.

Experiments

We compare the ability of our two models to acquire knowledge about the usage patterns of verbs in the input and generalize that knowledge to new verbs. Firstly, we examine construction preferences in two related classes of verbs. Secondly, we test whether the models use an abstract representation of the dative alternation to help learn new verbs.

Verb argument preferences

We examine how our models acquire the usage patterns of verbs in the input by looking at verbs that participate in two different alternation patterns. Earlier, we demonstrated the dative alternation in examples (3) and (4). The benefactive alternation is a related pattern, in which verbs alternate between a double-object form and a *prepositional benefactive* form, as in the following examples:

- (5) John made his friend a sandwich.
(OBJ, OBJ2, PREP = null, NSLOTS = 2)
- (6) John made a sandwich for his friend.
(OBJ, PP, PREP = for, NSLOTS = 2)

We consider all verbs involved in the dative and benefactive alternations, as listed by Levin (1993, Sections 2.1 and 2.2). We test three constructions: the prepositional dative (PD); the double-object construction (DO), whether dative or benefactive; and the prepositional benefactive (PB). Using the samples of the model parameters, we estimate the posterior predictive likelihood of each of these frames for each of the verbs in the given classes. For a given test frame \mathbf{y}_0 , using verb v , and the observed data \mathbf{Y} ,

$$\begin{aligned}P(\mathbf{y}_0|\mathbf{Y}) &= \sum_k P(\mathbf{y}_o|k, \mathbf{Y})P(k|v, \mathbf{Y}) \\ &= \sum_k \prod_j P(y_{0j}|\theta_{jk})P(k|\pi_v)\end{aligned}\quad (1)$$

This likelihood is averaged over all 1,000 samples per child.

Figure 2 shows the behaviour of both models. We average the likelihoods over all 12 children, and over all verbs in the following cases: (a) verbs listed as dative but not benefactive, (b) verbs listed as benefactive but not dative, and (c) verbs in both classes. In both models, both dative and benefactive verbs show a high likelihood for the DO frame, and a somewhat higher likelihood for the appropriate prepositional frame

²<http://www.gatsby.ucl.ac.uk/~ywteh/research/software.html>

Figure 2: Argument preferences for known dative and benefactive verbs in Models 1 and 2. Shorter bars indicate higher likelihood. The two models show similar behaviour.

(PD and PB, respectively) than for the inappropriate one (PB and PD, respectively). Verbs that occur in both classes show closer likelihoods for all three frames.

These results suggest that both models can acquire the argument structure preferences of verbs in the input. In this case, the ability of Model 2 to acquire verb alternation classes is not necessary. Both models are able to cluster verb usages into a range of constructions and acquire appropriate usage patterns over a range of verbs. Both models acquire approximately 20 different constructions. Model 2 acquires 35-40 verb classes, depending on the child.

Novel verb generalization

Children as young as three years of age have been shown to use abstract representations of the dative alternation (Conwell & Demuth, 2007). When young children hear a sentence like *I gorped Charlie the duck*, they appear to know that the same meaning can be expressed by saying *I gorped the duck to Charlie*. We test this generalization in our models by presenting a novel verb in one form of the dative and measuring the likelihood of the alternating form.

We test each model by independently presenting it with a novel verb in three different situations: (a) two instances of the prepositional dative, (b) two instances of the double-object dative, or (c) one instance of each. Only in case (c) is the verb explicitly seen to be alternating. We test the ability to generalize alternation behaviour by comparing the likelihood of the unseen *alternating* form with an unseen form unrelated to the alternation. The non-alternating frame is the sentential complement (SC) frame, which occurs in 1-1.5% of the input, approximately the same overall frequency as either of the two dative frames. For example, if we train the novel verb using only the PD, yet the DO frame shows a higher likelihood than the unrelated SC frame, then we can say that the model has generalized the dative alternation.

Since the novel verbs are *not* in the observed data, we must further iterate the Gibbs sampler, using the new data, to obtain

Figure 3: Generalization of novel dative verbs in Models 1 and 2, under various training conditions. Shorter bars indicate higher likelihood.

the appropriate samples of the verb-level distribution π_v . For each of the 1,000 parameter samples per child we obtained from the original simulations, we re-initialize the model with the parameters from the sample, add in the novel data for case (a), (b), or (c), then do a further 350 iterations, recording 10 new samples of the model parameters. This gives 10,000 new samples per test case, per child. Using equation (1) and the new samples, we estimate the posterior predictive likelihood of each of the three constructions. This gives an estimate of the relative preferences for a verb's usage and is a direct measure of the acquired lexicon. Translating this estimate to production, as seen by Conwell and Demuth (2007), would require a model of how discourse and other factors influence dative production (*e.g.*, de Marneffe et al., submitted). This is beyond the scope of this paper.

Figure 3 shows how the ability to acquire verb classes aids generalization. In Model 1, without verb classes, only the frames already seen with the novel verb are highly likely. This means that Model 1 is unable to generalize beyond observed data. In contrast, Model 2 shows appropriate generalization for the dative alternation. When the novel verb is trained with the prepositional dative, the double-object dative shows a much higher likelihood than the unrelated SC frame. A similar effect occurs with DO-only training: the PD frame is now more likely than the SC frame, although only slightly. Compared with Model 1, *both* dative frames obtain a higher likelihood across all three training cases, while the SC likelihood remains low. The ability to acquire alternation classes improves the ability to learn *both* alternating constructions.

One aspect of our results differs from the behaviour observed in children. Our verb-clustering model is more likely to generalize to the double-object form when trained only on a prepositional form, than the other way around (*i.e.*, generalizing from a DO to a PD). However, three-year-old children seem to be biased to the prepositional form, the opposite effect (Conwell & Demuth, 2007). We suggest that this is a result of our small corpora. High-frequency dative verbs

tend to be biased toward the double-object form (Campbell & Tomasello, 2001). However, Gries and Stefanowitsch (2004) show that out of 40 alternating verbs in the larger ICE-GB corpus, 19 are prepositional-biased. This strongly suggests that more low-frequency verbs are prepositional-biased than otherwise. A small corpus will likely over-represent a double-object bias because of undersampling of low-frequency verbs. By applying Model 2 to larger corpora of child-directed speech in future work, we hope to correct this issue.

Conclusions

In this paper, we show how verb alternation classes contribute to generalization in verb learning. We develop a hierarchical Bayesian model, Model 2, that is capable of acquiring knowledge of verb argument structure at multiple levels of inference simultaneously. We demonstrate this using the wide range of verbs and constructions contained in a corpus of naturalistic child-directed speech.

By clustering individual verb usages, both of our models acquire a variety of argument structure constructions and learn their patterns of use over hundreds of verbs. Furthermore, Model 2 learns groups of verbs that occur with similar usage patterns. Using the dative alternation as a key example, we demonstrate how this knowledge of alternation classes can be generalized to novel verbs, as observed in the behaviour of children and adults. This verb class model can acquire and apply this knowledge without any prior expectation of which constructions and alternations may or may not be relevant.

In contrast to previous analyses of the dative alternation (Perfors et al., 2010; de Marneffe et al., submitted), we demonstrate its acquisition in the context of many other constructions, verbs, and alternations. Despite the low frequency of the participating constructions, our model successfully acquires the dative alternation. This is a strong endorsement of hierarchical Bayesian models of language acquisition.

This approach offers a potential bridge between differing theoretical positions in language acquisition. By simultaneously learning at multiple levels of abstraction, our model connects a usage-based representation of language, as proposed by Tomasello (2003), with weak abstract representations similar to those championed by Fisher (2002). Other usage-based Bayesian models, such as that of Alishahi and Stevenson (2008), offer a similar opportunity, although our model develops higher-level abstractions regarding the structured knowledge of verbs.

One of the key features of usage-based constructions is that they couple form to meaning (Goldberg, 2006). Moreover, Fisher argues that abstract syntactic representations influence semantics in verb learning, and vice-versa. By augmenting our model's input with semantic properties, we will examine the interaction of syntax and semantics in verb alternations. We will investigate how an argument alternation may convey semantic information, as in Scott & Fisher's (2009) demonstration of 28-month-old children inferring causation in transitivity-alternating verbs.

Frequent Frames as Cues to Part-of-Speech in Dutch: Why Filler Frequency Matters

Richard Eduard Leibbrandt (Richard.Leibbrandt@flinders.edu.au)

David Martin Ward Powers (David.Powers@flinders.edu.au)

Abstract

The Frequent Frames model (Mintz, 2003) attempts to assign words to word categories based on their distributional patterns of usage. This model is highly successful in categorizing words in child-directed speech in English, but has been shown by Erkelens (2008) to be less effective with Dutch material. We show that extending the amount of contextual information in a frame by making use of the full utterance context does not improve categorization performance, but that constraining the fillers of Frequent Frames to be relatively less frequently occurring words does improve categorization significantly. We connect the latter result to a basic dichotomy in some languages between function words and content words, and conclude that, at least for English and Dutch, paying attention to this dichotomy is of greater importance for distributional bootstrapping proposals than the specific distributional contexts that are used to categorize words.

Keywords: Language learning; Distributional bootstrapping; Parts-of-speech; Function words; Frequent frames

Introduction

The parts-of-speech of a language (word classes such as nouns, verbs and adjectives) are of crucial importance in describing the grammar of the language. A vast amount of research has aimed to delineate the processes by which children learn to categorize words into the parts-of-speech of their native language. Researchers favouring *semantic bootstrapping* approaches (Grimshaw, 1981; Pinker, 1984) have proposed that early word categories are formed by grouping together words that refer to the same dimensions of concrete meaning, such as actions or objects. On the other hand, following early proposals by Maratsos & Chalkley (1980), proponents of *distributional bootstrapping* have argued that word categories can be induced by observing that certain groups of words are used in similar linguistic contexts, whether these contexts are defined at the level of words, morphemes, or even phonological or prosodic phenomena.

In recent years, it has become feasible to implement specific distributional bootstrapping proposals as computer algorithms that attempt to categorize words purely by analysing distributional patterns in large corpora of natural utterances (Cartwright & Brent, 1997; Redington, Chater & Finch, 1998). For instance, Redington et al. (1998) found that words in child-directed English speech could be categorized with a high level of success by considering only

very local utterance contexts made up of words that occur in close proximity to the target word.

A particularly successful distributional model has been the *Frequent Frames* model of Mintz (2003, 2006a, 2006b). Frequent frames are defined as a disjunct frame occurring around a target word, made up of the word immediately preceding and the word immediately following the target, so that all frequent frames have the form a_b , with a and b standing for specific words, and the underscore representing a slot that can accept a variety of filler words. For example, in the three-word sequence “a house and”, the frame is “a _ and”, and the filler is “house”. Once all frames of this form have been collected from a corpus, only the most *frequent* ones are retained for the purpose of categorization. This reflects the intuition that, if two words co-occur frequently on either side of another word across several utterances, this is likely to be due to some meaningful linguistic relationship between them. All words occurring in the same frequent frame are assigned to the same category, and frames that have more than 20% overlap in their set of slot fillers have their categories amalgamated into larger, more general categories. This amalgamation step is crucially important: by grouping together frames that accept similar sets of words, the child may be able to hypothesize that a word used in one verb frame may also be legitimately used in another verb frame; without amalgamation, this kind of generalization is not possible.

Frequent Frames provide a very successful categorization of the words that occur in them, with Mintz (2003) reporting values greater than 0.9 for the evaluation measures *accuracy* and *completeness* when the model was implemented on a set of English corpora. However, recently Erkelens (2008) has shown that, in the case of child-directed speech in Dutch, Frequent Frames provide a less accurate basis for part-of-speech categorization than they do for English: whereas the use of Frequent Frames in English yielded an accuracy figure that exceeded the random baseline by 0.52 for tokens and 0.46 for types, a replication with a Dutch corpus could attain an improvement in accuracy over baseline of only 0.33 for tokens and 0.25 for types.

Full-Utterance Frames As Distributional Contexts

An important issue in distributional bootstrapping is to decide on the most appropriate usage contexts to consider for the purpose of categorization. One possible reason for the purported lower utility of Frequent Frames in Dutch

may be that Dutch simply allows a greater amount of flexibility in the range of structures in which particular words are able to occur. This raises the possibility that the contextual window employed by Frequent Frames may simply have been too small, and that it may be necessary to consider a wider amount of lexical context around a word in order to distinguish between different constructions. The maximum amount of context for a word used in an utterance is arguably the entire utterance, and so from a practical point of view it may be useful to explore the use of frames that comprise a full utterance at a time.

Tomasello (2006) has suggested a prominent role in language development for *utterance-level constructions*, expressions that can be used as complete utterances and are associated in a routinized way with certain communicative functions. Pine & Lieven (1993) provide evidence that some children assemble their earliest multi-word utterances by starting with “frozen”, unanalysed phrases and proceeding to analyse these into fixed parts with variable slots into which various elements can ultimately be inserted (although some children instead form multi-word utterances by combining familiar single words together).

Given both these pragmatic and theoretical considerations, Leibbrandt and Powers (2008) evaluated a distributional bootstrapping proposal that makes use of schematic representations of complete utterances, with most words in the utterance lexically specified and one or two additional word positions serving as slots, for example “Are you going to X it?” or “That’s the X”. Under Leibbrandt & Powers’s proposal, words that occur in the same full-utterance frame slot are categorized as belonging to the same word category. This approach was highly effective for categorizing word tokens in a natural corpus of child-directed English speech, attaining levels of correctness in part-of-speech classification that were comparable to those achieved by Frequent Frames (Mintz, 2003).

The Function Word - Content Word Dichotomy

Another important factor in distributional bootstrapping proposals is the basic dichotomy that exists in many languages between content word classes (the classes that carry lexical meaning, such as nouns, verbs and adjectives) and function word classes (the classes that are more closely involved with grammar, such as determiners, conjunctions and prepositions).

Attending to the positional relationships between function and content words has been proposed to be of importance to the language-learning child. For instance, Valian and Coulson (1988) found that learning an artificial language is made easier by increasing the frequency of function words that can serve as anchor points for distributional analysis, and suggest that children may seek out the most frequent elements in language in order to learn about the patterns in which parts-of-speech are allowed to occur in a language.

Gerken, Landau & Remez (1990) point out that function words could be crucial in the two tasks of *word segmentation* and *word labeling* (category assignment).

Function words are potentially useful in segmentation because recognizing the relatively small number of function words makes it easier to separate out the far more heterogeneous open-class words that are interspersed between them. Function words could also aid labeling, because they occur in very stereotypical positional relations to open-class words, for instance, “the” is often followed by a noun (or sometimes by an adjective which is followed by a noun), and “-ing” is usually preceded by a verb root.

Because it cannot be assumed that children know *a priori* which words are function words and which are content words, this distinction would have to be learned on the basis of perceptible cues in the language spoken to children. English function words can be identified by a number of phonological cues, including syllable complexity, stress and vowel quality (Morgan, Shi & Allopenna, 1996), and even newborn infants are able to distinguish English function words from content words (Shi, Werker & Morgan, 1999).

Another feature of the distributional approach of Leibbrandt and Powers (2008) that may have contributed to its successful categorization performance is that it attempts to take the function word - content word dichotomy into account by making use of another cue that may plausibly be available to children: most function word types occur more *frequently* in speech than most content word types. Leibbrandt and Powers attempted to approximate the distinction between function words and content words in English by sharply distinguishing between the two sets of frequent and less frequent words, defined as respectively the set of the top *N* most frequently-occurring words in a corpus, and the set of all other words. When creating full-utterance frames for their distributional analysis, they applied the constraint that only frequent words could be used as the lexically-specific words in a frame, and only less-frequent words could be used as the slot fillers that were embedded in the frames.

Adapting The Frequent Frames Model

Erkelens (2008) argues that different cues are useful to differing extents in different languages, and that the occurrence of a word in a frequent frame is not as useful a cue to part-of-speech for the Dutch-learning child as it is for English. While we agree with the former point, we will attempt to show that the utility of Frequent Frames for categorization in Dutch may have been underestimated.

In the remainder of this paper, we report on a series of four experiments intended to investigate whether the Frequent Frames model can be modified to deal successfully with Dutch material. In Experiment 1, we replicate the results of Erkelens (2008) with a larger corpus and Frequent Frame set, and confirm that the unmodified Frequent Frames model is less useful for categorization in Dutch than in English. In Experiment 2, we investigate whether the distributional model of Leibbrandt & Powers (2008) is able to improve over the categorization results of Frequent Frames (we preempt our results here by confirming that it does). As Leibbrandt and Powers’s approach differs in two

ways from the Frequent Frames approach, it then becomes important to investigate whether this improved performance is due to both differences, or only one. In Experiment 3, therefore, we modify the Frequent Frames approach to use the complete utterance as the context for categorization, and in Experiment 4, we constrain Frequent Frames to be composed of only frequent (function) framing words, and to take only less-frequent (content) filler words.

Experiment 1

Method

The corpus used in these experiments was the Groningen corpus (Wijnen & Bol, 1993), taken from CHILDES (MacWhinney, 2000), and consisting of data from seven Dutch-learning children in the Groningen area, recorded between the ages of 1;05 and 3;07. The corpus was minimally preprocessed for computer-readability, and all sentences uttered by adults were used. Data from all seven children were merged together in order to increase the data set size for the purpose of data clustering.

Frequent Frames were extracted according to the method used by Mintz (2003). Candidate frames were extracted from each utterance in the corpus, by forming a frame from every three consecutive words in each utterance and replacing the middle word with a slot marker. The frames with the highest frequency of occurrence in the corpus were retained as the set of *frequent* frames. Frequency statistics were collected on how often each word occurred in the slot position of each frequent frame throughout the corpus.

The studies by Mintz (2003) and Erkelens (2008) made use of a set size of 45. Because it was desirable in the present work to apply clustering to the data, a slightly larger frame set of 250 frames was used. These top 250 frames were grouped into clusters of frames by means of average-linkage hierarchical clustering (Sokal & Sneath, 1963), with the initial distances between frames given by Spearman's ranked correlation coefficient. Frames were clustered together if they occurred in the corpus with similar sets of slot-filler words.

Clustering makes it possible to make generalizations about the acceptability of words in frames in which they have not been attested in the corpus. If the clustering algorithm produces K clusters of frames, these clusters correspond to K hypothesized categories. Any word token which occurs in any frame belonging to a particular cluster is then assigned to the category corresponding to that cluster.

Evaluation Measures And Significance

All the experiments reported here involve the task of categorizing words into word categories based on the context in which they are used. In each case, there is an empirical allocation of words to unlabelled categories, which needs to be evaluated by a comparison with the "true" distribution of word tokens into their parts-of-speech. This "true" distribution was created by us after manually inspecting each of the particular word tokens in contextual

usage. We made use of the same categories that were used by Erkelens (2008) in her "standard analysis", namely: verbs (including auxiliaries and copula), nominals (nouns, proper names and pronouns), adjectives, prepositions, adverbs, determiners, WH-words, conjunctions and interjections.

Unsupervised categorization models such as Frequent Frames are usually evaluated by means of the mathematical measures *accuracy* and *completeness*, using a *pair counting* approach. A formal definition of these two measures falls outside the scope of this paper, but they can be intuitively understood as expressing the extent to which word tokens assigned to the same category by the model do in fact belong to the same part-of-speech, and the extent to which word tokens which belong to the same part-of-speech were in fact categorized together by the model, respectively.

It is possible to report accuracy and completeness both in terms of the number of word *tokens* correctly categorized and in terms of the number of word *types* correctly categorized; results reported here are based on word type categorization only.

It should be noted that one cannot simply compare accuracy and completeness scores between experiments that make use of different sets of data. Any comparison has at least to take into account the magnitude of the *difference* between accuracy (or completeness) attained by the model, and the baseline accuracy (or completeness) attained by randomly allocating of words to categories.

In order to address this difficulty, we make use of *permutation tests* to assess the significance of differences between evaluation measures, both within and between experiments. Within an experiment, it is possible to assess whether the value of an evaluation measure is significantly higher than the baseline value, by generating a randomized sample of values for that measure and determining how often an equal or higher value occurs in the sample. Between experiments, it is possible to determine whether an obtained value for an evaluation measure in one experiment is significantly better than a value for the same measure in another experiment, by generating a random sample for each experiment separately, taking the differences between pairs of values from the two samples, and comparing this sample of differences to the difference between the originally obtained values.

There is also typically a trade-off between accuracy and completeness, and it is possible to artificially inflate one measure at the expense of the other. For this reason, it is necessary to consider both values together when evaluating the results of an experiment. In addition, we will also report values for the *F measure*, calculated as the harmonic mean of accuracy and completeness, which summarizes both measures and takes on a high value only when they are both high in value.

Results

Firstly, an analysis of the 250 most frequent frames in the pooled corpus confirmed the conclusion drawn by Erkelens

(2008) that frequent frames are not as reliable a basis for the categorization of Dutch words as they are for English words. The categorization accuracy for the top 250 frames from the pooled corpus (displayed in Table 1) was 0.60, against a random baseline of 0.31, i.e. categorizing on the basis of frequent frames rather than by randomly assigning categories improved accuracy by only 0.29. This result is comparable with Erkelens’s (2008) 0.25 increase in accuracy, suggesting that the differences between that study and the current experiment (a different corpus and a larger set of frequent frames) did not materially affect the results. As might be expected, completeness was almost equal to the random baseline (and near zero), as frame clusters have not yet been created. These results confirm that the individual frames have some utility in predicting the part-of-speech of their slot-filler words, but that their accuracy is far from perfect.

Table 1: Accuracy and completeness for the top 250 frequent frames before clustering, against results from Mintz (2003) and Erkelens (2008). Random baseline figures in italics.

<i>Study</i>	<i>Language</i>	<i>Measure</i>	<i>Value</i>
Mintz (2003)	English	Accuracy	0.93 (0.47)
Erkelens (2008)	Dutch	Accuracy	0.58 (0.33)
Experiment 1	Dutch	Accuracy	0.60 (0.31)
Experiment 1	Dutch	Completeness	0.01 (0.01)

Hierarchical clustering was applied to the frames based on the distributional patterns of their filler words¹. The results are shown in Table 2. Accuracy decreased sharply, as should be expected, as assigning every frame to its own unique category corresponds to the maximum attainable accuracy value. While completeness increased by a large amount in absolute value, it did not exhibit a large advantage over the random baseline completeness value.

Table 2: Evaluation of word token categorization after hierarchical clustering of the top 250 frequent frames into 12 clusters. Random baseline figures in italics.

Accuracy	0.429 (0.327)
Completeness	0.405 (0.308)
F	0.417 (0.317)

Discussion

These results replicate the findings of Erkelens (2008) that frequent frames have some utility as a basis for the prediction of the part-of-speech of Dutch words, but that they are not nearly as reliable as they are in English.

¹ The number of clusters produced by hierarchical clustering affects the obtained results. Procedures exist for choosing an optimal number of clusters, but for the sake of consistent comparison across the four experiments described here, the number of clusters produced was fixed at 12 in each experiment.

Experiment 2

Method

As in Experiment 1, we made use of the Groningen corpus. Here, however, we attempted to apply the lexically-specific frame approach proposed by Leibbrandt and Powers (2008). A list was compiled of the most frequently occurring word types in the Groningen corpus. This requires a choice of an arbitrary frequency cutoff point, and in this experiment the top 300 most frequent words were selected as the frame-building words. This set included the most common function words in Dutch, including pronouns (*ik, hij, ze*), determiners (*een, de, het, deze, dat*), and forms of the copula (*ben, zijn*) as well as a number of common content words.

All utterances were rewritten as lexically-specific frame candidates, by replacing every word that was not on the frequent-word list by a placeholder symbol X. From this set of candidate *dichotomous full-utterance frames*, the 250 frames with the highest frequency of occurrence were retained for analysis.

As in Experiment 1, co-occurrence data was collected about the frequency with which different words occurred in each of the frames, and the set of frames was clustered based on similarity in their sets of filler words. Note that, because of the way in which the frames were constructed, all slot fillers were taken from the set of less-frequent words.

Results

A number of intuitively sensible Dutch full-utterance frames were produced by this process, for example “Daar is de X” (“There’s the X”), “Gaat ie X?” (“Is he going to X?”) and “Heel X” (“Very X”), frames which could reasonably be expected to take noun, verb and adjective fillers respectively. Note that none of these example utterance structures could have been covered by the Frequent Frames approach, as the slot word occurs at the end of the frame in each case.

Table 3: Evaluation of word token categorization after hierarchical clustering of the top 250 dichotomous full-utterance frames. Random baseline figures in italics.

Accuracy	0.752 (0.431)
Completeness	0.407 (0.233)
F	0.528 (0.302)

The results of categorization evaluation after clustering are shown in Table 3. Accuracy, completeness and F were all significantly higher than baseline, as assessed by a permutation test ($p < 0.01$). Furthermore, categorization performance was significantly better than in the Frequent Frames approach of Experiment 1, as assessed by a permutation test of F value differences ($p < 0.01$).

Discussion

This experiment has shown that the frame selection approach used by Leibbrandt and Powers (2008) produces frames that are far more reliable indicators of the part-of-speech of a word in Dutch than the standard Frequent Frames proposed by Mintz (2003). As stated, this approach differs from Frequent Frames in two ways, making use of full-utterance contexts and accepting only less-frequent word (content word) fillers. In the next two experiments, we attempt to determine whether the improved performance shown here is due to one, or both, of these properties.

Experiment 3

Method

From each utterance in the corpus, candidate frames were extracted that contained all the words in the utterance except for one target word, which was turned into a variable slot (so that each utterance yielded as many candidate frames as there were words in the utterance). For example, the utterance “Dat is het vliegtuig” yielded the frames “X is het vliegtuig”, “Dat X het vliegtuig”, “Dat is X vliegtuig” and “Dat is het X”. The most frequently occurring of these candidate *frequent full-utterance frames* were selected for evaluation. As before, word occurrence frequencies were calculated for each frame, and frames were clustered together based on the patterns of words that occurred in their slots.

Results

Evaluation results are shown in Table 4. While all evaluation measures were significantly greater than baseline ($p < 0.01$), the full-utterance frames did not provide a better basis for categorization than Frequent Frames; on the contrary, the categorization using Frequent Frames in Experiment 1 performed significantly *better* than the categorization with full-utterance frames, as assessed on a permutation test of differences in F measures ($p < 0.01$).

Table 4: Evaluation of word token categorization after hierarchical clustering of the top 250 frequent full-utterance frames. Random baseline figures in italics.

Accuracy	0.428 (0.267)
Completeness	0.249 (0.156)
F	0.315 (0.197)

Discussion

Clearly, the relatively low utility of Frequent Frames in categorizing Dutch words shown in Experiment 1 was not merely due to an insufficient amount of contextual information. In this experiment, increasing context to comprise the whole utterance did not improve categorization, as one might have expected from the superior results with dichotomous full-utterance frames in

Experiment 2, and it seems that the success of those frames had nothing to do with their being based on full utterances.

Experiment 4

Method

Candidate frames were extracted from the corpus in the same way as for Experiment 1, i.e. the candidate frames were all Frequent Frames. However, following the approach taken in Experiment 2, we retained frames for the final evaluation set only if both the frame-building words (i.e. the first and third words) occurred in the list of the most frequent words in the corpus. Equally importantly, only words that were not in the frequent-word list were accepted as slot fillers for the frames. The most frequent such *frequent dichotomous frames* were selected and clustered as in the previous experiments.

Results

Evaluation results are shown in Table 5. It is immediately noticeable that the values of all measures are higher than for any of the other 3 experiments. For instance, comparison with Table 1 reveals that accuracy in this experiment is similar to the level of accuracy attained by Mintz (2003) with English frames. All measures are significantly above their baseline ($p < 0.01$), and categorization performance is significantly greater than for Experiments 1 and 3 ($p < 0.01$), but not significantly different from Experiment 2.

Table 5: Evaluation of word token categorization after hierarchical clustering of the top 250 frequent dichotomous frames. Random baseline figures in italics.

Accuracy	0.921 (0.611)
Completeness	0.513 (0.340)
F	0.659 (0.437)

Discussion

In this experiment, we have seen evidence that, contrary to the results of Erkelens (2008), Frequent Frames may yield high accuracy and completeness in categorizing Dutch words, *provided* that the frames are composed of the set of frequent words in Dutch (usually function words) while the categorization targets are taken from the relatively less frequent words, i.e. essentially content words.

Every one of the 250 frames in Experiment 1 was already composed of two frequent words. However, only 105 of those frames were retained in the evaluation set for Experiment 4. Therefore, the large improvement in categorization performance was due to the requirement that fillers should be less-frequent words, thereby effectively dropping function word fillers from the categorization. This seemed to result in a great number of frames being added to the evaluation set that were strongly associated with only one content word class (verbs, nouns, or adjectives).

General Discussion

The experimental results in this paper show that a simple distributional approach is effective in categorizing words in Dutch child-directed speech. Both the dichotomous full-utterance frame approach of Leibbrandt & Powers (2008) used in Experiment 2 and the Frequent Dichotomous Frames approach of Experiment 4 yielded significantly better categorizations than either Frequent Frames or Frequent Full-Utterance Frames, with no significant difference between the two models relative to their random baselines (although Frequent Dichotomous Frames achieved a higher F value in absolute terms, and so may arguably be preferred). By contrast, extending the context used for distributional analysis to a full utterance as in Experiment 3, paradoxically decreased performance. This suggests that the extent of context used in distributional bootstrapping may be less crucial than the kinds of words used for frames and fillers respectively.

A simple modification to the Frequent Frames model is therefore able to overcome the shortcomings with Dutch material identified by Erkelens (2008). We suggest that the reason why the Frequent Dichotomous Frames model yields such a successful categorization is that the less-frequent words being categorized are mostly content words. In other words, it may be the case that the only useful targets for distributional analysis are the content word classes such as noun, verb, adjective and adverb. While pronouns, auxiliary verbs, etc. can also be identified by their distribution, these words may simply be learned on a one-by-one basis.

The weaker results of the original Frequent Frames model may have been due to a conflation of legitimate content word contexts with other cases where a function word in the frame slot indicates a different linguistic construction. For instance, the Frequent Frame “die _ wel” accepts a variety of verbs, and the pronoun “die” serves as the subject of the verb. When the slot is filled by the adverb “ook” to form “die ook wel”, however, this is a different construction where “die” is the object of a verb outside the frame, or else the subject of an unstated verb. Eliminating function-word fillers avoids the conflation of contexts.

While the results from this corpus analysis speak less directly to how children *actually* learn parts-of-speech than the results of an experimental study would, they demonstrate the feasibility of exploiting a particular form of information in child-directed language. In concurrence with the proposal by Valian & Coulson (1988) that function words serve as anchor points indicating the structure of an utterance and facilitating distributional analysis, we suggest that it would be useful for children to make a distinction between function and content words, based on various cues such as phonology, greater occurrence frequency, etc. When children encounter a function word occurring in the slot position of what would normally be a distributional frame, they would then be able to avoid carrying out the normal process of categorizing the word on the basis of the frame, and to treat the function word as part of the structural information in the utterance only.

When ‘More’ in Statistical Learning Means ‘Less’ in Language: Individual Differences in Predictive Processing of Adjacent Dependencies

Jennifer B. Misyak (jbm36@cornell.edu)

Morten H. Christiansen (christiansen@cornell.edu)

Department of Psychology, Cornell University, Ithaca, NY 14853 USA

Abstract

Although statistical learning (SL) is widely assumed to play a key role in language, few empirical studies aim to directly and systematically link variation across SL and language. In this study, we build on prior work linking differences in nonadjacent SL to on-line language, by examining individual-differences in *adjacent* SL. Experiment 1 documents the trajectory of adjacency learning and establishes an individual-differences index for statistical bigram learning. Experiment 2 probes for within-subjects associations between adjacent SL and on-line sentence processing in three different contexts (involving embedded subject-object relative-clauses, thematic fit constraints in reduced relative-clause ambiguities, and subject-verb agreement). The findings support the notion that proficient adjacency skills can lead to an over-attunement towards computing local statistics to the detriment of more efficient processing patterns for nonlocal language dependencies. Finally, the results are discussed in terms of questions regarding the proper relationship between adjacent and nonadjacent SL mechanisms.

Keywords: Predictive Dependencies; Sentence Processing; Bigrams; Serial Reaction Time; Artificial Grammar

Introduction

With the expansion of studies on statistical learning (SL) over the past decades, focus has intensified towards probing the potential role for probabilistic sequence learning capabilities in acquiring and using linguistic structure (e.g., Gómez, 2002; Saffran, 2001). A clearer understanding has in turn begun to crystallize about the ways in which SL mechanisms may underpin language across various levels of organization—phonetic, lexical, semantic, syntactic—and across differing timescales—phylogenetic, ontogenetic, and microsecond unfoldings. Largely missing from this picture, however, is empirical evidence that directly links language and SL abilities within the typical population.

There are, though, a few recent studies that address the issue of whether better statistical learners are indeed better processors of language. In a small-scale study of individual differences, Misyak and Christiansen (2007) observed that standard measures of SL performance are positively associated with comprehension accuracy for various sentence-types in natural language. Conway, Bauernschmidt, Huang and Pisoni (2010) reported that better SL performance correlates with better processing of perceptually-degraded speech in highly-predictive lexical contexts. Misyak, Christiansen and Tomblin (2010) found that more-skilled statistical learners of nonadjacent structure were also more adept at the on-line processing of long-distance dependencies in natural language. Thus far, these

results would support the general assumption that SL and language processes are systematically interrelated, with positive correspondence in intraindividual variation across them. But is it always the case that greater SL is associated with better language functioning? Or, may excelling at one of these implicate poorer performance at the other?

Such ability-linked reversals in performances within a cognitive domain would not be unprecedented. As an example, bilingual individuals appear to possess more efficient ‘inhibitory control’ processes than their monolingual peers across a number of studies, which has usually been imputed in some manner to bilinguals’ greater experience with ‘control’ processes for suppressing irrelevant information in the course of successfully using two languages (see Bialystok et al., 2004). However, in a negative priming paradigm where distractor locations that were supposed to be previously ignored became relevant for facilitating responses to a current trial (as they do for monolinguals), bilinguals are at a disadvantage in the cognitive control task, with decreases from a neutral baseline in performance accuracy (Trecanni et al., 2009). Analogously then, might there be natural language contexts in which superior SL skill also becomes disadvantageous?

One possibility is that a statistical learner may focus too much on computing certain statistics, while ignoring others, with repercussions for their linguistic processing. For example, language embodies predictive dependencies that can be broadly characterized as involving either *adjacent* or *nonadjacent* temporal relationships. Thus, a good adjacency learner might perform poorly on nonadjacent dependencies in language. Introducing a new task for documenting micro-level trajectories and individual differences in SL, Misyak et al. (2010) were able to link variation in *nonadjacent* SL positively to signature differences in reading time patterns for the complex *nonlocal* dependency structure of center-embedded object-relative clause sentences. However, this study raises a new set of questions, including ones that directly bear on the above hypothetical, namely: Does the timecourse of *adjacent* SL differ from that of nonadjacent SL? Can substantial differences in adjacent SL also be empirically related to on-line sentence processing? And if so, might this differ from the kinds of positive correlations observed for nonadjacency processing?

We investigated these questions by adapting the AGL-SRT paradigm from Misyak et al. (2010) to isolate the learning of adjacent dependencies. The task implements an artificial grammar (AG) within a modified two-choice serial reaction-time (SRT) layout, using auditory-visual sequence-

strings as input. Experiment 1 thus documents the group trajectory and range of individual differences for adjacency learning obtained from this task. A ‘bigram index’ reflecting individual differences in adjacency learning is then used to probe relationships to the processing patterns observed in our subsequent natural language experiment (Experiment 2).

Experiment 1: Statistical Learning of Adjacencies in the AGL-SRT Paradigm

The ability of humans to use adjacent statistical information has been demonstrated across various studies. As early as two months of age, humans can identify bigrams, or first-order adjacent pairs, from the co-occurrence frequencies of elements within a constrained temporal sequence (Kirkham, Slemmer & Johnson, 2002). Throughout later development and adulthood, humans can also use adjacent conditional probabilities to locate relevant constituent-boundaries in a continuous stream composed of nonwords, tones, visual elements, or nonlinguistic sounds (see Gebhart, Newport & Aslin, 2009, for a review). And further, both children and adults can learn adjacent predictive dependencies that signal the underlying phrase structure of an artificial language (Saffran, 2001).

Below, we adapt the biconditional grammar of Jamieson and Mewhort (2005) to examine adults’ SL of bigrams. This grammar was chosen since it is defined by first-order transitions only, imposes no positional constraints on element placement, and generates strings of equal length. These merits thereby permit us to effectively isolate the learning of predictive adjacencies by our participants.

Method

Participants Thirty native English speakers from the Cornell undergraduate population (15 females; age: $M=19.4$, $SD=0.8$) were recruited for course credit.

Materials Participants observed sequences of auditory-visual strings generated by an eight-element grammar in which every element could be followed by one of only two other elements, with equal probability. Each string consisted of 4 elements, with adjacent probabilities between them as shown in Table 1. The nonwords (*jux*, *tam*, *hep*, *sig*, *nib*, *cav*, *biff*, and *lum*) were randomly assigned to the stimulus tokens (*a*, *b*, *c*, *d*, *e*, *f*, *g*, *h*) for each participant to avoid

Table 1: Transition probabilities for elements at positions n and $n + 1$ of a string, with n as an integer from (0, 4).

Element at n	Element at position $n + 1$ of string							
	<i>a</i>	<i>b</i>	<i>c</i>	<i>d</i>	<i>e</i>	<i>f</i>	<i>g</i>	<i>h</i>
<i>a</i>	0	.5	.5	0	0	0	0	0
<i>b</i>	0	0	.5	.5	0	0	0	0
<i>c</i>	0	0	0	.5	.5	0	0	0
<i>d</i>	0	0	0	0	.5	.5	0	0
<i>e</i>	0	0	0	0	0	.5	.5	0
<i>f</i>	0	0	0	0	0	0	.5	.5
<i>g</i>	.5	0	0	0	0	0	0	.5
<i>h</i>	.5	.5	0	0	0	0	0	0

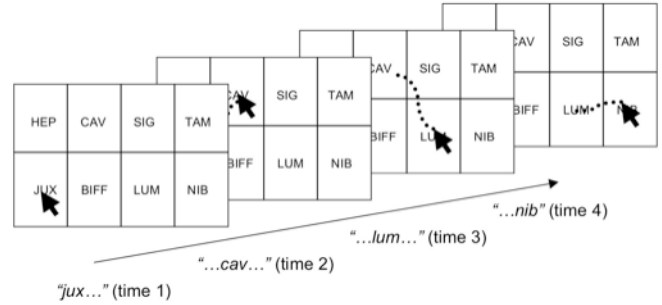

Figure 1: The pattern of mouse clicks for a single trial with the auditory target string “*jux cav lum nib*.”

potential learning biases due to specific sound properties of words. Auditory versions of the nonwords were recorded from a female native English speaker and length-edited to 550 ms. Written versions of nonwords were presented with standard spelling in Arial font (all caps) and appeared within the rectangles of a 2 x 4 computer grid (see Figure 1). Each of the 4 columns of the computer grid, from left to right, displayed the nonword options corresponding to the 1st thru 4th respective elements of a string. Ungrammatical strings were created by introducing an incorrect element at the 2nd or 3rd string position, with the next element being one that legally followed the incorrect one (e.g., as in “*a *d e g*”).

Procedure Each trial corresponded to a different configuration of the grid, with each of the eight written nonwords centered in one of the rectangles. Every column contained a nonword (target) from a stimulus string, as well as a foil. The first column contained the selection for the first element of a string, the second column contained the selection for the second element, and so on. For example, a trial with the stimulus string *jux cav lum nib*, as shown in Figure 1, might contain the target *jux* and the foil *hep* in the first column; the target *cav* and the foil *biff* in the second column; the target *lum* and the foil *sig* in the third column; and the target *nib* and the foil *tam* in the fourth column. Each nonword appeared equally often as target and as foil within and across the columns. The top/bottom locations of targets and foils were randomized and counterbalanced.

Participants were informed that the purpose of the grid was to display their selections and that a computer program randomly determines a target’s location within either the top or bottom rectangle. On every trial, participants heard an auditory stimulus string composed of four nonwords and were instructed to respond to each nonword in the sequence as soon and as accurately as possible by using the computer mouse to select the rectangles displaying the correct targets.

Thus for any given trial, after 250 ms of familiarization to the visually presented nonwords, the first nonword of a string (the target) was played over headphones. Next, the second, third, and fourth words of a given string were each played after a participant had responded in turn to the prior nonword. For example, on a trial with the stimulus string *jux cav lum nib*, the participant should first click the rectangle containing *JUX* upon hearing *jux* (Fig. 1, left), *CAV* upon next hearing *cav* (Fig. 1, center-left), *LUM* upon hearing *lum* (Fig.

l, center-right), and NIB upon hearing *nib* (Fig. 1, right). After a participant had responded to the last nonword, the screen cleared for 750 ms before a new trial began.

An intended consequence of this design is that, for any given trial, the first element of a string cannot be anticipated in advance of hearing the auditory target. However, all subsequent string transitions might be reliably anticipated using statistical knowledge of the bigram structure. Thus, as participants become sensitive to the bigrams, they should be able to anticipate the string transitions, which should be evidenced by faster response times (following standard SRT rationale). Accordingly, our dependent measure on each trial was the reaction time (RT) for a predictive target, subtracted from the RT for the non-predictive initial-column target (which serves as a baseline and controls for practice effects). The predictive target used in this calculation was equally distributed across all non-initial columns across trials. Analogously, for an ungrammatical string trial, if participants are sensitive to the bigrams, then their RTs for incorrect, or violated, elements should be slower; thus, the DV for ungrammatical trials was the RT for the illegal target subtracted from the initial-target RT.

There are 64 unique strings ($8 \times 2 \times 2 \times 2$) defined by the grammar; these were all randomly presented once each for each grammatical block of trials. Training consisted of six grammatical blocks, followed by an ungrammatical block of 16 trials and then a single grammatical ('recovery') block. Transitions across blocks were seamless and unannounced.

After these eight blocks, participants were informed that the strings had been generated according to rules specifying the ordering of nonwords and were asked to complete two tasks involving prediction and bigram recognition, respectively. The prediction task consisted of 16 trials that were procedurally similar to the trials observed during training, but with the omission of the auditory target for the final column.¹ Instead, participants were told to select that nonword in the final column that they believed best completed the sequence.

In the bigram task, participants were randomly presented with 32 test items of auditory nonword-pairs. They were requested to judge whether each pair followed the rules of the grammar by pressing 'yes'/'no' computer keys. Half of the test items were the 16 bigrams licensed by the grammar (e.g., *a b*); the remaining half were illegal pairings formed by reversing each bigram (e.g., *b a*). Thus, successful discrimination reflects knowledge of the conditional bigrams, rather than only sensitivity to co-occurrences.

Results and Discussion

Analyses were performed on only 'good' trials—that is, accurate string-trials with only one selection for each target.

¹ Instructing participants to complete string *endings* allows for maximal procedural similarity to the speeded training trials without introducing additional cue prompts that would be needed if the aurally-omitted element varied across non-initial columns. It also avoids any indirect feedback effects from presenting the next element after a participant's correct/incorrect medial selection.

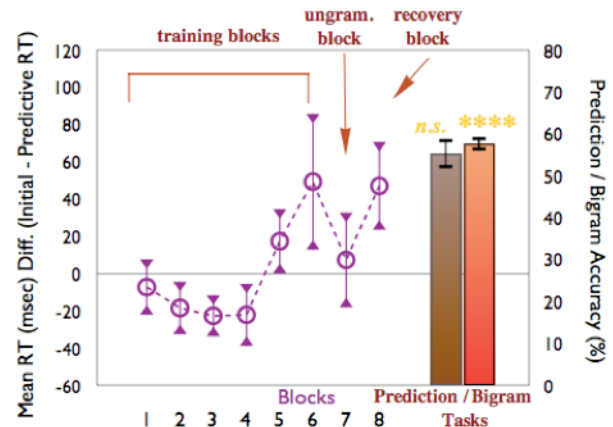

Figure 2: Group learning trajectory (mean RT difference scores per block) and accuracy for prediction (left bar) and bigram (right bar) tasks.

Prior to analysis, the data from five participants were omitted (2 for withdrawing participation; 2 for improperly performing the task, with less than 40% good trials; and 1 for abnormally elevated RTs, averaging in excess of 1470 ms per single response). For remaining participants, good trials averaged 88.2% ($SD=5.9$) of training block trials.

Mean RT difference scores, as described above (i.e., for grammatical trials: initial-target minus predictive-target RT; for ungrammatical trials: initial-target minus illegal-target RT) were computed for each block and submitted to a one-way repeated-measures analysis of variance (ANOVA) with block as the within-subjects factor. Since the assumption of sphericity was violated ($\chi^2(27) = 113.27, p < .001$), degrees of freedom were corrected using Greenhouse-Geisser estimates ($\epsilon = .33$). Results indicated a main effect of block on RT difference scores, $F(2.31, 55.36) = 3.82, p = .02$. As seen in Figure 2, mean RT difference scores appear to increase by the final training block, decrease in the ungrammatical block, and increase once again in the recovery block. As RT difference scores measure the amount of facilitation from the predictive targets, an improvement in scores across blocks (as seen here) reflects sensitivity to the adjacent dependencies.

Planned contrasts between the ungrammatical block and preceding/succeeding grammatical blocks confirmed a performance decline for the ungrammatical trials (Block 6 minus Block 7: $M = -42.0$ ms, $SE=19.6$, $t(24) = 2.14, p = .04$; Block 8 minus Block 7: $M = 39.8$ ms, $SE=17.8$ ms, $t(24) = 2.23, p = .04$). This provides evidence for participants' learning of the sequential dependencies, consistent with standard interpretations in the sequence learning literature for comparing RTs to structured versus unstructured material (e.g., Thomas and Nelson, 2001).

Since the amount of exposure to the dependencies during training is equivalent to that which a similar number of participants ($n=30$) received in the Misyak et al. (2010) study of nonadjacent SL, this invites a comparison of group learning trajectories. The RT timecourse pattern documented here for adjacent SL is very similar to that observed for nonadjacent SL, but with greater variance in

performance for the final training block and with ostensibly more modest (albeit not statistically different) performance in the recovery block. In both cases, sensitivity to the statistical structure does not show signs of emerging until after considerable exposure (the 5th block of training).

Mean accuracy on the prediction task was 55.3% ($SD=17$), which was not above chance ($t(24) = 1.51, p = .14$)—despite 20% of participants scoring at or above 75%. However, accuracy on the bigram task reflected adjacency learning ($t(24) = 4.66, p < .0001$), with a mean of 57.6%. This performance level is consistent with participants' judgment accuracy in an AGL study with manipulations of this same type of grammar when participants are tested with ungrammatical items containing few rule violations (Jamieson & Mewhort, 2009). Bigram scores further ranged from 37.5 – 71.9%, but with less variance ($SD=8$) than that observed in the prediction task. In post-study questioning, only four participants disclosed that they had noticed any general pattern in the sequence but were unable to verbalize at least one instance of a bigram, suggesting that their performance in the bigram task was not the product of explicit recall or well-formulated meta-knowledge. Next, we use scores on this bigram index to assess whether and how variation in adjacent SL may be associated with differences in processing local and nonlocal language dependencies.

Experiment 2: Individual Differences in Language Processing and Statistical Learning

Sensitivity to both local and long-distance relationships is indispensable to processing natural language, and pervades basic aspects of our everyday sentence comprehension and production—such as those involved in relating the modified subject/object of a described action or state to the main event of a sentence (embedded relative clauses), in identifying whether someone is the recipient or doer of an action (agent-patient thematic roles), and in correctly linking subjects with their verbs (number agreement). The aim of Experiment 2 is to investigate whether predictive processing as exemplified by adjacent SL is empirically related to the on-line processing of such natural language contexts. Consider the following examples of the sentence-types that constitute the focus of the current experiment.

- (1a-b) The reporter [that attacked the senator / that the senator attacked] admitted the error.
- (2a-b) The [crook/cop] arrested by the detective was guilty of taking bribes.
- (3a-b) The key to the [cabinet/cabinets] was rusty from many years of disuse.

In the first sentence example, the subject-relative (SR; 1a) and the object-relative (OR; 1b) versions differ with respect to the manner in which the embedded verb *attacked* relates to its object. This involves a more complex, backwards-tracking long-distance dependency (to the head-noun) for ORs. In prior studies using materials resembling those in (1a-b), greater processing difficulty is elicited at the main verb of ORs compared to that of SRs, with considerable

individual differences in the magnitude of this effect (e.g., Wells, Christiansen, Race, Acheson & MacDonald, 2009).

Next, consider the sentence pair (2a-b), which is temporarily ambiguous between a main verb (MV) and a reduced relative (RR) clause interpretation. Its resolution is influenced by the constraint of thematic fit—the fit between the head noun phrase (*the crook* or *the cop*) and the verb-specific roles of the verb (*arrested*). Given verb-specific conceptual knowledge, the reader knows that *cop* is a typical agent of *arrested*, whereas *crook* is a typical patient. Controlling for animacy, thematic fit functions as an immediately integrated constraint computed over the noun and adjacent verb—with its effect on RTs occurring in the subsequent agent NP region (McRae, Spivey-Knowlton & Tanenhaus, 1998). Thus, the second condition (2b) in which the initial noun is a typical agent for the adjacent verb will elicit greater processing difficulty for the RR interpretation than that for the corresponding patient condition (2a). For our purposes, this provides an example of sensitivity to a local relation relevant for on-line sentence processing.

Lastly, (3a-b) illustrate subject-verb number agreement. In English, it is required that a number-marked subject (*key*) agrees with the number-marking of its verb (*was*). This is the case irrespective of the numerical marking of any intervening material (e.g., *to the cabinet/s*), and individuals are sensitive to this fact during reading. When a sentence's head noun is singular, individuals read longer at the MV in a condition where the 'distracting' local noun (*cabinets*) mismatches in number (i.e., is plural) than in a condition where the local noun matches the head noun's number (i.e., is singular); shorter reading latencies are also found for the word after the verb in the match condition (Pearlmutter, Garnsey & Bock, 1999). Although subject-verb agreement may occur locally between adjacent constituents, materials in the literature (and here) have involved a nonlocal dependency created from interposing a prepositional phrase.

Method

Participants The same participants from Exp. 1 participated directly afterwards in this experiment for additional credit. Because the analyses reported below involve correlations with the bigram index from Exp. 1, data was omitted for those participants already excluded in Exp. 1 analyses and from three others (2 for bilingual status and 1 for declining to participate in the second task).

Materials There were four sentence lists, each consisting of 9 practice items, 60 experimental items, and 50 filler items. The experimental items were sentences drawn from previous studies of sentence processing: 20 subject-object relative clauses (SOR; Wells et al., 2009), 20 reduced relative ambiguities influenced by thematic fit (TF; McRae et al., 1998), and 20 subject-verb agreement transitives (S-V; Pearlmutter et al., 1999). A yes/no comprehension probe followed each item. Item conditions within sentence sets were counterbalanced across lists.

Procedure Each participant was randomly assigned to a list, whose items were presented in random order using a

a standard word-by-word, moving window, self-paced reading paradigm. Millisecond reading times (RTs) per word and accuracy were recorded for analyses.

Results and Discussion

Overall comprehension accuracy across participants was high, $M = 87.4\%$, $SD = 7.6$. RTs in excess of 2500 ms (0.2% of data) were removed, and remaining RTs were then length-adjusted for the number of characters in a word using a standard procedure (Ferreira & Clifton, 1986). Unless otherwise noted then, all RTs reported below for each of the sentence sets have been length-adjusted, with the same sentence regions examined as those in the original studies. RTs connected with relevant effects for each of the sets were then used to probe for associations with individuals' bigram scores from Experiment 1, as summarized below.

Subject-Object Relatives. Results replicated the main effect for clause-type at the MV from Wells et al. (2009), $F(1, 21) = 5.55$, $p = .03$. OR MVs were read reliably longer (91 ms) than SR MVs. However, there was no significant correlation between bigram scores and MV RTs for either SR ($r = .04$, $p = .85$) or OR ($r = -.16$, $p = .47$) sentences. Thus, differences in adjacent SL did not appear to directly map onto differences in processing long-distance dependencies in these relative clauses.

Thematic Fit. The influence of TF was replicated at the 2-word MV region (e.g., *was guilty*), $F(1, 21) = 6.42$, $p = .02$, albeit not at the directly preceding agent NP region.² Agent conditions were read 39 ms longer than patient conditions at the MV region. The correlation between bigram scores and unadjusted RTs at the MV of the 'congruent' patient condition was not significant ($r = .29$, $p = .19$); but for the 'incongruent' agent condition, the correlation reached marginal significance ($r = .40$, $p = .06$), with better adjacent statistical learners taking *longer* to read the disambiguating verb phrase. This suggests a tendency for greater bigram sensitivity (in adjacent SL) to negatively correspond with resolving nonlocal ambiguity when the local TF constraint provides an opposing bias to the RR clause interpretation.

Subject-Verb Agreement. A 34 ms effect of match (i.e., the difference between match and mismatch conditions) was obtained at the verb, $F(1, 21) = 31.28$, $p < .0001$, which replicated Pearlmutter et al.'s (1999) findings. There was a smaller effect of match (23 ms) at the post-verb region, $F(1, 21) = 4.48$, $p = .05$, which was also numerically present but not reliable in Pearlmutter et al. Additionally, the correlation between bigram scores and RTs was significant for the effect at the verb ($r = .51$, $p = .02$), with better bigram learning corresponding to a larger effect of match condition. To further examine differences in processing patterns according to SL status, a median-split was performed on bigram scores, establishing 57.8% as the cut-off for defining membership in either a "high" bigram ($n = 11$, $M = 63.9\%$,

Figure 3: RT patterns on the S-V agreement sentences by bigram group (high/low) and condition (match/mismatch).

$SD = 4.0$) or "low" bigram group ($n = 11$, $M = 51.4\%$, $SD = 5.8$). Significant bigram-group differences emerged for the effect of match condition across regions (as shown in Figure 3). While the low-bigram group did not elicit a significant effect of match condition at either the verb or post-verb region ($p = .13$ and $p = .91$, respectively), the high-bigram group showed a clear effect in both regions (both p 's $< .001$). As apparent in Fig. 3, the high-bigram group demonstrated greater sensitivity to the interference created by the locally mismatched marking of the noun in the prepositional phrase (which was irrelevant for computing agreement). Thus, the better adjacent SL of the high-bigram group was related to generally less efficient processing than that by their low-bigram peers of the long-distance dependency entailed by the initial noun and verb. Since bigram groups did not differ in comprehension accuracy for any sentence-types in the experimental sets (all p 's $> .15$), nor fillers ($p = .83$), these RT patterns were not the result of a speed-accuracy tradeoff.

Our findings suggest that adjacent SL skill may not directly tap into the processes most relevant for handling long-distance dependencies in natural language—even though nonadjacent SL abilities appear to do so. Thus, while Misyak et al. (2010) reported a positive association between differences in nonadjacent SL and processing for the same SOR clauses as used here, no correlation was detected for adjacent SL. More generally, this is consistent with the lack of within-subjects correlation found between adjacent and nonadjacent SL in Misyak and Christiansen (2007).

However, while 'high' bigram learners may not differ from 'low' learners on processing long-distance relations as such, their increased sensitivity to local relations might interfere with the processing of the longer-distance elements within the sentence. This tendency is seen in the TF set, where above-average bigram tracking abilities seem to have a negative effect for processing the MV—the site where the initial, nonlocal ambiguity must be resolved. Similarly, too much sensitivity to local information is clearly evidenced within the last sentence set, where the irrelevant marking of an adjacent noun negatively affects better bigram learners' resolutions of S-V agreement, with protracted RTs also at the MV site of integrating the long-distance dependency.

² The later-occurring but nonetheless reliable effect of thematic fit is likely due to differences in the length of the moving window used in this study (1-word) and that by McRae et al. (2-word).

General Discussion

This study investigated the processing of adjacent predictive dependencies to address questions related to the timecourse of adjacent SL and the nature of any empirical association to natural language variation. While a learning trajectory similar to nonadjacent SL was documented in Exp. 1, findings from Exp. 2 indicated that above-average gains in adjacent SL performance do not necessarily translate to gains in language processing. Notably, those individuals who were strongly attuned to tracking statistical bigrams exhibited a *negative* pattern of correlations to tracking longer-distance aspects of language when either countervailing adjacent constraints or nearby distractive elements were present. This inverse pattern was not evidenced, though, when processing long-distance relations without conflicting local information (in the SOR clauses).

Instances where better bigram learners were worse language processors (or tended towards less efficient RT patterns) occurred when the integration of adjacent information (between a head-noun and part-participle verb) induced greater difficulty for resolving an ambiguity as a RR (the TF constraint in Exp. 2)—or when locally irrelevant information disrupted agreement computations between a nonlocal subject and verb (S-V agreement in Exp. 2). It would appear in these situations that those better in adjacent SL, although excelling at bigram pattern recognition in the SL task, are overly attuned to adjacency patterns and become more susceptible to local ‘garden-paths’; in such cases, it may be the ‘over-focus,’ rather than any preexisting weakness in processing long-distance dependencies (as evidenced by parallel performance of groups in the SOR set) that hinders efficient resolution of nonlocal relationships.

This interpretation of our findings suggests that intraindividual differences in processing biases for the integration of competing constraints among adjacent- and nonadjacent dependencies may contribute to variation across SL-linked language processing skills. As such, it speaks to an open issue regarding whether different systems or different processing biases may be entailed by adjacent and nonadjacent processing capabilities in humans. It has been proposed, for instance, that the two forms of processing may be subserved by separate brain areas (Friederici et al., 2006), or that the two types of SL are only nominally distinct as the outcome of task-specific attention processes that may selectively hone in on adjacent or nonadjacent statistics (cf. Pacton & Perruchet, 2008). The findings here, of negative and specific associations between adjacent SL and aspects of language processing, suggest that future individual differences research incorporating careful attention to a diversity of natural dependency-structures may be needed to help establish the proper relation between these two manifestations of SL and the extent to which they may ‘tap’ into the same underlying mechanisms.

Statistical Learning of Complex Questions

Abstract

The problem of auxiliary fronting in complex polar questions occupies a prominent position within the nature versus nurture controversy in language acquisition. We employ a model of statistical learning which uses sequential and semantic information to produce utterances from a bag of words. This linear learner is capable of generating grammatical questions without exposure to these structures in its training environment. We show that the model performs superior to n -gram learners on this task. Implications for nativist theories of language acquisition are discussed.

Keywords: Language acquisition; complex syntax; poverty of the stimulus; statistical learning; distributional information.

Introduction

It is a central question in language acquisition which aspects of our knowledge of language are learned from experience and which are part of our biological endowment for language. Nativist arguments often identify some property of a language and argue that it is not learnable from typical child-directed speech. By abductive reasoning, innate language-specific knowledge is offered as the best explanation of why children come to know this property regardless. The problem of auxiliary fronting in so-called complex polar questions (CPQ hereafter) is a key issue in this nature versus nurture debate.

According to Chomsky (1980), English yes/no-questions are formed from declaratives by displacing an auxiliary. The sentence “The man is happy” transforms into a question by subject-auxiliary inversion: “Is the man happy?”. Declaratives with a relative clause can contain two identical auxiliaries as in “The man that is hungry is happy”. Chomsky asked how children could learn that the main clause auxiliary should be placed in front, rather than the auxiliary which comes first. Only the former rule yields a grammatical CPQ.

- (1) a. Is the man that is hungry happy?
- b. *Is the man that hungry is happy?

He claimed that children have no basis in experience to adopt the correct rule since examples such as (1-a) do not occur in child-directed speech. In addition, children should adopt the rule which generates (1-b) because (i) it is supported by experience of simple yes/no-questions and (ii) the correct rule is “far more complex” in that it requires sensitivity to the hierarchical structure of a sentence. But children rarely, if ever, make mistakes as in (1-b) (Crain & Nakayama, 1987; Ambridge, Rowland, & Pine, 2008). They do not seem to generalize in a structure-independent way. To explain this error-free behavior, Chomsky postulated innate structure-dependent constraints on learning.

The above formulation of this poverty-of-the-stimulus argument makes a number of controversial assumptions. There

is accreting evidence, for instance, that learning the syntax of questions does not involve learning movement rules (Dabrowska & Lieven, 2005; Estigarribia, 2009). An inadequate description of the learning target in terms of transformational rules might obscure empiricist solutions to the problem. Secondly, auxiliary fronting has been isolated from all the rest of language. Although there is some consensus that structures (1-a) are highly infrequent, the input environment of a child might provide other sources of indirect evidence for the correct rule (Pullum & Scholz, 2002). Another critical assumption is that the structure-independent rule (1-b) is simpler and *should* be preferred in the absence of innate constraints. Yet, if there is no reason to believe that children should overgeneralize there is no explanatory necessity for such constraints; the nativist argument would be preempted.¹

Despite these reservations, it is clear that any theory of language acquisition which places more emphasis on the role of experience needs to explain how the syntax of complex questions can be acquired. Ideally, such an explanation demonstrates that a concrete, implemented learning mechanism built on justifiable assumptions can acquire auxiliary fronting from plausible input distributions.

Linear versus hierarchical models

Several models of language learning have recently been proposed which explicitly address the issue of auxiliary fronting. These models can roughly be divided into linear and hierarchical approaches. Linear models do not explicitly represent the hierarchical structure of a sentence’s organization into phrases and clauses. All models briefly discussed here share the assumption that CPQs do not occur in child-directed speech, they learn solely from indirect evidence.

In the framework of data-oriented parsing, Bod (2009) showed that derivations of parse trees for grammatical CPQs are shorter (or more probable) than those for ungrammatical CPQs given the training data. The model assumes that subtrees are representational primitives in the mind of a human learner. Structure-dependent processing is built into the learning mechanism but it is still a question of linguistic experience whether the correct generalizations are supported in this model. Perfors, Tenenbaum, and Regier (2006) demonstrated that an ideal Bayesian learner favors a hierarchical over a linear grammar to fit a training corpus. This grammar could parse grammatical CPQs while the linear grammar could not. The model, however, did not strictly learn grammars from data, but rather selected one from a given set. How grammar selection bears on the process of child-language acquisition

¹ A more detailed discussion of the assumptions behind this nativist argument can be found in Fitz (2009).

needs to be elucidated. They argued that linear models have little to contribute to the auxiliary fronting debate because structure-dependent processing requires hierarchical representations. This assumption has been challenged by a number of linear approaches. If a linear model learning auxiliary fronting behaved in a manner consistent with structure-dependent processing, this would suggest that explicit representations of hierarchical structure might be superfluous. Clark and Eyraud (2006) proposed a linear alignment learner which substituted relativized NPs for simple NPs if they occurred in identical contexts in the corpus. As a result, the learner could generate grammatical CPQs if and only if their component clauses occurred in training. A simple recurrent network was used by Lewis and Elman (2001) to successfully learn CPQs from artificial language input. The scope of this approach is difficult to assess since the model seems to have been tested on a single item only. The most widely received linear approach used n -gram learners on untagged corpora of child-directed speech (Real & Christiansen, 2005). The authors showed that a Bigram model could reliably classify pairs of grammatical/ungrammatical CPQs by assigning higher sentence probability to the former on 96% of the tested items. They suggested that indirect statistical information extracted from strings of words might be sufficient for children to infer the correct rule of auxiliary fronting. These results were scrutinized by Kam, Stoyneshka, Tornyoova, Fodor, and Sakas (2008) who argued that the success of the Bigram model was largely due to a single distinguishing bigram which was supported by accidental phonological facts about English. When they added structural and lexical diversity to the test items, the model failed. Moreover, they argued that the bigram approach might not be valid cross-linguistically.

The Adjacency-Prominence learner

In our own work we aimed at showing that these difficulties could be overcome by a linear statistical model which in addition to n -gram based sequence learning uses meaning to constrain sentence production. The statistical information on which the learner draws had two components. The *adjacency* statistic was collected over bigrams in the training corpus. It measured how often two words which co-occurred in sentences, occurred adjacent to each other. The key addition over n -gram models was the *prominence* statistic. The learner tracked which words frequently preceded other words in the input environment. Words which on average were found earlier in a sentence than other words were considered more prominent. Using this statistic, a hierarchy was created which ordered words in an utterance in terms of their prominence. More prominent words then tended to be sequenced earlier in production. While the adjacency statistic selected words based on the previous word in an utterance, the prominence statistic selected words based on their prominence relation with remaining words in an utterance. This process is illustrated schematically in Figure 1. Both statistics were combined into the Adjacency-Prominence learner (AP-learn-

er for short). This model of syntax learning was introduced in Chang, Lieven, and Tomasello (2008) where it was tested on a variety of typologically-distinct languages. Formal def-

initions of the two kinds of statistics are given in Table 1. Note that the adjacency statistic differs from forward transi-

Table 1: AP-learner statistics.

$C(w_{n-1}, w_n)$	Frequency of bigram $w_{n-1}w_n$
$\text{Pair}(w_a, w_b)$	Frequency of words w_a, w_b occurring together in the same sentence in any order
$P(w_a, w_b)$	Frequency of word w_a occurring before w_b in a sentence at any distance
Length	Number of words in bag-of-words
η	Balance parameter ²
Adjacency	$\text{Adj}(w_n) = C(w_{n-1}, w_n) / \text{Pair}(w_{n-1}, w_n)$
Prominence	$\text{Pro}(w_n) = \sum_{w_b} P(w_n, w_b) / \text{Pair}(w_n, w_b)$ where w_b are all words in the bag (except w_n)
Adjacency-Prominence	
$\text{AP}(w_n) = \text{Length} \times \text{Adj}(w_n) + \text{Pro}(w_n) \times \eta$	

tional probabilities because bigram counts are normalized by the frequency of word pairs instead of the first unigram. The prominence statistic of a word is a sum over its prominence relation with other words. To give a comparable weight to the adjacency statistic, it was multiplied by the number of remaining words in an utterance.

Evaluation

The performance of the AP-learner was evaluated in a sentence generation task. We assumed that speakers aim to produce utterances which express the meaning they intend to convey. To approximate constraints that meaning places on sentence production, a target utterance was split into an unordered bag-of-words. The learner then had to use its syntactic knowledge, extracted from the training corpus, to order this bag-of-words. Sentences were produced incrementally one word at a time. At each word position, all words in the bag were competing for the next slot in the utterance. The

²This parameter was used to calibrate the contribution of both statistics to word choice. It was held fixed across experiments.

learner could use forward probabilities from the preceding word (adjacency) but also the prominence ordering over the words left in the bag to predict the next word. The prominence value for a given word could dynamically change as the set of word options diminished during production.

Training and test items were identified as questions or declaratives by prepending a marker *quest/decl* to each sentence. Utterance generation was initialized by creating a bag-of-words including the marker for the target sentence. For each word in the bag, the adjacency and prominence statistic was collected and the word with the highest combined value was selected (see Table 1). The word was appended to the marker and removed from the bag-of-words. This procedure continued recursively until the bag was empty. The string of words produced by the learner was compared with the target utterance and its grammatical alternatives. For instance, the bag-of-words obtained from “Is the dog that is running happy?” also generated “Is the dog that is happy running?”. If the learner produced either form, the sentence prediction accuracy count was incremented. Likewise, if either of the ungrammatical alternatives (with a displaced embedded clause auxiliary) was produced, the output was counted as a structure-independent generalization error.

Real and Christiansen (2005) tested their *n*-gram learners in a grammaticality judgement task in which CPQs with lower cross-entropy were classified as grammatical. Our learner, in contrast, had to actually produce sentences from a bag-of-words and not merely classify them. Statistical information sufficient for classification might not be suitable for production. Chang et al. (2008) argued that bag-of-word generation is an adequate task to assess and compare statistical learners across languages.

The remainder of this paper is organized as follows. First, we demonstrate that the AP-learner can learn the syntax of complex questions in the absence of positive evidence and that overgeneralization does not occur. Then we compare the AP-learner with *n*-gram models and show that it performs superior. Finally, we identify conditions under which the AP-learner does make structure-independent errors. Such conditions arguably do not obtain in child-language acquisition. We conclude with a discussion of the results.

Method

Language input

The AP-learner was trained on an artificial English-like language with transitives and intransitives as basic construction types. From these constructions, simple declaratives, simple polar questions, complex declaratives, and polar questions with relative clauses could be generated (see Table 2). The language had number and noun-verb agreement, tense (past/present) and aspect (progressive/simple). Nouns could be animate and inanimate, or substituted by pronouns. Over a lexicon of 104 words and inflectional morphemes the language generated approximately 2.8×10^9 distinct sentences. It was suggested by Ambridge et al. (2008) that structure-in-

Table 2: Structures generated by the artificial language.

Sentence type	Example
Simple declarative	The guys buy it.
Simple polar question	Was the dog sleeping?
Complex declarative	A girl that is hitting him plays.
Complex polar question	Is a cat that is grumpy thirsty?

dependent generalizations such as

- (2) Are the boys **that running** are eating?

may not occur in development because they violate word co-occurrence patterns in English (boldface bigram). In similar vein, Kam et al. (2008) argued that the good performance of the Real and Christiansen (2005) model was due to these relative clause initial bigrams. To ensure that our learner could, in principle, generalize erroneously, we separated plural markers and inflectional morphemes for tense and aspect from the word stem. Thus sentence (2) was represented in our artificial language as

- (3) Are the boy -s **that run** -ing are eat -ing?

The boldface bigram occurred frequently in the training corpus, for example in sentences such as “The boy -s that run are kick -ing the toy”. This made it more difficult for the AP-learner to retain the embedded clause auxiliary in CPQs.

Results

Experiment 1

The first experiment tested whether the AP-learner was able to produce correct CPQs when trained only on simple declaratives, simple polar questions and declaratives with relative clauses. The learner was trained on 20,000 sentences randomly generated from the artificial language. 50% of these were simple sentences, the others were complex. 50% of the simple sentences were questions, the others were declaratives. Crucially, the training corpus did not contain any instance of a CPQ or any other question with a relative clause. Thus, it was tested whether the statistical information contained in the trained structures was sufficient for the AP-learner to generalize to the syntax of the novel CPQs. If so, this would support the idea that indirect evidence from frequent structures which are attested in child-directed speech might be sufficient to learn the correct subject-auxiliary inversion rule for complex polar questions.

The test set contained 40 CPQs randomly generated by the artificial grammar. All CPQs had an intransitive main clause. 20 had a center-embedded intransitive relative-clause (II), and 20 had a transitive relative-clause. Half of the transitive embeddings were subject-relativized (ITS), the other half were object-relativized (ITO). All tested CPQs were ambiguous in that the main clause auxiliary was identical with the embedded clause auxiliary. Auxiliaries could be singular or plural, past or present tense. Three actual test questions are listed

in Table 3. In contrast to the study of Realı and Christiansen

Table 3: Sample test questions.

Type	Example
II	Were the boy -s that were dirty play -ing ?
ITS	Was a brother that was push -ing them hungry ?
ITO	Is a cat that a boy is chase -ing jump -ing ?

(2005), the set of tested CPQs was structurally diverse (intransitive and transitive embeddings, subject- and object-relativized) and not limited to the auxiliary “is”.

When evaluating the learner’s output for ITS and ITO questions, only those grammatical alternatives were considered which preserved clause type and the grammatical role of the relativized constituent. For instance, when tested on ITOs, the learner’s utterance had to have an intransitive main clause, and the transitive embedding had to have an object gap in order to count as an accurate production. The results of this experiment are shown in Figure 2.³ The mean sentence pre-

Figure 2: AP-learner tested on three kinds of CPQs.

diction accuracy was 91.25% versus 8.75% incorrect productions. On CPQs of type II, the AP-learner reached 100% accuracy. Slightly lower was the accuracy on ITS (94%) and ITO structures (71%). This difference between subject- and object-relativized transitives is consistent with developmental data on relative-clause acquisition in English-speaking children (Diessel & Tomasello, 2005). The AP-learner made mistakes on this task, it did not produce all test questions correctly. Importantly, however, none of the learner’s incorrect productions matched an ungrammatical CPQ which would reflect structure-independent generalization. Although the AP-learner did not experience any instance of a CPQ in training, it correctly generalized the syntax of subject-auxiliary inversion from simple polar questions and declaratives with relative clauses to the formation of complex questions. When

³All modelling data reported here are averaged over 10 randomly generated training sets to ensure that results were robust with regard to the artificial language used to create input environments.

we added either ambiguous CPQs or CPQs with mixed number, tense and aspect (or both) to the training set, the learner’s performance did not improve on any of the tested question types. These results suggest that the distributional information contained in simple polar questions and complex declaratives support the learning of structure-dependent generalizations even if the learner does not explicitly represent the hierarchical organization of CPQs into clauses and phrasal units. Since both these structures—simple questions and relative clause constructions—typically occur in child-directed speech, children might be exposed to sufficient indirect evidence to induce the syntax of auxiliary fronting in the absence of positive examples.

Experiment 2

In the previous experiment, the AP-learner showed differences in production accuracy between II, ITS and ITO questions. To trace the origin of differential performance, it was helpful to compare the AP-learner with Bi- and Trigram models of statistical learning. Both these models were trained, tested and evaluated in exactly the same way as the AP-learner. Figure 3 shows the prediction accuracy of the different models by CPQ type. All models displayed the same qualita-

Figure 3: AP-learner in comparison with n -gram models.

tive behavior in that II questions were easier to produce than ITS, which were easier than ITO. Both n -gram models performed similar to the AP-learner on II questions. These CPQs were shorter than the other question types and thus had fewer choice points for prediction error. Moreover, ungrammatical II questions frequently contained word sequences which were not supported by the training corpus (e.g., “that happy”). The models followed a principle of non-monotonic learning to produce grammatical II questions: in the absence of evidence to the contrary, embedded clause auxiliaries should not be omitted. The Trigram model came close to the AP-learner on ITS questions (82%), whereas the Bigram model dropped below 40% accuracy. Errors made by the Bigram model mostly occurred sentence-initially (e.g., “quest Is chase”), whereas

Trigram model errors mostly occurred in the relative clause (e.g., wrong verb type). The AP-learner was less vulnerable to these kinds of errors because it did not rely exclusively on co-occurrence frequencies. In addition to adjacency, the model could also use the prominence statistic which informed it that a subject should precede a verb form in the main clause and that a transitive verb should be produced in the relative clause (instead of an intransitive) when there was a direct object (e.g., a pronoun) left to sequence in the bag-of-words. Neither n -gram model produced any correct ITO question, whereas the AP-learner produced 71% correct ITOs. The Bigram model made the same errors as in ITS questions and sequenced a verb form after the initial auxiliary. The Trigram model often converted ITOs into grammatical ITS questions. The AP-learner also made such conversion errors, but less frequently. Again, the prominence statistic helped the model to place subject noun phrases before the verb form in transitive embeddings and this information was not available to the other models.

Kam et al. (2008) argued that Bigram models are not sufficient to learn the syntax of complex questions from noisy, realistic corpora. Our results support their findings for idealized input environments. The AP-learner was superior to both n -gram models when tested CPQs could not reliably be generated from a bag-of-words based on forward probabilities alone.

Experiment 3

As mentioned in the introduction, Chomsky’s argument for the innateness of structure-dependent constraints on language learning has two prongs. Children have no basis in experience to infer the correct rule for auxiliary fronting, and they should overgeneralize by displacing the linearly-first auxiliary, as witnessed in simple polar questions in their language input. In Experiment 1, we found no evidence for either claim. The AP-learner could produce more than 90% grammatical CPQs without having experienced such structures in training. Although the model made some mistakes, it never produced ungrammatical CPQs in which the embedded clause auxiliary was omitted. In a third experiment we attempted to elicit overgeneralizations by creating input conditions which mislead the AP-learner into producing structure-independent errors. To do this, multiple word tokens were distinguished with markers in forward order of their occurrence within one sentence. Question (3), for instance, was now represented as

(4) are1 the1 boy1 -s1 that1 run1 -ing1 are2 eat1 -ing2 ?

After the model had produced a CPQ from a marked bag-of-words, the markers were removed and the output was compared with the equally unmarked target questions (grammatical and ungrammatical versions).

Distinguishing constituents in this way created clause-specific similarities between auxiliaries in different structures. The auxiliary are1 in test item (4) resembled the auxiliary in simple polar questions and the embedded clause auxiliary

in complex declaratives from the training set. The auxiliary are2 resembled the main clause auxiliary in complex declaratives. These similarities were picked up by the adjacency-prominence statistics, as shown in Figure 4. Now the AP-

Figure 4: Structure-independent errors occurred when multiple auxiliaries were distinguished in the corpus.

learner produced only 13.75% correct CPQs. Out of the total incorrect CPQs, 65.5% were structure-independent errors in which the question-initial auxiliary was omitted from the relative clause rather than the main clause. Hence, the AP-learner could be forced to generalize erroneously when constituents were forward marked. Children, however, learn the syntax of questions from input which is not marked in this way. It is therefore not self-evident, as Chomsky suggests, that children should adopt the wrong auxiliary fronting hypothesis in the absence of innate constraints. In order to substantiate this claim, one would have to argue that children perceptually distinguish and track multiple auxiliary tokens in a way similar to the AP-learner in the above experiment. Unless this can be done convincingly, there is no reason to believe that children should overgeneralize. As a consequence, it is no longer puzzling that they in fact rarely do (Crain & Nakayama, 1987; Ambridge et al., 2008). Moreover, there is no need to posit innate constraints on learning as the best explanation of why they do not. One crucial premiss of the poverty-of-the-stimulus argument breaks away. Experiments 1 & 3, we believe, jointly shift the burden of proof back to those who claim that a biological endowment for structure-dependent processing is necessary to block overgeneralization.

Discussion and conclusions

Using a statistical model of syntactic development adapted from Chang et al. (2008), we demonstrated that the syntax of complex polar questions was learnable to a high degree of accuracy even when these structures were not present in the language input to the model. The tested questions were more diverse, both lexically (auxiliaries) and structurally (rel-

ative clause types), than the items used in Realı and Christiansen (2005) which may answer to some of the criticism posed by Kam et al. (2008). Our learner, however, was collecting more than n -gram statistics to accomplish this task. In addition to adjacency, it used a prominence ordering over words that were left to sequence. Words which were more prominent in sentences of the learner's experience were more accessible for production. Thus, the AP-learner was not relying on the presence (or absence) of particular bigrams to produce grammatical questions and it outperformed several n -gram models. Importantly, it was also shown that errors the learner made did not reflect structure-independent generalizations. To elicit these errors, the learning environment had to be manipulated such that it no longer resembled natural language input to children. This casts some doubt on the claim that children should overgeneralize in the absence of innate constraints.

On the downside, the AP-learner was trained on an artificial English-like language which did not exhibit the noisiness, diversity and distributional properties of child-directed speech. Our results should therefore be interpreted as a proof-of-concept that under idealized conditions a statistical learner which draws on sequential and semantic information can learn the syntax of complex polar questions from simpler and similar structures in the input. It remains to be tested whether this approach scales to real corpora and in particular whether it works for different languages which permit complex polar questions other than auxiliary-initial ones (Kam et al., 2008).

We do not suggest here that the adjacency-prominence statistic is all that is required to learn the syntax of complex questions. For one thing, the learner made mistakes where adults do not. The inclusion of meaning constraints (bag-of-words) into a statistical learning model was not sufficient to guarantee error-free learning or rule out the production of grammatical alternatives. Tighter semantic constraints and additional sources of information might be necessary.

Compared with other models which have previously been proposed to show the data-driven learnability of auxiliary fronting, the AP-learner did not make assumptions about the nature of syntactic representations in children, or the operations performed on such representations. The model learned from untagged raw text by means of simple, domain-general mechanisms and did not incorporate language-specific knowledge or biases. The model's task to produce rather than classify sentences is closer to experimental paradigms in developmental psychology than grammaticality judgement and incremental word prediction is consistent with current theories of language processing (Pickering & Garrod, 2007). Furthermore, the evaluation standard did not depend on language-specific assumptions about syntactic categories or on sentence probabilities which are difficult to interpret. Even though the AP-learner did not explicitly represent the hierarchical structure of complex questions or syntactic rules operating on such representations, it performed as if it respected the structure-dependence of auxiliary fronting. Thus, surface

distributional information might be sufficient for a statistical learner to resolve the Chomskyan challenge.

Effector-specific Motor Interference in Action Simulation

Peggy Tausche, Anne Springer and Wolfgang Prinz

(Max Planck Institute for Human Cognitive and Brain Sciences, Leipzig, Germany)

Abstract

Neuroscientific findings suggest that observing temporally occluded actions evokes a mental simulation of the occluded action part. This action simulation may involve corresponding motor programs in the observer and is suggested to run in real time. The present study aimed to investigate whether real-time action simulation relies on effector-specific motor representations. Our participants watched transiently occluded actions performed either with the arms or the legs and had to predict the action course after occlusion. Participants also responded to the task with a movement involving either their arms or legs. Simulation performance broke down when the observed effector and the moved effector corresponded. In contrast, simulation was intact when the effectors did not correspond. The results are in line with previous research and extend it by showing that interference effects can occur within the real-time course of action simulation. Furthermore, shared representations between action simulation and action execution are effector specific.

Introduction

In everyday life, humans experience hundreds of situations in which other people's actions are temporally or partially occluded. Nevertheless, observers perceive the actions in a fluent manner. It is suggested that humans fill the perceptual gap with a mental simulation of the unseen action parts. This action simulation implies the establishment of a mental representation of the unseen part that is equivalent to the visual representation during visual perception.

In the Common Coding framework, it has been argued that action execution and action perception share a common coding system (Prinz, 1990, 1997). This might enable observers to understand, anticipate and predict others' ongoing behavior (Blakemore & Frith, 2005; Prinz, 2006; Wilson & Knoblich, 2005; Wolpert & Flanagan, 2001). Behavioral studies supported this assumption by showing that concurrent action execution and action observation can interact with each other (Brass, Bekkering, & Prinz, 2001; Brass, Bekkering, Wohlschläger, & Prinz, 2000; Kilner, Paulignan, & Blakemore, 2003; Stürmer, Aschersleben, & Prinz, 2000). An influence of action observation on action execution was shown by Brass et al. (2000). They showed that the observation of a lifting movement of the index finger led to faster execution of a lifting movement with the index finger

relative to the middle finger, even when the observed movement was irrelevant to the task. Other studies have investigated the influence of action execution on action perception (Daprati, Wriessnegger, & Lacquaniti, 2007a, 2007b; Jacobs & Shiffrar, 2005). Jacobs and Shiffrar (2005) showed that the ability to discriminate between two observed walking speeds is selectively impaired in walking observers as compared to cycling and standing observers. Taken together these findings propose a bi-directional link between action perception and action production.

While several studies support a bi-directional link between action perception and action production on the level of movements (Brass, et al., 2001; Brass, et al., 2000; Kilner, et al., 2003; Stürmer, et al., 2000), others were able to provide evidence for a link on the level of goals (Bekkering, Wohlschläger, & Gattis, 2000; Hamilton & Grafton, 2006; Woodward, 1998). This suggests that a common representational system of action execution and action observation might be hierarchically organized (1990).

Neurophysiologic findings support this idea by showing a different nature of the so called mirror neurons. These neurons are located in area F5 in the macaque monkey brain (Gallese, Fadiga, Fogassi, & Rizzolatti, 1996) and fire both when the monkey observes an action and when it performs this action on its own. Studies using functional magnet resonance imaging (fMRI) and transcranial magnetic stimulation (TMS) have provided significant evidence that such a mirror neuron system also exists in the human brain (Fadiga, Fogassi, Pavesi, & Rizzolatti, 1995; Grezes, Armony, Rowe, & Passingham, 2003; Rizzolatti & Craighero, 2004). Moreover, there is evidence that there are "strictly congruent" mirror neurons which fire only when the observed and the executed action correspond in means and goals. In contrast, "broadly congruent" neurons generalize across different means and goals (Gallese, et al., 1996).

Other studies have addressed the question of the underlying processes of action simulation itself (Graf, et al., 2007; Prinz & Rapinett, 2008). For instance, Graf and colleagues (2007) recently proposed that the internal simulation of observed actions runs in real-time. The authors used a paradigm in which the participants perceived temporally occluded sequences of point-light actions. In their studies they presented the beginning of an action sequence which was interrupted by an occluder. The occluder was followed by a static test posture. Two independent variables

were manipulated: occluder time (100, 400 or 700 ms) and test posture time (the time which would pass behind the occluder) (100, 400 or 700 ms). The participants' task was to decide whether the test posture was a continuation of the previous seen action in the same visual angle, or whether it was rotated in depth. In accordance with the real-time simulation hypothesis, the participants showed best performance when occluder and test posture time corresponded. Furthermore, performance decreased as the time distance between occluder and test posture time increased. The authors argued that the internal representation of the action is updated in real time and that this leads to high task performance when the upcoming test posture corresponds to a real-time outcome. Furthermore, task performance decreases with increasing dissimilarity in the internal representation and the test posture.

Our study connects to this work by investigating the role of motor representations in this action simulation process. In extension to previous research on motor interference in action observation and action discrimination (Daprati, et al., 2007a, 2007b; Jacobs & Shiffrar, 2005), we focussed on motor interference effects *within the real-time course* of action simulation (as proposed by Graf et al., 2007). Moreover, we wondered whether motor representations, which might be used in action simulation, are organized on an effector-specific level.

It has been suggested that humans have a long-term body representation which contains the basic spatial arrangement of different body parts (Reed & Farah, 1995). A structural overlap between one's own and another person's body enables humans to represent visual, motor and proprioceptive inputs from both bodies within a common code in a shared representational system which in turn would lead to more interactions between both processes. When a common code is used for one process (e.g., action execution), it is not or less available for the other process (e.g., action perception), which should lead to interference. Accordingly, we hypothesized that a structural overlap on the effector-specific level (i.e., the same effector is involved in action simulation and action execution) would lead to increased interference effects as compared to no structural overlap (i.e., different effectors are involved in action simulation and action execution).

In order to investigate this, we adopted the action prediction task used by Graf et al. (2007) and combined it with a secondary motor task. This motor task was performed simultaneously to the action prediction task and involved either the same effector as the relevant effector in the point-light action or a different effector.

Methods

Participants: Thirty right-handed participants (mean 25 years; range 20 – 35 years; 14 female) were tested. One participant's data had to be excluded from the analysis, because of a faulty response device which caused the loss of a part of the data set. Thus, data analysis was based on a total number of 29 participants. All participants reported normal or corrected-to-normal vision and were naive with respect to the purpose of the study. They were paid for their participation. Informed written consent was obtained from each participant prior to the experiment.

Material: We used six film sequences showing a point-light character (Johansson, 1973, 1975) performing familiar actions. These were three arm-related actions (tennis, throwing something with one hand, throwing something with both hands) and three leg-related actions (knee-bends, standing up from a chair, standing up from the floor). We chose actions which were rated on a visual analogue scale as being highly arm- or leg-related by an independent sample ($N = 15$). All actions of the present study were familiar everyday actions and all participants could easily recognize and name them. This is unique and contrasts with other studies using very simplistic and artificial movements (Brass, et al., 2000; Kilner, et al., 2003; Reed & Farah, 1995; Reed & McGoldrick, 2007), thus allowing us to investigate the involvement of effector-specific motor representations in action simulation of complex and familiar actions.

We used point-light stimuli (instead of real films), because these stimuli are known to emphasize motion information instead of alternative sources of information like social information. The videos were taken from a stimulus set provided by Graf et al. (2007) and showed a male right-handed agent recorded using a motion capture system (Vicon Motion Systems Ltd., Oxford, UK). Each point-light display consisted of 13 black dots that were located at the major joints and were 2 mm in diameter. The point-light character was about 7 cm in height and actions were performed within an area of 340 pixels width and 312 pixels height at the center of the screen. An occluder of the same size was presented as a square.

Design and Data Analysis: As in the original paradigm of Graf et al. (2007), we manipulated the factors occluder time (100, 400 and 700 ms) and test posture time (TPT; 100, 400 and 700 ms). A combination of each level of both factors resulted in a condition in which occluder time and TPT correspond (i.e., time distance of 0 ms) and conditions in which occluder time and TPT did not correspond (i.e., time distance of 300 ms and 600 ms, respectively). Participants had to decide whether the test posture was a continuation in the same visual angle, or whether it was rotated in depth. In accordance with Graf et al. (2007), we used

this task, because no explicit judgments about the timing of the actions were requested. Therefore subjects were explicitly instructed to decide whether the test posture was a correct or rotated continuation at any point in time which avoids that task instruction generates potential real-time effects. In order to investigate effector-specific interference effects in action simulation, we introduced a secondary motor task, which was either performed with the arms or with the legs. Participants were instructed to hold their hands/feet on two home buttons during the action sequence of the action prediction task and to perform a discrete bimanual/bipedal movement in order to provide a response to the action prediction task. The movement was a reaching movement towards two diagonally opposite buttons of an arrangement of four different target buttons (e.g., pressing the right upper key with the right hand and pressing the left lower key with the left hand simultaneously in order to give a “correct continuation” response) (Figure 1). The location of the target keys were randomized across participants. Participants were asked to respond immediately when the static test posture appeared and a time out for their response was set at 4000 ms (time out trials were excluded from data analysis).

Figure 1: Schema of the experimental setting (exemplary for arm responses). The actions for the action prediction task were presented on the screen. The hands or feet rested on the home buttons (dark gray). The motor task involved a discrete bimanual/bipedal movement towards two diagonally opposite target keys in order to give a response to the action prediction task.

The experiment consisted of 648 trials (3 occluder times x 3 test posture times x 2 response devices [same, rotated] x 2 video effector [arm versus leg] x 2 response effector [arm versus leg] x 9 repetitions) divided into two experimental sessions with a break of one to two hours in between. Each session consisted of 324 trials divided into 12 blocks. The factor response effector (arm versus leg) was constant within one session. The order of the sessions was randomized across participants. The factor occluder time was blocked and the order of blocks was balanced across participants, with the restriction that two identical

occluder times did not follow each other. The factors video effector (arm versus leg) and test posture time were completely randomized. Prior to the first session, participants received an initial familiarization phase where all actions were presented twice. This was followed by a practice phase containing different actions as in the experiment (knee-bends, leapfrog, basketball). The practice phase consisted of 30 trials and was performed with the same effector that was required in the first experimental session. Prior to the second session, a practice phase of 15 trials was performed again using the other effector, which was required in the second session. The experimental sessions lasted about 1.5 and 1 hour, respectively. Feedback was given to the participants during the practice and the experimental phases.

Data analysis focused on error rates and reaction times (RTs). RTs were defined as the time between TPT onset and leaving the home buttons. RTs were only analyzed for correct responses. Due to the fact that spatial and temporal aspects were mixed in the rotated trials, the analysis included only unrotated trials.

Our analyses were based on compatibility between the relevant effector in the action prediction task and the effector in the action execution task. Compatible trials were those trials in which the video effector and the response effector corresponded (arm/arm and leg/leg); incompatible trials were the trials in which the video effector and the response effector did not correspond (arm/leg and leg/arm). Compatibility was considered to be an adequate factor for the analysis because participants were required to predict exactly the same actions and to answer with their arms and legs in both compatible and incompatible trials. This allowed us to control for stimulus-dependent effects (due to variability within the point-light actions) and to control for response-dependent effects (due to variability between arm and leg responses), which are not in the center of interest in this study.

Results and Discussion

Error rates: We performed an analysis-of-variance (ANOVA) with the factors occluder time, test posture time (TPT) and compatibility. Error rates showed a significant main effect of TPT ($F(2, 56) = 38.395$; $p < .001$; $\eta^2 = .578$) with significantly higher error rates in the long TPT as compared to short and medium TPTs ($ps < .001$; Bonferroni corrected). No main effect of occluder time and no main effect of compatibility were found ($Fs < .1$). A significant two-way interaction between the factors occluder time and test posture time was found ($F(2, 112) = 2.835$; $p < .05$; $\eta^2 = .092$). In line with Graf et al. (2007), lowest error rates were found when occluder time and test posture time corresponded. No other two-way interaction reached significance ($Fs < 1$). Most importantly, the three-way interaction between the factors occluder time, TPT and

compatibility was significant ($F(4, 112) = 2.664$; $p < .05$; $\text{Eta}^2 = .087$). There was no significant occluder time \times TPT interaction in the compatible condition ($F < 1.8$), while this interaction was reliable in the incompatible condition ($F(4, 112) = 3.660$; $p < .01$; $\text{Eta}^2 = .116$). This indicates that incompatible trials, in contrast to compatible trials, involved real-time action simulation processes.

A way of confirming this effect and to increase power is the analysis of the time distance effect. In a further step, we collapsed the different occluder times and TPTs across time distances (time distance of 0 ms, 300 ms and 600 ms, respectively) and performed an ANOVA with the factors time distance (0, 300 and 600 ms) and compatibility. Data showed a significant main effect of time distance ($F(2, 56) = 11.235$; $p < .001$; $\text{Eta}^2 = .286$). As put forward in the real-time hypothesis, error rates were significantly higher in the greatest time distance as compared to the short and medium time distance ($ps < .001$; Bonferroni corrected). Again, there was no main effect of compatibility ($F < .1$). Most interestingly, data showed a significant interaction between the factors time distance and compatibility $F(2, 56) = 5.050$; $p < .05$; $\text{Eta}^2 = .153$, with a significant main effect of time distance in the incompatible trials ($F(2, 56) = 13.461$; $p < .001$; $\text{Eta}^2 = .325$), while there was no reliable effect of time distance present in the compatible trials ($F < 1.9$) (Figure 2). Again, this indicates that incompatible trials, in contrast to compatible trials, involved real-time action simulation processes.

Figure 2: Error rates plotted as a function of time distance dependant on the compatibility between video effector and response effector. Error rates showed a significant time distance effect in incompatible trials, while no reliable time distance effect was present in compatible trials.

Reaction times: We performed an ANOVA with the factors occluder time, test posture time (TPT) and compatibility. Reaction times showed a significant

main effect of occluder time ($F(2, 56) = 4.745$; $p < .05$; $\text{Eta}^2 = .145$), with significantly shorter RTs in the medium as compared to the short occluder time ($p < .05$; Bonferroni corrected). A significant main effect of TPT ($F(2, 56) = 23.389$; $p < .001$; $\text{Eta}^2 = .455$) was found with increasing RTs with increasing TPT ($ps < .01$; Bonferroni corrected). Furthermore, a significant main effect of compatibility was found ($F(1, 56) = 6.362$; $p < .05$; $\text{Eta}^2 = .185$), with shorter RTs in compatible as compared to incompatible trials. A significant two-way interaction between the factors occluder time and test posture time was found ($F(2, 112) = 6.568$; $p < .001$; $\text{Eta}^2 = .19$), with longest RTs when occluder time and test posture time did not correspond. Neither other two-way interactions nor the three-way interaction reached significance ($Fs < 1$).

Again, we collapsed the different occluder times and TPTs across time distances (time distance of 0 ms, 300 ms and 600 ms, respectively) and performed an ANOVA with the factors time distance (0 ms, 300 ms and 600 ms) and compatibility. Data showed a significant main effect of time distance ($F(2, 56) = 5.337$; $p < .01$; $\text{Eta}^2 = .160$). RTs were significantly higher in the long time distance as compared to the short and medium time distance ($p < .05$; Bonferroni corrected). There was a main effect of compatibility ($F(1, 56) = 6.123$; $p < .05$; $\text{Eta}^2 = .179$), with significantly faster RTs in compatible as compared to incompatible trials. No significant time distance \times compatibility interaction was found ($F < .4$) (Figure 3).

Figure 3: Reaction times plotted as a function of time distance dependant on the compatibility between video effector and response effector.

General Discussion

The present study aimed to investigate the role of motor representations in action simulation by focussing on motor interference within the real-time course of action simulation. Furthermore, it was investigated whether motor representations, which might be used in

real-time action simulation, are organized on an effector-specific level.

Overall, the results showed two major findings: First, our data showed that action simulation and action execution share a common representational system. Action simulation is considered to run in real time (Graf, et al., 2007), but we could show interference in the time course of action simulation in an online action prediction task. To our knowledge, our results are the first to demonstrate that a secondary motor task leads to an interference effect within the real-time course of action simulation. We assume that the preparation of the to-be-executed action takes resources of the same representational system as action simulation, which in turn leads to a lack of resources which might be necessary for an action simulation to run in real time.

Second, we were successfully able to show that this motor interference effect was effector-specific. That is, real-time action simulation broke down when the action prediction task and the action execution task involve the same type of effector as compared to a different type of effector, although the predicted and the executed actions differed in terms of the kind of action, the exact trajectory and action goals. This allows us to specify that shared representations are coded on an effector-specific level and that they can generalize across different kinds of actions, trajectories and goals. This finding is in line with other studies (Reed & Farah, 1995; Reed & McGoldrick, 2007). For example, Reed and McGoldrick (2007) showed that the task performance in a body posture memory task is selectively impaired when a concurrent movement task is applied that involves the same type effector as the body posture memory task as compared to a different type of effector. In this study the only structural overlap regards the effector while the kind of the action, the trajectory and the goals differs between both tasks. The idea that shared representations might be organized hierarchically is also supported by imaging studies showing that parts of the mirror neuron system are organized in a somatotopic pattern which resembles the classical motor homunculus (Buccino, et al., 2001; Buccino, et al., 2004). In line with the common coding framework (cf. Introduction), these results suggests the existence of a hierarchically organized matching system of action observation and action execution.

As mentioned above, real-time simulation was no longer applied in trials, in which the relevant effector in the action prediction task and in the action execution task corresponded. Nevertheless, it is reasonable to assume that real-time action simulation was replaced by another process because task accuracy was comparable between compatible and incompatible trials. Possible candidates of processes are either the memorizing of the arrangement of certain points of the point-light display and matching them onto the test posture which was presented after the occluder or

memorizing the test postures and the according feedback and applying a memory process without any simulation process. Although we cannot make any assumptions about the type of process which was applied in compatible trials, we can completely rule out a real-time simulation process. One could speculate that real-time simulation is the default process and that a blocking of a common coding system by a secondary motor task leads to a breakdown of such a process and requires the application of an alternative process.

However, the motor interference effect in real-time action simulation was statistically reliable only in error rates. There are several reasons which might account for that fact. First, we used quite a demanding task. Participants' error rates were relatively high (about 23 percent). This is in contrast to other studies that involve very simplistic and easy tasks showing a compatibility effect in the RTs, which could show floor effects in error rates (Brass, et al., 2001; Brass, et al., 2000). Second, we used a decision task. It is likely that this requires higher cognitive processes in order to reach the decision rather than a reaction towards a certain stimulus. An indication of this is the fact that RTs were much longer (average of 820 ms) than RTs for simple reactions towards a certain stimulus (about 300 ms) (Brass, et al., 2001; Brass, et al., 2000). Third, although we instructed our participants to respond as fast and as accurately as they could, it is possible that they focused more on task accuracy. They had a quite long time in which to give a response (time out of 4000 ms) and participants received feedback on the basis of accuracy while no explicit feedback was given regarding speed. It is likely that this caused participants to focus on task accuracy rather than task speed, which in turn lead to a visible effect of compatibility on action simulation in error rates.

In conclusion, this study demonstrates for the first time motor interference *within the real-time course* of action simulation. This indicates that real-time action simulation of temporally occluded actions and action execution share a common representational system. Preparation for action execution leads to the activation of these shared representations, which in turn leads to a lack of representations for action simulation. This, in turn, causes interference in the real-time cause of action simulation. Finally, we were successful in showing that this representational system is specific on the level of effectors, even when the actions differ in terms of the kind of the movement, trajectories and goals.

Abstract

Schematic language (e.g., prepositions) and depictions (e.g., line drawings) reduce the rich detail of the visual world to a coarser level of description. We investigated how these schematic forms may be represented in the brain. Recent neural evidence suggests that such representations may be computed in the dorsal pathway of the visual system, the same pathway involved in processing motion, including simulated motion in static scenes. Drawing on this association, we examined the stimulus conditions and mental sets that give rise to simulation, and by hypothesis, representations in the dorsal stream. Simulated motion was evident for scenes that were highly schematic, as opposed to highly realistic (Experiment 1), and when realistic scenes were processed schematically (Experiment 2). The results suggest that dorsal stream representations capture the schematic aspects of visual experience, rather than more fine-grained information. In affording simulation, these representations may facilitate certain types of reasoning and inference.

Keywords: schematic representations; mental simulation; dorsal stream; implied motion; word meaning.

Introduction

In physics and engineering textbooks, simple line drawings are often used to illustrate complex physical phenomena. These drawings tend to be highly schematic, representing idealized examples of the processes in question. Schematic depictions of this sort may be useful not only because of their visual simplicity, but also because they have a fundamental cognitive basis. In particular, they may map onto mental representations that are themselves schematic in nature and that may afford certain perceptual and cognitive advantages over representations that more veridically capture the rich detail of the visual world. In this research, we investigate the nature of these hypothesized schematic representations and how they might be realized in the brain.

A distinction between representations that are more detailed or featural and those that are more schematic or configural has been proposed to underlie the meanings of words. Landau and Jackendoff (1993) argued that the representations associated with the meanings of object nouns, which encode detailed featural information, differ from those associated with the meanings of prepositions, which encode coarser configural properties. Moreover, they hypothesized that these different types of representations are computed in different processing pathways in the brain. A highly influential model originally proposed by Ungerleider and Mishkin (1982) points to two separate streams for the processing of visual information: a ventral stream,

responsible for the identification of objects on the basis of visual properties such as shape, size, color, and texture (the “what” system), and a dorsal stream, responsible for the localization of objects in space (the “where” system). Landau and Jackendoff proposed that the meanings of object nouns are processed in the “what” system and the meanings of prepositions in the “where” system.

While several of Landau and Jackendoff’s (1993) conjectures have been supported by subsequent neural research, recent work suggests that the dichotomy between object nouns and prepositions may not adequately capture processing differences in the two streams. Beyond localizing objects in space, the dorsal stream appears to be responsible for certain aspects of object perception. For example, several areas of the dorsal stream are activated during the passive viewing of objects. The caudal part of the intraparietal sulcus (CIP) shows sensitivity to the shapes of objects even when their location is unspecified (Grefkes & Fink, 2005). Similarly, activity in the V5/MT complex has been linked to differences in the shapes of objects in static images (Chandrasekaran et al., 2006). These findings suggest that the ventral stream is not the only pathway in which objects are processed; the dorsal stream is also sensitive to certain object properties, notably shape.

Nonetheless, the two streams appear to differ in the level of abstraction at which they process objects. Whereas the dorsal pathway is primarily concerned with identifying the principal axes, surfaces, and dimensionality of an object, the ventral pathway fills in featural details such as size, color, and texture (Farivar, 2009). Consistent with this characterization of the two streams, Lehigh and Sereno (2006) observed that neurons in the dorsal area LIP were sensitive to shape but less able to differentiate shapes than neurons in the ventral area AIT (see also Chandrasekaran et al., 2006). These findings suggest that the ventral stream makes fine-level distinctions, while dorsal stream processing is at a coarser, more schematic level.

Intriguingly, the dorsal stream is also invoked in the perception of implied motion; that is, the kind of motion suggested by frozen-action photographs or speed lines in cartoons. In an imaging study, Kourtzi and Kanwisher (2000; see also Senior et al., 2000) observed activation in V5/MT in response to still photographs of agents or objects in motion (e.g., an athlete about to throw a discus). These findings suggest a way in which dorsal stream processing might be examined behaviorally. When people perceive implied motion from a static scene, it is highly likely that

they are processing the scene in the dorsal stream. Hence, the perception of implied motion can be used as an index of dorsal stream processing, and by hypothesis, of the schematic representations that support such processing.

A necessary condition for taking advantage of this association is to find a way to measure the perception of implied motion. An experimental paradigm developed by Freyd, Pantzer, and Cheng (1988) offers such a measure. In Freyd et al.'s study, participants were presented with a line drawing of a scene depicting a potted plant supported by a pedestal. The scene was then replaced by one in which the pedestal was removed, but the plant was in exactly the same position as it had been previously. This second scene was then replaced with a third scene in which the plant's position was shifted slightly (higher or lower) or remained the same. The participants' task was to indicate whether the plant in the third display was in the same position as in the second. Freyd et al. reasoned that if people viewed the pedestal as exerting a force on the pot, they might (implicitly) expect the plant to move downward due to the influence of gravity. As predicted, participants were more likely to report "same" to a downward shift than an upward one. These results support the hypothesis that motion will sometimes be perceived when a force acting on an object is suddenly removed. This phenomenon of implied motion from disequilibrium is one of several types of *displacement*, in which the mental representation of a target's location is displaced in the direction of (implied) target motion (see Hubbard, 2005, for a review).

Predictions. Based on subsequent neural research, it is highly likely that the implied motion perceived by participants in Freyd et al.'s (1988) study involved processing in the dorsal stream (in particular, area V5/MT). If so, it should be possible to modulate displacement by varying the properties of the visual stimulus. Lobmaier et al. (2008) employed this technique in an fMRI study of face processing, observing greater dorsal (V5/MT) activation to blurred faces (which preserved configural information) than to scrambled faces (which disrupted configural information but preserved detailed featural information) and greater ventral activation to scrambled than to blurred faces. Thus, changing the properties of the visual stimulus changed which pathway was primarily used to process the stimulus.

The findings of Lobmaier et al. (2008) suggest that the perception of implied motion in static scenes will be more pronounced when stimuli are highly schematic, as opposed to highly realistic. Highly schematic stimuli are more likely to be processed in the dorsal stream than in the ventral stream; processing in the dorsal stream should produce larger effects of implied motion, and hence a stronger displacement effect. If this initial prediction is supported, we might find that displacement can be modulated in other ways as well. In particular, it might be possible to influence how a stimulus is processed by varying the observer's mental set. Because relational words like verbs and prepositions encode the world in a relatively schematic fashion, describing a scene by using a high proportion of

such words (as opposed to words that encode featural information, such as adjectives) should engage the dorsal stream and result in greater displacement. Drawing a scene might also modulate one's mental set, with more schematic drawings leading to greater displacement. We tested these predictions in the following two experiments.

Experiment 1

In our first experiment, we investigated whether implied motion would be perceived in scenes that varied in realism. We contrasted realistic scenes that resembled photographs with schematic scenes that resembled line drawings, similar to those used by Freyd et al. (1988). Our prediction was that the schematic scenes would engage the dorsal stream more than the realistic scenes, and hence that there would be greater displacement for the schematic scenes than for the realistic ones. Following Freyd et al., we also varied whether the initial picture in the sequence showed a support relation (e.g., a pedestal supporting a plant vs. a plant floating in mid-air), in order to confirm that displacement was due to the perceived removal of a force rather than some perceptual bias to infer that unsupported objects will move downward. Thus, we predicted that displacement would be more likely when the initial picture depicted a support relation than when it did not.

Method

Participants. Fifty-nine Emory University undergraduates received course credit for participating in the experiment.

Materials. We created a set of materials based on the scenes shown in Figure 1. The scenes depicted a room either rich in photorealistic detail (Realistic format) or schematically sketched, as in a line drawing or diagram (Schematic format). The Schematic scene was a contoured rendering of the Realistic scene, with all fine detail removed so that only the basic outline of the objects was visible. All other aspects of the two display formats were identical. Each display was 27.3 cm x 15.7 cm (45.5° x 28.9° visual angle).

Figure 1: The Realistic (top) and Schematic (bottom) support displays used in Experiment 1.

There were four variants of each display format. In the original version shown in Figure 1, a potted plant (height: 2.3 cm / 4.3°) is supported by a marble pedestal at the center of the room (*support display*). In the other three versions, the pedestal was removed and the plant was either in exactly the same position (*no-support display*), slightly raised (*up display*), or slightly lowered (*down display*). In the latter two displays, the plant was 0.15 cm (0.3°) higher or lower, respectively, than its original position. All displays were created using a graphics package called Discreet 3D Studio Max, version 7.

Design and Procedure. Participants were randomly assigned to either the Realistic or Schematic display format and to either the Support or No Support trial type, in a fully crossed between-subjects design with four conditions: Realistic-Support, Realistic-No Support, Schematic-Support, and Schematic-No Support. Figure 2 depicts the trial structure. In the Support conditions, each trial began with the presentation of the support display, which remained on the screen for 250 ms. Following a 250-ms interstimulus interval (ISI), the no-support display appeared for 250 ms. Another 250-ms ISI was followed by one of three test displays: no-support (showing the plant in the same position as it had been previously), up, or down. The test display remained on the screen until participants made a response. The No Support conditions were identical, except that the first stimulus of each trial was the no-support display.

As in Freyd et al. (1988), participants were asked to indicate whether the plant in the test display was in the same position as it had been in the previous (no-support) display. They were instructed to press the ‘S’ key for *same* and the ‘D’ key for *different*. The instructions emphasized both speed and accuracy. Participants were also told that they should not expect an equal number of same and different trials, and that they should process the entire display rather than the plant alone. There were a total of 60 randomly ordered trials, 20 with each test display.

Figure 2: The structure of individual trials, shown with stimuli from the Realistic-Support condition of Experiment 1 and all conditions of Experiment 2.

Figure 3: Accuracy on up and down trials across conditions in Experiment 1 (error bars are +/- 1 SEM).

Results

The main finding was that displacement occurred only for schematic scenes that depicted an initial support relation. As shown in Figure 3, participants in the Schematic-Support condition were more likely to indicate “same” when the plant was shifted down than when it was shifted up. No such asymmetry was observed in the other three conditions.

These findings were supported by a mixed ANOVA on participants’ accuracy patterns in which format (realistic vs. schematic) and support (initial display showed vs. did not show a support relation) were between-subjects factors and target position (up vs. down) was a within-subjects factor. [The data of 3 participants were excluded from analyses for making *same* responses on greater than 75% of the trials, leaving 14 participants in each condition.] There was a significant main effect of target position [$F(1,52) = 7.01, p < .02$], with accuracy lower for down trials ($M = 62\%$) than for up trials ($M = 70\%$). However, this asymmetry between up and down depended on both format and support, as shown by a significant interaction between target position and format [$F(1,52) = 8.78, p < .005$] and a significant three-way interaction [$F(1,52) = 7.01, p < .02$]. Accuracy was significantly lower for down than for up trials only in the Schematic-Support condition (up: $M = 77\%$, down: $M = 50\%$), $t(13) = 4.11, p < .005$. There was no asymmetry in the other three conditions, and no other main effects or interactions were significant (all $ps > .2$).¹

Discussion

The results of Experiment 1 replicate the findings of Freyd et al. (1988) in confirming that people simulate

¹ The RT data showed the same general patterns as the accuracy data across both experiments, though some analyses did not reach statistical significance. In this paradigm, as noted by Freyd et al. (1988), there are often too few correct responses to calculate a reliable RT for some trial types (e.g., down trials in the Schematic-Support condition of Experiment 1).

motion in static scenes only when there is perceived removal of a force. However, the results also highlight an important caveat to this conclusion. The simulation processes associated with the perception of implied motion are engaged more when visual stimuli are schematic, as opposed to realistic. We suggest that displacement varied as a function of realism because the properties of the schematic materials reflected the kinds of representations that are hypothesized to exist in the dorsal stream to a greater extent than did the properties of the realistic materials.

Although there was no evidence of mental simulation in the Realistic conditions, this does not imply that realistic materials cannot lead to the simulation of motion. The materials in the Realistic conditions consisted of certain features (e.g., color, texture) that could be processed only in the ventral stream, but they also included features that could be processed in the dorsal stream (e.g., shape). Because schematic language (e.g., prepositions) and depictions (e.g., line drawings) reflect a relatively coarse level of description, activities that promote the use of such forms might induce a more schematic conceptualization of experience. If sufficiently biased through such activities, people might focus on the schematic aspects of realistic materials, in which case even realistic materials might lead to the perception of implied motion.² This possibility was examined in the next experiment.

Experiment 2

Experiment 2 examined whether a prior task prompting people to focus on the schematic properties of a realistic stimulus might induce greater simulated motion. Participants completed the same task as in Experiment 1, but this time they were shown only the realistic stimuli. Prior to this task, participants engaged in activities designed to vary the mental set they used when subsequently processing the realistic scene. Half of the participants were asked to describe the scene in writing, while the other half were asked to draw the scene. Within each of these groups, half of the participants were asked to describe or draw the scene in a realistic manner, while the other half were asked to describe or draw the scene in a schematic manner. The key prediction was that schematic processing, whether induced by describing or drawing, would engage the dorsal stream to a greater extent, and hence lead to greater displacement, than would realistic processing.

Method

Participants. Seventy-nine Emory University undergraduates participated in the experiment as part of a course requirement. **Materials, Design, and Procedure.** The materials included the same photorealistic stimuli used in Experiment 1. Participants were randomly assigned to either the Describe or Draw condition and to either the Realistic or Schematic format in a fully crossed between-subjects design with four

conditions: Describe-Realistic, Describe-Schematic, Draw-Realistic, and Draw-Schematic.

In all conditions, participants were shown the support display, in which the plant is supported by the pedestal. In the Describe-Realistic condition, participants were asked to describe the room “in rich detail, as if describing the details of a photograph.” In the Describe-Schematic condition, participants were asked to describe the room “schematically, as if describing the details of a diagram.” Similarly, in the Draw-Realistic condition, participants were asked to depict the room “in rich detail, as if your drawing were a photograph,” whereas in the Draw-Schematic condition, they were asked to depict the room “schematically, as if your drawing were a diagram.” Participants were given 5 minutes to describe or draw the room. Then they completed the implied motion task using the materials from the Realistic-Support condition of Experiment 1 (see Figure 2).

Results

The results showed that varying the mental set of the observer modulated the perception of implied motion. Displacement was observed for realistic scenes when a prior task induced participants to process the scenes schematically, but not when the task induced them to process the scenes realistically.

These findings were supported by a mixed ANOVA on participants’ accuracy patterns. [The data of 7 participants were excluded from analyses for making *same* responses on greater than 75% of the trials, leaving 18 participants in each condition.] There was a significant main effect of target position [$F(1,68) = 7.51, p < .01$], with lower accuracy for down trials ($M = 62\%$) than for up trials ($M = 72\%$), just as would be expected if participants were simulating downward motion. A significant interaction between target position and format [$F(1,68) = 5.13, p < .03$] showed that the asymmetry between down and up trials was larger in the Schematic conditions than in the Realistic conditions. Within the Schematic conditions (collapsing across Describe and Draw), accuracy on down trials ($M = 61\%$) was significantly lower than on up trials ($M = 78\%$), $t(35) = 3.64, p < .001$. Within the Realistic conditions, the difference in accuracy between down ($M = 63\%$) and up ($M = 65\%$) trials was not significant ($p > .7$). No other main effects or interactions were significant (all $ps > .09$).

The lack of a three-way interaction between target position, format, and medium [$F(1,68) = 1.15, p > .2$] suggests that the down-up asymmetry for the Schematic format (relative to the Realistic format) was comparable in both the Describe and Draw conditions. However, the Schematic format showed a greater asymmetry than the Realistic format only for participants who had produced drawings, $F(1,34) = 6.12, p < .02$ (see Fig. 4). The difference between the two formats was not significant for participants who had written descriptions ($p > .4$).

Post-hoc analysis indicated that the magnitude of displacement correlated positively with the proportion of relational terms (prepositions and verbs describing spatial relations) in participants’ descriptions ($r = .45, p < .01$), but

² This prediction is consistent with findings showing that displacement can be influenced by variables such as observers’ conceptual knowledge and expectations (see Hubbard, 2005).

Figure 4: Accuracy on up and down trials across conditions in Experiment 2 (error bars are ± 1 SEM).

did not correlate with the proportion of adjectives ($r = -.26$, $p > .1$). In addition, descriptions from the Describe-Schematic condition had a significantly higher proportion of relational terms [$t(35) = 3.02$, $p < .005$] and a marginally lower proportion of adjectives [$t(35) = 1.74$, $p = .09$] than descriptions from the Describe-Realistic condition. Ratings of participants' drawings (by a separate group, $N = 15$) on a 1-to-9 Likert scale of "realism," defined as the extent to which a drawing included cues to 3D properties such as depth and texture, were also collected. On average, raters assigned significantly higher realism ratings to drawings from the Draw-Realistic condition ($M = 5.0$) than drawings from the Draw-Schematic condition ($M = 4.7$), $t(14) = 2.32$, $p < .04$. Thus, participants who showed greater displacement were those who had used more schematic language or produced more schematic drawings.

Discussion

The results of Experiment 2 provide further support for the idea that implied motion is more likely to be perceived when a scene is conceptualized in a schematic fashion. When conceptualized schematically, the scene may be processed primarily in the dorsal stream, which is largely responsible for the mental simulation of motion. While we found clear effects of drawing on simulation, the effects of verbal description were less compelling. However, an association between simulation and relatively schematic aspects of language in participants' descriptions suggests that verbal description can in fact modulate processing. In particular, the positive correlation between relational terms and the displacement effect is exactly what would be predicted if relational language leads people to process visual stimuli in a schematic fashion, presumably in the dorsal stream. Further, the lack of correlation with adjectives is not surprising, as adjectives encode information presumably processed in the ventral stream.

In sum, the results suggest that everyday activities such as writing and drawing can direct attention to different aspects

of visual stimuli and influence how they are processed. Schematic processing may cause the visual world to be represented more like a line drawing than a photograph, and this format of representation may invoke simulation processes in the dorsal stream.

General Discussion

The results from this research suggest that the mental simulation of motion in static scenes depends on the realism of the scenes and the observer's mental set when processing them. Experiment 1 showed that simulation occurred during the processing of highly schematic scenes resembling line drawings, but not highly realistic scenes resembling photographs. Experiment 2 showed that simulation can occur even for highly realistic scenes when they are processed schematically; that is, when prior activities induce the observer to focus on their schematic properties. Because the simulation of motion is strongly associated with processing in the dorsal visual pathway, the conditions under which implied motion is perceived offer a window into the kinds of representations associated with dorsal stream processing. Consistent with previous evidence indicating that the dorsal stream operates at a relatively coarse level in the perception of objects, our findings are suggestive of a format of representation in which the rough contour of objects and the spatial relations among them are preserved, but detailed featural information is lacking. The sparseness of such representations, much like the line drawings in physics textbooks, may be especially suited for the mental operations at work in the simulation of motion.

This link between schematic representations and simulation highlights the potential utility of such representations for reasoning. In particular, reasoning about physical systems sometimes involves forming a mental image of a system and then "running" it (Hegarty, 2004). For example, when solving problems involving interlocking sequences of gears, people often mentally rotate the gears before discovering the abstract rule that governs how they turn, namely that odd and even gears turn in different directions (Schwartz & Black, 1996). Our findings suggest that more schematically rendered or imagined gears may be easier to mentally rotate, which could influence the tendency to re-represent the problem in terms of a rule. Thus, the use of schematic representations may be beneficial for certain types of problem solving and inference.

One key question concerns exactly what visual properties constitute a "schematic" representation, as opposed to a "realistic" one. In future work, we plan to employ the same behavioral paradigm used in the present experiments to specify which aspects of visual stimuli give rise to simulation, and hence reflect properties of schematic representations in the dorsal stream. If, for example, displacement is minimized or eliminated when visual properties such as depth cues or surface gradients are absent, it would imply that schematic representations include such information. Similarly, if displacement persists even when the stimuli are primitive 3D shapes (e.g., spheres, cylinders), it would imply that schematic representations need not have any shape detail beyond simple geometric forms.

Although we found no evidence of simulated motion with realistic materials under neutral conditions, other studies (e.g., Kourtzi & Kanwisher, 2000; Senior et al., 2000) have used realistic materials specifically to identify the neural correlates of simulated motion. However, these studies used single static stimuli in which motion was strongly implied (e.g., frozen-action photographs), whereas our stimuli invoked more subtle forms of motion (slight changes in spatial position) solely through the sequential nature of their presentation. Our findings suggest that the use of schematic stimuli in the former paradigm might lead to even greater simulated motion. Interestingly, displacement effects in a handful of studies using realistic stimuli have been regarded as validating the widespread use of more impoverished stimuli (Hubbard, 2005), but to our knowledge, the current study is the first to manipulate realism directly. Our findings caution against the assumption that simulation for schematic materials will carry over to more ecologically rich contexts.

Together with recent neural work, our findings have implications for models of the neural bases of word meaning. While Landau and Jackendoff (1993) argued that the dorsal and ventral streams map onto different grammatical categories (preposition vs. noun), it is likely that certain aspects of the meanings of object nouns are represented in the dorsal stream as well. Processing differences in the two streams may be better accounted for by a distinction often made in lexical semantics between structural and idiosyncratic aspects of word meaning (Levin & Rappaport Hovav, 2009). Words for spatial relations, for example, can be divided into a structural component, which specifies the abstract geometry of a spatial relation, and a more idiosyncratic component, which distinguishes spatial terms on the basis of more fine-grained geometric information. We suggest that schematic representations computed in the dorsal stream may reflect structural components of word meaning.

Our findings also suggest a novel perspective on the interface between language and thought (Wolff & Malt, 2010). Recent research has focused on how language might augment thought by putting in place representational systems essential for certain kinds of abstract thinking (e.g., reasoning about exact quantities; Gordon, 2004; see Wolff & Holmes, in press, for a review). In our second experiment, more schematic language was associated with greater simulation, suggesting instead that language may serve as a vehicle to abstraction, promoting the use of schematic representations rather than directly instantiating them. Importantly, however, language may be just one of many vehicles to abstraction. Other types of processing (e.g., drawing) may be just as likely to induce a schematic conceptualization of experience. Thus, it may be the schematic representations themselves, rather than the means by which they are recruited, that offer especially powerful tools for thinking.

Abstract

Recognizing where one action ends and another begins is an automatic and seemingly effortless process that supports understanding of goal-directed action. One characteristic of such action segmentation is that it is hierarchical; it reflects the goals and sub-goals of an actor, which correspond to coarse- and fine-grained action units respectively. We report on the success of one method of assessing hierarchical segmentation of naturalistic footage taken from an extensive corpus of unscripted human action (Speechome project, e.g., Roy et al., 2006). Results indicate that hierarchical segmentation occurs in an on-line fashion, with event boundaries marked by surges in attention that are modulated based on whether a boundary marks a fine, intermediate, or coarse unit. We also describe a method by which objective changes in an actor's movement can be measured and analyzed as a predictor of participants' segmentation behaviors.

Keywords: action segmentation; event processing

Drawing inferences and generating predictions about others' actions are processes most people undertake every day. The ways in which people use such inferences and predictions to make sense of others' action is supported in part by the ability to segment continuous action into discrete units. For instance, while observing an individual preparing dinner, we might identify and recognize individual units of action such as chopping a carrot, opening a refrigerator, or rinsing off a dish. Investigations of action segmentation have suggested that people are highly consistent in where they judge event boundaries to exist; people typically report dynamic human action to consist of units corresponding to initiation or completion of goals, with considerable agreement across individuals regarding where event boundaries are located (Baldwin & Baird, 1999; Newton, Engquist, & Bois, 1977; Zacks, Tversky, & Iyer, 2001). Further, action segmentation is seemingly spontaneous and automatic, engaged in as a routine and ongoing component of perception (Hard, 2006; Zacks & Swallow, 2007).

The apparent ease with which people recognize breakpoints in action is remarkable given the complexity of the action stream itself. Human action is unquestionably a rich and highly variable stimulus; it is evanescent, often proceeds without pauses to mark the completion of individual units, and frequently features occlusion of relevant objects and body parts. Further, the underlying structure of action is also complex, typically characterized

by a hierarchy reflecting the goals and sub-goals of an actor (e.g., Schank & Abelson, 1977).

Notably, human observers' skill in segmenting the action stream has been observed on a variety of different levels in line with this hierarchical structure. For example, segmentation of "chop carrot" can be on a *coarse* level, with event boundaries noted at the onset and offset of the entire chopping event, or it can be on a *fine* level, with each vertical movement of the knife noted as marking a discrete unit. In tasks assessing hierarchical segmentation, here again a high degree of consistency has been observed in people's segmentation behaviors (e.g., Hard, 2006; Zacks et al., 2001a), and fMRI studies have revealed differing activation levels in frontal and posterior areas in response to fine and coarse event boundaries, suggesting that the distinction between fine and coarse units is psychologically real on a neural level (e.g., Zacks et al., 2001b).

The ability to determine when one action has ended and another has begun, as well as segmenting action on multiple levels, supports how we make sense of the goal-directed action we observe in others. The fact that hierarchical event segmentation appears to be a relatively effortless process despite the complexity of the action stream itself suggests the workings of an equally complex system enabling this segmentation. Of particular relevance for the current studies, work by Hard and colleague (e.g., Hard, 2006; Hard & Recchia, 2006) suggests that event boundaries are processed differently than within-unit moments, with the detection of boundaries associated with a transient increase in cognitive processing load.

The idea that event boundaries might elicit an upsurge in cognitive processing is consistent with a comprehensive account of action segmentation put forth by Zacks and colleagues. These authors (e.g., Kurby & Zacks, 2007; Zacks et al., 2007) describe the Event Segmentation Theory, an account of how the human observer perceives and conceptualizes action in terms of events. A crucial component of Event Segmentation Theory rests on the observer's ability to make predictions about upcoming action. Such prediction generation is considered a spontaneous, online process that integrates incoming sensory information with prior knowledge and learning in an attempt to create a stable "event model." Event units correspond to periods in which prediction error rate is low; the observed action is consistent with the predictions being

made by the perceptual system, and the event model is stable. For example, within the event of cleaning off plates at the kitchen sink, the predictive system is able to generate accurate predictions of further plate cleaning based on such cues as the person's movements and prior knowledge about kitchen clean-up. Event boundaries, in contrast, are experienced when prediction error rate is high; to extend the example above, such boundary moments are likely to occur at the completion of a task (e.g., cleaning off plates in the kitchen) and before the initiation of another task (e.g., wiping the countertop), because these moments correspond with a reduced ability to predict the onset and content of the second event.

In order to update the event model at moments of reduced predictability, the system is believed to increase attention to the perceptual characteristics of the action stream and to activate new event schemata to replace the prior unsuccessful one. Hard and colleague (Hard, 2006; Hard & Recchia, 2006) provided an empirical test of whether boundaries were indeed associated with differential degrees of cognitive processing. As their methodology formed the basis of the first experiment in the current study, an in-depth explanation of their methods is in order. These authors reasoned that well-known paradigms developed for investigations of hierarchical processing of text would also be suitable for revealing aspects of hierarchical processing of action. In one such text processing study, individuals saw one word at a time from a passage of text and advanced themselves through word-by-word by pressing a button. The length of time between button presses was the primary dependent variable in this "moving window" method, with the idea being that longer reading times would be indicative of increased cognitive load associated with integration of past elements within and across text units into comprehensible larger units. Results indicated that participants tended to spend longer periods of time on words located at the ends of unit boundaries. Further, this "wrap up" effect was modulated by the level of any given unit; reading times were longer for words located at the ends of clauses and longer still for words located at the ends of sentences (Haberlandt & Graesser, 1989).

To study processing of hierarchical action using a similar technique, Hard and colleague adapted the moving window method for use with human action by asking participants to advance through a sequence of still-frame images. These images were taken from regular time intervals of footage of scripted human goal-directed action (e.g., one still-frame image sampled every second). Following this "slideshow" viewing phase, participants watched the live action footage from which the still images had been sampled and marked with a button press the locations of action boundaries (hereafter, 'breakpoints'). Participants completed this segmentation task a total of three times, providing judgments on fine, intermediate, and coarse levels.

Results from the slideshow task indicated that participants tended to spend a longer period of time looking at images close in time to moments judged to be breakpoints in

comparison to images taken from within action units, suggesting that breakpoints elicited surges in attention. Further, paralleling results observed in text processing, the effect was modulated by the level of the action breakpoint, with slides close in time to moments judged as coarse-grained breakpoints receiving the longest looking times and those near fine-grained breakpoints receiving the least. This phenomenon, dubbed the dwell time effect, provided evidence that hierarchical segmentation occurs as part of real-time perception, without requiring explicit after-the-fact judgments of breakpoint locations. It further demonstrated the cognitive importance of action breakpoints; heightened attention was associated with moments participants explicitly judged to be breakpoints, and this effect was modulated based on whether that breakpoint was judged to be coarse, intermediate, or fine.

In the current paper, we report on another study that investigated hierarchical processing of action, this time using in vivo recordings collected from the Human Speechome Project. Audio-video data was collected from the home of a single child using 11 ceiling mounted cameras and 16 boundary layer microphones. Over the first three years of the child's life, 90,000 hours of video was collected, representing roughly 70% of the child's waking experience (Roy et al., 2006).

As described above, past work has made much progress on elucidating the cognitive processes that make up the system enabling segmentation; however, these studies have examined segmentation of either scripted or animated scenes (e.g., Hard, 2006; Hard & Recchia, 2006; Zacks, 2004; Zacks et al., 2001a; Zacks, Kumar, & Abrams, 2009). The use of Speechome footage has the advantage of providing unscripted activity, allowing a test of the validity of methods that have been successful in revealing aspects of hierarchical segmentation of more artificial action scenes. Validation of the dwell time paradigm in Speechome footage additionally provides opportunities for the assessment of automated means of detecting action units, the topic taken up in Study 2.

Study 1 Method

Stimuli

Images for a slideshow viewing task were created by extracting one image every second from a 108-second movie clip take from the Speechome corpus (e.g., see Figure 1). The clip selected depicts an adult male preparing a meal. This video clip also served as the live action footage for which participants provided explicit segmentation judgments. For the explicit segmentation task, a different, 40-second clip of a woman cleaning the kitchen was used for training purposes.

Participants and Procedure

Participants were 28 university students (14 male) receiving class credit for participation. The experiment had two major phases, the *slideshow viewing task* and the

Figure 1: Sample image from slideshow depicting a person preparing food.

explicit segmentation judgment task. All participants began the session with the slideshow viewing task, in which they were instructed to advance at their own pace through the 108 still-frame images. Participants were told to click a mouse to advance the pictures. A Macintosh G4 computer was used to present stimuli on a 19.5" x 12" monitor, and Psychtoolbox (Brainard, 1997) was used to record participants' responses.

Following the slideshow, participants heard a brief description of how action can be seen as consisting of units, and examples of fine, intermediate, and coarse units in actions unrelated to those displayed during test were provided in these instructions. Participants then provided explicit judgments of where they believed breakpoints to be located, first providing judgments for the training video and then for the 108-second test (Speechome) video. Participants indicated their judgments with a key press. Participants were asked to provide segmentation judgments on fine, intermediate, and coarse levels, resulting in a total of three viewings of the movie clip. Half of the participants were asked to segment on a fine level on their first viewing of the clips, followed by segmenting on an intermediate level, and finishing with segmenting on a coarse level (fine-to-coarse order). The other half was asked to segment in the reverse order (coarse-to-fine order). Assignment of participants to these orders was random.

Study 1 Results

Do participants' explicit segmentation judgments reflect understanding of hierarchical structure?

One important preliminary question to answer is whether participants understood our instructions regarding segmentation on fine, intermediate, and coarse levels. Because we planned to compare the dwell times provided by each subject to their explicit breakpoint judgments made afterwards, it was important to ensure that participants differentiated among fine-, intermediate-, and coarse-level breakpoints during the explicit segmentation task.

Evidence for this understanding comes in part from results indicating that participants provided significantly different numbers of judgments for breakpoints at different levels, with fine-level breakpoints receiving the most judgments (M fine = 39.04 [SD = 23.32]), intermediate-level breakpoints receiving the next most (M intermediate = 12.68 [SD = 8.86]), and coarse-level breakpoints receiving

the least (M coarse = 5.75 [SD = 2.81]), $F(1.13, 30.42) = 61.44, p < .0001$. (Greenhouse-Geisser statistics are reported due to violations in sphericity.) A significant linear trend characterized these data, $F(1, 27) = 64.18, p < .0001$. Thus, participants were clearly capable of recognizing breakpoints on different levels, providing the predicted differences in number of judgments according to level (fine vs. intermediate vs. coarse). As well, although individual differences in number of judgments were substantial (particularly in fine and intermediate judgments, as evidenced by the large standard deviations), 100% of participants provided the most judgments for fine breakpoints and the least for coarse breakpoints (sig. by a binomial test, $p < .0001$).

Participants were also fairly consistent in where they marked the locations of breakpoints. Figure 2 displays the number of fine, intermediate, and coarse level judgments across the 108 seconds of footage, with judgments "binned" into one-second intervals. As demonstrated by the distinct peaks and valleys reflecting moments commonly judged and rarely judged as breakpoints, respectively, it is apparent that participants frequently marked the same moments for all three levels of judgments, a pattern largely consistent with past studies using the same explicit segmentation method (e.g., Hard, 2006; Zacks et al., 2001a; Zacks et al., 2009).

Figure 2: Participants' explicit judgments of fine, intermediate, and coarse level boundaries.

Does dwell time increase at breakpoints?

We next turned to one of the major hypotheses guiding Study 1, namely that participants' dwell time would be longer for images judged to be breakpoints compared to those that weren't. We used the participants' own explicit segmentation judgments, provided during the segmentation task, as the basis for determining which slides were considered breakpoints. Specifically, we applied a binning method, splitting the 108-second test clip into 1 second intervals, each corresponding to a single slide. Breakpoint judgments that fell into a given interval were matched to the corresponding slide, allowing us to classify breakpoint vs. non-breakpoint slides for each participant.

We then treated participants' raw dwell times to individual slides according to the following steps. Outliers (>3 SD above an individual's mean dwell time to all 108 slides) were removed from the data. Data were positively skewed, and thus a log transformation was applied. Due to

participants' tendency to dwell longer on slides at the beginning of the sequence and to speed up as the task continued, most participants' data were consistent with a power function. Significant portions of the variance were accounted for by the model for all participants (highest p value was .02). Thus, data were de-trended, and the residuals calculated based on the power function were used for analysis.

Because there were unequal numbers of slides in the different classifications (e.g., far fewer slides classified as breakpoints vs. non-breakpoints), means for each type were divided by standard deviations of that type, producing an effect size. All reported analyses are on these scores, hereafter referred to as dwell time scores. (Note that dwell time scores can be zero or negative since the residuals represent the difference between actual dwell time and times predicted by the power function; however, it is still the case that higher dwell time scores indicate overall longer dwelling on any given slide.)

A 2 (breakpoint status: breakpoint vs. non breakpoint) \times 2 (segmentation order: fine-to-coarse vs. coarse-to-fine) mixed ANOVA (with breakpoint status as a within-subjects variable and segmentation order as a between-subjects variable) revealed only the predicted breakpoint status effect. Dwell time scores for breakpoint slides ($M = .124$, $SEM = .046$) were higher than for non-breakpoint (within-unit) slides ($M = -.044$, $SEM = .026$), $F(1, 26) = 6.40$, $p = .02$. The main effect for segmentation order was not significant (M fine-to-coarse = .01, $SEM = .03$; M coarse-to-fine = .07, $SEM = .02$), $F(1, 26) = 3.1$, $p > .05$, nor was the segmentation order \times breakpoint status interaction significant, $F(1, 26) = .03$, $p > .05$. Dwell time scores were thus higher for breakpoints than non-breakpoints, supporting the first hypothesis.

Do dwell times vary according to fine, intermediate, and coarse levels?

Using the same binning method used to distinguish between breakpoint and non-breakpoint slides for each participant, classification of slides as breakpoints vs. non-breakpoints for each individual participant, slides were additionally categorized as falling at fine, intermediate, and coarse level boundaries. We then examined whether the dwell time effect was modulated based on whether a breakpoint was judged to be on a fine, intermediate, or coarse level. A 3 (segmentation level: fine, coarse, intermediate) \times 2 (order: fine-to-coarse vs. coarse-to-fine) mixed between-within ANOVA was run, with segmentation level as the within-subjects variable and order as the between-subjects variable. Because of sphericity violations, we report Greenhouse-Geisser statistics. The predicted main effect for segmentation level was found, $F(1.52, 39.43) = 16.17$, $p < .0001$ (see Figure 3 for means). These differences were characterized by a significant linear trend, $F(1, 26) = 21.20$, $p < .0001$, with coarse-level breakpoints receiving the longest dwell times, intermediate-level breakpoints receiving the next longest, and fine-level breakpoints

receiving the shortest dwell-times. The main effect for order was not significant (M coarse-to-fine = .161, $SEM = .057$; M fine-to-coarse = .087, $SEM = .073$), $F(1, 26) = 1.23$, $p > .05$; there also was no order \times segmentation level significant interaction ($F(1.57, 39.43) = .95$, $p > .05$).

Figure 3: Dwell-time scores to slides designated as fine, intermediate, and coarse breakpoint. Data were characterized by a linear trend, $p < .0001$.

Study 2

Another line of investigation in action segmentation has focused on determining what perceptible features in the movement stream are relevant to segmentation. For instance, in the same study in which Hard and Recchia (2006) showed attentional differences to event boundaries, they additionally found that greater body movements on the part of the actor (as measured by overall pixel change between slides) significantly predicted observers' segmentation behavior. Similarly, in Zacks and colleagues' (2009) investigation of live action, the authors studied how changes in movement features such as the actor's acceleration and speed were predictive of observers' explicit segmentation judgments. In that study, an actor wore magnetic tracking devices on his hands while filming an action sequence, allowing for later extraction and calculation of the relevant movement features. The authors found that several movement features, including speed, acceleration, and change in distances among the actor's hands and head were predictive of observers' segmentation judgments, particularly for fine-grained event markings (see also Zacks 2004 for similar analyses with animated figures).

The ability to predict event boundaries based on perceptible features that can be extracted from video has great relevance to designers of informational systems that use identified actions as units of analysis. In addition to testing the validity of the dwell-time methodologies in naturalistic action, another goal of the current paper was to assess whether features visible in the action input were predictive of individuals' segmentation judgments. In Study 2, we extracted a set of predictive features, then analyzed how well these predictors correlated to the human judgments collected for Study 1

Study 2 Method

A set of motion features was extracted from the Speechome test clip using an accurate, semi-automatic

tracking system to annotate the positions of the body and hands of the actor appearing in the video (DeCamp & Roy, 2009). Positions were recorded as image coordinates (2D positions on the image, as compared to 3D positions in real space). Body position was defined as the center of the visible portion of the actor's head and torso. The positions of the hands were defined relative to the position of the body in order to reduce the covariance between them. After the position information was collected from the test video, it was used to compute the speed and acceleration of each body part, resulting in six features (see Table 1). The first and last seconds of data were also removed from analysis at this point because it was not possible to robustly define speed and acceleration at these points.

Kernel density estimation was applied to the breakpoints at each granularity level (i.e., fine, intermediate, and coarse). While this process smoothed the data, it also provided a continuous distribution of the breakpoints over time, which was more convenient for analysis than the raw judgment counts. Density estimation was performed with a Gaussian kernel. Bandwidths were selected for each level using unbiased cross-validation, resulting in 0.92 s for fine breakpoints, 1.13 s for intermediate, and 1.27 s for coarse.

Study 2 Results

We found that each of the six features was significantly correlated to each breakpoint distribution (all p 's < .001, see Table 1). The body speed feature achieved the highest correlation ($r = 0.71$) when correlated with coarse-grained judgments (see Figure 4). Right and left hand speeds had maximum correlations of 0.64 and 0.35, respectively. The acceleration features performed slightly worse, but were nevertheless significant.

Table 1: Correlations Between Visual Features and Breakpoint Distribution

	Correlation		
	Fine	Intermed	Coarse
Body Speed	0.49	0.65	0.71
Right-Hand Speed	0.47	0.64	0.64
Left-Hand Speed	0.45	0.44	0.35
Body Accel	0.40	0.52	0.54
Right-Hand Accel	0.35	0.51	0.47
Left-Hand Accel	0.34	0.40	0.36

Figure 4: Univariate linear regression on coarse breakpoint distribution using body speed as predictor.

Discussion

In Study 1, we examined human observers' segmentation of naturalistic action, taking our stimuli from a large corpus of unscripted action (Speechome, e.g., Roy, 2006). Participants tended to dwell on images depicting breakpoints longer than non-breakpoints, and this difference was modulated based on whether a breakpoint was judged to be marking the completion of a fine-, intermediate-, or coarse-level unit. Despite the fact that our stimuli depicted naturalistic action, as well as the fact that participants had a decidedly different viewpoint of the action sequence itself than past studies of action (i.e., a ceiling-mounted camera provided the stimuli, and thus participants saw the actor from above), we replicated past findings of the dwell time effect (e.g., Hard, 2006; Hard & Recchia, 2006). Our findings suggest that the dwell time effect is a robust and valid phenomenon, capable of providing another window into the cognitive processes underlying segmentation.

The fact that participants' implicit behavior (dwell time) was associated with their explicit segmentation judgments also offers an exciting direction for future research within the developmental domain. There is clear indication already that infants as young as nine months can segment an action stream, a remarkable finding given infants' relatively impoverished understanding of goals and intentions (e.g., Baldwin et al., 2001; Saylor et al., 2007). Although this work represents an important demonstration of infants' action processing skill, the adaptation of dwell time methodology to this population has the potential to further expand our understanding of the developmental trajectory characterizing the segmentation process. The looking time methods used in these past developmental studies were not suitable for discerning hierarchical processing; further, the work examining hierarchical processing in adults has largely relied on participants' explicit understanding of what constitutes fine, intermediate, and coarse units (e.g., Zacks et al., 2001a, 2001b; Zacks et al., 2009), a task that is clearly beyond the capacity of infants and young children. We are actively pursuing adapting dwell time techniques for use both with preverbal infants as well as young preschool-aged children (e.g., Meyer, Hard, & Baldwin, 2009), a methodological advance that will allow us to study hierarchical processing across the lifespan.

In Study 2, we examined how perceptible movement features predicted human observers' judgments. Our results demonstrated that specific sources of information (i.e., head and hand speed and acceleration) were significantly associated with participants' segmentation judgments. Our results are consistent with similar movement change analyses performed by Zacks et al. (2009), suggesting that analysis of movement features may have broad utility in the design of automated systems of action analysis.

Notably, we additionally observed results that differed from those of Zacks et al., (2009); whereas we observed lower correlations as the judgment granularity was increased (i.e., correlations were highest when examining coarse-grained judgments and lowest when examining fine-grained

judgments), Zacks and colleagues actually observed the opposite. We speculate that this might be attributed to the differences between videos; in our footage the actor had no discernible facial features, and local movements of the hands and fingers were difficult to see; this may have reduced the ability of subjects to identify breakpoints as consistently at finer granularities. As well, the actor in our video moved his entire body through space (e.g., walking from a kitchen island to the sink), whereas the actor in Zacks et al.'s videos was seated. These gross bodily movements were frequently judged as coarse breakpoints and were clearly associated with several of our movement cues. Finally, the use of 2D video annotations in place of 3D motion sensor features may have provided less accurate measures that limited our ability to predict finer-grain events. In any event, the differences we observe offer inviting topics for future investigation relevant to the development of automated action analysis.

To summarize, we both validated the dwell time effect in naturalistic stimuli as well as found objective movement parameters predictive of individuals' segmentation behavior. The latter finding is of great relevance for researchers developing automated action analysis systems. Given that tracking whole people is now feasible for many types of video, current tracking technologies may enable the first steps towards systems that can automatically segment and identify actions from raw video, opening up new possibilities for human behavioral analysis.

Human action is an undeniably rich and complex stimulus. Yet, as we parse the events of our daily lives with little thought or apparent effort, the process may strike us as trivially easy. Nevertheless, the complexity of human action is apparent upon any attempt at formalization, and it poses a considerable challenge towards understanding human cognition. In this paper, we supply part of the solution by demonstrating how the human mind reacts and imparts structure to action sequences as they unfold. We also provide promising results from attempts to predict and model these reactions, suggesting future possibilities for the data driven analysis of events at a massive scale.

Abstract

We report on a functional magnetic resonance imaging (fMRI) study of the perception of human and artificial agents. Participants viewed videos of familiar body movements enacted by the android Repliee Q2, the human after whom it was modeled, and the “skinned” version of Q2 revealing its mechanical parts. We used a neural adaptation (repetition suppression) analysis to reveal brain areas sensitive to body movements, and explored whether the identity of the perceived agents modulated these responses. We found significantly higher activity in a distributed network of brain areas for the android, most notably in anterior intraparietal cortex. The responses for the human and the robot with the mechanical appearance resembled each other. We interpret these results within the framework of predictive coding and suggest that the “uncanny valley” phenomenon may have its roots in processing conflicts within the brain’s action perception system.

Keywords: action perception; body perception; biological motion; social robotics; artificial agents; neuroimaging; fMRI; uncanny valley

Introduction

In the near future, artificial agents and humanoid robots are expected to be part of our daily lives, not only in entertainment and retail, but also in important domains such as healthcare and education (Billard, Robins, Nadel, & Dautenhahn, 2007; Dautenhahn, 2007; Kanda, Ishiguro, Imai, & Ono, 2004). Thus, exploring human factors in interactive robot design and development is crucial (Ishiguro, 2007; MacDorman & Ishiguro, 2006). Conversely, experiments using artificial agents can address questions about the functional properties of mechanisms involved in the perception of others’ actions (Blake & Shiffrar, 2007; Rizzolatti & Craighero, 2004). Here, we summarize a neuroimaging study that we performed as part of an interdisciplinary research program that aims to reveal factors that can guide the design of future artificial agents, as well as to improve our understanding of action and body movement perception more generally.

In primates, the perception of body movements is supported by network of lateral superior temporal, inferior parietal and inferior frontal brain areas (Rizzolatti & Craighero, 2004). Here we will refer to this network as the Action Perception System (APS). The frontal and parietal nodes of the system are known to contain mirror neurons, which respond not only when the monkey executes a particular action, but also when it observes another individual perform the action. The existence of a similar system in humans has been suggested by several neuroimaging and lesion studies (e.g., Fadiga, Fogassi, Pavesi, & Rizzolatti, 1995; Grafton, Arbib, Fadiga, & Rizzolatti, 1996; Hari et al., 1998; Iacoboni et al., 1999; Saygin, 2007; Saygin, Wilson, Dronkers, & Bates, 2004).

The neural activity in premotor and parietal regions during action perception is often interpreted within the framework motor resonance, where “an action is understood when its observation causes the motor system of the observer to ‘resonate’” (Rizzolatti, Fogassi, & Gallese, 2001). But what are the boundary conditions for this resonance?

There is a small neuroscience literature on the perception of artificial agents, including robots (Chaminade & Hodgins, 2006; MacDorman & Ishiguro, 2006). Unfortunately, the results are not consistent. Some experiments have reported that robot actions affect the observers’ own motor processing or the activity of the APS, whereas others have argued that the APS does not respond, or responds weakly if the perceived actor is an artificial agent (Catmur, Walsh, & Heyes, 2007; Chaminade, Hodgins, & Kawato, 2007; Gazzola, Rizzolatti, Wicker, & Keysers, 2007; Kilner, Paulignan, & Blakemore, 2003; Oberman, McCleery, Ramachandran, & Pineda, 2007; Press, Gillmeister, & Heyes, 2007; Tai, Scherfler, Brooks, Sawamoto, & Castiello, 2004). Furthermore, the specific roles of biological appearance or biological motion have not been sufficiently explored in these experiments, but is an area of interest in social robotics, cognitive neuroscience, and vision science (Chaminade, Hodgins, & Kawato, 2007; Cook, Saygin, Swain, & Blakemore, 2009; Kanda,

Miyashita, Osada, Haikawa, & Ishiguro, 2008; Minato, Shimada, Itakura, Lee, & Ishiguro, 2006; Oyedele, Hong, & Minor, 2007; Saygin, Wilson, Hagler, Bates, & Sereno, 2004).

On the one hand, it seems reasonable that the closer the match between the observed action and the observers' own sensorimotor representations, the more efficient the simulation will be. In support for this, the APS is modulated by whether the observer can in fact perform the seen movement (Calvo-Merino, Grezes, Glaser, Passingham, & Haggard, 2006; Casile & Giese, 2006). The appearance of the observed agent may be additionally important (Buccino et al., 2004; Chaminade, Hodgins, & Kawato, 2007).

On the other hand, human resemblance is not necessarily always a positive feature in robots. The "uncanny valley" phenomenon points out that as a robot is made more human-like in its appearance, the reaction to it becomes more and more positive and empathetic, until a point is reached at which the robot becomes oddly repulsive (Mori, 1970). The effect is well-known in robotics and animation. For example, the movie *Polar Express* (Warner Bros) was criticized for the characters that viewers found creepy and disturbing. The more recent feature *Avatar* (20th Century Fox) received praise for animations that did not fall into the uncanny valley. Despite such well-known examples, and significant anecdotal evidence, there is little scientific data to characterize the uncanny valley (MacDorman, Green, Ho, & Koch, 2009; Steckenfinger & Ghazanfar, 2009).

The Present Study

This paper briefly describes the approach we took to this topic and summarizes the data from an fMRI repetition suppression study. We performed fMRI as participants viewed video clips of human (H) and robotic agents carrying out recognizable actions. We used Repliee Q2, a humanoid robot developed at Osaka University in collaboration with Kokoro Ltd (Ishiguro et al., 2006). This robot has a very human-like appearance (Figure 1b). In order to achieve this, the robot's face was modeled after an adult Japanese female (Figure 1a). Importantly, Repliee Q2 was videotaped both in its original human-like appearance (the Q2H condition, Figure 1b) and in a modified, more mechanical appearance (the Q2R condition, Figure 1c). In this latter condition, we removed as many of the surface elements as possible in order to reveal the electronics and mechanics underneath. The silicone covering the face and hands could not be removed, so we used a custom mask and gloves to change the appearance of these body parts. The end result was that the robot's appearance became obviously mechanical (e.g., metal arms and joints).

There were three conditions: human (H), robot with human appearance (Q2H) and robot with mechanical appearance (Q2R). However, since the Q2H and Q2R are in fact the same robot, the kinematics are identical for these two conditions. In terms of appearance, H and Q2H are very close to each other, whereas Q2R lies on the mechanical end. In terms of kinematics, H represents truly biological

motion and Q2H and Q2R are identical, both with mechanical kinematics.

Figure 1. Still frames from the videos used in the experiments depicting the three agents.

The articulators of Repliee Q2 were programmed over several weeks at the Intelligent Robotics Laboratory at Osaka University. The same movements were videotaped in both appearance conditions (Q2R and Q2H). The human (the same female adult to whom Repliee Q2 was designed to resemble) was asked to watch each of Repliee Q2's actions and then perform the same action naturally. All agents were videotaped in the same room and with the same background. A total of 8 actions per actor were used in the experiment, including both transitive (drinking water from a cup, picking up a piece of paper from a table, grasping a tube of hand lotion, wiping a table with a cloth) and intransitive actions (waving hand, nodding affirmatively, shaking head (negative), and introducing self). Video recordings were cut into 2 second long clips, were converted to grayscale, cropped to a uniform size.

20 right handed healthy adults participated. We used a 3T Siemens Allegra scanner at the Wellcome Trust Centre for Neuroimaging in London, UK and a standard T2* weighted gradient echo pulse sequence to obtain functional images (TR=2340 ms, TE=65 ms). 36 slices were acquired at an in-plane resolution of 3 x 3 mm and a through plane resolution of 2 mm and 1 mm gap. Each participant was given exactly the same introduction to the study and the same exposure to the videos prior to scanning since prior knowledge can affect attitudes to artificial agents differentially (Saygin & Cicekli, 2002). Participants were told whether each agent was a human or a robot such that by the time scanning started, they were not uncertain about the identity of the android.

A limitation of previous neuroimaging studies on this topic is that they explored the BOLD fMRI response (Logothetis, 2008). Repetition suppression (henceforth RS, also called fMRI adaptation) is a method applied to fMRI from neurophysiology and refers to the phenomena of reduced neural response to a repeated stimulus compared to the response to a novel stimulus (Grill-Spector & Malach, 2001; Henson & Rugg, 2003; Krekelberg, Boynton, & van Wezel, 2006). RS affects neurons sensitive to the repeated stimulus, so it can be used as a means to explore functional properties of brain areas. In recent years, RS has been applied to the study of action perception (Chong, Cunningham, Williams, Kanwisher, & Mattingley, 2008; Dinstein, Gardner, Jazayeri, & Heeger, 2008; Dinstein, Hasson, Rubin, & Heeger, 2007; Fujii, Hihara, & Iriki,

2008; Hamilton & Grafton, 2006, 2008; Kilner, Neal, Weiskopf, Friston, & Frith, 2009; Lestou, Pollick, & Kourtzi, 2008). This approach was well-suited to our goals as it allows us to test whether neurons in the APS code for biological appearance or biological motion.

Participants watched the action videos in 30 second blocks. There were 12 videos in each block with a 500 ms ISI. Each video was preceded by the same video and the other videos equal number of times and orders were counterbalanced across runs. Each video was preceded by

Figure 2. Repetition suppression results for the human (a), Q2H (b), and Q2R(c).

the same video (Repeat) or a different video (Non-repeat). To make sure subjects attended throughout, every 30-seconds, they were presented with a statement about which they made a True/False judgment using a button box (e.g., “I did not see her waving her hand”). The fMRI data were analyzed with SPM5 using standard procedures (<http://www.fil.ion.ucl.ac.uk/spm>).

Results

For each agent, we identified regions showing a repetition suppression effect at $p < 0.05$ and cluster size of > 30 voxels. The effect of repetition suppression differed between the agents (Figure 2). Posterior temporal cortex showed suppression for all agents, but in the left hemisphere there was significantly less response to Q2R. This area corresponds the Extrastriate Body Area or EBA (Peelen, Wiggett, & Downing, 2006), which responds to the visual perception of the human body.

We otherwise did not find evidence for APS coding for the biological appearance or biological movement of the perceived agents. Instead, in comparison to H and Q2R, a larger network showed suppression for Q2H, despite the use of the same procedures and thresholds. This of course,

brings to mind the uncanny valley, except we observed “hills” in the form of increased neural responses rather than valleys. Although we cannot include the details here due to space constraints, a region of interest (ROI) analysis further quantified these results, revealing a significant interaction in the inferior parietal lobule between the agents.

Discussion

We interpret these data within the predictive coding framework, which is based on minimizing prediction error though recurrent interactions among levels of a cortical hierarchy (Bar, 2009; Friston, 2005; Kilner, Friston, & Frith, 2007). During the perception of H and Q2R, where there is no mismatch between the appearance and the movement of the agent. For Q2H on the other hand, there is a human-like appearance that leads to a conflict when this information is integrated with the movement kinematics of the agent. This will lead to the generation of a prediction error, which is propagated in the network until the errors of each node are minimized. It is possible to measure prediction errors using neuroimaging (Friston, 2010). It is not possible from the current data to know the exact source and time course of error propagation, but it is clear that the cortical network is engaged strongly during the perception of Q2R compared with the agents that lead to less prediction error. The effect is largest in parietal cortex, which is the node of the network that links the posterior, visual components of the APS and the frontal, motor components (Matelli & Luppino, 2001; Seltzer & Pandya, 1994).

The present study is only a beginning. This framework provides hypotheses that we are testing in new studies. We are now utilizing animation to modulate the appearance and movement parameters more precisely (although this may lead to decrease in presence (Sanchez-Vives & Slater, 2005), whose importance in modulating APS is currently not known). We also need to use other neuroimaging and psychological methods in addition to, or in conjunction with fMRI to study the temporal dynamics of action processing.

With brief exposure times, Repliee Q2 can be mistaken for a human being, but longer exposure usually triggers the feeling of repulsion or discomfort characteristic of the uncanny valley (Ishiguro, 2006). While we did not explicitly assess the uncanny valley in this study, our results suggest an intriguing relationship between the APS and this phenomenon. We are currently exploring this in more sophisticated analyses as well as with new experiments.

In summary, we found that a robot with very humanlike appearance can cause differential responses compared with the same robot with a mechanical appearance, or with a human being that maximally resembles the robot. These differences were found in a network of brain areas, but most prominently in inferior parietal cortex, which connects the posterior areas involved in the visual perception of actions and biological motion to premotor areas in frontal cortex. We propose these “hills” in the brain activity reflect the prediction error that is generated as the brain processes these stimuli. We suggest that the uncanny valley may arise from

processing conflicts in the APS, and can be investigated using fMRI.

Acknowledgments

This research was supported by an innovative research grant to A.P. Saygin from the Kavli Institute for Brain and Mind (UCSD). Additional support was contributed by the European Commission and by the Wellcome Trust. We are grateful to members of the Intelligent Robotics Laboratory for their help in creating the experimental stimuli and to Jon Driver, Chris Frith, James Kilner and members of the Wellcome Trust Centre for Neuroimaging for their support of the fMRI study. We also appreciate discussions with Karl MacDorman, Takashi Minato, Javier Movellan, and Marty Sereno in the early stages of this project.

Abstract

We present and test a theory of cognitive disequilibrium to explain the dynamics of the cognitive-affective states that emerge during deep learning activities. The theory postulates an important role for cognitive disequilibrium, a state that occurs when learners face obstacles to goals, contradictions, incongruities, anomalies, uncertainty, and salient contrasts. The major hypotheses of the theory were supported in two studies in which participants completed a tutoring session with a computer tutor after which they provide judgments on their cognitive-affective states via a retrospective judgment protocol. Hidden Markov Models constructed from time series of learners' cognitive-affective states confirmed the major predictions as well as suggested refinements for the theory of cognitive disequilibrium during deep learning.

Keywords: affect dynamics, hidden markov model, learning.

Introduction

Deep learning and problem solving are emotionally rich experiences. Students experience boredom when the material does not appeal to them, confusion when they have difficulty comprehending the material and are unsure about how to proceed, frustration when they make mistakes and get stuck, and perhaps even despair and anxiety when their efforts seem to be futile and the big exam is creeping around the corner. This negative picture of the emotional experiences that accompany learning has a complimentary positive side. Students experience curiosity when they encounter topics that interest them, eureka moments when insights are unveiled and major discoveries made, delight when challenges are conquered, and perhaps even flow-like states (Csikszentmihalyi, 1990) when they are so engaged in learning that time and fatigue disappear.

There have been several theories that link cognition and affect very generally (Bower, 1981; Mandler, 1984; Ortony, Clore, & Collins, 1988; Russell, 2003; Stein & Levine, 1991). While these theories convey general links between cognition and emotions, they do not directly explain and predict the sort of emotions that occur during complex learning, such as attempts to master physics, biology, or computer literacy. Researchers in many different fields are familiar with Ekman's work on the detection of emotions from facial expressions (Ekman, 1984). However, the emotions that Ekman intensely investigated (e.g., sadness, happiness, anger, fear, disgust, surprise) have minimal relevance to learning in typical academic settings (D'Mello,

Craig, Sullins, & Graesser, 2006; Kort, Reilly, & Picard, 2001; Lehman, D'Mello, & Person, 2008). Instead, the pervasive cognitive-affective states during complex learning include confusion, frustration, boredom, flow/engagement, and sometimes delight, surprise, anxiety, and curiosity (D'Mello et al., 2006; Lehman, Matthews, D'Mello, & Person, 2008).

The identification of the cognitive-affective states that occur during learning is critical, but it could be argued that merely knowing *what* states occur has limited utility. What is missing is a specification of *how* these states evolve, morph, interact, and influence learning and engagement. What is required is a fine-grained analysis of the rapid dynamics of the cognitive-affective processes that naturally occur during effortful learning activities.

Although affect dynamics has been generally ignored by theories that link affect and cognition during learning, one theory, called the cognitive disequilibrium theory, does address transitions between states. The theory postulates an important role for *cognitive disequilibrium* in comprehension and learning processes, a notion that has a long history in psychology (Berlyne, 1960; Festinger, 1957; Piaget, 1952). Cognitive disequilibrium is a state that occurs when learners face obstacles to goals, contradictions, incongruities, anomalies, uncertainty, and salient contrasts (Graesser, Lu, Olde, Cooper-Pye, & Whitten, 2005; Otero & Graesser, 2001; Piaget, 1952).

The cognitive disequilibrium theory is depicted in Figure 1 as a state transition network. The nodes (circles) in the figure represent the cognitive-affective states (in parentheses) and their presumed causes (in bold). Links represent situations that trigger transitions between the different states.

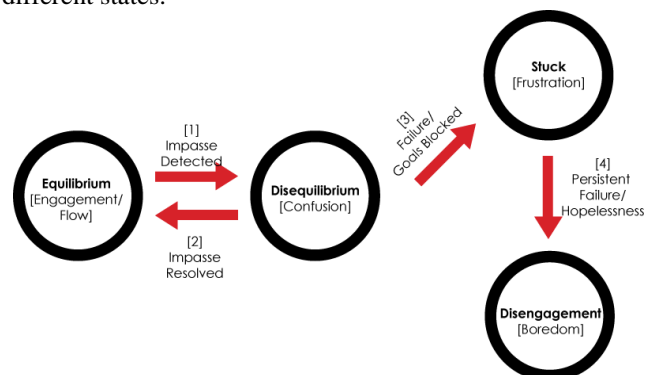

Figure 1. Cognitive Disequilibrium Theory

The theory assumes that learners are in a base state of engagement (perhaps a degree of flow) until they are confronted with a contradiction, anomaly, system breakdown, or error, and when they are uncertain about what to do next (Forbes-Riley & Litman, 2009; Graesser et al., 2005; Siegler & Jenkins, 1989; VanLehn, Siler, Murray, Yamauchi, & Baggett, 2003). Confusion is a key signature of the cognitive disequilibrium that occurs when an impasse is detected (Link 1). Learners must engage in effortful problem solving activities in order to resolve the impasse and restore equilibrium. Equilibrium is restored when the source of the discrepant information is discovered and the impasse is resolved, thereby causing learners to revert back to the engaged state (Link 2).

However, this form of productive confusion associated with impasse resolution can be contrasted with hopeless confusion. This occurs when the impasse cannot be resolved, the student gets stuck, and important goals are blocked. The theory hypothesizes that learners will experience frustration in these situations (Link 3). Furthermore, persistent frustration may transition into boredom, a crucial point at which the learner disengages from the learning process (Link 4).

We have confirmed some of the predictions of the theory in previous publications (D'Mello & Graesser, in review; D'Mello, Taylor, & Graesser, 2007). In particular, we have assessed the presence of oscillations between flow and confusion as well as transitions from confusion to frustration and frustration to boredom. However, verifying the presence of these transitions represents only one important component of the theory. The other crucial component that has not been yet empirically supported pertains to the internal causes that give rise to the observed cognitive-affective patterns. These include an *equilibrium* state that presumably activates the flow/engaged experience, a *disequilibrium* state that causes confusion, a *stuck* state that causes frustration, and a *disengaged* state that emits boredom. Our previous analyses so far have exclusively focused on transitions between the cognitive-affective states but have not explicitly addressed their causes. It is important, however, that both components of the theory be verified before it can be accepted as a useful explanation of the cognitive-affective phenomena that underlies deep learning.

Unfortunately, it is difficult to model the causes that underlie the cognitive-affective expressions. These states can be *observed* via facial expressions, body movements, and contextual cues, but the internal causes are *hidden* (i.e. they cannot be directly observed). This limitation can be alleviated via modeling techniques that permit the simultaneous modeling of both hidden and observed variables. In particular, the present paper describes a study in which Hidden Markov Models (HMMs) were used to model both the observed cognitive-affective states (confusion, frustrations, etc) and their hidden causes (equilibrium, stuck, etc), thereby testing the two components of cognitive disequilibrium theory. The HMMs

were parameterized from learners' self reports on their cognitive-affective states via a retrospective judgment protocol after a tutorial session with AutoTutor, an Intelligent Tutoring System with conversational dialogues (Graesser et al., 2004).

Brief Description of HMMs

Hidden Markov Models are valuable tools for modeling system with sequential observable outcomes when the states producing the outcomes cannot be directly observed (i.e. they are hidden). They are widely used to model complex phenomenon with applications in a variety of disparate domains, such as automatic speech recognition, tutorial discourse, computational biology, financial economics, computer vision, and earthquake detection (Jurafsky & Martin, 2008; Rabiner, 1989).

HMMs are characterized by a set of parameters that can be estimated from available data. If there are m hidden states ($H = h_1, h_2, h_3, \dots, h_m$) and n observable states ($O = o_1, o_2, o_3, \dots, o_n$), then the parameters include a $m \times n$ emission probability matrix (E) and a $m \times m$ transition probability matrix (T). The emission probability matrix specifies the conditional probability of emitting an observed state o_t at time t given that the system is a hidden state h_t at the same time point [$\Pr(o_t|h_t)$]. On the other hand, the transition probability matrix specifies the conditional probability of transitioning from the current hidden state h_t to the next (or same) hidden state at the next time interval h_{t+1} [$\Pr(h_{t+1}|h_t)$].

As an example consider a simplified model of two hidden states for equilibrium (E) and disequilibrium (D) and two observed states for flow (F) and confusion (C). Here, $m = n = 2$ and both matrices are of size 2×2 . The emission probability matrix would consist of the following four conditional probabilities: $\Pr(F|E)$, $\Pr(C|E)$, $\Pr(F|D)$, and $\Pr(C|D)$. Since it is assumed that a given hidden state emits one of the observable states, $\Pr(F|E) + \Pr(C|E) = 1$ and $\Pr(F|D) + \Pr(C|D) = 1$.

The transition probability matrix would also consist of four probabilities: $\Pr(E|E)$, $\Pr(F|E)$, $\Pr(D|D)$, and $\Pr(E|D)$. Once again, $\Pr(E|E) + \Pr(D|E) = 1$ and $\Pr(D|D) + \Pr(E|D) = 1$. Hence, given that a learner is in one of the hidden states, we can probabilistically determine which cognitive-affective state is most likely to be observed as well as what the next hidden state is likely to be.

Methods

Study 1

Participants. 28 undergraduate students (5 male and 23 female) from a large mid-south university participated for extra credit in their psychology courses.

Interaction with AutoTutor. Participants interacted with AutoTutor for 32 minutes on one of three randomly assigned topics in computer literacy: hardware, Internet, or

operating systems. AutoTutor is a validated intelligent tutoring system that helps learners construct explanations by interacting with them in natural language with adaptive dialogue moves similar to human tutors (Graesser et al., 2004). AutoTutor's dialogues are organized around difficult questions, such as why, how, what-if, what if not, how is X similar to Y, that require answers involving inferences, explanations, and deep reasoning. Although each question requires 3-7 sentence-like ideas in a correct answer, learners rarely give the complete answer in a single conversational turn. Therefore, the tutor scaffolds the construction of an answer by an adaptive dialogue with pumps for information, hints, prompts, assertions, summaries, and feedback. AutoTutor delivers its dialogue moves via an animated conversational agent that speaks the content of the tutor's turns.

A video of the participant's face and computer screen was recorded during the tutorial session (see Figure 2). Gross body language was tracked using Tekscan's Body Pressure Measurement System (not described here).

Figure 2. Learner interacting with AutoTutor

Judging Cognitive-Affective States. Participants provided self-judgments of their cognitive-affective states immediately after the tutorial session; learning activities during the session were not interrupted. Similar to a cued-recall procedure (Rosenberg & Ekman, 1994), the judgments for a learner's tutoring session proceeded by playing a video of the face along with the screen capture video of interactions with AutoTutor on a dual-monitor computer system (see center and right monitor in Figure 2). The screen capture included the tutor's synthesized speech, printed text, students' responses, dialogue history, and images, thereby providing the context of the tutorial interaction.

Participants were instructed to make judgments on what affective states were present at any moment during the tutoring session by manually pausing the videos (called *spontaneous* judgments). They were also instructed to make judgments at each 20-second interval; the video automatically stopped every 20 seconds (called *fixed* judgments). If the learner was experiencing more than one affective state, the learner was instructed to mark each state

and indicate which was most pronounced. However, only the first choice (more prominent) affective states were included in the subsequent analyses.

Participants were provided with a checklist of seven states (boredom, flow/engagement, confusion, frustration, delight, surprise, and neutral) for them to mark along with definitions of the states. Hence, judgments were made on the basis of the participants' facial expressions, contextual cues via the screen capture, and the definitions of the cognitive-affective states.

Study 2

The participants were 30 undergraduate students (13 male and 17 female) from a mid-south university in the U.S. who participated for extra course credit.

Study 2, was similar to Study 1, but with two important differences. While participants in Study 1 interacted with the traditional typed-input version of AutoTutor, Study 2 participants spoke their responses to a new spoken-input AutoTutor. In addition to changing the input modality, there were a number of technical improvements in the new version of AutoTutor (version 3.1). These include improvements in conversational smoothness via a contextually-sensitive dialogue management module, state-of-the-art semantic and statistical natural language understanding mechanisms (Jurafsky & Martin, 2008), and an updated domain knowledge base for computer literacy.

The second difference between the two studies pertains to the retrospective affect judgment protocol. While participants in Study 1 provided affect judgments every 20 seconds and in-between each 20 second block, participants in Study 2 provided judgments at three pre-selected points plus some random points in the tutorial session. These included: (1) a few seconds after AutoTutor completed a dialogue move, (2) immediately before the learner started expressing his or her spoken response to the tutor, and (3) other randomly selected points in the dialogue. Participants provided approximately 30-35 cognitive-affective ratings at each of these three judgment points. These constituted the fixed judgment points. Similar to Study 1, the participants could stop the video at any time and make spontaneous judgments.

Results and Discussion

The retrospective affect judgment procedure yielded 2967 and 3099 self reported cognitive-affect judgments for Studies 1 and 2, respectively. A time series that preserved the temporal ordering of the cognitive-affective states was constructed for each participant. On average, there were 106 states ($SD = 9$) per time series for Study 1 and 103 states ($SD = 14$) for Study 2.

Since the goal of this paper is to investigate transitions between different states, and not persistence in the same state, the data was recoded to eliminate repetitions between states. For example, the sequence $X \rightarrow Y \rightarrow Y \rightarrow Z$ was converted to $X \rightarrow Y \rightarrow Z$. This process reduced the length of the time series to a mean of 64 states for both studies ($SD_1 =$

19, $SD_2 = 15.24$). On average, there was a state transition every 32.38 and 32.77 seconds for Studies 1 and 2, respectively ($SD_1 = 11.17$, $SD_2 = 9.58$). The recoding process did not alter the distribution of the cognitive-affective states.

Estimating Parameters of HMMs

The current analyses focused on discovering the parameters of HMMs that best explain the relationship between observable cognitive-affective states and the hidden variables that presumably govern their behavior. In particular, we estimated the parameters of an HMM with six observable states and four hidden states. The hidden states were equilibrium, disequilibrium, stuck, and disengaged, whereas the observable states were boredom, flow/engagement, confusion, frustration, delight, and surprise. Although the theory does not explicitly address the presence of delight and surprise, the states were included in the present analyses because they occasionally occur during learning sessions with AutoTutor (Graesser et al., 2006).

The present analyses constructed separate HMMs for each study from the time series of the cognitive-affective states. Parameters of the two matrices of each HMM were estimated with the Baum-Welch algorithm, which is the standard procedure used to train HMMs (Jurafsky & Martin, 2008; Rabiner, 1989). The algorithm begins with a set of initial parameters and then iteratively improves the estimates of these parameters by comparing how well the model constructed at each iteration fits the data. The algorithm converges when the discrepancy between the predictions made by the model and the training data minimally vary (i.e. within a preset threshold).

The choice of initial parameters plays an important role in the estimation process (Jurafsky & Martin, 2008). The initial parameters can be randomly seeded if there is no prior theory guiding their selection. In our case, the cognitive disequilibrium theory provides some important guidelines for initial parameter selection. For example, the theory hypothesizes that flow/engagement is expected to accompany the equilibrium state. Hence, the initial emission matrix was seeded such that the Flow|Equilibrium probability was slightly higher (.18) than the other emissions stemming from the equilibrium state. In particular emissions for Boredom|Equilibrium, Confusion|Equilibrium, etc. were set to $.164 [(1 - .180)/5 = .164]$. In this fashion, a small increase in emission probabilities was provided to confusion in the disequilibrium state, frustration in the stuck state, and boredom in the disengaged state.

The initialization process for the transition probability matrix was quite different. Here, transitions into the same hidden states were set to zero (because we are interested in modeling transitions to other states), while transitions to other hidden states were set to .333. Hence, each hidden state had an equal probability of transitioning to any other hidden state. The HMMs were seeded in this fashion to test whether hidden state transitions in the converged HMMs

aligned with predictions of the cognitive disequilibrium theory. For example, equilibrium should transition into disequilibrium more frequently than stuck and disengaged.

It should be noted that the initial distribution of hidden states were also set to .25. The initial parameters of the HMM's are listed in Table 1 (see *Init* band). HMMs initialized on the basis of these parameters converged in 30 and 29 iterations for Study 1 and Study 2, respectively.

Exploring the Structure of the Converged HMMs

Before delving into the structure of the HMMs, we first evaluated how well the HMMs captured the dynamics of the state transitions in the two sets of analyses. In the first analysis, we compared each HMM to its random surrogate, which was an HMM that was seeded with the same initial parameters but was trained on randomly shuffled time series. Random surrogate comparisons provide a convenient face-validity test for time series analyses, because random shuffling eliminates all temporal dependencies between events while preserving the priori probabilities of individual events. The results indicated that the log-likelihood (LL) for HMM's constructed on the basis of a randomly shuffled time series was significantly ($p < .05$) lower than the LL for HMMs constructed from the original time series ($d = 1.36$ and 1.33 for Study 1 and Study 2, respectively).

The second analysis focused on the generalizability of the HMMs. Here we compared HMMs constructed and validated on the entire training set to HMMs constructed on partial data sets using a leave-one-out cross validation procedure (LVOCV). LVOCV involves constructing N HMMs, where each HMM is trained on time series from $N - 1$ participants and tested on the time series of the remaining one participant. Correlations between the LL of LVOCV HMMs and HMMs trained on the entire data set were almost perfect ($r = .99$ for both Studies).

Table 1 lists the parameters of the HMMs for Study 1 and Study 2. As could be expected, the parameters of the emission matrix indicate that the flow state is emitted during equilibrium, confusion during disequilibrium, frustration when stuck, and boredom when disengaged. Hence, the converged emission matrix accurately models the hypotheses of the cognitive disequilibrium theory.

Although the transition matrix was seeded such that transitions between the hidden states were equivalent (.333), a different distribution of transitions emerged after training. In particular, consistent with the theory, the equilibrium state is more likely to transition into disequilibrium than the other states. As predicted, the disequilibrium state is more likely to transition back into equilibrium and the stuck state than the disengaged state.

The patterns were somewhat more murky for the stuck state. Although we hypothesized that stuck should transition into disengagement more frequently than equilibrium or disequilibrium, this pattern was not observed in the HMM for Study 1. The results were more in line with the theory for the HMM for Study 2, where stuck was equally likely to transition into disengagement and disequilibrium, but not

equilibrium. Finally, the theory does not explicitly address transitions from the disengaged state, and the HMMs did not reveal any clear transition pattern for this state.

It is also important to indicate that we constructed two additional HMMs for Studies 1 and 2. These HMMs were identical to the HMMs listed in Table 1 but were seeded

with randomly initialized parameters instead of the theoretically derived initial parameters. The structure of these randomly-seeded HMMs were quite similar to the HMMs listed in Table 1, indicating that our theoretically derived initial parameters did not bias the models.

Table 1. Parameters of HMMs

HMM	Current Hidden State	Emission Matrix						Transition Matrix			
		Current Observed State						Next Hidden State			
		<i>Bor</i>	<i>Con</i>	<i>Del</i>	<i>Flo</i>	<i>Fru</i>	<i>Sur</i>	<i>Eq.</i>	<i>Dq.</i>	<i>St.</i>	<i>Dg.</i>

Notes. *Eq.* = equilibrium, *Dq.* = disequilibrium, *St.* = stuck, *Dg.* = disengagement

Discussion

The present paper used HMMs to test a theory of cognitive disequilibrium that is applicable to the dynamics of cognitive-affective states in deep learning environments. The major predictions of the theory were verified via the emission and transition matrices of the HMM which aligned with different aspects of the theory. In particular, the results supported an equilibrium state that emitted flow/engagement, a disequilibrium state that emitted confusion, and transitions between the equilibrium and disequilibrium states. These results support the assertion that students in the state of engagement/flow are continuously being challenged within their zones of optimal learning (Brown, Ellery, & Campione, 1998; Vygotsky, 1978) and are experiencing two-step episodes alternating between confusion and insight.

The HMMs confirmed the presence of a transition from disequilibrium to the stuck state that emitted frustration. However, the prediction of a transition from the stuck state to the disengaged state was only partially supported. The converged HMMs suggest that in addition to the predicted transition from the stuck to disengaged states, transitions from stuck to the disequilibrium and even the equilibrium states are permissible.

These transitions from frustration suggest that it is important to differentiate between different exemplars of frustration. Similar to the discrimination between productive and hopeless episodes of confusion, there might also be different manifestations of frustration. For example, being stuck for a short period of time and then obtaining an insight might trigger delight and cause a transition into the equilibrium state. Some evidence for this assertion can be obtained from the emission matrix which indicates that delight is sometimes emitted from the stuck state. Alternatively, the stuck state can transition into the disequilibrium state when an additional impasse is detected. The third manifestation of frustration is one that is predicted by the theory. Here, persistent failure and hopelessness from being stuck will eventually trigger disengagement, where the learner detaches from the learning session.

In summary, there appear to be three alternatives for transitions from frustration and the stuck state: (a) frustration is alleviated when a resolution is reached, (b) frustration oscillates with confusion when a stuck student detects an additional impasse, and (c) frustration transitions into boredom when a hopelessly stuck learner disengages from the learning session. Testing the fidelity of these transitions will require further empirical research.

Productive Failure in Learning the Concept of Variance

Manu Kapur

National Institute of Education, Singapore

Abstract

In a study with 140, ninth-grade mathematics students on learning the concept of variance, students experienced either direct instruction (DI) or productive failure (PF), wherein they were first asked to generate a quantitative index for variance without any guidance before receiving direct instruction on the concept. Whereas DI students relied only on the canonical formulation of variance taught to them, PF students generated a diversity of representations and formulations for variance but were ultimately unsuccessful in developing the canonical formulation. On the posttest however, PF students performed on par with DI students on procedural fluency, and significantly outperformed them on data analysis, conceptual insight, and transfer items. These results challenge the claim that there is little efficacy in having learners solve problems targeting concepts that are novel to them, and that direct instruction alone is the most effective approach for teaching novel concepts to learners.

Introduction

Proponents of direct instruction bring to bear substantive empirical evidence against un-guided or minimally-guided instruction to claim that there is little efficacy in having learners solve problems that target novel concepts, and that learners should receive direct instruction on the concepts before any problem solving (Kirschner, Sweller, & Clark, 2006). Kirschner et al. (2006) argued that “Controlled experiments almost uniformly indicate that when dealing with novel information, learners should be explicitly shown what to do and how to do it” (p. 79). Commonly-cited problems with un-guided or minimally-guided instruction include increased working memory load that interferes with schema formation (Tuovinen & Sweller, 1999; Sweller, 1988), encoding of errors and misconceptions (Brown & Campione, 1994), lack of adequate practice and elaboration (Klahr & Nigam, 2004), as well as affective problems of frustration and de-motivation (Hardiman et al., 1986).

Klahr & Nigam’s (2004) often-cited study compared the relative effectiveness of discovery learning and direct instruction approaches on learning the control of variable strategy (CVS) in scientific experimentation. On the acquisition of basic CVS skill as well as ability to transfer the skill to evaluate the design of science experiments, their findings suggested that students in the direct instruction condition who were explicitly taught how to design un-confounded experiments outperformed their counterparts in the discovery learning condition who were simply left alone to design experiments without any instructional structure or feedback from the instructor (I will return to this study in more detail in the discussion section). Further experiments by Klahr and colleagues (Chen & Klahr, 2008; Strand-Cary & Klahr, 2008), and others as well have largely bolstered the ineffectiveness of discovery learning compared with direct instruction (for reviews, see Kirschner et al., 2006).

Be that as it may, the above findings do not necessarily imply that there is little efficacy in having learners solve novel problems, that is, problems that target concepts they have not learnt yet (Schmidt & Bjork, 1992). To determine if there such an efficacy, a stricter comparison for direct

instruction would be to compare it with an approach where students first generate representations and methods on their own followed by direct instruction. Expectedly, the generation process will invariably lead to failure, that is, students are rarely able to solve the problems and discover the canonical solutions by themselves. However, this very process can be productive for learning *provided* direct instruction on the targeted concepts is subsequently provided (Kapur, 2008; Koedinger & Aleven, 2007; Schwartz & Bransford, 1998; Schwartz & Martin, 2004).

As a case in point, I present evidence from an on-going research program on *productive failure* (Kapur, 2008; Kapur & Kinzer, 2009; Kapur et al., 2007).

Designing for Productive Failure

There are at least two problems with direct instruction in the initial phase of learning something new or solving a novel problem. First, students often do not have the necessary prior knowledge differentiation to be able to discern and understand the affordances of the domain-specific representations and methods underpinning the targeted concepts given during direct instruction (e.g., Schwartz & Martin, 2004). Second, when concepts are presented in a well-assembled, structured manner during direct instruction, students may not understand why those concepts, together with their representations, and methods, are assembled or structured in the way that they are (Chi et al., 1988; diSessa et al., 1991; Schwartz & Bransford, 1998).

To overcome these two problems, a learning design should focus squarely on first engaging students in processes that serve two critical cognitive functions, which in turn, prepare students for subsequent direct instruction: a) activating and differentiating prior knowledge in relation to the targeted concepts, and b) affording attention to critical features of the targeted concepts.

Productive failure is one such learning design. It comprises two phases—a generation and exploration phase followed by a direct instruction phase. In the generation and exploration phase, the focus is on affording students the opportunity to leverage their formal as well as intuitive prior knowledge and resources to generate a diversity of *structures*—concepts, representations and solution methods—for solving a complex problem; a problem that targets concepts that they have not been formally taught or learnt yet¹. Research suggests that students do have rich *constructive resources* (diSessa & Sherin, 2000) to generate a variety of structures for solving novel problems (diSessa et al., 1991; Schwartz & Bransford, 1999). At the same time,

¹ The complexity of the problem is in relation to the learner. The problem is complex to the learner because the learner does not know the canonical representations and methods for solving it. To someone who knows these, the problem is no longer complex.

research also suggests that one cannot expect students, who are novices to the target content, to somehow generate or discover the canonical representations and domain-specific methods for solving the problem (Kirschner et al., 2006).

However, the expectation for the generation and exploration phase is not for students to be able to solve the problem successfully. Instead, it is to generate and explore the affordances and constraints of a diversity of structures for solving the problem. To the extent that students can persist in this process, the process not only activates but also differentiates their prior knowledge (as evidenced in the diversity of student-generated concepts, representations and methods). Furthermore, a comparison and contrast between the various structures also affords opportunities to attend to critical features of the targeted concepts (more on this in results section). Consequently, the generation and exploration phase provides the necessary foundation for developing deeper understanding of the canonical concepts, representations, and methods during direct instruction.

Empirical evidence for PF comes from a series of design experiments in grades seven through nine in Singapore mathematics classrooms (Kapur, 2009a, 2009b; Kapur et al., 2008; Kapur & Lee, 2009). Working with approximately 300 students from four public schools, the studies compared PF and DI designs for a two-week, curricular unit on average speed. Findings suggested that PF students produced a diversity of linked problem representations and methods for solving the problems but were ultimately unsuccessful in their efforts. Despite seemingly failing in their problem-solving efforts, PF students significantly outperformed DI students on both procedural fluency and complex analysis problems on the posttests. Furthermore, PF students also demonstrated significantly better transfer performance in adapting and building upon the targeted concepts to learn new concepts on their own.

These findings are consistent with other research programs that suggest that conditions that maximize performance in the shorter term are not necessarily the ones that maximize learning in the longer term (Clifford, 1984; Schmidt & Bjork, 1992). Examples of such research programs include VanLehn's (2003) work on *impasse-driven learning*, Schwartz and Bransford's (1998) work on *preparation for future learning*, Schwartz and Martin's (2004) work on *inventing to prepare for learning*, diSessa's (1991) work on *meta-representational competence*, Koedinger and Aleven's (2007) work on the *assistance dilemma*, among others (Kapur & Rummel, 2009).

Collectively, these research programs support the argument for designing conditions for learners to persist in the process of solving novel, complex problems without instructional support structures initially. Even though such a process invariably leads to failure in the shorter term, the extent to which this process affords learners opportunities to explore and generate a variety of representations and methods, the process can be germane for learning.

The purpose of this paper is to report findings from an ongoing, classroom-based research program on productive failure in a public school in Singapore.

Method

Participants

Participants were 140, ninth-grade mathematics students (14-15 year olds) from an all-boys public school in Singapore. Students were almost all of Chinese ethnicity. Students were from four mathematics classes; three classes taught by one teacher (teacher A), and the fourth class by another teacher (teacher B). Students had no instructional experience with the targeted concept—variance—prior to the study, although they had learnt the concepts of mean, median, and mode in grades 7 and 8.

Research Design

A quasi-experimental, pre-post design was used with two classes ($n = 31, 35$) taught by teacher A assigned to the 'Direct Instruction' (DI) condition, and the other two classes ($n = 35, 39$), under teachers A and B, assigned to the 'Productive Failure' (PF) condition.

First, all students took a five-item paper and pencil pretest ($\alpha = .75$) on the concept of variance. Not surprisingly, not a single student demonstrated canonical knowledge of the concept, and there was no significant difference between the four classes either, $F(3,136) = 1.665, p = .177$. Next, all classes participated in four, 55-minute periods of instruction on the concept as appropriate to their assigned condition. After the second and fourth periods, students from all classes took a five-item, five-point (1(low) - 5(High)) Likert scale engagement survey ($\alpha = .79$). Finally, all students took a six-item, paper and pencil posttest ($\alpha = .74$) comprising items on procedural fluency, data analysis, conceptual insight, and transfer.

In the DI condition, the teacher first explained the concept of variance and its canonical formulation as the square of

the standard deviation ($SD^2 = \frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n}$) using a data

analysis problem. Next, the teacher modeled the application of the concept by working through several data analysis problems, highlighting common errors and misconceptions, and drawing attention to critical features of the concept in the process. The data analysis problems required students to compare the variability in 2-3 given data sets, for example, comparing the variability in rainfall in two different months of a year, or comparing the consistency of performance of three soccer players, and so on. Thereafter, students worked face-to-face in triads on more data analysis problems. The teacher then discussed the solutions with the class. After each period, students were given similar data analysis problems for homework, which the teacher marked and returned to the students, usually by the following period.

The PF condition differed from the DI condition in only one important aspect. Instead of receiving direct instruction upfront, students spent two periods working face-to-face in triads to solve one of the data analysis problems on their own. The data analysis problem presented a distribution of goals scored each year by three soccer players for a twenty-year period. Students were asked to generate a quantitative index to determine the most consistent player. During this

generation phase, no instructional support or scaffolds were provided. Following this, two periods were spent on direct instruction just like in the DI condition. Note that because students in the PF condition spent the first two periods generating an index for variance, they solved fewer data analysis problems overall than their counterparts in the DI condition. To make this contrast even sharper, PF students did not receive any data analysis problems for homework.

Hypothesis The hypothesis tested was that *productive failure will be more effective than direct instruction in learning the concept of variance*. That is, expecting to replicate earlier work on productive failure (Kapur, 2008, 2009; Kapur & Lee, 2009), I hypothesized that students from the PF condition will be able to generate and explore various representations and methods for generating an index for variance (diSessa et al., 1991), but will not be successful in developing or discovering the canonical formulation on their own (Kirschner et al., 2006). However, this seeming failure would be integral for: a) engendering the necessary prior knowledge differentiation (evidenced in the diversity of student-generated structures), and b) drawing attention to critical features of the concept of variance (evidenced in the comparisons between the student-generated structures), which may help students better understand the concept when presented by the teacher during direct instruction subsequently (Schwartz & Bransford, 1998). This better understanding would result in better procedural fluency, data analysis, conceptual insight, and transfer.

Process Results

Process data included group-work artifacts produced on A4 sheets of paper. These provided a rich source of data about the nature of problem representations and methods generated by the students in the PF and DI conditions.

In the PF condition, groups produced four major and *progressively sophisticated* categories of methods and representations. The four categories were: a) central tendencies, b) qualitative methods, c) frequency methods, and d) deviation methods.

Category 1: Central Tendencies. Groups started by using mean, median, and in some cases, mode for data analysis. This was not surprising because students had been taught these concepts in the earlier grades. However, relying on central tendencies alone, it was not possible to generate a quantitative index for variance because the problem was designed in a way to keep the central tendencies invariant.

Category 2: Qualitative methods. Groups generated graphical and tabular representations that organized the data visually and were able to discern which player was more consistent. The visual representations (see Figure 1) afforded a qualitative comparative analysis between the players, but did not provide a quantitative index for measuring consistency even though the ideas of spread and clustering are quite evidently important qualitative conceptual underpinnings for the concept of variance.

Category 3: Frequency methods. Groups built on the qualitative methods to develop frequency-based measures of consistency. For example in Figure 2, groups used the frequency of goals scored within certain intervals to argue

that the player with the highest number of goals in the interval containing the mean was the most consistent. Other groups counted the frequency with which a player scored above, below, and at the mean. Frequency methods demonstrated that students could quantify the clustering and bunching up trends in the qualitative representations.

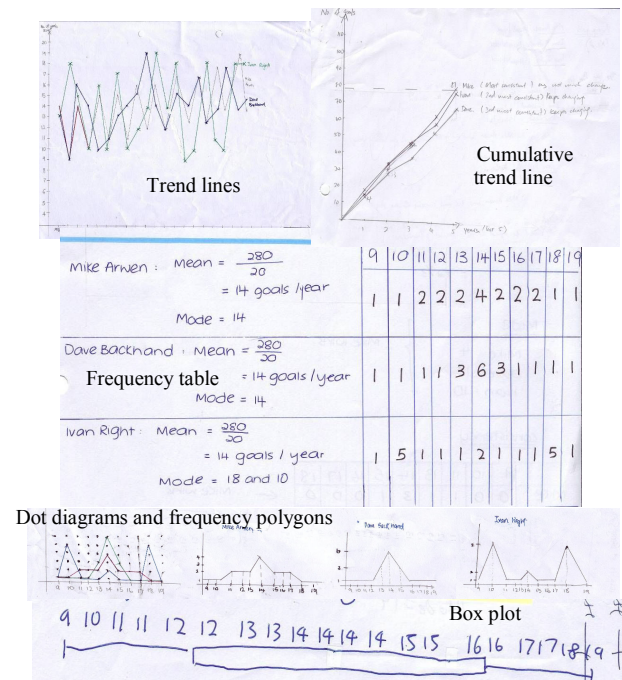

Figure 1 Examples of qualitative representations/methods

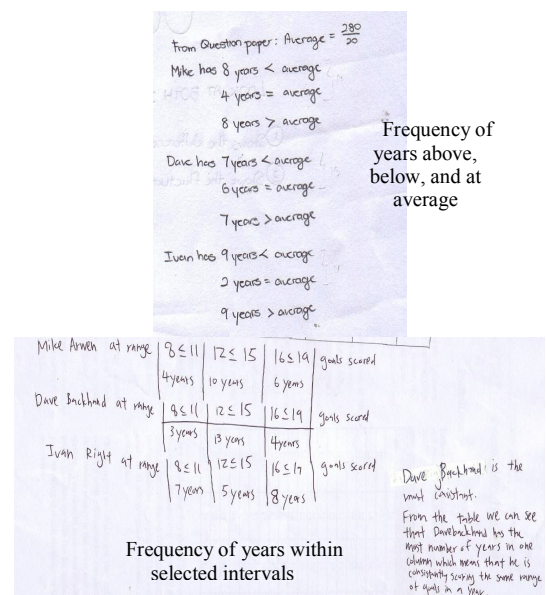

Figure 2 Examples of frequency representations/methods

Category 4: Deviation methods. Figure 3 presents some examples of the deviation methods. The simplest deviation method generated was the range (Deviation method 1, or simply D1). Some groups calculated the sum of year-on-year deviations (D2) to argue that the greater the sum, the

lower the consistency. Among these, there were those who considered absolute deviations (D3) to avoid deviations of opposite signs cancelling each other—an important conceptual leap towards understanding variance. Finally, there were some groups who calculated deviations about the mean (D4) only to find that they sum to zero. For both the D3 and D4 categories, some groups further refined their method to consider not the sum of the deviations, but the average (D5).

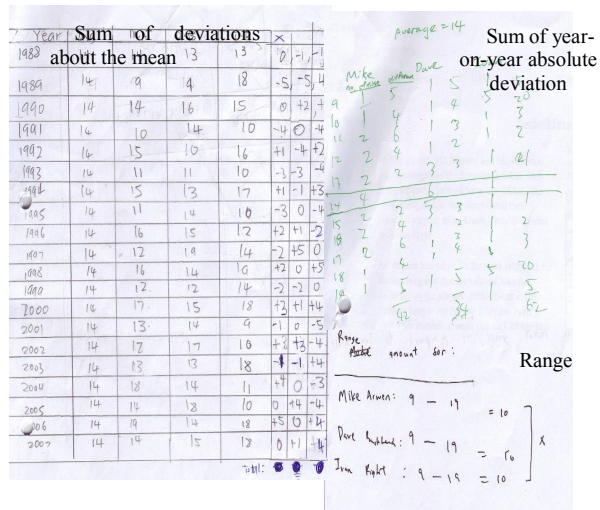

Figure 3 Examples of deviation-based representations and methods

In both the PF classes, all groups demonstrated representational competence at the Category 3 level or greater. Only 2 groups from PF-A and 1 group from PF-B did not reach Category 4. Consistent with the hypothesis, none of the groups were able to develop let alone use the canonical formulation on their own.

More importantly, note that these structures evidence the hypothesis that students will in fact be able to generate a rich diversity of structures to solve the problem without having first learnt the targeted concept of variance, and that comparisons between these structures will afford students the opportunities to attend to deep conceptual features of the concept. The latter needs more elaboration:

- Comparing central tendencies with qualitative representations afforded an opportunity to attend to the feature that central tendencies alone cannot convey information about variance, and that different distributions with the same mean can have different variance.
- A comparison between the frequency methods and the qualitative methods afforded the opportunity to attend to the quantification of qualitative data into a mathematical index that returns a value for consistency.
- Because the deviation methods consider the relative position of a data point, a comparison with the frequency methods afforded students the opportunity to attend to the feature that, for consistency, it is not only important to count a point but also consider its position in relation to other points.

- Range (D1) afforded students the opportunity to attend to the feature that considering just the extreme points may not be a good measure of consistency, because it tells us nothing about the distribution in the middle. Comparing D1 with any of the qualitative representations easily afforded attention to this feature.
- A comparison between D2 and D3 afforded students the opportunity to attend to the feature of why deviations must be positive. The comparison clearly shows that when deviations are left with their signs intact, positive and negative deviations cancel out resulting in a case where the variance could be highly underestimated.
- A comparison of D3 and D4 methods afforded students the opportunity to attend to the feature of why the reference point must be a fixed point (e.g., the mean), or else the index is sensitive to ordering of data. If the reference point for the deviation is not a fixed point, then a re-ordering of the data will result in a different value of consistency for the same formulation.
- A comparison between the sum and the average afforded the opportunity to attend to the feature of how dividing by the number of data points helps compare samples of different sizes.

In the DI condition, analysis of students' classroom work revealed that all students relied only on the canonical formulation to solve data analysis problems. This was not surprising given that the canonical formulation is relatively easy to compute and apply, and was corroborated with data from homework assignments. The average performance (i.e., percentage of problems solved correctly) on the homework assignments was high, $M = 93.2\%$, $SD = 5.3\%$. Finally, on the mean of the two self-reported engagement ratings, there was no significant difference between the PF condition, $M = 3.84$, $SD = .51$, and the DI condition, $M = 3.82$, $SD = .43$, $F(1, 138) = .035$, $p = .852$.

These process findings serve as a manipulation check demonstrating that students in the PF condition experienced "failure" at least in the conventional sense. In contrast, DI students were not only just as engaged as PF students but also demonstrated successful application of the canonical formulation to solve several data analysis problems. The high engagement ratings and performance results also suggest that the DI condition was not simply a case of poor instruction.

Outcome Results

Post-test The six-items on the posttest comprised:

- one item on procedural fluency (calculating SD for a given data set),
- two items on data analysis (comparing means and SDs of two samples; these items were similar to the data analysis problems covered during instruction),
- two items on conceptual insight (one item dealing with sensitivity to ordering of data points, and another with outliers), and
- one item on transfer (item requiring the development of a normalized score for comparing incommensurable distributions. Note that normalization was not taught

during instruction, and therefore, students needed to flexibly adapt and build upon what they had learnt.).

Maximum score for each item was 10; two raters independently scored the items using a rubric with an inter-rater reliability of .96. Performance on the four types of items formed the four dependent variables. Controlling for the effect of prior knowledge as measured by the pretest, $F(4, 134) = 1.890, p = .112$, a MANCOVA revealed a statistically significant multivariate effect of condition (PF vs. DI) on posttest scores, $F(4, 134) = 16.802, p < .001$, partial $\eta^2 = .33$. There was no significant difference between the classes *within* the PF or DI conditions, nor was there any significant interaction between prior knowledge and experimental condition.

- i. On the procedural fluency item, there was no significant difference between the PF condition, $M = 7.66, SD = 3.97$, and the DI condition, $M = 7.98, SD = 3.89, F(1, 137) = .819, p = .367$.
- ii. On the data analysis items, students from the PF condition, $M = 14.11, SD = 4.20$, significantly outperformed those from the DI condition, $M = 11.38, SD = 4.86, F(1, 137) = 10.290, p = .002$, partial $\eta^2 = .07$.

It is important to note that PF students who were not given any homework and exposed to fewer data analysis problems still managed to perform on par with DI students on procedural fluency, and better than DI on data analysis in spite of DI students receiving homework and more practice and feedback on data analysis problems during instruction.

- iii. On the conceptual insight items, students from the PF condition, $M = 16.40, SD = 6.41$, significantly outperformed those from the DI condition, $M = 8.20, SD = 6.15, F(1, 137) = 51.359, p < .001$, partial $\eta^2 = .27$.
- iv. On the transfer item, students from the PF condition, $M = 4.93, SD = 2.99$, significantly outperformed those from the DI condition, $M = 3.07, SD = 2.35, F(1, 137) = 14.505, p < .001$, partial $\eta^2 = .10$.

Discussion

These findings are consistent with previous studies on productive failure with other mathematical topics and profile of students (Kapur, 2009a, 2009b; Kapur et al., 2008; Kapur & Lee, 2009), and also with other studies (e.g., Schwartz & Bransford, 1998; Schwartz & Martin, 2004). Notwithstanding the limitations of what can be achieved in a single study carried out within a particular domain, context and classroom-based setting, implications arising from the findings are simple and significant: There is indeed an efficacy in having learners generate and explore representations and methods for solving problems on their own even if they do not formally know the underlying concepts needed to solve the problems, and even if such unsupported problem solving leads to failure initially. The process analysis showed that this seeming failure was integral for: a) engendering the necessary prior knowledge differentiation (evidenced in the diversity of student-generated structures), and b) drawing attention to critical features of the concept of variance (evidenced in the comparisons between the student-generated structures), which may help students better understand the concept

when presented by the teacher during direct instruction subsequently (Schwartz & Bransford, 1998).

This study contributes to the ongoing debate comparing the effectiveness of direct instruction with discovery learning approaches (e.g., Kirschner et al., 2006; Klahr & Nigam, 2004; Dean & Kuhn, 2007); discovery learning being often epitomized as the constructivist ideal. It is perhaps worth clarifying that a commitment to a constructivist epistemology does not necessarily imply a commitment to discovery learning. Simply leaving learners to generate and explore without consolidating is unlikely to lead to learning, or at least learners cannot be expected to “discover” the canonical representations by themselves as indeed our findings suggest. Instead, a commitment to a constructivist epistemology requires that we build upon learners’ prior knowledge. However, one cannot build upon prior knowledge if one does not know what this prior knowledge is in the first place. It follows that at the very least the burden on the designer (e.g., teacher, researcher) is to first understand the nature of learners’ prior knowledge structures; the very structures upon which the claimed “building” will be done. Designing for productive failure presents one way of doing so, wherein students first generate and explore representations and methods, and in the process externalize their prior knowledge structures, before direct instruction.

Interestingly, one could argue that Klahr & Nigam’s (2004) study supports the above contention although it is often cited as a stellar example of the superior effectiveness of direct instruction over discovery learning. A careful reading of the study suggests that before assigning students to either a direct instruction or a discovery learning condition, Klahr and Nigam conducted a baseline assessment where they asked students to design four experiments on their own. As expected, only 8 out of the 112 students were able to design four un-confounded experiments, that is, the success rates before any instruction on the control of variables strategy (CVS) were very low. Students who were subsequently assigned to the discovery learning condition simply continued to design these experiments but without any instruction on CVS or any feedback. However, for students in the direct instruction condition, the instructor modeled and contrasted the design of both confounded and un-confounded experiments with appropriate instructional facilitation and explanation to make them attend to critical features of why CVS, unlike confounded experiments, helps isolate the effects of a factor. It was not surprising therefore that Klahr and Nigam found direct instruction to be more effective than discovery learning as described earlier in this paper.

From the perspective of productive failure however, the baseline assessment in Klahr and Nigam’s (2004) study seems to function very much like the generation and exploration² phase where students generate their own structures (in this case, experiments) to solve a problem that targets a concept (in this case, CVS) that they had not learnt yet. If so, the very effects that Klahr and Nigam attribute to

² Indeed, Klahr & Nigam (2004) themselves termed it the “exploration phase.”

direct instruction *alone* seem more appropriately attributed to a generation and exploration phase (their baseline assessment) followed by direct instruction. Therefore, much as Klahr and Nigam set out to show, in part, that there is little efficacy in students exploring and solving problems requiring concepts they have not learnt yet, their findings can be reinterpreted to support precisely the opposing contention that such exploration can in fact be efficacious provided some form of direct instruction follows, for without it, students may not learn much (as indeed the performance of the students in the discovery learning condition revealed). Thus argued, designing for a certain level of failure (as opposed to minimizing it) in the initial learning phase may well be productive for learning in the longer run. Future research would do well not to (over)simplistically compare discovery learning with direct instruction, but instead understand conditions under which these approaches can complement each other productively.

Abstract

This article reports an investigation involving a series of studies carried out to critically examine the hypothesis that presence of 2 or 3 counterintuitive concepts in a story makes it more memorable than stories containing fewer or more such concepts. Our results paint a more complicated picture involving a number of interacting factors with contribution of the counterintuitive concepts to the global story cohesion emerging as a key factor.

Keywords: Memory, culture, folktales, concept learning.

Introduction

A number of recent studies have found that minimally counterintuitive concepts are recalled better than intuitive and maximally counterintuitive ideas (Barrett & Nyhof, 2001; Boyer, 1994, 2001; Boyer & Ramble, 2001). Better memorability for minimally counterintuitive concepts, these researchers argue, explains why such concepts form part of widespread religious beliefs and other widely shared cultural beliefs. However, as Atran (2003) has argued, these findings on their own are not sufficient to explain why most of the widespread cultural folktales contain only a small number of counterintuitive concepts¹ and are mostly composed of intuitive concepts. How and why do the apparently less memorable intuitive concepts continue to be successfully transmitted along with a small number of counterintuitive concepts? Does the presence of counterintuitive concepts improve overall recall for a story? If so, would an even larger number of counterintuitive concepts make the story even more memorable or would memorability drop if counterintuitive concepts are added beyond a certain number?

Norenzayan, Atran, Faulkner, and Schaller (2006) report on an investigation carried out to study these questions. They selected 42 Grimm Brothers folktales such that half of the stories were judged to be “culturally successful” (they attracted more Google hits) and the other half were considered to be “culturally unsuccessful” (because they received fewer Google hits). Counterintuitive concepts present in each story were then counted. They found that a vast majority of the culturally successful folk tales had two or three counterintuitive ideas whereas counterintuitive ideas were more evenly distributed among the unsuccessful

folktales. Subjects were then asked to read the stories and answer a number of questions to determine if the subjects thought that the stories were familiar, memorable, easy to understand, easy to transmit, and interesting enough to tell others. Their results show that stories with more Google hits were judged by the subjects to be more memorable and worth telling their friends. On the basis of this evidence, Norenzayan *et al.* argued that stories that contain two or three counterintuitive ideas enjoy memorability advantages over stories that have fewer (0 or 1) or more (4, 5, 6, or larger) counterintuitive ideas. They further argue that this should be true for all stories and not just Grimm Brother’s tales or just Northern European folktales from the 19th century, or just for narratives of a certain length. They call stories containing 2-3 counterintuitive concepts as *MCI narratives* and state, “we propose that MCI narratives are culturally successful partly because they enjoy a stronger cognitive advantage in recall than other narrative templates” (Page 549)(Norenzayan, Atran, Faulkner, & Scaller, 2006). Let us call the hypothesis that stories containing 2 or 3 counterintuitive ideas are more memorable than stories containing fewer or more concepts as the MCI-hypothesis.

The objective of this paper is to carefully examine the MCI-hypothesis and its implications. This is accomplished through a series of studies. Initially, we replicate Norenzayan *et al.*’s methodology but then complement it with other techniques.

Study I

This study replicates Norenzayan *et al.*’s methodology for a different set of folktales. Aesop’s fables are folktales credited to a Greek slave named Aesop who is thought to have lived from 620 to 560 BC. Most of the short stories contain between 50 and 500 words and are organized around moral themes. A number of stories contain counterintuitive concepts such as anthropomorphic animals. While Aesop’s fables have survived for hundreds (if not thousands) of years and are widely known around the world, not all tales are equally well known. This study used George Fyler Townsend’s collection (1867) containing 350 fables. Using Norenzayan *et al.*’s methodology, Google hits were computed for all 350 fables by querying for “Aesop” and the title of a story (e.g., “The Hare and the Tortoise”). Besides Google’s initial estimate of the number of matching documents (which was the only measure used by Norenzayan *et al.*), this study also computed the actual

¹ The rest of the article uses the terms MCI concepts or simply counterintuitive concepts when referring to minimally counterintuitive concepts.

number of documents returned once Google was asked to retrieve all of the matching documents. Unfortunately, the rankings on the two counts did not match. The present study used the actual number of documents found as a more reliable indicator of a fable's popularity. The top 21 most popular tales had an average of 488 actual and 6321 estimated hits while the bottom 21 least popular tales had 80 actual and 197 estimated hits.

Figure 1: Distribution of counterintuitive concepts among the popular and unpopular Aesop's fables.

Next, a hypothesis-blind coder and the author coded the stories for the number of counterintuitive concepts in them. We agreed on 100% of the initial coding shown in Figure 1. It shows that contrary to predictions of the MCI hypothesis, a majority of popular fables do not have 2 or 3 counterintuitive concepts. Instead, 11 of the 21 popular stories contain 0 or 1 counterintuitive concept while remaining 10 have 2 or 3 counterintuitive concepts. A majority of unpopular stories (16 out of 21) also had 1-2 counterintuitive concepts and only 5 unpopular stories had 2-3 counterintuitive concepts.

A problem with studies reported so far is that they do not directly measure the memorability and are therefore unable to directly test the MCI hypothesis. The next study was designed to directly test the hypothesis that having 2-3 counterintuitive concepts makes a story more memorable than stories containing fewer or a larger number.

Study II

Material & Method

We decided not to use an existing set of stories (such as Grimm Brother's stories or Aesop's fables) because we wanted better control over (a) the number of concepts embedded in each story, and (b) subject's prior exposure to the stories. We designed three short stories containing 300-400 words each. Two of the stories, namely, "The Journey Home" and "The Trader" had been used in previous experiments (Barrett & Nyhof, 2001; Boyer & Ramble, 2001; Upal, 2005; Upal, Gonce, Tweney, & Slone, 2007) while the third story "The Night" was designed specifically for this experiment. Three versions of each story were created. Version I had one counterintuitive idea, while the second version had three and the third version had six counterintuitive ideas in it. Six packet-groups were then designed such that each packet-group contained all three stories and all three story types.

The balanced Latin square experiment required creation of thirty six distinct packets. Thirty six University of Toledo undergraduate and graduate students ranging in age from 18 to 24 were recruited to participate in the experiment. Subjects were asked to carefully read all three stories so that they could answer some questions about them. Next they were asked to solve simple arithmetic problems for one minute. Following that they were asked to write down as much of each story as they could remember. Story recall was measured by dividing each story into individual idea units constituting each story. The ideas roughly corresponded to the sentences in each story, although this wasn't always the case as some sentences were judged to have multiple concepts in them. "The Trader" was determined to have significantly smaller number of ideas (around 30) than "The Journey Home" or "The Night" each of which had roughly the same number of idea units (around 50 each).

Subject responses were coded using a binary coding scheme to measure whether a subject had recalled an element in the story or not. Story recall was measured by dividing the number of ideas a subject recalled by the total number of ideas in the story. Thus a perfectly recalled story would be assigned the recall value of 1 while a story that is not recalled at all would get the recall value of 0. The author and a hypothesis blind coder created two initial codings. We agreed on 89% of the initial coding. Disagreements were resolved through discussion to create one final coding.

Results

The recall rates for 1, 3, and 6 counterintuitive versions of the stories (Figure 2) show that story recall does not significantly vary as a function of the number of embedded counterintuitive concepts. This is true for both the overall story recall rates and also for each of the individual stories we studied.

Figure 2: Overall story recall rates for 1, 3 and 6 concept versions of the stories.

Discussion

Our results not only call into question the MCI-hypothesis, they also indicate the need to seek an alternative answer to the question of what distinguishes memorable counterintuitive stories from forgetful ones? Previously (Upal, 2005, 2010; Upal, et al., 2007), I have argued that in order to answer these questions, we need to pay attention to cognitive processes involved in comprehension of text (Graesser, Singer, & Trabasso, 1994; Kintsch, 1998). Discourse analysis researchers and psycholinguists have

identified global cohesion among the elements of a text as a key factor in memorability (Halliday & Hasan, 1976).

Cohesion of a piece of text is defined as connections among various elements of the text and is not just a function of the text itself but also of the background knowledge that the reader possesses. The connections that make a text more or less cohesive include coreferences as well as causal and logical connections among its various elements. A text is better remembered by a reader if its constituents can be made coherent by the reader (Trabasso, Suh, Payton, & Jain, 1995). Furthermore, the more effort a reader spends in making a text coherent, the more memorable the text (Kim, 1999). Building on this and other work in cognitive science (Schank, 1999; Schank & Abelson, 1977) and humour research (Suls, 1983), I proposed a hypothesis that emphasizes the role played by the context in which counterintuitive concepts are embedded in making those concepts more or less memorable. This account suggests that, similar to other expectation-violating and schema-incongruent concepts, counterintuitive ideas are better remembered because they attract a reader's attention by violating the reader's expectations about what is to come next in the text. When a reader's expectations are violated, she attempts to resolve the situation by reasoning to justify the inclusion of expectation-violating information in the text by invoking a variety of knowledge that the reader possesses. If this postdiction effort is successful, the expectation-violating concepts become richly linked to the reader's existing mental representations, which were retrieved to explain the inconsistency to derive a coherent theme. They also become richly connected to the derived story theme itself. This may make counterintuitive elements of a narrative more likely to be recalled when the story title is provided as a cue.

This view suggests that memorability for a story should be mediated through story cohesion. Thus counterintuitive stories should only be remembered well if they can be made coherent by a reader. If a counterintuitive story is too incoherent (or judged too difficult to make coherent given a reader's motivation level) then it should not be well remembered.

The next study was designed to test this hypothesis. I wanted to know whether inclusion of various types of counterintuitive concepts equally affects story memorability. Depending on the context, inclusion of some counterintuitive concepts may, for instance, increase cohesion of a story while addition of other counterintuitive concepts may decrease it. Would inclusion of both types of concepts equally affect story memorability? The above account would suggest that stories including cohesion-enhancing concepts should be remembered better than stories that contain cohesion suppressing concepts.

Study III

Material and Method

I designed three short (95-125 words) Aesop-like fables. Each story involves two human or animal protagonists who

happen to meet. At the end, the moral lesson of the story (the same as the story title) is uttered by one of the main characters. Four versions of each story were designed: (1) Coherent-Counterintuitive (CC), (2) Coherent-Intuitive (CI), (3) Incoherent-Counterintuitive (IC), and (4) Incoherent-intuitive (II).

In the coherent-counterintuitive version, both of the main characters are counterintuitive but their counterintuitiveness is *causally relevant* for making sense of the story and for connecting various elements of the story and for deriving the coherent theme that is the story title. For instance, in the CC version of "obscurity brings safety", the protagonists are an invisible-man and an all-seeing-woman. The counterintuitive property of each character is causally relevant because it allows a reader to make sense of the events to follow and to connect them to the moral lesson of the story. For instance, all-seeing-ability of the woman allows a reader to understand why she is able to see an otherwise invisible man. Man's invisibility is needed to understand woman's advice to him to become visible to make his life more enjoyable and why he decides to paint himself skin-tone and then why, on being mugged after becoming visible, he regrets his actions and utters, "obscurity brings safety." These particular counterintuitive properties are causally relevant because, without them, the story and its title make little sense and are not as coherent.

In the coherent-intuitive version, the protagonists are replaced by intuitive beings. However, their intuitive properties are still causally relevant to explaining the events in the story. For instance, in the CI version of "obscurity brings safety", the invisible-man is replaced by a reclusive man and the all-seeing-woman is replaced by a kind-but blunt woman. The man's reclusiveness allows the reader to understand why he is advised by the caring woman to go out and why the man regrets following her advice.

In the incoherent-counterintuitive version, the main characters are counterintuitive but their counterintuitiveness is irrelevant to the events in the story and does not help a reader in her attempt to derive a coherent theme from the story. For instance, the IC version of "obscurity brings safety" includes "a man who has feet for hands" and a "woman who is made of iron". These properties do not help the reader to make sense of why the woman asks the man to stop being invisible and why he decides to paint himself or why he proclaims that "obscurity brings safety" upon unfolding of the story's events.

In the incoherent-intuitive version, the main characters are intuitive beings whose explicitly mentioned intuitive properties are irrelevant to the events in the story and do not allow the reader to derive the moral lesson in the story's title. For instance, the II version of "obscurity brings safety" features "a man with brown hair" and "a woman with dark circles around her eyes." Both properties have little to do with the woman's advice, the man's actions, or the story title/theme.

Each subject packet included three stories. Varying the story order and story type yielded 192 possible packets. Out

of these, 40 packets were randomly selected to be given to 40 Occidental College male and female Cognitive Science and Psychology undergraduates who participated in the experiments for extra credit. After reading all three stories, subjects were instructed to solve simple arithmetic problems for one minute. Following that they were asked to write down as much of each story as they could remember. The subject responses were coded for recall by the author and a hypothesis blind coder following the same methodology as in Study 2. We also measured the number of words recalled and also recall rates for counterintuitive and intuitive descriptions of the protagonists. The two coders agreed on 96% of the initial coding. Disagreements were resolved through discussion to create one final coding.

Results & Discussion

The results are shown in Table 1. There was a significant effect of story cohesion while there was no significant effect of the number of counterintuitive concepts.

Table 1: (a) The first three tables show story recall data for individual stories, (b) the last table shows the overall results. The leftmost column shows the mean recall rates for propositions describing story protagonists. The middle column shows the recall rate for all of the story elements including the protagonists. The rightmost column shows the recall rate for the rest of the story elements.

(a)			
Obscurity Brings Safety			
	Protagonist recall	Overall Story Recall	Story Minus Protagonist recall
Coherent-Counterintuitive	100	82	77.5
Coherent-Intuitive	64.4	87.5	59.5
Incoherent-Counterintuitive	86.4	62.7	56.8
Incoherent-Intuitive	65	55	52.5

Never Laugh at Someone			
	Protagonist recall	Overall Story Recall	Story Minus Protagonist recall
Coherent-Counterintuitive	100	100	100
Coherent-Intuitive	100	100	100
Incoherent-Counterintuitive	57.1	57.1	57.1
Incoherent-Intuitive	54.5	54.5	54.5

No Gratitude From the Wicked			
	Protagonist recall	Overall Story Recall	Story Minus Protagonist recall
Coherent-Counterintuitive	72	72	72
Coherent-Intuitive	45.8	45.8	45.8
Incoherent-Counterintuitive	33.3	33.3	33.3
Incoherent-Intuitive	90	90	90

(b)			
	Overall		
	Protagonist recall	Overall Story Recall	Story Minus Protagonist recall
Coherent-Counterintuitive	92.4	92.4	92.4
Coherent-Intuitive	74.1	74.1	74.1
Incoherent-Counterintuitive	61.1	61.1	61.1
Incoherent-Intuitive	65	65	65

The coherent stories were significantly better recalled than incoherent stories ($F(1, 117) = 15.019$ $p = 0.00018$). Contrary to predictions of the MCI hypothesis, stories containing 2 counterintuitive concepts were not better recalled than stories containing 0 counterintuitive concepts ($F(1, 117) = 0.38129$ $p = 0.53811$). In fact, while the differences were not statistically significant, stories containing 2 counterintuitive concepts were less well recalled than stories without any counterintuitive concepts in them. If we control for cohesiveness and vary the number of counterintuitive ideas in a story, we get two distinct trends. As shown in **Error! Reference source not found.**, when counterintuitive ideas enhance cohesion, their addition makes a story more memorable (although not significantly so). However, when counterintuitive concepts cannot be easily integrated to derive the story theme, their addition results in lower recall (again differences are not statistically significant).

Table 3(b) shows that coherent-counterintuitive stories were best recalled, followed by coherent-intuitive stories, which were better recalled than incoherent-intuitive stories. However, only recall for incoherent-counterintuitive stories was significantly lower than recall for coherent-counterintuitive and coherent-intuitive stories ($F(3, 115) = 6.3828$ $p = 0.00049$). The subjects recalled only half of the ideas from the stories in which incoherent protagonists were not causally relevant to the story theme.

Incoherent stories also prompted some subjects to add unsolicited comments to their written responses such as, "the story was unclear", "this was a weird story" and "I didn't understand the story at all." Incoherent-counterintuitive stories solicited more (2) comments than incoherent-intuitive stories (1 comment). There was also some evidence to suggest that subjects were attempting to make sense of the incoherent stories. For instance, consider the incoherent-counterintuitive version of Gratitude, where the man decides to go home and mow his lawn and have dinner with his family but the wolf is still mysteriously saved. Two subjects inferred that the man saved the wolf by helping it before going home while another subject said that the man saw the wolf on his way back and saved it! Three subjects made the incoherent version of Laugh coherent by changing it. Instead of the man making fun of the woman's body and then surprisingly telling the woman never to laugh at people's body, two of the subjects changed the story so that the man realizes on his own that he should never have

laughed at the woman's body. Another subject changed the story to suggest that the woman made fun of the man!

Results of this study further call into question the notion that inclusion of 2-3 counterintuitive concepts makes a story more memorable and more transmissible. Our results indicate that counterintuitive concepts only make a story more memorable if they can be easily integrated to make the story coherent. Having gathered some support for our hypothesis that story cohesion is key to explaining story recall, I wanted to see whether difference between story cohesion could account for difference in popularity for Aesop's Fables. The final study was designed to investigate this possibility.

Study IV

Material and Method

I designed 32 study packets by randomly ordering the 42 (21 popular and 21 unpopular) stories selected in Study I. Each story was followed by seven randomly ordered questions. Replicating Norenzayan *et al.*'s methodology for their Study 2, I asked subjects to first rate each tale on the following six attributes on 7-point scale (anchored by endpoints labeled *strongly disagree* to *strongly agree*). Subject responses were used to measure their perception of each story's:

- *familiarity* ("I have heard this story before"),
- *memorability* ("Right now if someone asked me to close my eyes and tell them the story that I just read, I think I could recall all or most of the critical elements of the story"),
- *likelihood of transmission* ("If I told a 7-year-old this story, he or she would tell it to other children"),
- *interest value* ("This story was interesting"),
- *understandability* ("This story was easy to understand"), and
- *moral lesson* ("This story has a strong moral lesson").

In addition to the above six factors measured by Norenzayan *et al.*, I added the query "I could easily make a few modifications to the story (such as changing the main characters) to make the story's moral lesson even more apparent". Believing that incohesive stories should be judged by adult English readers as more amenable to a change than cohesive stories, I thought that subject responses to this question should be inversely related to story cohesion.

Thirty two adult male and female subjects from DRDC-Toronto participated in this experiment for remuneration. These experiments were individually conducted by a Research Assistant.

Results & Discussion

As shown in Table 2, subjects rated popular and unpopular stories differently on all of the dimensions we measured. Subjects were more familiar with fables that attracted a higher number of Google hits than those that attracted fewer hits. This provided independent support for

labeling of the stories mentioned on more Google-indexed websites as popular. This suggests that using Google to measure popularity of an idea is a valuable tool identified by Norenzayan *et al.* This should address lack of availability of data and should prompt more research in this area.

The results also provide some justification for the assumption that memorability had something to do with the popularity of the widespread Aesop fables, as subjects rated popular stories as more memorable than unpopular ones. These results are similar to those of Norenzayan *et al.* who also found that their subjects rated popular and unpopular Grimm Brother's tales to vary significantly along the dimensions of memorability, understandability, and likelihood of transmission.

Table 2: Mean subject ratings on various psychological variables as a function of whether a fable is popular or not.

Subject Ratings	Popular	Unpopular	t	p
Familiarity	-1.08	-2.49	14.51	<.001
Memorability	2.02	1.46	9.57	<.001
Likelihood of transmission	0.06	-0.68	10.16	<.001
Interest value	0.77	-0.09	11.27	<.001
Understandability	2.11	1.47	9.88	<.001
Moral Lesson	1.40	0.54	9.68	<.001
Cohesion	1.14	0.25	10.45	<.001

Unlike Norenzayan *et al.*, who did not find significant differences between subject's ratings of the popular and unpopular Grimm Brother's tales along dimension of interest value and moral lesson, our subjects rated popular stories as significantly more interesting and as significantly more likely to have "a strong moral lesson" than unpopular stories. The difference between our results and theirs could be due to the differences in the materials used (Aesop's fables versus Grimm Brother's folk tales) or due the experimental design factors such as differences in sample size (32 subjects \times 42 stories = 1342 sample points in our experiment versus 65 subjects \times 6 stories = 390 sample points for their experiment).

Our results also support the hypothesis that motivated this experiment, namely, that popular and unpopular stories differ along the dimension of story cohesion. Subjects not only rated popular stories higher on the dimension of "having a strong moral lesson," they also thought that popular stories were harder to modify to make story's "moral lesson more apparent" as compared to unpopular stories. To see whether differences in story cohesion can account for differences in memorability between stories, we computed an aggregated cohesiveness measure by combining the subject ratings in response to the moral lesson and "needing modification" questions, and performed a correlational analysis of aggregated cohesiveness and story memorability. We found that cohesiveness was

strongly correlated with memorability (Pearson Correlation Coefficient $r = 0.71$, $N = 42$, $p < 0.001$). This suggests that cohesiveness of Aesop's fables can explain most of the difference in memorability among Aesop's fables while the number of counterintuitive concepts present in a story cannot. Furthermore, correlation between cohesiveness and memorability becomes even stronger when only counterintuitive stories are considered. For stories containing at least one counterintuitive concept, the correlation is stronger ($r = 0.75$, $N=34$, $p < 0.001$), it is even stronger for stories containing at least 2 counterintuitive concepts ($r = 0.81$, $N = 16$, $p < 0.001$), and it is higher still for stories containing 3 counterintuitive concepts of which there were only three ($r=0.90$, $N = 3$, $p < 0.001$). These results suggest that counterintuitive elements added to a story have to make sense in the context of the story for it to be memorable and that this is especially true as more and more counterintuitive concepts are added to a story. To the extent that the inclusion of counterintuitive concepts can be justified in the context of a story, there may not be a fixed upper limit to the number of counterintuitive concepts that can be included in a memorable story. A writer's creative ability to imagine counterintuitiveness-justifying contexts may be the real limiting factor. If the context in which counterintuitive concepts are embedded does not allow a reader to justify the inclusion of those concepts and make the story cohesive, then that story will not be remembered well. This also answers Norenzayan *et al.*'s question as to why despite all of their memorability advantages counterintuitive concepts never appear alone and are always communicated along with an even larger number of intuitive concepts. The paper suggests that this may be because a context built by intuitive concepts is needed to justify, make sense of, and give meaning to the counterintuitive concepts.

Conclusion

The results of studies reported here call into question the notions that (a) there is a single cognitively optimal template for all narratives, and that (b) inclusion of 2-3 counterintuitive concepts makes a story more memorable and hence more transmissible. This paper suggests that relationship between inclusion of counterintuitive concepts and memory for narratives may be more complicated than previously suggested. The experiments reported here support the hypothesis that inclusion of counterintuitive concepts can make a story more memorable only if they allow a reader to use her/his background knowledge to make the story more coherent. These results have important implications not only for those interested in understanding how elements of culture become widespread but also for those interested in designing memorable messages for influencing target audiences. Thus, cultural scientists cannot ignore the socio-cultural context at the time of diffusion if they want to understand how certain folktales came to be widely distributed in a population. Marketing professionals cannot just throw in a certain number of counterintuitive concepts (or more generally expectation violating or schema

incongruent elements) into a message to make it more sticky. For such elements to add value to a message, one must carefully consider all aspects of the context which include both the cultural knowledge that members of the target audience bring to the table and the structure and content of the story to which these concepts are being added.

Abstract

Research has shown that disfluency – the metacognitive experience of difficulty associated with a cognitive task – engenders deeper processing. Since deeper processing typically leads to better retention, this paper examined whether decreasing perceptual fluency of educational materials would improve retention. Study 1 found that harder to read fonts led to increased retention in a controlled laboratory setting. Study 2 extended this finding to real-world classroom environments. It appears as though perceptual disfluency can function as a desirable difficulty in education. Implications and caveats are discussed.

Introduction

It seems logical that to effectively communicate an idea, one should present it in a manner which is clear and easy to follow. Educators follow this principle when designing textbooks—the order, wording, and formatting is designed to help students read the information with minimal effort. Indeed, there is evidence to support the notion that students benefit from decreased cognitive demands when learning new concepts (Sweller and Chandler, 1994).

While it is commonly accepted that reducing extraneous cognitive load is beneficial to student learning, there is some research that seems to suggest there are exceptions to this rule. In fact, research shows that in certain instances, it may be beneficial to *increase* extraneous cognitive load (e.g. Bjork 1994). These aptly named “desirable difficulties” create additional cognitive burdens but nonetheless improve learning.

For example, in one experimental paradigm (Hirshman & Bjork, 1988), participants are asked to remember pairs of words, such as “bread : butter.” Hirshman and Bjork found that requiring subjects to mentally generate missing letters in a word pair, such as “bread : b_tt_r,” leads to improved recall performance over participants who read the word pair without any missing letters. Bjork extended this strategy to realistic educational settings, finding that students who complete simple fill-in-the-blank sentences are better able to

retain information than students who read the same sentences with the key words filled in and underlined for them (Richland, Bjork, Finley, & Linn, 2005).

It seems counterintuitive that imposing unnecessary strain on students’ limited cognitive capacity would actually improve performance, yet desirable difficulties seem to exploit nuances in our cognitive systems. Importantly, these instructional techniques *appear* sub-optimal. Without conscious recognition and implementation on behalf of cognitive psychologists and educators, it is likely that these techniques would not even be considered for use.

It is important to explore such techniques and seek out new methods of presentation that better reflect or utilize the way we process information. One such technique may come from explorations on the metacognitive experience of fluency—the subjective feeling of ease or difficulty which is associated with almost any mental task (Alter & Oppenheimer, 2009). For instance, a blurry photograph is disfluent because it is difficult to discern, a whisper is disfluent because it is difficult to hear, and a foreign word may be disfluent because it is difficult to pronounce. Fluency has been shown to influence our judgments in a variety of ways, including our judgments of truth, confidence, intelligence, or familiarity (for a review, see Alter & Oppenheimer, 2009). Importantly, recent studies have begun to explore how fluency influences cognitive processing in ways that might yield positive educational outcomes.

Recent work in fluency has demonstrated that when a problem is disfluent, people adopt a more deliberate processing strategy (Alter, Oppenheimer, Epley, & Eyre, 2007). In one experiment, participants were asked to read logical syllogisms and indicate whether they were true or false. Participants who read the syllogisms in a difficult to read (i.e. *disfluent*) font performed significantly better on the task than those who read the syllogisms in a clear, easy to read font. The authors replicated this result in three distinct cognitive domains. In this way, disfluency may be categorized as a desirable difficulty and can be used to improve student learning by encouraging them to select more accurate problem solving strategies.

Contemporary educational reform measures strive to create learning environments that encourage students to engage deeply with course content because of the numerous forms of evidence suggesting that deep processing increases learning. Most importantly, deeper processing facilitates later recall. For example, participants who are asked whether words appear in capital or lower case letters (low level of processing) do worse at later recall than participants who construct a rhyme for the words (moderate processing) or are asked to define the words (deep processing) (Craik & Tulving, 1975). Therefore, if disfluency facilitates deeper processing, then there is reason to expect that disfluent educational materials will lead to improved retention in the classroom.

The simplest and most standard fluency manipulation is a font manipulation. Information presented in an easy to read font is more fluent than *information presented in a difficult to read font*. The beauty of this manipulation is that it is so easy and cost effective to implement. To the extent that disfluency yields better learning outcomes, the intervention could be implemented on a wide scale with limited logistical or financial challenges.

The purpose of the present research is to empirically examine whether fluency can operate as a desirable difficulty to improve retention in classroom environments.

Study 1

First we aimed to show that disfluency led to better retention in a highly controlled laboratory environment. Twenty eight participants were recruited through the Princeton University paid subject pool and compensated \$8 for their time. Participants' ages ranged from 18-33. Participants were given 90 seconds to learn about three species of aliens. Each alien species had seven features, for a total of 21 features that needed to be learned (see Figure 1 or examples of the features to be learned). This task was meant to approximate taxonomic learning that might occur in a biology classroom; fictional alien species were used so that participants had no prior knowledge that might contaminate results.

In the disfluent condition, the stimuli were presented in either 12 point Comic Sans MS 75% greyscale (see Figure 1a) or 12 point *Bodoni MT* 75% grayscale font. In the fluent condition, the stimuli were presented in 16-point Arial 100% black font (See Figure 1b). A between-subjects design was used, such that each participant was only exposed to one font. As is evident from the examples below, while the disfluent text is obviously harder to read than the fluent text (when they are presented side by side) in a between subject design reader's in the disfluent condition were unlikely to even consciously notice the added difficulty the disfluent text engendered.

The pangerish

- *Ten feet tall*
- *Eats green, leafy vegetables*
- *Has blue eyes*

The norgletti

- Two feet tall
- Eats flower petals and pollen
- Has brown eyes

Figure 1: Example stimuli from Study 1. The top panel shows the disfluent font, and the bottom panel shows the fluent font.

After studying the material for 90 seconds, participants were distracted for 15 minutes with unrelated tasks. Participants' memory for the material was then tested. For each participant, seven of the features were randomly asked about. For example "how tall is the pangerish?" or "what color eyes does the norgletti have?"

One outlier was eliminated from consideration for being more than 3 standard deviations from the mean. Participants in the fluent condition were accurate 72.8% of the time. Meanwhile, participants in the disfluent condition successfully remembered the information 86.5% of the time. This difference was statistically significant ($t(26) = 2.3, p < .05$). There were no differences in retention between the different disfluent fonts (Comic Sans vs. Bodoni), suggesting that it was not the specific font that led to the difference, but rather the disfluency. In sum, after a 15-minute delay, participants in the recalled nearly 15% more information when the material was presented disfluently than fluently. Moreover, as learning time was constrained, this cannot be due to longer study times for the disfluent materials, which suggests that instead more effective learning strategies were adopted.

While this provides strong preliminary evidence that fluency could be a desirable difficulty in education, there are several reasons why we might be concerned about its generalizability to actual classroom environments. First, the materials we used, while tightly controlled, were not the sorts of materials that would be used in real classroom settings. Different types of materials might elicit different effects. Second, while the effects in Study 1 persisted for 15 minutes, the time between learning and testing is typically much longer in the real world.

Further, while paid laboratory participants may be willing to persist in the face of challenging fonts for 90 seconds, added difficulty may undermine motivation for actual students. Students may just give up, rather than deeply processing the material – particularly as the semester progresses and stress levels rise. Therefore, we ran a large

field study to determine whether these results would persist outside of the lab.

Study 2

222 high school students (ages 15-18) from a public school in Chesterland, Ohio participated in the study. This school accommodates approximately 930 students from grades 9-12 and reported a 98.6% graduation rate in 2008. The school's grades 9-12 are taught by 54 teachers.

Classes were selected for this research using the following criteria: the same teacher must have been teaching at least two classes of the same subject and difficulty level with the same supplementary learning material (PowerPoint presentations or handouts). Six classes met these criteria and agreed to participate. These classes were AP English, Honors English, Honors Physics, Regular Physics, Honors US History, and Honors Chemistry.

The different sections of each class were randomly assigned to either a disfluent or control category. Teachers were instructed to send all relevant supplementary learning materials to the experimenters prior to distributing them to students. At no point did the experimenters ever have face-to-face contact with the students or teachers; editing was done by proxy in Princeton, New Jersey. The fonts of the learning material in the disfluent category were either changed to **Haettenschweiler**, *Monotype Corsiva*, or *Comic Sans Italicized* or copied disfluently (by moving the paper up and down during copying) when electronic documents were unavailable. In the control category, no edits were made to the materials before returning them to teachers. The font size of the supplementary material was not changed unless the original size when converted to disfluent font made the font illegible, in which case the font size was increased until it was readable. One teacher refused to administer Haettenschweiler and so that class was changed to Comic Sans Italicized.

No other changes were made to the students' learning environments, materials, curricula, or to the teachers' classroom routine. To determine the effects of disfluency, the results of the normal assessment tests for the class were collected and analyzed.

The z-scores of the students' test performance were used as a common metric to compare students across different courses. As shown in table 1, average z-scores of the students were higher in the disfluent condition than in the control.

An independent samples t-test of the average z-scores revealed a significant improvement of the students' test scores in the disfluent condition ($t(220) = 3.38, p < .001$): students in the disfluent condition scored higher on their tests ($M = .164, SD = .103$) than those in the control ($M = -.295, SD = 1.05$). There were no reliable differences between the different disfluent fonts. That is, it was not the specific of the font that mattered, but rather the fact that it was disfluent.

	Control	Disfluent
AP English	-.058	.135
Honors English	-.175	.131
Physics Honors	-.251	.215
Physics Normal	-1.13	.42
History	-.177	.112
Chemistry	.023	-.017
Total	-.295	.164

Table 1: Average z-score for fluent and disfluent supplementary materials across the 5 usable classrooms. Note that the z-scores do not sum to 0 across conditions because of unequal sample sizes by condition.

The effects of different kinds of disfluent material were examined using a two-level ANOVA to compare the effects of disfluent worksheets and PowerPoint presentations. This test revealed that the PowerPoint presentations were significantly more effective than the documents in improving student performance when presented in a disfluent format ($F(1, 184) = 9.38, p < .01$). However it is difficult to read too deeply into this latter finding, as the only classes that used powerpoint materials were the physics classes. As such, we cannot know if the difference was due to the type of material that was being studied, or the manner in which it was presented. Nonetheless, the difference highlights possible future avenues of exploration.

Discussion

In two studies we showed that making the text disfluent by using a hard to read font improved learning. In Study 1, participants recalled 14% more material when the material was initially presented in a disfluent font. In Study 2, students performed better on exams in actual classrooms the fonts of the supplementary materials were harder to read. This occurred for both science and non-science courses, and for different difficulty levels (AP, honors, and regular). This provides strong preliminary evidence that disfluency can indeed function as a desirable difficulty in educational settings.

There are, however, some important caveats that need to be considered in relation to these findings. First, while a small amount of disfluency was able to improve performance, at some level disfluency will necessarily impair functioning. After all, if the font is impossible to read, then the information cannot be encoded, let alone retained. It is unclear from these studies what the optimal level of disfluency is, nor the relative detriment that being overly disfluent might engender.

Secondly, there is the issue of adaptation. One reason that disfluent text might lead to better retention is that it serves as an alarm signal that this material is challenging and merits extra consideration (c.f. Alter et al., 2007). To the extent that students become used to disfluency, they might

no longer adopt deeper processing strategies when exposed to hard to read font. Study 2 was limited to a single semester's worth of materials for logistical reasons. It is unclear whether these effects would persist over longer periods of time.

Third, a large literature has demonstrated that disfluent materials are liked less than fluent materials (for a review see Alter and Oppenheimer, 2009). It may be that while students retained the information better under disfluency, they also liked the material less. This could mean that they are less likely to pursue further studies in the topic (e.g. in college) or are otherwise demotivated in subsequent educational situations. Of course, it is also possible that the increased effort necessary to engage with this material will create cognitive dissonance, which will cause them to like the material more (c.f. Cooper, 2007). This is an empirical question, that will require additional research to resolve.

Fourth, it is quite possible that there are moderators for this effect that these initial studies did not detect. Other forms of desirable difficulties have been shown to be moderated by factors such as the nature of the materials (McDaniel et al., 2000) the nature of the testing (Thomas & McDaniel, 2007), and the abilities of the learner (Macnamara et al., 1996). One could imagine that less motivated students from a less successful school might be more inclined to give up on the material rather than persist and encode it more deeply. Future investigation should look into these issues.

Despite these potential drawbacks, disfluency is a promising form of desirable difficulty because it requires no retraining of teachers, no restructuring of curricula, and can be implemented with minimal cost. Given the results of the present studies, it seems worthwhile to investigate disfluency as an educational intervention further.

Abstract

We argue that the concept of relational priming (e.g. Schunn 1996, Day 2007) can be extended from priming of specific relations to generating a cognitive state during which subjects are particularly likely to encode and use relations. We conducted an experiment in which three groups of subjects did different tasks before a target matching to sample task was introduced which contrasted a relationally versus an attributionally similar alternative. Subjects in one condition were asked to solve tasks involving relational reasoning while subjects in another condition were asked to tasks involving only attributes. As expected subjects in the first condition were more likely to pick up the relationally similar alternative while in the second condition the results reversed relative to a control group. In conclusion we argue that this study shows that encoding of relations can be a subject to unconscious context influence.

Keywords: relational priming; context dependence; encoding of relations, cognitive state

Introduction

Since Gentner's Structure Mapping theory (Gentner 1983) a great deal of research has been concentrated upon analogical reasoning in terms of mapping of higher-order relations. Although the mechanisms employed by the mapping process have been extensively studied little is currently known about the nature of the processes involved in relational encoding. This study attempts to scratch the surface of this complex matter by asking the question of whether the process of relational encoding is subject to certain external and internal context influences. While the answer to this question certainly would not reveal the nature of the encoding process it would hopefully tell us something about certain specific aspects of its functioning.

Currently there is some agreement that the phenomenon of relational priming exhibits a somehow automatic (i.e. not subjected to voluntary control, external influence and conscious experience) nature (e.g. Kokinov 1996, Schunn 1996, Day 2007, Hristova 2009)¹. The abovementioned studies employ different methodologies ranging from naturalistic-like settings (Schunn 1996) to Stroop-like interference Reaction Time paradigms (Hristova 2009).

¹ But see Spellman et al. (2001) whose results indicate that relational priming took place only when participants were explicitly instructed to pay attention to the relations existing between the stimuli (words) involved in the studies.

There is however a common thread among these research projects – the use of specific relations. In other words all these (and other) studies concentrated on exploring the relational priming by using concretely represented, nameable relations. The same naturally holds true for relational priming in psycholinguistic research (e.g. Gagne 2005, Estes 2006).

Instead of continuing this well established line of research we concentrated on the question of whether a global cognitive state can be induced in which people are more likely to encode relations in general. It can be said that we are still concerned with relational priming but we employ a rather broad, holistic and abstract definition of the phenomenon.

We hypothesized that subjects confronted with tasks explicitly involving relational reasoning will subsequently be more likely to continue this style of reasoning when dealing with completely different tasks. We also hypothesized that subjects forced to encode and use attributes of objects will be considerably less likely to encode (and use) relations in subsequent tasks. In other words we argue that not only specific relations can be primed with similar other relations but also a "relational mode of thinking" can be induced by use of specific task requirements. Thus we claim that relational priming (and consequently "attributional priming") is a much more complicated and abstract phenomenon than currently conceived by traditional research in the area.

Another hypothesis related to the current study concerns the subjects' ability to cope with the particular priming task. Since we argue that task requirements can possibly induce a particular cognitive state it follows that the degree to which this actually happens should depend upon a subject's particular ability to successfully cope with the task at hand (the priming task).

Experiment

In the current experiment we tested three different groups of subjects in order to see whether prior tasks influence significantly relational and attributional reasoning during a target task. In the first condition subjects solved six different mental rotation tasks, in the second condition subjects solved six items from Raven Progressive Matrices test (e.g. Raven 2003) and in a third condition no task preceded the target task. The three groups are called attributional, relational and control conditions respectively.

The target task was a single matching to sample task borrowed from Medin et al. (1990). During this task subjects were required to choose the more similar from two alternative figures to a target figure. One of the alternatives embodied a unique common relation with the target (we called this one the relational alternative) while the other shared a unique attribution with the target (we called it the attributional alternative).

We hypothesized that subjects in the relational condition would be more likely to pick up the relational alternative in the target task (compared to the control group where no priming task was present) because the Raven Progressive Matrices test requires subjects to encode and map complex higher-order relations. On the other hand since the mental rotation task involved dealing with attributes and first order relations between parts of objects we expected that subjects from the attributional condition would be more likely to choose the attributional answer to the matching to sample task (again compared to the non primed control condition). As mentioned above we also hypothesized that there would be a correlation between subjects' levels of performance on the prior tasks and the degree of subsequent relational priming. Moreover since subjects in the attributional task were expected to be less likely to give relational answers to the target task we expected a negative correlation between levels of performance during the priming task and the proportion of relational answers to the target task in the attributional condition. By the same logic we expected a positive relationship to exist in the relational condition.

Design. A simple between group design was employed which involved three independent groups of subjects allocated to the attributional, the relational and the control conditions. The three levels of our independent variable were defined by the task the subjects in the respective condition had to solve before the target matching to sample task. The dependent measure was defined as whether a given subject gave a relational or attributional answer to the target task. The target task was the same for all participants.

Stimuli. The stimuli for the attributional condition consisted of six mental rotation tasks. Each task involved sixteen versions of a particular letter from the Latin alphabet. Thus there were six letters in that condition and each letter appeared sixteen times. Each version of a letter was presented in a rotated position. For eight of the versions it was possible to obtain the original letter via mental rotation (these represented the so called true versions of a particular task since the subjects' task was to indicate whether the particular version could or could not be rotated in order to arrive at the original letter) and for the other eight versions it was impossible to do so for these versions were rotated mirror images of the original letter (these were called the false versions). Each letter (both the true and the false versions) was rotated at eight different angles. The degrees of rotation were 40, 80, 120, 160, 200, 240, 280 and 320 degrees. The six letters used for each of the six tasks were

Z, R, F, N, P, S. Each individual task was represented as the sixteen versions of a particular letter arranged in a 4x4 matrix printed on an A4 portrait sheet of paper. The order of the true and false versions as well as the order of the eight different angles of rotations was randomized across the six tasks. The order of the six tasks was randomized across participants. Since subjects were required to make a judgment for each letter version in each task (i.e. subjects were asked to indicate whether a particular version was a rotated original letter or a rotated mirror image of the original letter) there were $6 \times 16 = 96$ judgments made by each participant in the attributional condition. A sample of three letters is presented at figure 1. The top three letters represent instances of the false alternatives and the bottom three letters represent instances of the true alternatives.

Figure 1. Examples of the mental rotation task.

Subjects from the relational condition were presented with six of the Raven Progressive Matrices items. These items were the odd numbered items from series E (the last series) from the test. Thus subjects had to solve items E1, E3, E5, E7, E9 and E11. The items were presented in this ascending order for all participants in this condition. Subjects in this condition were asked to fill the blank in each item with one of the options available at the bottom of the page. The original instruction from the test was given to each participant. The original test panes were used.

The target matching to sample task presented to the participants at the end of the experiment was borrowed from Medin et al. (1990). It is depicted in figure 2. The target is at the top of the figure and is denoted with T. The two alternatives are denoted with B1 and B2 respectively. The subjects' task was to indicate which one of the two options was more similar to the target. As already mentioned the B1 option shared a unique attribute with T (a checked circle) while the B2 option shared a unique relation with T (same shading of the objects).

Procedure. In both the attributional and the relational conditions subjects were given a maximum amount of time of one minute for each individual task (one item from the Raven test or one mental rotation task consisting of sixteen individual versions of a letter). In the attributional condition subjects were instructed to make as many accurate judgments as possible for each task for one minute. In the relational condition subjects were instructed to try to solve each item correctly for one minute. Prior to the experiment subjects from the attributional condition were given a practice trial consisting of sixteen versions of the letter L.

Figure 2. Example of the matching to sample task.

The subjects from the relational condition were given the original instruction from the Raven test as well as items C9, D3 and D8 as complementary practice trials. In each condition after the instruction the experimenter encouraged the participants to try to solve the practice task all by themselves and explained their errors as well as the correct solutions when needed after the one minute maximum time interval. After the experimenter was convinced that subjects understood the procedure the real study began.

The experimenter used a stop watch in order to keep track on time for each task.

In both the relational and the attributional conditions participants indicated their responses verbally and the experimenter wrote down their answers on a scoring sheet. In the attributional condition subjects were instructed to indicate whether a version of a letter could be rotated to its original position by moving from the top row down and moving from left to right within a particular row of a given matrix of sixteen versions of a letter. In case a participant failed to answer to all versions of a mental rotation task within a minute the sheet containing the matrix was removed out of her sight but the participant was asked to try to guess the correct answers for the remaining versions of the letter. Similarly in the relational condition if a person didn't answer to a Raven item within one minute the pane was taken out of her sight but the participant was asked to try to guess the correct answer anyway.

A thirty seconds interval separated the six priming trials from each other in each experimental condition.

Immediately after the end of the initial stage the target stimulus was presented in an ostensibly unrelated task and the subject was asked to indicate whether B1 or B2 option was "more similar" to the T figure (see figure 2). No time limit was present during the final task.

The subjects from the control condition proceeded immediately to this final stage of the experiment, i.e. they were not involved in any prior task.

After the participants indicated their answers they were asked whether they spotted the relational similarity between the target and the B2 option. After their answer was written down by the experimenter the subjects were debriefed and the experiment finished.

Note that the two priming task are both quite different from the target task. Thus it seems rather unlikely that some specific features of the priming tasks may have influenced subjects' judgments during the final matching to sample task.

Subjects. 110 students from New Bulgarian University participated in the study for partial course credit. Thirty five participated in the attributional condition, thirty five participated in the relational condition and forty participated in the control condition. Overall there were 62% females and 38% males in the study which were allocated proportionally to all three conditions.

Results and Discussion. Table 1 below shows the raw number of subjects within each condition which gave the attributional and the relational answers to the target task. Numbers in parentheses represent the respective percentages.

table 1.

	#Attrib. Answers	# Rel. Answers	Total
Attrib. Cond.	29 (83%)	6 (17%)	35 (100%)
Rel. Cond.	11 (31%)	24 (69%)	35 (100%)
Contr. Cond.	24 (60%)	16 (40%)	40 (100%)

The results are summarized in figure 3 below. The bars represent the proportion of people giving the relational answer in each condition.

figure 3

As can be seen the data are in line with our hypotheses: subjects from the relational condition were more likely to pick up the relational answer during the matching to sample task compared to subjects in the control condition. Also the subjects from the attributional condition picked up the attributional answer more frequently compared to the baseline control condition. In order to assess the significance of our results we conducted a series of statistical analyses. First we fitted a logistic regression model to the data with our three experimental conditions treated as a single

categorical predictor and subject's answer as a categorical dependent variable (a relational answer was coded as 1 while an attributional answer was coded as 0 for each participant). The model including our independent variable significantly outperformed the null model (including only the intercept): Chi Square of Likelihood Ratio Change (2) = 20.049, $p < 0.001$. Thus we see that there is a highly significant effect of our independent variable. Since we defined our control condition as the reference condition for the analysis the b coefficients of the model represent the difference between the other two conditions to the control condition. These were $b = -1.17$ (1), $p = 0.034$ for the attributional condition and $b = 1.19$ (1), $p = 0.015$ for the relational condition. Thus we see that the relational task significantly increases the probability of relational answer while the attributional task decreases it relative to the control condition.

The pseudo R^2 estimate (Nagelkerke) for the effect of the independent variable was equal to 0.224 – a reasonably high estimate.

Since both conditions were significantly different from the control condition and since their coefficients were with opposite signs it logically follows that the two experimental conditions were significantly different from each other.

In order to further support our results we conducted a series of chi squared analyses. First we assessed the significance of our independent variable as a whole. As with the regression analysis the results were highly significant – chi square (2) = 19.109, $p < 0.001$. We proceeded with three post hoc comparisons which compared the proportions of relational answers between all three groups. The results showed that the relational and the attributional conditions were significantly different from each other – chi square (1) = 18.9, $p < 0.001$. Both the conditions were also significantly different from the control condition – chi square (1) = 4.705, $p = 0.03$ for the difference between the control and the attributional conditions and chi square (1) = 6.122, $p = 0.013$ for the difference between the control and the relational conditions. Thus we see that all our conditions exhibited different proportions of relational answers². Looking back at figure 3 we see that subjects from the relational condition were most likely to give a relational

answer to the target task while those from the attributional condition were least likely to do so. The control condition was somewhere in between the other two.

These results strongly support our main hypothesis about the possibility to induce a cognitive state which enhances subjects' ability to encode relations. However there still exists the possibility of people encoding the relation embodied in the target task with approximately equal frequency but for some reason being more prone to choose it in the relational condition. When asked about whether they had spotted the "same shading" relation, however, only two participants from the control condition claimed they had and only one participant from the relational condition did so (these numbers refer only to subjects who gave the attributional answer to the target task, of course; all subjects who responded relationally reported spotting the unique relation). Thus such an alternative explanation seems highly unlikely. Overall the results support our hypothesis of relational priming being an abstract and profound phenomenon with deep impact on cognitive functioning.

Previously we stated our additional hypothesis that subjects' ability to cope with the priming tasks at question should correlate with the degree to relational priming they exhibit. Moreover we hypothesized that there should be a positive correlation between the number of correctly solved trials in the relational condition and the proportion of relational answers to the target task and a negative correlation between the number of correctly solved trials in the attributional condition and the proportion of relational answers to the target task. In both conditions we expressed the number of correctly solved trials as percentages from the overall number of trials. The overall number of trials was six in the relational condition and ninety six for the attributional condition. We calculated the point biserial correlations between these measures and the dependent variables separately for each experimental condition. The results indicated a significant positive relationship in the relational condition – $r_{pbis} = 0.36$, $p = 0.018$ (one tailed). There was also a significant negative relationship in the attributional condition – $r_{pbis} = -0.31$, $p = 0.037$. Thus it seems that our hypothesis is supported from the data³. These results seem reasonable since we can not expect subjects to be primed by task requirements if they are unable to fulfill the particular task.

Conclusion

In this study we successfully demonstrated that relational priming extends beyond the use of particular relations. It

² Technically speaking we should decrease our significance levels when performing these kinds of multiple comparisons in order to keep the type 1 error probability equal to 0.05 for all comparisons simultaneously. This was achieved by adopting a 0.033(3) level of significance for each comparison (we assumed a directed alternative hypotheses because we had strong prior expectations about the results from the study). We see that all our comparisons fall below this level of significance. Here we reported the probabilities from two-tailed tests which should be divided by a factor of two in order to obtain the one-tailed probabilities which fall way below the adopted significance level (although the chi square tests are regarded as inherently two-tailed a test of equality of proportions can be performed which has a one-tailed version; for the case of 2x2 tables the equality of proportions and the chi square tests are mathematically equivalent). Thus we can be confident that all three groups differ significantly from each other.

³ We tested this hypothesis further by conducting logistic regression analyses with the percentage of correct responses as independent covariate and the response to the target task as a dependent variable. In the case of the relational condition the full model significantly outperformed the null model - Chi Square of Likelihood Ratio Change (1) = 4.63, $p = 0.031$. In the case of the attributional condition the results were marginally significant - Chi Square of Likelihood Ratio Change (1) = 3.833, $p = 0.05$. These results however test a two tailed hypothesis.

seems fertile to talk of cognitive states which enhance subjects' ability to encode relations. Moreover it appears that such cognitive states may be induced through external context factors. We consider our results relevant to the area of analogical mapping research since encoding of relations is obviously a prerequisite for subsequent mapping and transfer.

We also demonstrated that individual differences in terms of subjects' ability to cope with a particular task is a relevant variable for it significantly mediates the task's ability to induce the desired cognitive state for a particular subject.

We would like to stress that items from the Raven's test didn't embody the "same shading" relation of the target task and thus could not have possibly primed the relational answer directly. Also the tasks from the mental rotation condition did not involve any different or specific textures and consequently could not have primed the uniquely shared attribute of the attributional option of the matching to sample task.

Also few of the subjects who chose the attributional answer claimed to have spotted the uniquely shared relation so our results are likely to have arisen from influencing relational encoding rather than from manipulating subjects' relation vs. attribute preference.

Prior to the experiment we felt that using many matching to sample tasks (which would have enabled us to use parametric statistical analyses on one hand and would have granted our results with additional validity on the other) was not as warranted as it may appear at first. The reasons for this are straightforward – we suspected that once a particular subject have spotted the unique shared relation in one item they would search and easily find these relations on subsequent items. Thus we were afraid that no matter how many items we used our dependent measure would basically degenerate to a dichotomy. In such a case using parametric statistical analyses would be faulty and misleading. Another reason for avoiding the use of several different matching to sample tasks was that we speculated that our priming effect may exhibit a limited time duration and thus only the first few items would experience the effect. In case of counterbalancing the order of items across participants this effect might easily be obscured if we decided to run some comparisons at the items level.

Trying to replicate our results with different target item(s) and different priming tasks is a part of our future research agenda. Another part is exploring the duration of the priming effect.

Acknowledgements

This research was financially supported by the ANALOGY project (NEST program, contract 29088) funded by the EC.

We are grateful to Douglas Medin, Robert Goldstone and Dedre Gentner for publishing and making available online the stimulus material part of which we used in our study.

We would also like to thank Veselina Feldman and Kalina Bojadjieva whose usage of the Raven Progressive Matrices test as filler in another experiment dealing with analogical reasoning inspired a discussion which led to the current study.

Executive Control in Analogical Mapping: Two Facets

Anna Chuderska (ania.chuderska@gmail.com)

Institute of Psychology, Jagiellonian University
al. Mickiewicza 3, 31-120 Krakow, Poland

Abstract

In recent studies, analogy-making has been shown to depend on the ability to resist interference within working memory (WM). Less evidence refers to the other facets of executive control (EC), especially to the goal-directed selection of relational information. In this study, the load on two above mentioned EC functions and on WM capacity was manipulated in a single picture mapping task. Next to replicating the previous findings on the importance of dealing with distracter interference within WM, the current results demonstrate that the efficiency of relational mapping also depends on the goal-directed search for WM input, and that these two EC functions may be dissociable in mapping. Moreover, it was found that the impact of distraction can be linked to whether relations, in which distracters occur, have not exceeded WM capacity.

Introduction

Analogical reasoning is a flagship example of the human ability to flexibly form and manipulate explicit representations of structure (Hummel & Holyoak, 2003). Making an analogy requires identifying systematic relational correspondences between two analogs (e.g., situations), irrespective of superficial similarities (if they conflict with relational ones) or differences (especially, if they are huge) between them (e.g., Gentner, 1983). This structure-mapping process allows one to infer new goal-relevant information about one analog (*target*) from the second analog (*source*). Thus, analogy is an important tool for dealing with novelty and one of the major vehicles of human intelligence (e.g., Holyoak, 2005).

The inherent computational challenges of processing relational representations (Doumas & Hummel, 2005), and the fact that variance in the efficiency of analogical reasoning is only partially explicable by knowledge accretion (e.g., Doumas, Morrison & Richland, 2009), has made many researchers and theorists postulate that the emergence of analogy is underlain by the efficiency of some constitutional cognitive capacities (or parameters). Of these, working memory (WM) was considered to be the most important (see Morrison, 2005 for review). Yet, explaining analogy-making by WM constraints seems to be quite intricate.

More than WM Capacity

WM is a capacity-limited system responsible for active maintenance, rapid access and easy updating of goal-relevant information (Cowan, 2005). If WM is overloaded by a parallel task (Waltz, Lau, Grewal & Holyoak, 2000), impaired by brain damage (Waltz et al., 1999), or if the number of variables interacting in relational representation grows (Halford, Baker, McCredden, & Bain, 2005), relational reasoning becomes less efficient. According to relational complexity theory, the load of relational representation on WM increases exponentially with the number of interacting variables that must be concurrently manipu-

lated (i.e., relationally integrated). Human WM is probably typically limited to the parallel processing of up to one quaternary relation, that is a relational representation with four variables (Halford, Wilson & Phillips, 1998).

However, when reflecting on the limited nature of WM capacity, it is important to understand internal cognitive constraints on the proper selection of WM input, by means of which humans single-handedly, but with various degrees of success (e.g., Chuderska & Chuderski, 2009), abstract structural similarity between analogs from other structural and (sometimes very compelling) semantic information. It seems plausible that relational integration might be influenced by the efficiency of earlier goal-driven attentional selection (see Awh, Vogel & Oh, 2006 for a discussion of attention as the “gatekeeper” for WM), or by the efficiency of managing subsequent reasoning steps (e.g., Carpenter, Just & Shell, 1990), which are necessarily isolated out for reduction of complexity (Halford et al., 1998).

On the other hand, the content of variables integrated in WM may perceptually or semantically conflict with the structural information they convey (e.g., Markman and Gentner, 1993). Since processing many distracters leads to no success, the need to deal with distraction within WM, while analogizing, seems indispensable (e.g., Viskontas, Morisson, Holyoak, Hummel, & Knowlton, 2004).

The potential causes for processing irrelevant information by WM, or doing it inefficiently, are delineated in LISA – an artificial neural network model of relational reasoning (Hummel & Holyoak, 2003). LISA dynamically binds roles (i.e., variables) and fillers (i.e., their content) into relations by the synchrony of firing their distributed semantic (featural) and localist (structural) representations. The model contains an intrinsic capacity limit, since only a confined number of such role-filler bindings can oscillate cleanly asynchronously in one processing cycle. The weaker the inhibitory competition between active units, the less role-filler bindings are cleanly discriminated. The strength of inhibitory competition between propositions in problem representation also determines which of them will enter WM and in what order; this is critical for mapping performance (Kubose, Holyoak & Hummel, 2002). The weaker the inhibition, the less reliance LISA has on the importance assigned to propositions, and the less accurate will be its eventual mapping.

Thus, an important source of cognitive constraints in relational reasoning might come from the effectiveness of executive control. Executive control (EC) can be defined as a set of cognitive processes that, instead of representing mental states directly, influence and organize such states in the context of some internal goal. Recent theories assume that EC is an emergent process arising from the dynamic interaction of several independent, elementary control mechanisms (Braver, Gray, & Burgess, 2007; Engle & Kane, 2004). There is some evidence that these functions significantly correlate with abstract reasoning (see Chuderski & Nęcka, 2010, for a review).

Executive Control in Analogical Reasoning

The fact that the maintenance and proper application of a reasoning goal is critical for analogical reasoning might be inferred from findings which show that the frequency of recognizing relational similarity is higher when multiple, instead of single, objects are to be mapped across analogs (Markman and Gentner, 1993; Waltz et al., 2000). Such a manipulation might make the goal of relational processing more salient to participants and aid (or substitute) selection of what should enter WM for structural alignment. It could also be hypothesized that the overriding initial mappings, if they turn out to be incorrect (Keane, 1997), might call not only for inhibition, as proposed in LISA, but also for some goal management mechanisms. More directly, it was shown that mapping performance correlates with most of the proposed executive functions, with three of them (WM updating, switching, and dual-tasking) being accounted for through the monitoring and application of goal and through response inhibition (Chuderska & Chuderski, 2009).

Another function of control within analogical reasoning relates to resolving conflicts and coping with (distracter) interference. For example, Gray, Chabris, and Braver (2003) observed that brain activity in neural structures, recruited by a high-interference condition of a WM updating task, correlated with relational reasoning performance. Some evidence for links between abstract reasoning tests and response inhibition and interference resolution was reviewed by Dempster and Corkill (1999). If superficially similar objects are placed in different relational roles (i.e., are cross-mapped) in structures that are to be mapped, effective interference resolution seems necessary to overcome the observed relational mapping impediment, (e.g., Markman & Gentner, 1993). Cho, Holyoak, and Cannon (2007) manipulated the level of internal complexity and interference of a simple analogical mapping task, demonstrating that young participants' reaction times overadditively increased with relational complexity and interference. Similar decreases in performance by manipulating these two factors were observed in older adults (Viskontas et al., 2004). Richland, Morrison and Holyoak (2006) found that as children get older they are more efficient in dealing with both relational complexity and distraction, which was computationally accounted for by inhibitory competition in LISA (Morrison, Dumas and Richland, 2006).

It seems that goal-driven selection of relevant information for relational processing, as well as the inhibition of irrelevant information, constitute two sides of a "control coin" in analogical reasoning. No study to date has addressed both sides of the coin within a single task. For example, in the studies by Viscontas et al. (2004) and Cho et al. (2007) subjects were provided with all the relevant dimensions and were required to integrate them in WM while ignoring unequivocally irrelevant dimensions. In studies where similar relations were to be induced by the subjects themselves (e.g. Markman and Gentner, 1993; Waltz et al., 2000; Richland et al. 2006), no manipulation of the need for selectiveness occurred.

The goal of the presented study is to extend the empirical data on the role of EC in managing WM content in analogical reasoning with semantically meaningful material, which lacks the predetermination of a relevant relational structure. This will be done by attempting to

manipulate experimentally the processing requirements for the above two mentioned aspects of EC. The load of WM capacity will also be varied. Unlike in any previous study known to the author, the needs for attentional selection, interference resolution and relational integration will all be varied in a single analogical mapping task. This procedure should allow one to explore, whether the two postulated EC faculties have dissociable or interacting effects on WM performance in analogical mapping.

The Study

The picture-mapping paradigm was used, as introduced by Markman and Gentner (1993) together with a cross-mapping procedure, advanced by Richland et al. (2006) *inter alia* by relational complexity manipulation, and applied in numerous other studies of analogical mapping (e.g., Tohill and Holyoak, 2000; Waltz et al., 2000). The task consists in analyzing the two scenes, presented to participants at once, and then deciding which object from the target scene best goes with the indicated object from the source scene. The subjects are instructed to search for a common "pattern" in the two pictures. The scenes usually depict simple causal relations, such as "towing" (see example in Fig. 1 from the current study).

The relational complexity (RC) was operationalized as the number of relational arguments (i.e., objects forming a relevant relational structure) to be processed in parallel for successful mapping. Thus, it was slightly different from the study of Richland et al. (2006), where RC was manipulated by necessarily repeating the same relation in a scene. There were either binary (involving two objects) or quaternary (four objects) relations to be mapped.

Unlike in any previous study, the total number of objects in the scene, and therefore the saliency of relevant relations, was factorially varied. It was thought of as an operationalization of the need for a goal-directed selection of structure mapping input. The relevant relations were "hidden" among five or ten objects in total. All other relations than those that were relevant ones, which could be possibly identified among the objects in a scene, were unique to only one scene. Assuming that more overt relational similarity in relatively semantically impoverished analogs constitutes a cue for engaging in relational mapping (i.e., it reminds task's goal), respective enriching the scenes (independently of relational complexity) seems to be a clear-cut way to make this cue less direct and thus more dependent on internal activation. Moreover, having to search for a relevant structure through the number of propositions, clearly exceeding WM capacity, seems to be more dependent on the quality of goal monitoring over the necessarily sequenced reasoning steps.

Since Cho et al. (2007) demonstrated that distracting information is detrimental only if attended to and actively maintained in WM, the manipulation of the need for interference was constrained to the cross-mapping procedure. That is, the presence of semantically (and to some, but never to the full, extent also featurally) similar object in different relational roles was varied always within relevant relations - like in the studies by Markman and Gentner (1993), but unlike in those by Richland et al. (2006). This objective was to ensure that the subjects' attention was not diverted from the relevant relational structure by a distracter external to it, but rather to increase the probability that distraction will affect the attempted structure mapping.

Figure 1. The example of one set of pictures of the analogical mapping task. The towed passenger car (with the *boat-wagon* object as a counterpart), and the towing lorry (pairs N° 1-4) or the loading lorry (N° 5-8) were highlighted for mapping. Odd numbers label pairs with a distracter (the towing passenger car in *bs*). Pairs in third and fourth rows contain quaternary relations (towing and loading are to be integrated). First and third row present high-saliency pairs.

It was expected that all three above manipulations will decrease the subjects' ability for relational mapping, but that their impact would be differential due to tapping into qualitatively distinct, although highly intertwined, cognitive capabilities. Viskontas et al. (2004) and Cho et al. (2007), from their results obtained in a similar, relatively simple mapping task, argued that the overadditive effects of RC and distraction suggest that relational integration and inhibition depend on the common pool of WM resources. However, some researchers suggest there is no reason for EC to operate more or less strongly in different WM load conditions (e.g., Embretson, 1995; Unsworth and Engle, 2005). Also, in the scene-mapping study on children by Richland et al. (2006) RC x distraction interaction occurred only in a group of 3-4 year olds. Thus, it seemed worth re-examining the RC - distraction relationship in a picture mapping task of more realistic complexity and administered to adults. As to the manipulation of relevant relations' (goal's) saliency, it was hypothesized

that it will result in relational mapping decrements due to the worse discriminability of relevant relations.

However, no interaction between RC and saliency was expected. Although it appears that the whole scene has to be initially placed in WM to screen out irrelevant information, the impact of the difficulty of this selection process should not be different when more or less complex relations have to be integrated in WM for structure mapping. This is because the selection of input can be done incrementally, while RC taps into the exact WM capacity limits (Halford et al., 1998). Yet, RC and need for more rigid selection should additively affect the overall mapping performance.

Also, no interaction between saliency and distraction was expected due to the assumption that they reflect two different facets of EC, which are functionally distinct although highly related faculties (Braver et al., 2003). Thus, both EC manipulations in this study were expected to have additive influence on mapping performance.

The experiment reported here was a part of a bigger study to be reported elsewhere. Each participant solved the task reported here as their first in the whole session.

Method

Participants The participants were 122 inhabitants of Częstochowa, Poland (age = 16-44 years, $M = 22.15$, $S.D. = 3.77$, 62 females) recruited by flyers, newspaper and Internet ads. Each participant was paid 50 PLN (~10 EUR) and received a CD gift for their participation.

Materials and design. The scene mapping test contained a set of fifty-six picture pairs depicting every-day instances of common relations (e.g., destroying, giving) among conventional objects (e.g. a ceiling, money). All test items were similarly colorful and detailed, and were chosen from one hundred and three pilot items according to the items' reliability. No relation or object was repeated across the test. The quaternary (or equivalent) relations were created from the binary ones by extending the critical structure by two more objects necessary to be included in successful mapping. For instance, the relation of towing one object by another was extended by the third object, which remained behind for some reason, being loaded for transport by a fourth object (Fig. 1. 5-8). The example of distraction manipulation might be the changing role of a passenger car in a towing relation (Fig. 1., odd numbers). The spatial location of the corresponding objects was carefully varied within and across the pairs so as not to cue mapping. The pictures contained either five (Fig. 1., 1,2,5 & 6) or ten (Fig. 1., 3, 4, 7 & 8) objects in total. $2 \times 2 \times 2$ repeated-measures design, with three factors: relational complexity (bi- vs. quaternary relations), relational saliency (five vs. ten objects within a scene), and distraction (absent vs. present), resulted in eight fully balanced experimental conditions. In order to control for the difficulty of specific scenes, like in the Richland et al. (2006) study, counterbalanced versions of each scene were created to match each experimental condition. The assignment of an item's versions to a test's version, as well as of test's versions to participants, was randomized. Each participant solved 56 different scene pairs, seven per condition, and the other twelve items in the training set representative for all conditions. The items' presentation order was fully randomized.

Procedure The task was administered on laptop computers (1280 × 800 pix. display resolution) in a group of four to five participants accompanied by the experimenter. The pairs of pictures were presented horizontally, each 5×5 inches large, with the source picture always on the left. The administration software allowed for visual separation of objects to be taken into account by the participants. This was done by covering the rest of the picture, apart from a particular object, with a semi-transparent filter, when a mouse cursor was over this object. Objects sometimes were elements of bigger objects. For example, a hand was separated from "the rest" of a person in a relation where soiling a hand, was critical; or it allowed to impose consideration of a pair of people as one entity, where the relation between pairs of people was a part of the to-be-mapped structure. Two objects were to be mapped for each pair of scenes.

Each participant received the same oral, detailed self-paced written and movie instructions. Each of the

subsequent training items were followed by precise feedback. The instruction was to carefully explore pairs of pictures in order to first analyze what links exist between objects within each scene, and then to search for repeated pattern of these links across two scenes. The concept of the same relational role was carefully explained to participants and they learned that they will be required to indicate objects in the same roles in the other picture. They also learned that there might be two or four objects involved in a pattern, so that they should always search for the most complex pattern. Participants were instructed to first detect objects that need to be taken into account and then to verify if they recognized them correctly. A one-word name of an object appeared in the panel right under the picture when the cursor was over this object. The time for exploration was limited to 100 s, which had been validated as sufficient in pilot study. However, participants were encouraged to press a space bar as soon as they knew what the common pattern and object correspondences were. Once the time limit was reached or the space bar pressed, the first object in the source scene was highlighted and this picture became "frozen" for further exploration. The participants were to quickly click on this object with their mouse in the target scene, if they believed it played the same role as the highlighted one. As soon as they clicked in their chosen target object, a second object in the source scene was highlighted and its best counterpart in the target scene was also to be mouse-clicked. The choice of the first object excluded it from options for the second choice. There was a five second limit for a particular object's choice. Which relational role (i.e., agent or patient) was to be first placed in correspondence was randomized; in the distraction condition, however, the distracting object was always highlighted first. One object was highlighted across all versions/conditions, but the other object varied between RC-conditions of a scene, in the way that in quaternary relations the second highlighted object was always from the "extended" part of the structure. The participants took one refreshment break (max. seven minutes) after completing 28 test items. Together with instruction and training, the task took up to two hours, depending on participant speed and the duration of the break.

The dependent variable was correct choice for both objects counted on an all-or-none basis.

Results

All analyses were done with Statistica 8.0 software. Nondirectional null hypothesis significance tests (with α value adopted at .05) and their p values are reported.

Mean correct responses for all conditions are depicted in Table 1. Paired t -tests showed that performance in all conditions was above chance level, conservatively defined as .2. In the *high RC/low saliency/distraction* condition, the value of this statistic was: $t(121) = 4.83$, $p < .001$.

Table 1. Mean correct responses in all exp. conditions

Saliency	Distraction	Relational Complexity	
		Binary	Quaternary
High (5 objects)	No	.62	.50
	Yes	.40	.36
Low (10 objects)	No	.58	.40
	Yes	.32	.28

Each factor yielded a main effect, thus validating the experimental manipulation. A 2 (RC) \times 2 (saliency) \times 2 (distraction) MANOVA revealed that accuracy of relational mapping decreased: as RC increased ($F [1, 121] = 88.14, p < .001, \eta^2 = .42$), as saliency decreased ($F [1, 121] = 50.89, p < .001, \eta^2 = .30$), and when distraction occurred ($F [1, 121] = 292.98; p < .001, \eta^2 = .71$). The only reliable interaction was two-way RC \times distraction interaction, $F (1, 121) = 28.872, p < .001, \eta^2 = .19$. Post hoc tests (Tukey's HSD) indicated that differences between all means of this interaction were reliable, $p < .01$. As illustrated in Figure 2., the mapping accuracy dropped when distraction occurred, but the detrimental effect of cross-mapped foil was smaller in the high relational complexity condition.

Figure 2. Interaction between Relational Complexity and Distraction. Error bars indicate standard error of the mean.

Discussion

Using a modification of Richland et al. (2006) scene mapping task the role of EC and WM as constraints on structure mapping was examined in adults. Unlike in any previous study the requirements for goal maintenance and application, for dealing with distraction and for relational integration were factorially varied in a single task.

First of all, the results replicate the previous findings in children that with increasing number of variables to be integrated and with similar objects appearing in different relational roles the level of mapping performance drops (Richland et al., 2006). Importantly, however, the presented study extends this evidence by showing that decreasing the saliency of relevant relational structure in a task also reliably impedes structure mapping. Together, these outcomes clearly exemplify the role of two EC faculties in relational mapping. Namely, EC might not only be reflected in interference resolution (Cho et al., 2007) or inhibition (Viskontas et al., 2004) within WM. It seems that EC is also involved during prior goal-directed search through structurally and semantically complex information to select WM input, as relevant for mapping.

The reason that the need for goal management and application was pronounced in this study was probably due to the lack of the predetermination of relevant relational structure and to minimizing the probability of non-relational cues to correct objects' correspondences. This explanation seems to be in line with LISA incremental mapping algorithm (Hummel & Holyoak, 2003), which makes the mapping in the model very dependent on the importance assigned to propositions (Kubose et al., 2002).

The internal activation of a task's goal and proper application of this goal to the necessarily incremental

reasoning steps seems to be critically in play during selection and encoding of relational information, thus also before structure mapping is initiated within WM. The partial support for this conjecture comes from Gordon & Moser's (2007) study of eye movements' paths in a picture scene mapping task, in which people first scanned each scene in a given pair for meaningful relations and engaged in structure mapping only thereafter. The strong effect of distraction obtained in this study, together with a lack of reliable interaction between distraction and saliency of relevant relations, suggest that the two manipulated control requirements imposed qualitatively separate constraints on WM during relational mapping. These constraints pertain to the ability to select information for the purpose of identifying relevant relations to reason with, and to the ability to deal with interference when processing these relations.

Further, the lack of reliable interaction between relational complexity and saliency of relevant relations gives a hint that the ability to select relations for analogy might be qualitatively distinct from the ability to integrate these relations within WM. Although both processes are about abstraction, which definitely requires WM resources, only the second seems critically dependent on the capacity of this system. Further research is needed to resolve this issue.

Finally, the reliable underadditive interaction between relational complexity and distraction was a surprise. This finding counters previous results of the opposite direction of this interaction in (Cho et al., 2007; Viskontas et al., 2004 and Richland et al., 2006). It is neither in line with LISA, in which WM capacity and efficiency of dealing with distraction both depend on the same inhibitory competition algorithm (Hummel & Holyoak, 2003), nor does it support the hypotheses that EC operates equally strong in different WM load conditions (e.g. Embretson, 1995). The possible explanation for this result could relate to the limitation of WM capacity (Cowan, 2005). Accordingly, since critical processing takes place only in the highly limited, most active part of WM, it could be speculated, that the strength of the detrimental effect of distraction on mapping is linked to the probability of distracters entering WM. Thus, the interference, which was caused by the "reversed" object-role bindings in the distraction-conditions of this experiment, should have been stronger, if the distracters were a part of the structure successfully accommodated into WM. This was surely more the case for easier (i.e. binary), than for more complex (quaternary) relations.

Summary and Future Directions

The current study sheds some new light on the nature of EC constraints in relational reasoning. The results demonstrate that next to dealing with distraction within WM, the goal-directed selection of information to enter structure mapping is an important, and to some extent, maybe a dissociable constraint. They also hint at a possibility that cross-mapping is only detrimental when affected structure is successfully accommodated within WM. Further research on the intricate contributions of EC to relational reasoning could combine measuring of individual differences in EC functions with experimental manipulation of their load in relational reasoning task. This could provide precise tests of plausibility of computational models of analogy-making.

Acknowledgments

This work was sponsored by the Polish Ministry of Science and Higher Education (grant 1422/B/H03/2009/36, years 2009-2010, awarded to Edward Nęcka and Anna Chuderska). The author wishes to thank Katarzyna Musiał for her assiduous help in data collection, Jarosław Kwiatkowski for implementing the test and Maciej Bernaś for reliable IT support in the lab.

Abstract

A potential determinant of people's selective attention is offered by the structural-alignment view of comparison. This view holds that objects are compared via structured representations that align sets of features that share relational roles. A central claim of this account is that the comparison process directs attention towards alignable features. This prediction has been supported by offline measures by Markman and Gentner (1997), who showed that alignable features serve as better cues for recall than nonalignable features. The present study provides the first online test of the structure-alignment theory's claim that alignability drives selective attention. Consistent with this, we show that in addition to serving as better cues for recall, alignable differences are attended more than nonalignable differences. Within-trial attention dynamics revealed that attention to alignable differences increases over the course of the comparison process.

Keywords: comparison, alignment, attention, recall, eye movements, eye tracking

Introduction

The amount of information that inundates people's perceptual systems creates a significant challenge. As people move through their environment, they are faced with thousands of decisions about which information they should selectively attend and which they should filter out. They must decide that certain things are worth remembering and that others are not. How are such decisions made?

There are a variety of factors that influence selection of parts of the stimulus stream. Early work examining how people attend to complex visual scenes showed that people will fixate the most informative elements (Buswell, 1935; Mackworth & Morandi, 1967; see Henderson & Hollingworth, 1999 for review). Subsequent work explored people's tendency to attend to the most perceptually salient features (e.g., Henderson, Weeks, & Hollingworth, 1999; Parkhurst, Law, & Niebur, 2002). Work on schemata and memory suggests that semantic consistency with a schema determines what is later recalled (Bransford & Johnson, 1972; 1973; Brewer & Dupree, 1983; Rummelhart, 1980). Finally, recent eye tracking work in categorization (Rehder,

Colner, & Hoffman, 2009) and in natural scene perception (e.g., Hayhoe, Shrivastava, Mruczek, & Pelz, 2003) proposes that the information demands of the task are the biggest influences on what people selectively attend.

In the present study we test the idea that yet another determinant of people's selective attention is the comparisons they make. We will first review comparison processes and then evidence from Markman and Gentner (1997) showing that people have better recall when they are cued by elements from scenes that are part of structural alignment. Then, by replicating Markman and Gentner (1997) with an eyetracker, we provide an online test of the idea that structural alignment can drive selective attention.

Comparison

The ability to compare is an integral part of human cognition. Category membership is determined by the degree of similarity to category representations (Medin & Schaffer, 1978; Nosofsky, 1984). In problem solving, people find solutions by comparing new problems to previously solved problems (Chi, Feltovich, & Glaser, 1981; Ross, 1987). In episodic memory, probes are compared to memory traces (Hintzman, 1986). In analogy people compare base and target domains. (Falkenhainer, Forbus, & Gentner, 1989; Gentner, 1983; Hummel & Holyoak, 1997)

There have been a few approaches to modeling the comparison process, including computing distances in multidimensional space using feature vectors, (Shepard, 1962) or comparing features using set operations, Tversky (1977). And yet to account for human comparison of complex stimuli with relational structure, a third approach has been used. Borrowing from models of analogy (Falkenhainer et al., 1989), the structure-alignment account (Gentner, 1983) represents objects as features inside structures of relations. For example, structure-alignment theory posits that people will encode features (e.g., the people and objects in Figure 1A) as arguments to relational predicates: smokes(man, cigar) or paints(painter, model). On this account, significant processing is applied to building a representation of the relations between features in a scene

or object, and into determining which objects match on the basis of shared roles.

With structure alignment, a great deal more information is both represented and processed than what is proposed by simpler accounts. Rather than comparing sets of features alone, comparisons are made over features and their relations. To accomplish this, objects with the same relational role in both scenes are placed in correspondence, while objects with different roles in their respective scenes are not.

Alignable Differences and Attention

Structure alignment has the ability to represent and calculate similarity over structured representations. However, this ability comes at a processing cost; the alignment process must build structurally consistent matches that satisfy parallel connectivity and one-to-one mapping. Parallel connectivity requires that matching relations have matching arguments. For example, in Figure 1A and 1B, if the photographer is aligned with the painter, then the man with the backpack is aligned with the model. One-to-one mapping states that across representations each object can be aligned to at most one other object—the boy with the backpack cannot also be aligned with the man and the cigar. Thus, the mapping process in structural alignment involves more than simple feature comparisons.

As a result of the more extensive processing involved in structural alignment, three different kinds of output are produced (Markman & Gentner, 1993). Whereas the feature-based approaches distinguish only between commonalities (matching features) and differences (mismatching features), structural alignment produces commonalities on one hand, and two types of differences. Differences that are linked to the commonalities, or *alignable differences*, and those that are not, *nonalignable differences*. For example, the female figure in Figure 1A is an alignable difference with the boy in Figure 1B. However, the man in the chair is a nonalignable difference, since there is no corresponding object in 1B. Thus, instead of just two kinds information used in the similarity calculation, the structural alignment approach has three.

The three types of output allow structure alignment to make the unique prediction that comparisons will focus people's attention on alignable differences. There are two reasons for this. First, it has been shown that people tend to weigh commonalities more heavily than differences in similarity judgments (Tversky, 1977). Since alignable differences are a type of commonality (on the basis of the relational structure) they should receive more attention.

The second reason for additional focus on alignable differences is that the entire alignment process is geared towards building up relational structure. Since alignable differences are what compose that structure, they should receive a significant amount of attention.

Over the last decade there has been a growing amount of evidence that alignable differences in fact receive more weight than nonalignable differences. Markman and

Gentner (1996) showed that when given a choice, subjects were more likely to select scenes with nonalignable differences as being more similar to a base scene than scenes with alignable differences. In a second experiment they showed that similarity ratings were more affected by variability in alignable differences than by variability in nonalignable differences. Markman and Gentner (1993) showed that people tend to list more alignable differences than nonalignable differences.

In another demonstration of the importance of alignable differences, Markman and Gentner (1997) had subjects rate the similarity of ten pairs of scenes, like those in Figure 1. Later, subjects were either given probes that were part of an alignable or nonalignable difference, as in Figure 2. They found that on average, subjects recalled 2.35 pieces of information when memory probes were part of an alignable difference versus just 1.3 when the probes were part of a nonalignable difference. Thus, across a range of studies, people seemed to place more weight on alignable differences.

The critical implication of these findings is the idea that structural alignment can be one of the determiners by which people select relevant aspects of their environment. The most direct test of this idea is an online measure of people's selective attention behavior as they make comparisons.

Eyetracking and Selective Attention

It has been well established that eye movements and selective attention are closely linked. For example, Shepard, Findlay, and Hockey (1986) demonstrated that although attending without making corresponding eye movements is possible, it is not possible to make an eye movement without shifting attention. Since high quality visual information is acquired only from a limited spatial region surrounding the fovea, we move our eyes three times each second through high-velocity saccades to position the fovea on what seems important.

It is no surprise then that eye tracking has enjoyed success in numerous research areas that appeal to the construct of selective attention. For example, Rehder and Hoffman (2005a) showed that learning a category corresponded to abrupt shifts in fixations towards relevant information. Later, Rehder and Hoffman (2005b) replicated Medin and Schaffer's (1978) 5-4 category structure with an eye tracker and found that fixation times to stimulus dimensions matched the decisions weight estimated from behavioral responses.

More recently, researchers have begun to leverage the flexibility that eye movement analysis offers in terms of experimental design. It is now possible to examine how attention is allocated across different kinds of tasks (Rehder, Colner, & Hoffman, 2009) and across different stimuli and categories (Blair, Watson, Walshe, & Maj, 2009). The close link between attention and eye movements has been shown across a variety of cognitive tasks (see Liversedge & Findlay, 2000 and Rayner, 1998 for reviews).

Of course, the key advantage to using eye tracking for the present purposes is that it provides an online measure of what people attend to during the comparison process. While recall behavior, verbal protocols, and similarity ratings all point to the conclusion that alignable differences have a greater impact than nonalignable differences on comparison, these are all offline measures. Testing recall performance, for example, occurs well after the comparison process has taken place. Although offline measures can indicate what subjects preferred to encode, they can't tell us about processing dynamics as they unfold over time.

Finally, one of the key claims of structural alignment is that the comparison process can help people determine what information is worth attending to. If in fact alignable differences do not receive more attention than nonalignable differences, then the validity of this claim is called into question. The present study will provide an online test of whether people allocate more attention to alignable features than to nonalignable features.

Experiment

The goal of the present experiment is to use eye tracking as a source of data to measure how comparison processes direct people's attention to important pieces of information, and how that in turn relates to recall of that information. According to the structural-alignment approach, the process of comparison should lead people to attend to alignable over nonalignable differences. As a result of this boost in attention, alignable differences should serve as better cues for recall later on. To test this, we replicated Markman and Gentner (1997), using an eyetracker to monitor subjects' attention allocation. Subjects were fit with a head-mounted eye tracker and we recorded their eye movements to alignable and nonalignable differences as they rated the similarity of ten pairs of scenes.

The main result of interest is whether subjects tend to allocate a greater amount of attention to alignable differences than to nonalignable differences. The structure-alignment approach predicts that subjects' fixation times will be greater on average for alignable differences than for nonalignable differences. Such a finding supports the idea that comparison via structural alignment helps focus people on what's important in the environment.

We will also examine how attention to alignable differences unfolds over the comparison process. Such dynamics will have implications for models of comparison.

Method

Participants Twenty-eight University of Texas students participated for course credit. They were tested individually and assigned to a random order of items. For each item, half of the subjects saw one comparison scene, and half saw the other. At the same time, the assignment of aligned and nonaligned recall cues to each comparison scene was counterbalanced across subjects. This designed allowed us to separate out effects of alignability on attention allocation and memory from any specific object-salience effects, or

differences in subjects' ability to recall particular objects from the scenes.

Materials The stimuli in the current study were based on the Markman and Gentner (1997) materials, but were made more suitable for eyetracking by (1) removing unnecessary textures and (2) increasing the distances between objects to more clearly distinguish which were fixated.

Figure 1 shows an example stimulus. As in the original study, there were ten sets of picture triads (one base, and two comparison pictures). The base picture had two relational scenes within it and each comparison picture matched one of the relational scenes. For example, Figure 1A is a base picture. It contains a portrait relation (the artist is painting a portrait of the model on the right), and there is a burning-dropping relation on the left (the man is dropping ash from a lit cigar) on the left. Each comparison matched one of the relational scenes. For example, Figure 1B matches the portrait relation, and Figure 1C matches the base picture on the burning-dropping relation. On a given trial, the base scene and (one of the) comparison scenes are presented together on screen. Later, one object from each relational structure in the base scene was used as a recall cue. For example, as shown in Figure 2, the painter and the man in the chair from Figure 1A were used as recall cues.

The eye tracker was an SMI Eyelink II, which was set to track one eye at 250 Hz.

Procedure Subjects were first fitted and calibrated to the

Figure 1. Example stimuli. Panel A is the base picture. Panels B and C are the two comparison scenes.

eye tracker. Items (i.e., a pairing of a base and one comparison scene) appeared on the screen. At their own pace, subjects rated the similarity of the base picture to the comparison picture (on a 1-to-9 scale). Before each item

Figure 2. Two example recall cues. Depending on the comparison picture, either cue can be an alignable or nonalignable difference.

presentation subjects were asked to fixate a small circle in the center of the monitor. This was used both as a drift correction and as an indication that they were ready for the next trial. Subjects recorded their rating by typing one of the corresponding numbers keys on the keyboard.

After subjects provided the ten ratings they engaged in a reading task for 30 minutes.

During the recall phase subjects were presented with one of the recall cues. Half of the recall cues were from alignable differences and the other half were from nonalignable differences. Subjects' verbal responses were recorded by a computer microphone.

Results

Recall We first set out to test whether we replicated the basic finding from the original Markman and Gentner (1997) study that alignable cues yield better recall than nonalignable cues with the revised stimuli. Therefore, we examined the effect that alignability had on subjects' recall of the scenes, by counting the number of pieces of information recalled from the base scene as a function of whether they received an alignable or nonalignable cue during recall. The data were first transcribed from the voice recordings and then rated by a single rater. The instructions to the rater were that each proposition (adjective, noun, or verb) about the scene counted as a piece of information.

The average number of correctly recalled pieces of information for the alignable cues ($M = 1.8$, $SD = 1.2$) was reliably greater than the number of pieces of information recalled for the nonalignable cues ($M = 1.3$, $SD = 0.92$), $t(27) = 2.44$, $p < .05$. The analysis was also carried out by item, and the result was marginally reliable $t(19) = 1.84$, $p = .081$. Thus, the basic findings found by Markman and Gentner were replicated here.

Fixations For our initial analysis, we constructed heat maps of eye fixations to get a sense for where people were looking while judging picture similarity. Figure 3 shows heat maps of fixations superimposed over one of the items, with both comparison scenes. To construct these heat maps, each x-y coordinate of the fixations were weighted by their total fixation time and summed over all subjects for each item. The weighted fixation coordinates were then processed by a Gaussian kernel density estimator, with bandwidth estimation (Jones, Oliphant, & Peterson, 2001). The red spots of the heat map reflect greater average amounts of fixation time, and as a result, where subjects were attending. Overall, and as expected, in both panels of Figure 3 fixations were centered directly over the objects in

Figure 3. Example heatmap of fixations to an item, averaged over subjects for one of the ten items, with comparison scenes. In Panel A there are more fixations to the man smoking, but in Panel B, there are more fixations to the painter and model.

the scenes. However, the heat maps also show that the allocation of attention is very different depending on which comparison scene the subjects saw.

According to structure-alignment theory, more fixations should land near the objects that align with the comparison picture. For example, the comparison scene in Figure 3A aligns with the man smoking in the left half of the base picture whereas the comparison scene of Figure 3B aligns with the portrait relation on the right hand side of the base image. In fact, the heat maps in Figure 3 show the result predicted by structural alignment. There are more intense and concentrated hot spots over the man in the chair in Figure 3A, and lesser hot spots over the painter and the model. The reverse is true for Figure 3B, there are more intense hot spots over the painter and the model, and weaker hot spots over the man in the chair. The heat map presented in Figure 3 provides a clear illustration of how subjects allocate greater attention allocation to alignable differences in the scene.

Next, we extended the above analysis to all items. For this purpose we coded fixations according to whether they were to an alignable difference or to a nonalignable difference in the base picture. We then computed the total fixation time for alignable differences across all items, for each subject. The average total fixation time to alignable differences ($M = 1473$, $SD = 814$) was greater than that for nonalignable differences ($M = 1272$, $SD = 690$), $t(27) = 2.25$, $p < .05$. (Although item analysis was not statistically reliable $t(19) = 1.2$, $p = .28$., seven out of ten of the items showed the effect in the expected direction). Thus, as structure-alignment predicts, subjects allocated more fixation time to alignable differences as compared to nonalignable differences.

The above results showed that overall, the comparison process engaged by subjects in determining the similarity of two images caused them to fixate alignable differences over nonalignable differences. But how does the comparison process direct attention to important features in a scene, and at what point are people drawn to alignable differences? Figure 4 shows the probability of fixating alignable differences, nonalignable differences, and to the comparison scene as a function of time, for ten seconds of the trial.

To construct Figure 4 we determined, for each 50-ms interval, whether a subject was fixating one of those three

Figure 4. Probability of fixating the aligned, nonaligned, and comparison objects in the scene, as a function of time (seconds).

locations. We then averaged over all trials and subjects to examine attention allocation over the course of the trial.

The figure shows that as expected, subjects showed no immediate preference for the alignable or nonalignable differences in the base scene. (The initial preference for the comparison scene in the first 50 ms reflects that the comparison scene was a much larger area of interest than the individual alignable and nonalignable differences, and there's a greater baseline chance that eye fixations will happen to be there first.)

Figure 4 then shows that during the next second, there was a dramatic increase in fixations to all three locations, but especially to the comparison scene. In fact, after one second, there is a sudden decrease in fixations to the alignable and nonalignable differences. Fixations then shift from the comparison scene to the alignable differences in the base picture, until fixations to alignable differences peak, at around the two-second mark. After this, fixations gradually dropped off for all locations (as more and more subjects have already responded), with the most fixations allocated to the comparison scene. On average, subjects did not allocate more fixations to the nonalignable differences at any point in the trial.

Discussion

Markman and Gentner's (1997) result that people have greater recall performance when cues are part of alignable differences replicated in the present study. These results were consistent with other previous work showing that alignable differences have a greater impact than nonalignable differences on people's comparison behavior.

The main contribution here was that we were able to observe the structural alignment process online. The predictions for the eyetracking results, that more fixations should be allocated to the alignable features obtained. The unfolding of attention allocation over the course of the comparison process also appeared to make sense. As soon as subjects allocated a significant amount of attention to the

comparison and base scenes, attention was allocated to the alignable differences, as predicted.

Our results have clear implications for cognitive models. First, mechanisms of comparison need to represent relational structure to explain selective attention behavior towards stimuli with any high level of complexity. Standard models in category learning that contain geometric (Kruschke, 1992) or feature-based (Lee & Navarro, 2002) similarity metrics need to be modified to account for people's ability to represent and attend to relational semantics.

Models that already have the ability to represent relations are consistent with the eye tracking results from the present study. For example, Hummel and Holyoak's, (1997; 2003) LISA and Larkey and Love's (2003) CAB models look for surface-feature similarities between items and only later try to match lower- and higher-order relations. Such mapping patterns reflect the selective attention behavior of our subjects because subjects required two seconds on average to focus primarily on alignable differences.

That subjects in our experiment attended differentially to objects according to their placement in the relational structure provides a proof of concept for using eye movements for more detailed tests of computational models, including those that already have the ability to represent relational structure. Additional eyetracking data can be collected to constrain the various components, for example, by having people make comparisons over objects that with different levels of relations (e.g., higher order versus lower order), or by manipulating subjects working memory, models' changes in selective attention can be related changes in selective attention to humans directly.

One of the most interesting implications for our results is derived from considering the working memory constraints of models like CAB and LISA. Working memory functions in such models to constrain the types of relations considered. With less working memory only lower-order relations or superficial feature matches will be represented by the model. This predicts that the details of the relational structure that people can maintain will also be influenced by working memory constraints. As a result, another potential determiner of what people selectively attend to in a scene is their working memory. If their working memory is compromised, they will not be able to use relational structure to guide their selective attention. Thus, the present data provide clear predictions for future eyetracking studies.

The rich source of data provided by eyetracking was able to confirm predictions of structural alignment and shows promise for constraining and developing more detailed processing accounts of existing computational models of comparison. In addition, there are potential future directions for empirical studies that follow from the present work to explain how it is that people decide what to selectively attend in an information-rich world.

Abstract

We present a computational model for solving Raven's Progressive Matrices. This model combines qualitative spatial representations with analogical comparison via structure-mapping. All representations are automatically computed by the model. We show that it achieves a level of performance on the Standard Progressive Matrices that is above that of most adults, and that the problems it fails on are also the hardest for people.

Keywords: Analogy, Spatial Cognition, Problem-Solving

Introduction

There is increasing evidence that visual comparison may rely on the same structural alignment processes used to perform conceptual analogies (Markman & Gentner, 1996; Lovett et al., 2009a; Lovett et al., 2009b). An excellent task for exploring this is the Raven's Progressive Matrices (RPM) (Raven, Raven, & Court, 2000). In RPM problems (Figure 1), a test-taker is presented with a matrix of images in which the bottom right image is missing, and asked to pick the answer that best completes the matrix. Though RPM is a visual task, performance on it correlates highly with other assessment tasks, many of them non-visual (e.g., Snow & Lohman, 1989; see Raven, Raven, & Court, 2000, for a review). Thus, RPM appears to tap into important, basic cognitive abilities beyond spatial reasoning, such as the ability to perform analogies.

This paper presents a computational model that uses analogy to perform the RPM task, building on existing cognitive models of visual representation and analogical comparison. Our claims are:

- 1) Tasks such as RPM rely heavily on qualitative, structural representations of space (e.g., Biederman, 1987; Forbus, Nielsen, & Faltings, 1991). These representations describe relations between objects in a visual scene, such as their relative location. Importantly, these representations are hierarchical (Palmer, 1977); they can also describe larger-scale relations between groups of objects or smaller-scale relations between parts of an object.

- 2) Spatial representations are compared via structure-mapping (Gentner, 1983), a process of structural alignment first proposed to explain how people perform analogies. Structure-mapping is used here to compute the similarity of two images, to identify corresponding objects in the images, and to generate abstractions based on commonalities and differences.

We previously (Lovett, Forbus, & Usher, 2007) described a model based on these principles that achieved human

adult-level performance on two sections of the Standard Progressive Matrices test. That model was unable to handle the more difficult sections of the test because it only considered differences between pairs of images. This paper describes a more advanced model which performs at an above-average level on the hardest four sections of the test. It remains grounded in the same principles but is able to identify patterns of differences across rows of images. Like before, all inputs are automatically computed from vectorized input.

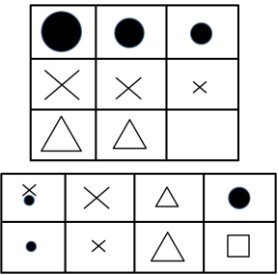

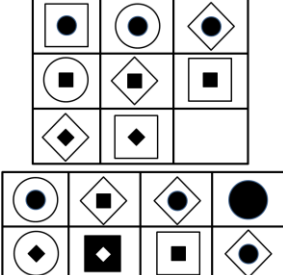

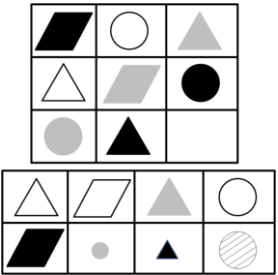

We first discuss Carpenter, Just, and Shell's (1991) computational model of the RPM. We then describe our model and its results on the Standard Progressive Matrices test. We end with conclusions and future work.

Background

The best-established model of Raven's Progressive Matrices was developed by Carpenter, Just, and Shell (1991). It was based on both analysis of the test and psychological studies of human performance. The analysis led to the observation that all but two of the problems in the Advanced Progressive Matrices, the hardest version of the test, could be solved via the application of a set of six rules (see Figure 1 for examples). Each rule describes how a set of corresponding objects vary across the three images in a row. The simplest, Constant in a Row, says that the objects stay the same. Quantitative Pairwise Progression (Figure 1A) says that one of the object's attributes or relations gradually changes. The other rules are more complex, requiring the individual to align objects with different shapes (Distribution of Three), or to find objects that only exist in two of the three images (Figure Addition or Subtraction, Distribution of Two).

The psychological studies suggested that most people solved the problems by studying the top row, incrementally generating hypotheses about how the objects varied across that row, and then looking at the middle row to test those hypotheses. This process began by comparing consecutive pairs of images in a row.

Armed with their observations, Carpenter et al. built two computational models to solve the Advanced Progressive Matrices: FAIRAVEN and BETTERAVEN. Both models used hand-coded input representations. They solved a problem by: 1) identifying which of the six rules applied to the first two rows, and 2) computing a mapping between those two rows and the bottom row to determine how to apply the same rules in that row.

Figure 1: Several examples of RPM problems. To protect the security of the test, all examples were designed by the authors. Included are the rules required to solve the problems according to Carpenter et al.’s (1991) classifications.

BETTERAVEN differed from FAIRAVEN in that it possessed better goal-management and more advanced strategies for identifying corresponding objects in a row. Whereas FAIRAVEN could perform at the level of the average participant in their subject pool, BETTERAVEN matched the performance of the top participants.

Since BETTERAVEN’s development, studies (Vodegel-Matzen, van der Molen, & Dudink, 1994; Embretson, 1998) have suggested that Carpenter et al.’s rule classification is a strong predictor of the difficulty of a matrix problem: problems that involve the more advanced rules, and that involve multiple rules, are more difficult to solve. In this respect, the models have had an important, lasting legacy. Unfortunately, they have two limitations. First, they operate on hand-coded input, hence the problem of generating the spatial representations is not modeled. Carpenter et al. justify this by pointing to the high correlation between RPM and non-spatial tasks, suggesting that perceptual encoding must not play an important role in the task. However, an alternate explanation is that the problem of determining the correct spatial representation for solving a matrix relies on encoding and abstraction abilities shared with other, non-visual modalities. The second drawback is that the six rules

identified by Carpenter et al. were hard-coded into their models. Thus, the models tell us little about how people discover those rules in the first place. That is, how do people progress from comparing pairs of images to understanding how objects vary across a row?

Our model addresses these limitations by using existing models of perceptual encoding and comparison. Spatial representations are automatically generated using the CogSketch (Forbus et al., 2008) sketch understanding system. These representations are compared via the Structure-Mapping Engine (SME) (Falkenhainer, Forbus, & Gentner, 1989) to generate representations of the pattern of variance across a row. We describe each of these systems, beginning with SME as it plays a ubiquitous role in our models of perception and problem-solving.

Comparison: Structure-Mapping Engine

The Structure-Mapping Engine (SME) (Falkenhainer, Forbus, & Gentner, 1989) is a computational model of comparison based on Gentner’s (1983) structure-mapping theory. It operates over structured representations, i.e., symbolic representations consisting of entities, attributes, and relations. Each representation consists of a set of

expressions describing attributes of entities and relations between entities. For example, a representation of the upper-left image in Figure 1B might include an expression stating that the square **contains** the circle.

Given two such representations, a *base* and a *target*, SME aligns their common relational structure to generate a mapping between them. Each mapping consists of: 1) correspondences between elements in the base and target representations; 2) *candidate inferences* based on expressions in one representation that failed to align with anything in the other; 3) a similarity score between the two representations based on the quantity and depth of their aligned structure. For this model, we normalize similarity scores based on the overall size of the base and target.

SME is useful in spatial problem-solving because a mapping between two spatial representations can provide three types of information. First, the similarity score gives the overall similarity of the images. Second, the candidate inferences identify particular differences between the images. Third, the correspondences can be useful in two ways. (a) Correspondences between expressions identify commonalities in the representations, and (b) correspondences between entities identify corresponding objects in the two images, a key piece of information for determining how an object varies across a row of images.

Finally, SME can take as input constraints on its mappings, such as requiring particular correspondences, excluding particular correspondences, or requiring that certain types of entities only map to similar types. While the psychological support for these constraints is not as strong as the overall psychological support for SME, we have found previously (Lovett et al., 2009b) that constraints can be useful for simulating a preference for aligning similar shapes when comparing images.

Perceptual Encoding: CogSketch

We use CogSketch (Forbus et al., 2008) to generate spatial representations. CogSketch is an open-domain sketch understanding system. Given a sketch consisting of line drawings of a set of objects, CogSketch automatically computes qualitative spatial relations between the objects, generating a spatial representation. This representation can then serve as the input to other reasoning systems.

There are two ways of providing input to CogSketch. A user can either draw out a sketch within CogSketch, or import a set of shapes created in PowerPoint. In either case, it is the user's responsibility to segment an image into objects—CogSketch does not do this automatically.

Essentially, the user is performing part of the job of perceptual organization (Palmer & Rock, 1994), the low-level visual operation that creates a set of entry-level units for processing. We focus on modeling the ways one must

Figure 2. A,B: Two arrow shapes. C: Part of an arrow.

reorganize these units—via grouping and segmentation—during the problem-solving processes.

Sketches can be further segmented by using a *sketch lattice*, a grid which indicates which objects should be grouped together into images. For example, to import the Raven problems in Figure 1 into CogSketch, one would create one sketch lattice for each of the two matrices in a problem, then import the shapes from PowerPoint and place them in the appropriate locations in each lattice. In this way, a user can specify an RPM problem for CogSketch to solve.

Generating Representations

Given a sketch, CogSketch automatically generates a set of qualitative spatial relations between the objects in it. These relations describe the relative position of the objects and their topology—i.e., whether two objects intersect, or whether one is located inside another. CogSketch can also generate attributes describing features of an object, such as its relative size or its degree of symmetry.

CogSketch is not limited to generating representations at the level of objects. It is generally believed that human representations of space are hierarchical (Palmer, 1977; Palmer & Rock, 1994). While there may be a natural “object” level of representation, we can also parse an object into a set of parts or group several objects into a larger-scale set. Similarly, CogSketch can, on demand, generate representations at two other scales: edges and groups.

To generate an edge-level representation, CogSketch parses the lines that make up an object into edges. It does this by identifying discontinuities in a line's curvature that indicate the presence of corners (see Lovett et al., 2009b for details). CogSketch then generates qualitative spatial relations between the edges in a shape, describing relative orientation, relative length, convexity of corners, etc.

To generate a representation at the level of groups, CogSketch groups objects together based on proximity and similarity. It can then identify qualitative spatial relations between groups, or between groups and individual objects.

Interactions with SME

We believe structural alignment plays an important role in comparing visual stimuli. CogSketch employs SME to determine how images relate to each other. However, the use of hierarchical representations means that SME can also compare two objects' edge-level representations to determine how the objects relate to each other. Our model uses this capability in two ways, discussed next.

Finding Shape Transformations CogSketch can compare two objects' shapes to identify transformations between them, e.g., the rotation between the arrow shapes in Figure 2. It does this via a simple simulation of mental-rotation (Shepard & Metzler, 1971): (1) Two objects' edge-level representations are compared via SME. SME's mapping identifies the corresponding edges in the two objects. (2) Pairs of corresponding edges are quantitatively compared to determine whether there is a consistent transformation

between them. In Figure 2, CogSketch could identify a rotation or a reflection between the arrows shapes.

CogSketch can identify two types of shape transformations: equivalence transformations (henceforth called simply *transformations*) and deformations. Transformations (rotation, reflection, and changes in overall size) leave an object's basic shape unchanged. Deformations (becoming longer/shorter, becoming longer/shorter in a part, adding/losing a part) change the object's shape.

Based on shape comparisons, a given set of objects can be grouped into *equivalent shape classes*—groups of objects that have a valid transformation between them, such as equilateral triangles of all sizes and orientations—and *strict shape classes*—groups of objects that are identical, such as upright, equilateral triangles of a particular size.

Comparison-Based Segmentation CogSketch can dynamically segment an object into parts based on comparisons with other objects. For example, to determine the relationship between the images in Figures 2A and 2C, it segments each object into its edges, and uses SME to identify corresponding edges. Grouping only edges in 2A that correspond to edges in 2C enables it to segment 2A into two objects, one of which is identical to 2C. The difference between 2A and 2C is then represented as: *A contains the same object as 2C, but with a second, angular object located above it.*

Our Model

Our model is based on Carpenter, Shell, and Just's (1991) finding that people generally begin solving a matrix problem by comparing adjacent pairs of images in each row of the problem. Our model begins by comparing the images in a row via SME. Based on the mappings between images, it generates a *pattern of variance*, a representation of how the objects change across the row of images. The model then computes a second-order comparison (Lovett et al., 2009B), using SME to compare the patterns for the top two rows and rate their similarity. If the rows are sufficiently similar, the model builds a generalization representing what is common to them; it then looks for an answer that will allow the bottom row to best match this generalization. If the top two rows are not sufficiently similar, the model makes a change to its problem-solving strategy.

Instead of identifying RPM-specific rules as Carpenter et al. did, we utilize two general classes of strategies (four strategies in all) for how a person might go about building patterns of variance. We believe these strategies should be applicable to a variety of spatial problems.

The two classes of strategies are Differences and Literal. Differences involves representing the differences between adjacent pairs of images in a row. For example, in Figure 1A the object is gradually getting smaller. Literal involves representing what is literally true in each image of the row. In Figure 1B, every row contains a square, a circle, and a diamond. There are also advanced versions of each strategy, described below. We now describe each strategy in detail.

Differences Strategy

1) Generate Representations CogSketch generates a spatial representation for each object in a row. While CogSketch can generate representations at multiple levels, the model begins with the highest-scale, and thus simplest, representation. Objects consisting of a single edge—or objects consisting of multiple edges that don't form a closed shape—are grouped together based on connectedness to form a single object, e.g., in the first image of Figure 1F, the vertical and diagonal edges are grouped to form a single object. Objects consisting of closed shapes are combined based on proximity and similarity to form *groups*, e.g., the sets of three squares in Figure 1F are grouped together. CogSketch then computes spatial relationships between the objects, and between objects and groups. It also computes object attributes, describing their shape, color, texture, etc.

2) Compute a Basic Pattern of Variance Consecutive pairs of images in the row are compared via SME to identify the corresponding objects. If there are leftover, unmatched objects in both the first and last images of the row, then these images are also compared. Corresponding objects are then compared to identify transformations between their shapes. Based on these comparisons, the model generates one of the following expressions to describe how an object varies between each pair of images: (a) *Identity*: The object remains the same. (b) *Transformation*: A transformation exists between the shapes. (c) *Deformation*: A deformation exists between the shapes. (d) *Shape Change*: The shapes change entirely. Shape changes are represented as a change between two strict shape classes. Essentially, this is equivalent to a person keeping “square changes to circle” in working memory. (e) *Addition/Removal*: An object is added or removed.

If an object is identical in every image in the row, then this is deemed unimportant, and not explicitly represented¹. The rest of these expressions are supplemented by any changes in the spatial relations and colors of the images, as identified by SME's candidate inferences, to produce a representation of the pattern of variance across the row.

3) Comparison-Based Segmentation For some problems, the appropriate set of objects to consider only becomes clear after images are compared. For example, in Figure 1E, one discovers after comparison that the third object in the row can be segmented into two parts, such that these parts correspond to the previous two objects in the row. Our model attempts comparison-based segmentation for a set of corresponding objects when: (a) The objects can be broken down into edges, i.e., they aren't filled-in shapes. (b) There is at least one total shape change between the objects, suggesting that they currently don't align well. (c) The changed shapes share some similar parts, i.e., edges with

¹ Carpenter, Just, and Shell (1991) found that the Constant in a Row rule, in which an object remains identical across a row, did not contribute to the difficulty of problems, suggesting that people simply ignore objects that don't change.

similar lengths and orientations. (d) There are no identity matches between objects.

Comparison-based segmentation is performed by breaking the objects into their edges, comparing their edges in a new pattern of variance, and then grouping the edges back together based on which sets of edges correspond across the images. This approach is key in solving Figure 1E. It also allows the model to determine that the vertical line and “X” shape are separate objects in Figure 1F. A similar approach is used to segment groups into subgroups or individual objects when they misalign.

4) Compute Final Pattern of Variance Repeat step 2) after segmentation and regrouping.

Advanced Differences Strategy

The advanced differences strategy is identical, except that in steps 3-4, SME mapping constraints are used so that objects only map to other objects in the same strict shape class (i.e., identical objects). Additionally, objects consisting of single edges (as when the shapes in Figure 1E are broken down into their edges) can only map to other single-edged objects at the same relative location in the image. This means the model will never find object transformations, but it will often find object additions/removals, making it ideal for solving problems like 1E and 1F, in which each object is only present in two of the images in a row.

Literal Strategy

The literal strategy represents what is present in each image in a row, rather than what is different between images. It begins by comparing images to identify any features found in all three images (e.g., the inner shapes in Figure 1B). It abstracts these features out, representing only the features in each image that are not constant across the row. If an object has a different shape from other corresponding objects in the row (e.g., the outer shapes in Figure 1B), then the model includes that object’s strict shape class in the representation.

Advanced Literal Strategy

The advanced literal strategy begins by applying the basic literal strategy. It then removes any references to the images in which the objects are found. Spatial relations between objects are also abstracted out. Thus, each object is represented independently, and allowed to match independently from the other objects in its image (e.g., Figure 1D). Alternatively, if each image contains only a single object, then an object is split up and each of its attributes are represented as a separate entity (Figure 1C).

Choosing the Best Strategy

Our model evaluates a strategy by computing patterns of variance for the top two rows and using SME to compare them and rate their similarity. If the similarity is above a threshold, the strategy is deemed a success. If not, a different strategy is tried. The strategies are tried in the following order, which approximates simplest to most

complex: Differences, Literal, Advanced Literal, Advanced Differences. If no strategy meets criterion, the model picks whichever Differences strategy receives the highest score—Literal strategies that fail to meet criterion are not considered, since by definition they expect a near-identical match between rows.

Selecting an Answer

Once a strategy is chosen, the model compares the pattern of variance for the top two rows to construct an analogical generalization (Kuehne et al., 2000), describing what is common to both rows. The model then scores each of the eight possible answers. An answer is scored by inserting that answer into the bottom row, computing a pattern of variance, and then using SME to compare this to the generalization for the top two rows. The highest-scoring answer is selected. In cases of ties, no answer is selected.

Solving 2x2 Matrices

The easier RPM sections involve 2x2 matrices. The model solves these by simply computing a Differences pattern of variance for the top row, and then selecting the best answer for the bottom row. If no answer scores above a criterion, the model attempts one strategy change: looking down columns, instead of across rows, to solve the problem.

Evaluation

We evaluated our model by running it on sections B-E of the Standard Progressive Matrices test, for a total of 48 problems. Only section A was not attempted, as this section relies more on basic perceptual ability and less on analogical reasoning. While section B uses 2x2 matrices, sections C-E use 3x3 matrices of increasing difficulty.

Each problem from the test was recreated in PowerPoint and then imported into CogSketch. The experimenters segmented images into objects based on the Gestalt grouping principles (Palmer & Rock, 1994).³ Recall that the model reorganizes the images into new sets of objects as necessary to solve a problem.

Results

Overall, the model correctly solved 44/48 problems. To compare this level of performance to people, we converted this score to a 56/60 on the overall test, as individuals who performed this well on the later sections typically got a 12/12 on section A (Raven et al., 2000, Table SPM2). A score of 56/60 is in the 75th percentile for American adults, according to the 1993 norms (Table SPM13).

If our model captures the way people perform the test, then problems that are hard for the model should also be hard for people. The four missed problems were among the six hardest problems for human participants, according to 1993 norms (Raven, et al., 2000, Table RS3C3).

³ In one problem, a dotted line was replaced with a gray line for simplicity.

Discussion

Overall, our model matched the performance of above-average American adults on the Standard Progressive Matrices, both in the problems that it got right and the problems that it missed. Thus, it demonstrates that qualitative representations and the Structure-Mapping Engine can be used to model the performance of typical participants on this task. Importantly, structure mapping played a ubiquitous role in the model; it was used to compare objects, images, and patterns of variance. Additionally, these comparisons were used to rate similarities, identify differences, find corresponding elements, and produce generalizations. Thus, the simulation demonstrates that a single mechanism can be used to perform all the necessary comparisons in this complex task.

Direct comparison with BETTERAVEN (Carpenter, Just, & Shell, 1990) is impossible, as it was only built for, and run on, the Advanced Progressive Matrices. However, if we apply the principles of the model and assume perfect performance, it would achieve a 59/60, missing one of the problems missed by our model. Of the other three problems our model missed, two were due to insufficiencies in its representations of object and group attributes. Because it computes its own representations, our model provides a reason that these problems are more difficult for people, i.e. they require encoding more advanced attributes. Thus, while our model might solve fewer problems, its failures predict and explain human performance.

Future Work

We have shown that our approach is sufficient for modeling human performance on Raven's Progressive Matrices. An important further step is to use the model to make new discoveries about how people perform spatial problem-solving. In a previous study (Lovett & Forbus, 2009), we used a similar model to identify possible cultural differences in the ways people represent space. RPM provides a number of unique opportunities to look at both spatial representation and analogical comparison, due to the complexity and diversity of the problems. By classifying problems based on the model strategies and model components required to solve them, we hope to gain a better understanding of both the factors that make one problem harder than another, and the cognitive abilities that make one person better than another at spatial problem-solving.

Although cognitive anthropology once was a pioneer in the cognitive revolution and a founding member of the cognitive science, over the years its participation and influence have diminished—to the detriment of both cognitive anthropology and cognitive science more generally. Meanwhile, though, interactions between culture and cognition are increasingly recognized as being of prime interest for cognitive science. Among the most important issues that call for anthropological expertise is the question of cognitive and/or linguistic universals (Evans & Levinson, 2009; Henrich, Heine & Norenzayan, in press; Norenzayan & Heine, 2005). Anthropology, with its expertise in culture and language, thus becomes an invaluable partner for respective research. But only recently, initiatives have been launched to re-calibrate the relationship among the subfields of cognitive science (Bender, Hutchins & Medin, in press).

This symposium is intended as one step in this direction, bringing together scholars from different disciplinary backgrounds (e.g., anthropology, linguistics, and psychology) to present what they regard as the main strengths of their respective disciplines and why and how this could be useful for each other.

The symposium is co-organized by an anthropologist and a psychologist who will give an introduction to the symposium's topic by summarizing some of the evidence for the cultural constitution of cognition (e.g., Beller & Bender, 2008; Beller, Bender & Song, 2009). The presenters are among the leading scientists in their fields. Besides striving for the re-integration of anthropology into cognitive sciences, each of them has contributed considerably to our expanding knowledge on the cultural constitution of cognition (for instance, in comprehensive monographs or articles in high ranking journals):

- Giovanni Bennardo of Northern Illinois University, having a background in anthropology, linguistics, and cognitive science, seeks to model cognitive conceptualizations for various cultural domains (e.g., Bennardo, 2009; Bennardo & Read, 2007).
- Anthropologist and ethnolinguist James Boster of the University of Connecticut is an expert on methodology

in cultural research and on intracultural variation (e.g., Boster, 1999, in press) and has published extensively on semantic categories (e.g., Majid, Boster & Bowerman, 2008).

- Asifa Majid from the MPI for Psycholinguistics in Nijmegen combines approaches from cognitive science, psychology, linguistics, and anthropology for her research into the semantic categorization of so far unquestioned domains as body categorization or sensory experiences (e.g., Majid, 2006; Majid et al., 2008).
- And Douglas Medin, being one of the leading scholars on categorization, learning, and decision making, has for many years now scrutinized the cultural constitution of cognition (e.g., Atran & Medin, 2008; Medin & Atran, 2004; Medin, Bennis & Chandler, in press).

Based on own cross-cultural (and often interdisciplinary) research, each presenter in this symposium will argue why anthropology is necessary for cognitive science and how it can contribute to a more comprehensive understanding of cognition (cf., d'Andrade, 1995; Hutchins, 1995). In particular, they will address the question of universals, from the level of syntax through semantic categories and sensory experiences to the relationship between human and nature.

Word order and a cultural model: From universal mind to cultural mind

Giovanni Bennardo

Goldin-Meadow et al. (2008, p. 9167) suggest that SOV (subject – object – verb) is the “natural [mental] order for humans” and that “as a language community grows and its functions become more complex, additional pressures may exert their influence on language form, in some cases pushing the linguistic order away from the semantically clear ArPA (actor, patient, action or SOV) order”. Tongan (in Polynesia) is typically regarded as a Verb-Initial language and specifically a VSO language. In this talk, a frequency analysis will be presented of a good number of Tonga texts that partially challenges this assumption. Besides, a founda-

tional cultural model ‘radiality’ (Bennardo, 2009) in Tongan cognition will be proposed as the engine that might be responsible for the move from ‘natural’ SOV to Tongan V-initial.

Are translation equivalents referential equivalents?

James S. Boster

Sets of translation equivalent emotion terms were identified in Polish and English. These terms (and others) were used in two tasks, one naming the emotion expressed in facial gestures of emotion, the other naming the emotions elicited by affectively evocative scenarios. In neither case were the translation equivalent terms referentially equivalent. However, treating the question as one requiring a yes/no answer does not do it justice. This paper measures degrees of translation and referential equivalence and compares those measures.

The senses in mind and culture

Asifa Majid

The cognitive sciences aim to understand the human mind but too often fall prey to unwarranted generalizations from a narrow subset of the population: Western, Educated, Industrialized, Rich, Democratic societies. Anthropologists provide one kind of corrective to this bias, providing ethnographies of many alternative ways of thinking. But we still struggle to grasp what is common across cultural groups, and what truly exceptional. I propose that large-scale cross-cultural comparison can bridge this gap between the fields. For example, it has been assumed that sensory experiences are differentially accessible to language. That is, it is easier to describe distal senses (vision, audition) than proximal senses (olfaction, taste). Current theories assume this to be an established fact on the basis of English data alone. In a large-scale collaborative project, involving 25 researchers and 22 languages, we have found the codability of the senses is culturally-relative. This is a challenge to existing theories.

Cognition in context: Why anthropology and the rest of cognitive sciences need each other

Douglas L. Medin,
Megan Bang, Ananda Marin & Sandra Waxman

There is a great deal to be said about the lack of interaction between Anthropology and the other cognitive sciences. Such analyses can be constructive. Our present focus leaves the abstract issues behind to focus on a set of empirical issues linked to psychological distance and how humans are conceptualized in relation to the rest of nature. Native-American and European-American perspectives are contrasted. The research we report begins with ethnographic observations and interviews and then shifts to an analysis of cultural artifacts (children’s books). We show how these data can be used in conjunction with the Trope and Liberman (2003) temporal construal theory to predict a number of related cul-

tural differences. The punch line is that Anthropology and the other cognitive sciences need each other if we are to understand cognition in context.

Abstract

Adult semantic networks show small-world structural properties that are believed to support language processing and word retrieval. The focus of this paper is to understand when these properties emerge in lexical development. We believe that they relate to the rate of word acquisition and vocabulary size. To address this, we examine the connectivity patterns of semantic networks of individual children and compare children on faster and slower vocabulary growth trajectories. The results show that small-world properties emerge early. However, children on slower growth trajectories, who are at risk for significant language delay, do not show these properties. The differences between typical and these so-called “late-talkers” persist, even when vocabulary size is equated. Late talkers’ vocabularies are not only acquired later, but also less cohesively, a fact that may relate to future language processing difficulties for these children. In brief, the results suggest that properties of network connectivity may play a role in early lexical development.

Keywords: semantic networks, language acquisition, corpus analyses, late talkers

Words connected to other words

Words exist in a sea of other words. The semantic relations among these words play an explanatory role in language comprehension and processing (e.g., Lund & Burgess, 1996; Jones & Mewhort, 2007). These relations are often studied in terms of semantic networks (Collins & Quillian, 1969; Steyvers & Tenenbaum, 2005). Recent advances in graph theory reveal that adult semantic networks have properties that may be important to language processing, and potentially also to word learning.

Graph theory, or network analysis, can be applied to any structure that consists of nodes connected to each other through links or edges. For example, nodes might be cities and links might be roads; or nodes might be proteins and links might be the molecules that bind with and activate them; or, nodes might be words and the links indices of semantic connectedness such as association strength or co-occurrence.

The semantic networks may be built from various sources, including corpora collected from written or spoken language, free association data, and hand-coded collections of words (e.g., Steyvers & Tenenbaum, 2005; Hills et al., 2009b). As such, they describe the typical mature language user. These

mature semantic networks exhibit what is known as small world properties (see Steyvers & Tenenbaum, 2005; Hills et al., 2009a). Small world characteristics allow for local structure but global access. In a network with small world characteristics, there are often clusters of densely connected nodes. The connections between the nodes of a cluster tend to connect to nodes in the same cluster. This contributes to the high local structure. However, there are also a few nodes in these dense clusters that have connections to nodes in other potentially distant clusters. This is the global access that allows easy movement and transition from one cluster to another. Quantitatively, these features are apparent in a high clustering coefficient (a measure of local connectivity) and an average geodesic distance (the shortest path between two nodes) on par with a random network of similar size and connection density. To aid in exposition, these properties are illustrated in Figure 1. Small-world properties are believed to support efficient processing, word retrieval, categorization and robustness to damage and deletion (Hills et al., 2009a; Griffiths, Steyvers & Firl, 2007, Steyvers & Tenenbaum, 2005).

Figure 1: Characteristics of small world structure.

Although it is known that adult semantic networks have small world characteristics, only a few studies have addressed their development and the role of network structure in language acquisition (e.g. Vitevitch 2008, Hills et al., 2009a, Hills et al., 2009b). Here, for the first time, we examine the network structures of the vocabularies of individual children at different points in development. We ask whether small-world properties are dependent on acquiring some number of English words and whether, for any vocabulary size, some children’s networks might show more robust connectivity patterns than other children’s

networks. Is network connectivity a general fact about the structure of language, or can we show that it is a relevant property at the scale of an individual? Finally, is the connectivity pattern for individual children related to rate of vocabulary growth?

To these ends, we examine the connectivity within the semantic networks of individual children who –by normative standards –are on a path of typical development and children who are on a slower path and one that past research shows is predictive of later language difficulties (e.g., Thal et al., 1997; Bishop & Leonard, 2000; Heilmann, et al, 2005).

Trajectories of Early Vocabulary Growth

Early word learning is first slow and then accelerates (Bloom 2000; Dale & Fenson, 1996), a fact that suggests that already learned words help new word acquisition (see Mitchell & McMurray, 2009). Vocabulary size at any point in development is thus a predictor of future vocabulary growth rates (Dupuy, 1974; Raven, 1948; Bates et al., 1992; Fenson et al., 1993; Thal et al., 1997). Figure 2 illustrates the normative vocabulary size as a function of age for children at the 50th percentile and the 20th percentile (Fenson et al, 1993; see also Dale & Fenson, 1996). Percentile is calculated by considering a child's age, number of words in their productive vocabulary and gender.

Figure 2: Trajectories of early vocabulary growth, representing children in the 50th percentile and children in the 20th percentile (drawn from Fenson et al, 1993).

The trajectory at the bottom—for children whose vocabulary size falls at or below the 20th percentile of children their same age—has attracted considerable attention in the study of early word learning. Many of these children not only stay on this slower trajectory, but about half go on to have serious deficiencies in language processing and even those who might seem to “catch up” often have measurable difficulties in language tasks (including reading) when they reach school age (e.g. Anderson & Freebody, 1981; Bishop & Leonard, 2000; Thal et al., 1997; Moyle et al, 2007). Moreover, early as well as later in development, these children show retrieval errors and word-finding difficulties (Bishop & Leonard, 2000).

Accordingly, we ask how vocabulary size in young children relates to the structure of semantic relations within those vocabularies and whether this structure is related to

individual children's rate of vocabulary growth. We examine a broad sample of children and specifically compare vocabularies of children not at risk for language deficits with children whose vocabulary size for their age puts them at risk for language difficulties. In the literature, these at-risk children are often called “late talkers;” we will also use that term although it is somewhat of a misnomer because they are not simply “late” but rather on a slower path of vocabulary growth. If small-world properties are important to the efficiency of language use—and perhaps also to new word acquisitions—then vocabulary structure and not just vocabulary size may be different for these children. Does the connectivity of words in the emerging semantic networks of late talkers differ from the network structure of children whose vocabulary has grown at a more typical pace?

Rationale for the Approach

We analyzed vocabularies from a broad sample of children who differed in age and vocabulary size but whose vocabulary size for age was above the 20th percentile and also from a sample of children, also varying in age and vocabulary size, whose vocabulary size fell below the 20th percentile for age at the time the vocabulary was collected. A semantic network was built for each vocabulary yielding a large set of individual networks that could be ordered by age and separately by vocabulary size.

To build individual networks, we connected the words in an individual's vocabulary, using co-occurrence in a large corpus of child-directed speech as the index of semantic relatedness. The co-occurrences in this corpus of child directed speech is presumed to index the relatedness of the individual words in the language (and that part of the language relevant to children) and in the learning environment in general. This measure of semantic relatedness is *not* the co-occurrences in the specific learning environments of individual children, a key point we will consider in the general discussion. Co-occurrences of words within the corpus formed the edges or links of a semantic network and the nodes were based on the words in each individual child's productive vocabulary.

In sum, the key question is whether and how semantic network connectivity changes as children's vocabularies grow and whether this differs for children whose vocabulary growth rate is sufficiently slow that they are considered at risk for language disorders.

Methods

Vocabularies.

Vocabularies from 73 children ranging in age from 16.2 to 34.6 months were selected for this study. These vocabularies derive from one-time visits of children to the Cognitive Development Laboratory at Indiana University and are measures of productive vocabulary via the Bates-MacArthur Communicative Developmental Inventory (Toddler or Infant form as appropriate to the child's age, Fenson et al, 1993). This is a parent checklist and parents were asked to indicate

which words on the checklist their child produced (Fenson et al, 1993). Total vocabulary as indicated by the parent was used to determine the percentile of the vocabulary size for the child's age. From this repository of child vocabularies we selected a random sample of vocabularies of children whose vocabulary size for their age fell above the 20th percentile and as large a sample as possible of children whose vocabulary size for their age fell below the 20th percentile (see Fenson et al, 1993). Table 1 provides the number of children in each group, means and ranges of their vocabulary size, age, and percentile.

Table 1: Age and percentile of children in study

	# children	Age range in months (mean)	Percentile range (mean)
All children	73	16.2-34.6 (22.1)	5-99 (25.6)
Late talkers	38	16.3-34.6 (24.3)	5-20 (12)
Typical talkers	35	16.2-26.6 (19.8)	25-99 (40.4)

Words.

For the network analysis, only the 291 words that are on both the Toddler and Infant forms were used. This allowed for a more accurate comparison across ages. Of the included words, 204 are nouns, 51 are verbs and the remaining 36 are adjectives, adverbs and function words.

Networks.

To build the networks, links between words were defined in terms of co-occurrences in the CHILDES database (MacWhinney, 2000). The co-occurrence method was taken from prior analyses by Riordan and Jones (2007) and related lemmas (cat, cats, hit, hitting) were counted as instances of the same lexeme. The matrix of co-occurrences was built using a process similar to the Hyperspace Analogue to Language (HAL) (Lund & Burgess, 1996) and the word co-occurrence detector (Li, Farkas & MacWhinney, 2004). For the 291 unique words, we formed a *291x 291 matrix*, where

each cell, ij , is filled according to the following rule: a moving window of size 15 moves word-wise through the corpus, with each cell ij , changed to a value of 1 if word j occurs both downstream and together in the same window with word i . This produces a directed network where each word is connected to another word by a directed link if it co-occurs downstream of that word in child directed speech. Frequency counts were taken as the number of occurrences of a given word in the corpus.

Results

The analyses reported here use four network statistics: *median in-degree*, *global clustering coefficient*, *redundancy*, and *geodesic distance*. Each provides a means of assessing connectivity within networks. Figure 3 shows four networks for four typically developing children and the index of connectivity for each of these networks. The four individual networks show considerable small-world structure with as few as 106 (or even 55) words. This suggests that these properties—characteristic of mature semantic networks—are evident even from the earliest stages of lexical development. This could merely reflect the structure of language such that any learner (or random sample of words from early vocabularies) would show these properties. Or, these properties could be more fundamentally related to how individual children build semantic structures for efficient language learning and processing. The comparison of typically-developing and late-talking children provides the relevant evidence.

In-degree.

In-degree is a measure that captures how many connections each node has directed towards it from other nodes. In the present case, the in-degree of the target word or node is the number of distinct words that occurred 15 or fewer words after the target in the CHILDES corpus. The median in-degree provides an overall picture of how sparse or dense a network is. In a sparse network, the words in the

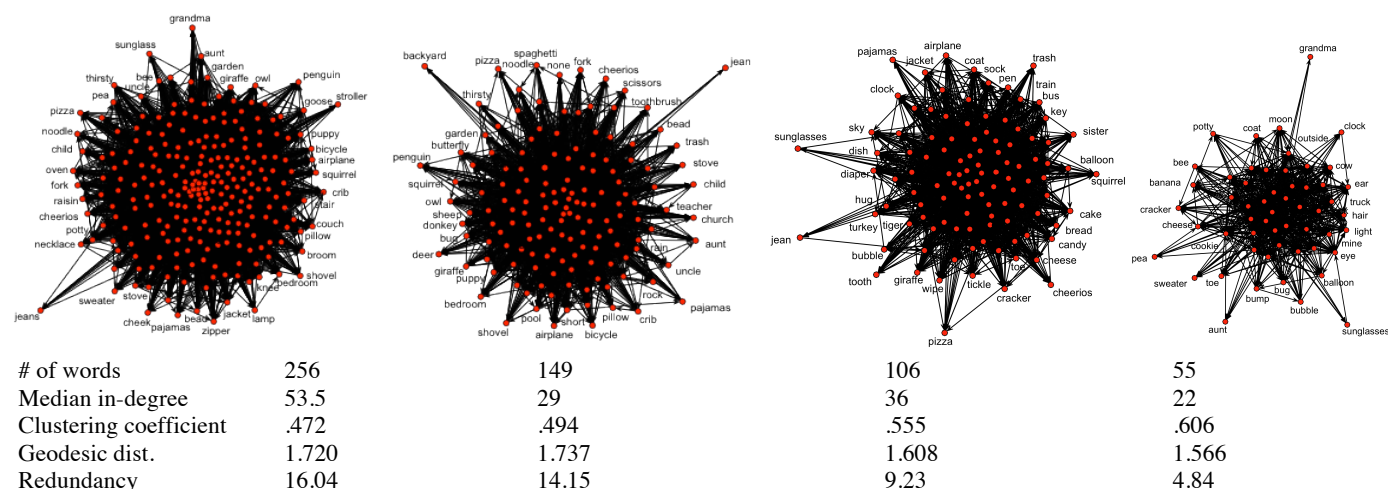

Figure 3: These semantic networks of typically developing children show that children develop small world structure even with relatively few words. Throughout development the semantic networks of children show high clustering coefficients and low average geodesic distance. The networks also quickly develop a high number of connections and multiple traversable pathways.

vocabulary are not as related to each other and so there can be more words than connections. In a dense network, many words are connected to each other; e.g., the median in-degree is nearly equal to the total number of words or nodes, many words in the network are semantically related and co-occur frequently in speech.

Regression analysis, with median in-degree as the independent variable and the child's MCDI percentile as the dependent, yielded a significant relation between in-degree and percentile with lower median values characterizing late-talkers even when age ($p<.001$) and vocabulary size ($p=.0162$) were controlled. The relation between in-degree and vocabulary size for the two groups is shown in Figure 4.

This indicates that there are more links in a typical talker's network than in a late talker's network even when the networks have the same number of nodes. Typical talkers learn words that are semantically connected to each other but late talkers are less likely to do so, as if perhaps, they learn words as individual islands, as if the *next* word learned is somehow independent of the prior learned words.

Figure 4: A graph of the median in-degree as a function of vocabulary size. The black line indicates typical talkers and the lighter line, the late talkers. ($p=0.016$).

Global clustering coefficient.

The clustering coefficient provides a measure of how well connected a node's neighbors are to each other. Small-world networks have high clustering coefficients, relative to networks of the same size (number of nodes) and density (ratio of observed links to possible links). A clustering coefficient of 1 indicates that all of a node's neighbors are themselves connected. A clustering coefficient of 0 indicates that none of a node's neighbors are connected to one another. This provides a measure of local clustering, as opposed to more global measure of density assessed with in-degree above. The late-talkers in the present study show a lower average clustering coefficient than late talkers when age is controlled ($\beta=-54.6$, $SE=21.991$, $p=0.0154$) and a near significant effect when vocabulary size is controlled

($\beta=34.53$, $SE=18.33$, $p=0.0638$). Figure 5 shows the clustering co-efficient as a function of vocabulary size for the two groups. As is apparent from the data points, there is both more variability by this measure among the youngest later-talkers than typically developing children and typically developing children appear to move toward a stable clustering coefficient earlier than do late talkers. The lower average clustering coefficient of late talkers suggests that they are less likely to learn words that fill out categories of closely related words that they already know, a result that again suggests that there may be fewer dependencies between new acquisitions and already learned words. Being unable to fill out categories of closely related words, these late talkers may have trouble reorganizing their current semantic understanding to create new categories and concepts.

Figure 5: A graph of the clustering coefficient as a function of vocabulary size. The black line indicates typical talkers and the lighter line, late talkers (lm , $p=0.064$).

Redundancy.

Redundancy captures the robustness of the network: in a highly redundant network, if a random connection is deleted, the deleted link will not alter the likelihood of a connected path between two words. For example, with a road network, if there are multiple ways to get between two places, then a road closure is not an insurmountable problem. However, if only one road connects two locations, then a closure of that road makes the two locations inaccessible to one another. Higher redundancy means more possible paths. As opposed to clustering coefficient and in-degree, redundancy provides a measure of the ease of accessibility in the network (from one node or word to another). Compared with the clustering coefficient, this provides a more global measure of cohesion across the network.

Regression analyses yielded significant differences between the two groups, with late talkers having less redundant networks when controlling for age ($p<.001$) and

vocabulary size ($p=0.015$). To quantify this, for a given network of 200 words, a late talker would have on average 11 possible pathways compared to 13 possible paths in a network for a typical talker (t -test, $p=0.016$, comparing all late talkers/typical talkers). Though this difference is small, the actual implication of this difference is that late talkers have many words that have only one or two connections, whereas typical talkers have fewer words with low redundancy suggesting a network more robust to change.

The difference in the number of possible pathways between nodes across the two groups suggests that the robustness of the two groups is also different. The typical talkers, building more redundant networks, are less likely to have trouble transitioning from one area of the network to another. The fluidity of their productive speech also would be less hampered by the forgetting of a few words. By having multiple ways of getting from one word to another, the typical talkers may more easily access one word following another. These differences may relate importantly to the word-finding and word-retrieval difficulties of late talkers, an important question for future work.

Average geodesic distance.

Geodesic distance represents shortest path length between two nodes. We computed the geodesic distance between all nodes excluding isolates or unconnected nodes. We then averaged the geodesic distance for all nodes, further excluding all cases in which there was no traversable path between two nodes. As networks grow larger, more connections are possible and the geodesic distance, or the shortest distance between two nodes, will often trend toward less than 2. This happens when a word that connects to all other words, such as “you”, is added to the semantic network. If word A is not directly connected to word B, word A is connected to word B through “you”, resulting in an average geodesic distance of approximately 2.

Late talkers have significantly different geodesic distances from typical talkers. When considering networks of similar size (i.e. words known), we see that typical talkers having a mean geodesic distance of 1.82 and late talkers having a mean geodesic distance of 2.55 (t -test, $p=0.0276$).

Another indication that these at-risk children are building networks with less global structure is the number of components in a network. Components are isolated clusters or words of a network that do not connect to other components in a network. Early on in vocabulary learning, it is possible to learn a word, or words, in complete isolation that is not semantically related to any other word or cluster. For example a child might learn a bunch of animals and a bunch of food words but be missing words like milk that would link the two clusters. Of the children in this study only 17 children showed networks that had more than one component, 14 of which are classified as late talkers.

The difference in geodesic distance and number of components suggests that late talkers are not building networks that allow for the same level of global access.

Discussion

The present study is the first analysis of the network structures of early vocabularies for individual children and the first to reveal potentially meaningful individual differences in the structures of these emerging networks. As such, there are still open questions and limitations that will need to be addressed. These include comparisons to randomly selected vocabularies of different sizes, linking of these differences in vocabulary structure to performance (such as word retrieval), and following individual children’s vocabulary growth. Nonetheless, the results provide three new insights: (1) Small-world properties are evident in the network structure of even very small and early vocabularies; (2) these properties are not the consequence of just learning any subset of early English words since—at any vocabulary size—there are individual children with more robustly connected networks than other children; and (3) the structure of these individual differences in network connectivity appears related not just to vocabulary size but to the rate of vocabulary development with children at risk for serious language deficiencies (by normative standards) showing less cohesive and less efficiently structured networks.

The broad sample of typically-developing children, children above the 20th percentile and who are not at risk for language deficiencies, show less variance in network structure, specifically clustering coefficient in our analysis, than do the late-talking children, a remarkable fact in its own right. These typically-developing children seem to be building semantic networks with many of the small-world properties found in adult semantic networks, showing higher in-degree, clustering coefficient, and redundancy, indicating that typical talkers are learning words more cohesively, with more semantic connectivity between learned words—both globally and locally—than do the networks of late talkers. Late talkers are not only learning more slowly but appear to be learning differently. One possibility consistent with the present pattern is that typically developing children build their vocabularies in ways such that learning itself is dependant on the semantic relations among already learned words or the semantic relations in the learning environment (Hills et al, 2009b) whereas late talkers just learn words, adding words as individual and unrelated items, not picking up on the semantic relations in the learning environment.

Because the semantic relations in these networks are themselves normative—reflecting the structure of the general learning environment and not the child’s specific learning environment—it is also, in principle, possible that these children’s learning environments present less semantic connectivity. Previous research has shown that learning environments, in terms of the kind and number of words that are spoken to children, do influence the kinds and number of words that children learn (e.g., Hurtado, Marchman & Fernald, 2008; Rowe, 2008; Hoff & Naigles, 2002; Huttenlocher et al, 1991). However, contemporary understanding of language-delayed children suggests that this may not be the sole factor in these delays (see Bishop &

Leonard, 2000). Still, a more detailed examination of individual language learning environments is in order.

Our evidence suggests that typical talkers are more likely to acquire words that share semantic associations with words they already know. This may be a consequence of the fact that they are more sensitive to semantic associations in the environment (what has been called *preferential acquisition*), or that they are more likely to use known words to direct the acquisition of new words (called the *lure of the associates*). Previous work has shown that both of these processes are predictive of word acquisition (Hills et al., 2009b), but these processes may also represent individual strategies for learning. This suggests an interesting direction for future research in individual differences in language acquisition.

Abstract

Parents provide children with both genes (nature) and linguistic input (nurture). A growing body of research demonstrates that individual differences in children's language are correlated with differences in parental speech. Although this suggests a causal link between parental input and the pace of language development, these correlations could reflect effects of shared genes on language, rather than a causal link between input and outcome. We explored effects of maternal input on English vocabulary development in internationally-adopted (IA) children—a population with no genetic confound. IA preschoolers demonstrated some of the same correlations with input as in previous studies; specifically, measures of input quality were significantly correlated with vocabulary. However, IA infants did not demonstrate this pattern. Differences between the age groups may be related to the pace of acquisition; more rapid vocabulary development in the preschoolers suggests that access to, and children's ability to make use of input, may be a limiting factor for the infants.

Introduction

There is a growing body of research demonstrating that individual differences in children's linguistic abilities are correlated with differences in parental speech (e.g., Hart & Risley, 1992, 1995; Hoff, 2003b; Zimmerman et al., 2009). While these studies and others strongly suggest that variation in parental language input contributes to variability in language development, such studies have an unavoidable confound: biological parents provide children with linguistic *and* genetic input. In fact, twin studies consistently find that language skills have moderate to high heritability (Stromswold, 2001) and Plomin and Dale go so far as to say “a case could be made that verbal measures are among the most heritable traits” (2000, p. 39). Rather than a direct causal link between input and outcome, these correlations between parental input and child outcomes could potentially reflect direct effects of shared genes on the verbal abilities of both parties. Here we investigate the role of maternal input in children's vocabulary acquisition when the influence of genetics is absent.

We start by discussing the existing literature on variability in maternal input and evidence for relations between input and child language outcomes. Then we present two experiments with IA children adopted at different ages to explore potential differences in uptake related to different paces of language acquisition. Then we conclude by discussing recent findings on the role of genetics in language development and how our results reconcile the gene-environment confound present in previous studies.

Variability in Maternal Language Input

An early study of differences in caregiver input (Elardo, Bradley, & Caldwell, 1977) investigated the home environment and language abilities of 74 typically developing children living in an urban setting. The majority of the children were African-American and one-third were on welfare at the time of the study. Caregiver input was measured via a home environment assessment (the Home Observation for Measurement of the Environment; Caldwell, Heider, & Kaplan, 1966) and children's language abilities were assessed with the Illinois Test of Psycholinguistic Abilities (Kirk, McCarthy, & Kirk, 1968). The study found that maternal involvement, maternal responsiveness, and providing appropriate play materials had the strongest correlations with children's language.

This study is part of a growing body of research linking individual differences in caregiver demographics to differences in their speech (e.g., Hart & Risley, 1992, 1995; Hoff, 2003b). In their seminal paper, Hart and Risley (1992) described the qualitative aspects of parental speech in 40 diverse families. The qualitative aspects of the parents' speech to their children were strongly related to socioeconomic status (SES); parents of higher SES were more verbal and had higher quality verbal interactions with their children. Hoff (2003b) found that mothers' mean length of utterance, number of word types, and number of tokens were each uniquely correlated with SES. Hoff also found that mothers' speech to adults varied with SES (2003a).

More recently Huttenlocher and colleagues examined caregiver speech to young children from 50 ethnically and economically diverse families via home video recordings (Huttenlocher, Vasilyeva, Waterfall, Vevea, & Hedges, 2007). Data were presented from 5 different time points collected when the target children were between 14 and 30 months old. The authors analyzed the composition of speech, the diversity of speech, and the quantity of speech. The results suggest that caregivers' education levels were significantly predictive of the quantity of spoken language and that this relation was more predictive than family income level. They also found that the complexity and diversity of caregiver speech increased linearly over time, while input quantity remained relatively stable.

Effects of Input on Language Development

One might expect such significant SES-related differences in maternal speech to affect children's language development; this is precisely what is found (see Whitehurst, 1997 for review). In an early study with middle-

class mothers Huttenlocher et al. found that the quantity of maternal language spoken significantly correlated with children's vocabulary growth from age 14 to 26 months (Huttenlocher, Haight, Bryk, Seltzer, & Lyons, 1991).

In a study of 22 mother-child dyads varying in SES Hoff-Ginsberg (1986) found several aspects of mothers' speech to correlate with children's language outcomes during the third year of life. Both functional and structural characteristics of maternal speech were predictive of children's language outcomes (e.g., the average number of noun phrases per utterance in maternal speech was predictive of the same feature in children). Another study by Hoff-Ginsberg (1998) found differences between siblings relating to birth order, though genetic influences are similar among siblings.

More recently, in a study of 33 high-SES families and 30 low-SES families Hoff (2003b) found that maternal mean length of utterance, number of word types, and number of word tokens were each uniquely predictive of children's vocabulary size. SES-related differences in maternal speech mediated children's language development such that children with low-SES mothers heard (on average) less rich language input and consequently had less developed language abilities. This finding is supported by a recent review of the literature on how SES relates to brain development (Hackman & Farah, 2009). Hackman and Farah reviewed studies of SES effects on neurocognitive development and found the strongest effects of SES on the brain areas associated with language and executive function.¹

In a more recent study focused on children learning Spanish as a first language, Hurtado and colleagues found that maternal input correlated with children's vocabulary growth from 18 to 24 months (Hurtado, Marchman, & Fernald, 2008). In addition, speed of word recognition at 24 months was related to quantity of maternal input. The effects of maternal speech on vocabulary size and word recognition speed overlapped considerably, suggesting that these abilities work together in lexical acquisition. Taken together these findings suggest that the observed correlations between parental input and child output may reflect a causal role of the input in language development (see also Weizman & Snow, 2001).

The Current Study

The current study extends this work by exploring the effects of maternal input on early vocabulary development in internationally-adopted (IA) children—a population which eliminates genetic confound. We previously demonstrated that early language acquisition in this population shows the same qualitative patterns that characterize typical language development, suggesting that similar learning processes may be at work (Snedeker, Geren, & Shafto, 2007).

In a more recent study (Snedeker, Geren, & Shafto, in press) we found that the rate of vocabulary acquisition in IA

infants was explained primarily by chronological age, while the rate of acquisition in IA preschoolers was explained primarily by time spent learning (i.e., months in the U.S.). Additionally, the preschool-aged IA children acquired English significantly faster than the IA infants, suggesting that for children adopted at older ages the developmental patterns in the early stages of English acquisition occur on an accelerated time table. The quantity and nature of language input may be even more critical to the pace of acquisition in older learners. The current study explored this possibility through experiments with children adopted in two distinct age groups.

In Experiment 1 we assessed English vocabulary in IA children adopted during the preschool years. In Experiment 2 we assessed English vocabulary in IA children adopted as infants, who may not learn English at such an accelerated rate due to less advanced cognitive abilities (e.g., memory). We tested two age groups to explore potential differences in the effects of maternal input due to differences in the pace of language development.

Experiment 1

Method

Participants Twenty-nine children aged 2;9 to 5;2 years who were adopted from Eastern Europe and China between the ages of 2;5 and 4;11 (M: 3;1 years) and had been in the U.S. for 0.5–6 months (M: 3.4 months) at the first assessment. All children were adopted by monolingual English speakers and were typically developing.²

All of the children were adopted into upper-middle class homes, with the majority of mothers having earned graduate or professional degrees (N=17). The other mothers earned a college degree (N=9) or attended some college (N=3).

Materials & Procedure Parents participated in monthly sessions until their child had been in the U.S. for 6 months; thus each child had 1–6 sessions (total=63). For each session parents completed the Words and Sentences form of the MacArthur-Bates CDI³ (CDI-2; Fenson et al., 2006) and recorded a language sample in their home. Families were sent a standard box of toys to use for the language sample, which were an average of 27 minutes long and were transcribed and analyzed using the CLAN program (MacWhinney, 2000).

Measures Once the language samples were transcribed, maternal utterances were coded for quantitative and qualitative features. The maternal input *quantity* variable was the number of words spoken per minute. Maternal input *quality* variables included: mean length of utterance (MLU), the number of word types spoken per minute (a measure of input diversity), percentage of utterances that were yes/no

¹ These findings are preliminary and do not preclude effects of SES on other cognitive domains.

² According to a parent report.

³ We validated the use of the CDI-2 with this population in a previous study (Snedeker et al., in press).

questions (*Is that your crayon?*), percentage of utterances that were wh-questions (*What color is that?*), and the percentage of utterances that were alternative questions (*Do you want to play with the truck or the car?*).

Because children had varying numbers of sessions, the maternal input variables were calculated for each session, and the average values for each variable were used as the predictors for that child. This means that for children with more than one recording session, no particular data point was chosen for use (which could have biased the results), and no data points were represented more than once in the analyses.

Results

CDI-2 ‘norms’ were calculated using data from a larger study of IA preschoolers ($N=182$). Stepwise regressions were conducted on CDI-2 vocabulary score with Time in the U.S. ($R^2=.54$, $p<.001$) and Age of Arrival ($R^2=.03$, $p<.001$) as predictors.⁴ Results were used to calculate standardized residual scores (SRSs) for vocabulary for the final session of the 29 participants in the current study. Specifically, the SRSs were used as a measure of how different children’s reported vocabularies were from their predicted vocabulary. Thus a negative SRS would indicate that a child’s reported vocabulary was lower than would be predicted by their Age of Arrival and Time in the U.S.

As a first pass raw correlations were conducted between the maternal input variables and children’s SRS (see Table 1). Then step-wise regressions were conducted on children’s SRSs using the maternal input variables (averaged across sessions) as predictors. At Step 1 maternal word types per minute was a significant predictor of SRS (adjusted $R^2=.56$, $p<.001$; see Figure 1). This suggests mothers with more diverse input had children with higher SRSs; their children exceeded their predicted vocabulary by larger amounts.

Figure 1: IA Preschoolers’ Vocabulary SRSs by Diversity of Maternal Input (Experiment 1).

⁴ Children’s Age at Test was not used as a predictor because it was significantly positively correlated with both Age of Arrival ($r=.95$, $p<.001$) and Time in the U.S. ($r=.19$, $p<.05$).

Percentage of maternal utterances that were yes/no questions accounted for additional variance (adjusted $R^2=.07$, $p<.001$) suggesting that mothers who asked more yes/no questions had children with higher SRSs. This suggests that higher levels of prompting or engagement facilitated vocabulary growth.

Contrary to previous findings, words per minute (*quantity*) was not a reliable predictor of SRS (partial $R^2=.002$, $p=.70$). However, this may be due to the high correlation between words per minute and word types per minute (see Table 1).

Experiment 2

Method

Participants Seventeen children aged 1;7 to 2;8 who were adopted from China between 8 and 16 months old (M: 12 months) and had been in the U.S. for 7–20 months (M: 15 months) at the first session. All children were adopted by monolingual English speakers and were reported to be typically developing.

All children were adopted into upper-middle class homes, with the majority of mothers having earned graduate or professional degrees ($N=11$). The other 6 mothers had all earned a college degree.

Materials & Procedure Parents completed monthly sessions until their child was 32 months old; thus each child had 1–12 sessions (total=71). Three of the children had some of their language samples recorded with their father instead of their mother. In order to maximize homogeneity across the language samples for all participants, individual sessions that were recorded with the father were excluded from analyses. This left a total of 64 sessions for analyses.

Measures The same as in Experiment 1.

Results

First CDI-2 ‘norms’ were calculated for the IA infants using data from a larger study of IA infants ($N=223$). Step-wise regressions were conducted on CDI-2 vocabulary score with Age at Test ($R^2=.45$, $p<.001$) and Age of Arrival ($R^2=.03$, $p<.001$) as the predictors.⁵ Results were used to calculate standardized residual scores (SRSs) for the final session of the 17 IA infants in the current study. As a reminder, a child’s SRS represents the difference between their reported and predicted English vocabulary (i.e., a z score).

As in Experiment 1, raw correlations were first conducted to determine the relations between the maternal input variables and children’s SRSs (see Table 2). Step-wise regressions were then conducted on children’s SRSs using maternal input variables (averaged across sessions) as predictors. The percentage of alternative questions

⁵ Time in the U.S. was not used as a predictor because it was significantly correlated with both Age at Test ($r=.89$, $p<.001$) and Age of Arrival ($r=-.28$, $p<.001$).

Table 1: Correlation matrix for Experiment 1 (IA preschoolers).

Measure	Words per minute	MLU	Word types per minute	Yes/no questions (% of utterances)	Wh-questions (% of utterances)	Alternative questions (% of utterances)
Words per minute (word tokens)	---					
MLU	.56**	---				
Word types per minute	.82**	.57**	---			
Yes/no questions (% of utterances)	.04	.14	.06	---		
Wh-questions (% of utterances)	-.29	-.03	-.05	.50**	---	
Alternative questions (% of utterances)	-.14	.02	-.03	.51**	.65**	---
Standardized residual vocabulary score (SRS)	.64**	.53**	.76**	.33	.01	.07

** $p < .01$

Table 2: Correlation matrix for Experiment 2 (IA infants).

Measure	Words per minute	MLU	Word types per minute	Yes/no questions (% of utterances)	Wh-questions (% of utterances)	Alternative questions (% of utterances)
Words per minute (word tokens)	---					
MLU	.61**	---				
Word types per minute	.57*	.62**	---			
Yes/no questions (% of utterances)	-.14	-.19	-.09	---		
Wh-questions (% of utterances)	-.12	.00	-.26	.52*	---	
Alternative questions (% of utterances)	.48 [†]	.41	.09	.02	-.12	---
Standardized residual vocabulary score (SRS)	.40	.16	.18	.20	-.21	.70**

[†] $p < .06$, * $p < .05$, ** $p < .01$

(e.g., “Do you want to play with the truck or the car?”) was the only significant predictor of SRS (adjusted $R^2 = .47$, $p < .01$). Mothers who asked more alternative questions had children with higher SRSs—children who exceeded their predicted vocabulary by greater amounts (see Figures 2 and 3).

Contrary to Experiment 1, maternal word types per minute and percentage of yes/no questions were not reliable predictors of SRS (adjusted $R^2 = -.03$, $p = .51$; adjusted $R^2 = -.001$, $p = .33$, respectively). This suggests that the features of maternal speech that seem to influence English vocabulary growth in IA children adopted as preschoolers might be less influential for IA children adopted as infants. Alternatively, the smaller sample size in the infant group may have made any additional effects of maternal input variables undetectable.⁶ As in Experiment 1, but contrary to previous findings, words per minute (input *quantity*) was not a reliable predictor of SRS (incremental $R^2 = .005$, $p = .72$). Unlike in Experiment 1, the raw correlation with words per minute was not significant either (see Table 2). However, the correlation value was moderate (.40), so one possibility is that the effect was suppressed by the variability present in our small sample.

⁶ For a moderate correlation ($r = .5$) with power of 80% a minimum sample size of 28 children is needed.

General Discussion

There were significant relations between some *qualitative* aspects of maternal input—maternal word types and yes/no questions—and English vocabulary ability for the preschool-aged IA children. This is in accord with previous findings of a positive relation between maternal input and children’s vocabulary development. Curiously, the relation between input and outcome differed in the two age groups. This difference occurred despite the fact that both age groups were adopted into families with similar SES (high), and thus were like the professional families from Hoff (2003b) who received quite rich language input.

One possible explanation for the difference between age groups is that perhaps older children are more sensitive to variation in input. IA children in both age groups are receiving input that is likely greater in quantity and quality than the general population (due to their high SES environment). However, the IA infants may be immersed in such a rich language environment that their maturational status may be limiting their ability to take advantage of the high quality and quantity of the input they are receiving. Specifically, the IA preschoolers may be more ready to make use of the input because their other cognitive skills (e.g., memory) are more fully developed. They can learn

Figure 2: IA Infants' Vocabulary SRSs by Diversity of Maternal Input (Experiment 2).

Figure 3: IA Infants' Vocabulary SRSs by Alternative Questions in Maternal Input (Experiment 2).

faster so input is more likely to be a rate-limiting factor. It may also feel more natural to speak more to an older child (IA preschooler) and more input likely results in greater variability in input that the child can exploit. There may be less variation in the input for the IA infants, providing less for the child to exploit.

Contrary to previous studies, we did not find a significant effect of maternal input *quantity* on vocabulary. However, the raw correlations between input quantity and vocabulary were significant for the IA preschoolers. The correlation likely disappears when put into the regression due to the high correlation between number of words and number of word types, with number of word types soaking up all the variance in children's SRS. This suggests that the amount of input may have an effect, but it is suppressed by effect of the input diversity. Another possible explanation for the discrepancy between the IA children in this study and prior findings is that there is a ceiling effect for the effect of environment. Specifically, there is evidence suggesting that environmental contributions may be greater in low-SES samples where environment is likely to be the limiting factor, and smaller in high-SES samples where it is less likely to be the limiting factor (Turkheimer, Haley,

Waldron, D'Onofrio, & Gottesman, 2003).

However, there is an important difference between the current study and previous ones. Previous studies have an unavoidable confound of environmental (often indicated by SES) and genetic influences on children's language development. Variation in parental language input may contribute to variability in language development, but biological parents provide their children with both linguistic and genetic input. Thus it is possible that correlations between parental input and child outcomes in previous studies reflect direct effects of shared genes on verbal abilities, and not a direct causal link between input and outcome. So what is the role of genetics in language development?

The Role of Genetics in Language Development

As part of the Twins' Early Development Study (TEDS) thousands of twins were studied to investigate the roles of environmental and genetic factors in children's language development (Oliver & Plomin, 2007; Plomin & Dale, 2000). One motivation for TEDS was a consistent set of findings from adoption and twin studies suggesting a significant effect of genetics on language ability. Although the early findings suggest that nonverbal and verbal abilities have a similar genetic correlation and are moderately correlated with each other (Plomin & Dale, 2000), later studies suggest a stronger environmental influence (Spinath, Ronald, Harlaar, Price, & Plomin, 2003). The myriad of studies published on TEDS data also suggest that the relative potency of genetic and environmental influences changes over time (Oliver & Plomin, 2007).

The genetic confound present in many studies of the effect of input on children's language development was removed in another recent study, which explored effects of teacher input on syntactic development (Huttenlocher, Vasilyeva, Cymerman, & Levine, 2002). The study measured children's syntactic growth over a school year and found it was predicted by qualitative aspects of their preschool teacher's syntactic input, suggesting a direct effect of input on acquisition. According to the authors, this pattern of findings suggests that observed correlations between language input and output in prior research may reflect a causal role of input in language acquisition. While it is true that these results cannot be explained by genetic factors, the focus was only on syntax. Also, when thinking about the effects of input over time it is likely that any effect of input would be compounded and thus we should expect significant predictive links with overall ability as well.

Conclusions

Like populations of children learning their first language from birth, maternal input (nurture) significantly correlated with English vocabulary development in IA children. These relations were strong despite the fact that IA children share no genetic influence (nature) with their adoptive parents. This reconciles the gene-environment confound present in previous studies and provides additional support for the role

of maternal input in children's vocabulary development. In addition, the inclusion of two different age groups provided insight into the contexts in which effects of language input are likely to be largest.

The development of language depends on many things including input, general cognitive skills (e.g., memory), etc. When cognitive skills are well developed and language acquisition is rapid, then the pace of language development is most likely to depend on the variation in input. Thus we see maternal input effects in the preschool-aged IA children even though the amount of (and variation in) input for all children was quite high. In contrast, when the pace of language acquisition is slower because cognitive skills are still developing, then language input may be less likely to be a limiting factor—particularly for children who are in input-rich environments (i.e., IA children).

Acknowledgments

We would like to thank Abbie Clafin, Nicole Gavel, Ellen Godena, Candice Ishikawa, Corinne Jones, Eva Liggett, Angela Lou, John Ste Marie, Ryan Sykora, Cathy Tillman, and K. Yvonne Woodworth for assistance with data collection and transcription; Katie Felkins for her endless assistance over the years; and the families who participated for their altruism. Who's afraid of similarity? Effects of phonological and semantic similarity on lexical acquisition.

Sarah Devi Sahni (sdsahni@gmail.com)

University of Wisconsin – Madison, Department of Psychology

Abstract

Children are sensitive to statistical regularities in speech and likely use these regularities when learning their native language. A central goal of current research is to understand which statistical regularities support different aspects of language acquisition and processing. In the current work we explore phonological and semantic similarity effects on early lexical acquisition. Using a computational model, behavioral findings from word learning studies are simulated and explored. With this model we demonstrate that acquisition can be facilitated by the distinctiveness of individual lexical mappings.

Introduction

Language acquisition research has robustly shown that children are sensitive to statistical regularities in speech, and utilize these regularities when learning their native language (for a review see Saffran & Sahni, in press). A central goal of current research in language acquisition is to understand which statistical regularities support different aspects of language acquisition and processing. Research on adult language processing has revealed that statistical regularities across words can affect lexical access and recognition (Dahan & Magnuson, 2006). Much of this work has examined effects of phonological similarity. Nevertheless, researchers have also examined the effects of semantic similarity along with phonological similarity (e.g. Mirman & Magnuson, 2008).

Phonological and semantic effects in lexical *acquisition* have also been examined. However, little of this work has simultaneously examined phonological and semantic effects in the same set of stimuli or set of studies. In the current work we used a computational model of word learning to investigate the influence of phonological similarity and semantic similarity on early word learning.

Phonological Similarity

Numerous researchers have shown that phonological similarity influences lexical recognition, recall, and access in adults (Dahan & Magnuson, 2006; Luce & Pisoni, 1998; Vitevitch & Luce, 1998; Vitevitch, Luce, Pisoni, & Auer, 1999). Luce's work demonstrates how lexical items that differ by a single phoneme (phonological neighbors) can be simultaneously activated and compete with spoken input (Luce & Pisoni, 1998). While this adult work suggests that phonological similarity impedes lexical processing, developmental work on phonological neighbors suggests that phonological similarity may aid typical lexical acquisition. Storkel (2004) examined whether phonological neighborhood density (together with word frequency and

word length) could predict the age of acquisition of early vocabulary items from the MacArthur-Bates Communicative Development Inventory (MCDI) lexical production norms (Dale & Fenson, 1996). She found that words with more phonological neighbors were acquired earlier than words with fewer phonological neighbors, even after accounting for effects of frequency and length. These results suggest that sound similarity (high phonological density) facilitates lexical acquisition.

In contrast with Storkel's work (2004), many nonce word learning studies suggest that infants struggle to learn words that are phonologically similar to one another or to words they already know. Using a habituation task, Stager and Werker (1997) found that 14-month-old infants were able to associate two novel labels with novel objects, but only when the labels were phonologically distinct, like *lif* and *neem*. Infants were unable to map phonologically similar labels *bih* and *dih* to separate objects. This result was quite surprising because using a similar task infants could discriminate the phonemic /b/-/d/ contrast at 8 months (Stager & Werker, 1997). Yet, it was not till 20-months that infants showed clear evidence of learning labels that differed on this contrast (Werker, Fennell, Corcoran, & Stager, 2002).

What can account for these disparate research findings? One important aspect of the child's environment that was not examined in this work is the referent or concept that labels map to. As similarity between labels affects lexical acquisition, it is likely that similarity between referents also affects acquisition. While there has been a significant amount of work investigating how young children will extend category labels based on referent properties', little work jointly examines the role of the label and the role of the referent in lexical acquisition.

Semantic Similarity

Some of the most interesting and revealing work on semantic development investigates label extension and categorization (Quinn & Johnson, 1997; Rakison & Oakes, 2003; Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976). Much of this work has emphasized how the structure of the environment enables infants to group objects and apply category labels to those groups. Their world is well structured; meaningful correlations occur and reoccur, while arbitrary correlations are rarely repeated. This experience allows children to tune into the meaningful and useful correlations in their world.

Research on the shape bias in categorization elegantly demonstrates how the structure of the environment can facilitate language learning. Many of the first words infants learn refer to categories of objects organized by shape.

Experience with these words seems to facilitate categorization abilities. Infants who know 150 words or more, can readily generalize names for newly learned objects to other objects with similar shapes while infants with less than 150 words cannot (Samuelson & Smith, 1999). Samuelson & Smith hypothesized that as children learn more words they extract organizing regularities and form generalizations. These generalizations may initially be restricted to a specific category (e.g. all spherical objects are balls). Then with increased exposure to labeled categories infants form second-order generalizations (e.g. things that are the same shape share a label). These generalizations allow infants to learn the category structure of the objects in their world. Crucially, it is only through sufficient exposure that infants' acquire higher-order generalizations and learn that objects that are the same shape are likely to share a label. If children acquire this bias due to the statistical regularities of the words they know, they must have significant experience with words organized by shape.

Storkel and Adolf (2009) assessed the effect of semantic set size on preschoolers' ability to learn new words. Semantic set size was defined as the number of objects that are meaningfully related to the target word. Subjects showed no difference in initial acquisition of items with large and small set sizes. However, one week after the initial test subjects showed better memory for objects with smaller set sizes. These results suggest that children can learn words more easily when they have a smaller semantic set size and the objects are more unique.

Rogers and McClelland's (2004) categorization model similarly predicts that it will be difficult to learn unique names for items that share many features with other items. Rogers and McClelland hypothesized that infants are sensitive to correlations among different types of directly observable features. These features, which co-occur in the exemplars of a single category, cannot individually define a category. Nor can a specific set of necessary and sufficient features define any category, there are always exceptions. However, the features that consistently co-occur, though not necessarily in every instance of a category, can define a category. For example, birds tend to fly, and have feathers, wings, and beaks. While these features do not always co-occur (penguins have wings but cannot fly) they frequently do and are said to coherently covary with one another. As infants interact in and explore their world they are naturally exposed to these correlations and regularities. Infants are sensitive to the coherent covariation and can use these constellations of features to identify new members of a category. Based on this work, two objects that share many properties will easily map to the same label. While this is beneficial when forming categories, it may be an impediment to children learning the names of similar objects, like "cup" and "glass".

In the current work we use a computational model of word learning to explore effects of phonological and semantic similarity on word learning. Research on phonological similarity is unresolved and suggests similarity

facilitates lexical acquisition in some situations but hinders acquisition in others. We propose that by using a computational model to explore effects of phonological and semantic similarity in a single task, we will be able to better understand this phenomenon.

Methods

The main goal of the model was to simulate behavioral experiments that tested infants' abilities to learn similar sounding labels (Werker & Fennell, 2004). In these studies, infants viewed novel objects on a video screen that were audibly labeled with a nonce word. Infants were repeatedly shown these stimuli until their interest had decreased and they were habituated. After habituation, infants received "same" and "switch" test trials. The same trials were the same as habituation trials. In switch trials the objects paired with each label were switched. That is, in switch trials *dih* was paired with the *bih* object, and *bih* was paired with the *dih* object. Longer looking times to switch trials were interpreted as dishabituation and evidence that children learned the mappings.

Architecture

The architecture of the model is presented in Figure 1. The model was composed of three layers: semantic, hidden and phonological. The phonological layer was the input layer and had 192 units (16 units coding phonetic features for each of 12 possible phonemes), the hidden layer had 200 units, and the semantic layer was the output layer and had 135 units. The semantic and phonological layers had recursive units as well as lateral connections between units within the layers. The semantic layer was the output layer over which targets were set and error was calculated.

Figure 1: Network Architecture

Training

Three networks initialized with different small random weights, were trained on 332 nouns from the MCDI production checklist (Fenson, et al., 1994). The networks' task was to learn the mapping from phonological labels to semantic referents. Networks were presented with a label on the phonological layer and were to activate the correct set of semantic features describing the referent on the semantic

layer. For example, networks that had learned the word *dog* would activate the 44 semantic feature units that describe a dog (i.e., eats, has tail, is fun, is lovable, etc.) when presented with the phonological representation of *dog* across the phonological input layer.

Networks were trained using standard backpropagation (Rumelhart, Hinton, & Williams, 1986), with cross-entropy error calculated across output units. The learning rate was set to .005 with no momentum. Networks were trained in batches of 20 words. Output activations and weight matrices were saved every 500 training trials to evaluate the course of learning. Training for each word continued until the activation of each semantic output unit was within 0.2 of its target value or training was manually halted for testing.

Testing

To simulate the behavioral experiments, an analog of habituation and the same-switch procedure was used to test the networks. The networks were trained to differing levels of vocabulary size to simulate the different ages at which infants succeed and fail at the task. At these different stages of training the habituation and same-switch test procedures were simulated in the models.

In the behavioral work by Werker and colleagues (Werker & Fennell, 2004), infants were initially habituated to the stimuli. That is, they were repeatedly exposed to label-object pairs until their looking time decreased by 50%. They were next shown “same” and “switch” test trials, in which the label-object pairing from habituation was either preserved or switched. An increased looking time to the switch trials indicated dishabituation and acquisition of the label-object pairings.

As with infant participants the networks were habituated to the stimuli. Error across the output layer served as the model analog to looking time (Schafer & Mareschal, 2001). To establish the baseline error rate for the habituation phase, models were presented with correct label-object pairings for either *bih-dih* or *lif-neem*. After the first presentation of the novel words, activation on the semantic layer was recorded and compared to the semantic representation of the appropriate referent. This error value provided the baseline error rate for the habituation phase. Models were trained on the pair of novel words until error on the output layer reduced by 50% of baseline. Models were next tested with same and switch trials. On both same and switch test trials error across the semantic output layer was recorded. This error represented the mismatch between a model’s expectations and the semantic target of the nonce label. As with infant looking times, larger error indicates surprise and dishabituation from training (Schafer & Mareschal, 2001).

Phonological Representations

Phonological representations of the MCDI nouns and nonce words were based on representations from Joanisse and Seidenberg (1999). See the appendix for a list of features used to represent the phonemes of each word. These representations were slot-based and centered on the first

vowel such that when words were compared, phonemes in the same slot position were compared with one another. For example, the words /sta:r/ and /ka:r/ were aligned in vowel-centered slots such that the /a:r/s were aligned even though /sta:r/ has two initial consonants while /ka:r/ only has one.

Slot-based representations have known limitations and can cause delays in training (Plaut, McClelland, Seidenberg, & Patterson, 1996). In these representations phonemes across slots are independent from one another, and cannot facilitate learning across slots. Therefore though knowing the word *pencil* may facilitate acquisition of *penguin* because of the word-initial overlap, knowledge of neither *penguin* nor *pencil* can facilitate learning *playpen*, which has a word-final *pen*. Despite these limitations, vowel-centering has been shown to minimize this problem (Harm & Seidenberg, 1999).

Semantic Representations

Semantic representations of the MCDI nouns were taken from Howell, Jankowicz & Becker (2005). Howell et al. used a set of 97 perceptually grounded features to code each word in the MCDI (see the appendix for a list of all features). These features were a subset of the McRae, de Sa, and Seidenberg (1997) empirically derived feature set. Howell et al. chose to use only features that were directly observable by children 8 to 28 months old. They then gathered ratings on these 97 features from human raters for each concept on the MCDI. The final vector for each concept was created by averaging raters’ scores.

Howell et al.’s patterns were composed of graded values that varied between 0 and 1, but the majority of features in the set were binary in nature (e.g., “is solid”, “is young” etc.). Therefore, all of the conceptually binary features were re-coded as 1’s and 0’s, with values above .5 becoming 1 and the remaining becoming 0. There were an additional 19 features that coded continuous dimensions (e.g., size, speed, colorfulness, etc.). These features were split into three units representing low, medium and high values of the feature. If a concept had a 0 on one of these continuous dimensions, the high, medium, and low units for that feature were all set to 0. This transformation resulted in semantic patterns using 135 units.

In addition to referents of words from the MCDI, representations for novel referents were created. To create these semantic representations an adult coder, blind to the hypotheses of the studies, looked at pictures and read descriptions of stimuli from published papers. Based on these pictures and/or descriptions each semantic feature was coded as 1 or 0, present or not present, for each novel object.

Results

Word learning experiments conducted by Werker and colleagues (2004) tested children between 14 and 20 months of age. To simulate results over this age range, we used the MCDI norms (Fenson, et al., 1994) to calculate the average number of words children at 14 months can understand. The

norms indicate that the majority of 14-month-olds know at least 64 words. The models reached this level of comprehension at 2500 weight updates. The MCDI comprehension norms do not have data on children older than 16 months, therefore a point later in training that corresponded to a larger vocabulary, 6500 weight updates and 306 known words, was used to simulate the 20-month data point.

We began by simulating the 14-month old studies. Weight matrices produced after 2500 training updates with the full MCDI vocabulary were loaded onto the models. Representations of the two nonce objects were paired with one label from each pair. As with the behavioral studies, the same nonce objects were used for *bih-dih* and *lif-neem*. Networks were habituated and tested with the same-switch procedure as described in the methods sections. All three models showed a larger switch preference when learning *lif* and *neem*, compared to *bih* and *dih* (see Figure 2). This was consistent with 14-month behavioral data (Werker & Fennell, 2004). This indicates that similar to children, the models found the switch trials to be a greater mismatch from what was expected when learning *lif* and *neem*, than when learning *bih* and *dih*.

Figure 2: Switch preference for the three networks and infants from Stager and Werker (1997). Difference in error for the networks is labeled on the left y-axis and difference in looking time in seconds for behavioral data is labeled on the right y-axis.

A repeated measures 2 (trial type: same, switch) x 2 (nonce pair: *bih-dih*, *lif-neem*) ANOVA was run on output error from test trials. The main effect of trial type [$F(1,4)=529.571$, $p<.001$] was significant, showing increased error on switch trials for both pairs. There was also a significant interaction between trial type and nonce pair [$F(1,4)=132.42$, $p<.001$]. This result revealed that the switch preference for *lif-neem* was significantly greater than that for *bih-dih*. This replicates the crucial finding that dishabituation is significantly greater for labels that are distinct. The interaction between nonce pairs and test item type is a crucial replication of the Stager & Werker (1997) data.

This computational model of word learning maps phonological representations of labels to semantic feature representations of referents through a 200 unit hidden layer. Weights coming in and out of the hidden layer are adjusted

via the backpropagation algorithm. As the model is trained the hidden layer magnifies differences from the input that map to the correct set of semantic features. The activation across the hidden layer can be thought of as an internal representation of the input that maps to the correct features in the output. If two phonological labels produce similar patterns across the hidden layer, the model will more readily map these to similar referents.

To better understand the models' behavior, hidden layer activations of the nonce words were examined prior to habituation. These activations represent the model's ability to discriminate the nonce labels based on current vocabulary size and composition, but prior to training on the nonce items. Weight matrices produced after 2500 and 6500 training trials on the nouns from the MCDI were loaded onto the networks. The networks were then tested on the *bih-dih* and *lif-neem* mappings. Activations produced on the hidden layer were recorded and the distance between patterns for labels in each pair was calculated. That is, for each model we compared activation patterns produced across the hidden layer for the label *bih* with the activation pattern produced by *dih*. Similarly, the hidden layer activation pattern produced by *lif* was compared to the pattern produced by *neem*. Euclidean distance between the two patterns was calculated to assess the model's ability to represent the input as two separate items (see Table 1).

Weight Update	Label	Distance between labels		
		Net 1	Net2	Net 3
2500	<i>bih-dih</i>	0.93	0.78	0.78
2500	<i>lif-neem</i>	2.07	2.025	2.13
6500	<i>bih-dih</i>	1.80	1.58	1.74

Table 1: Euclidean distance between hidden representations of yoked label pairs.

After 2500 weight updates, the distance between hidden layer representations of *lif* and *neem* was greater than the difference between *bih* and *dih*. This greater difference shows that the model is better able to represent *lif* and *neem* as distinct labels. Hidden layer representations were also compared at 6500 weight updates when the model successfully maps *bih* and *dih* to distinct referents. With a larger and more diverse vocabulary, the difference between hidden layer representations of *bih* and *dih* is much greater, indicating that the more experienced model is better able to represent them as separate labels. However, the difference is still not as large as between *lif* and *neem* after 2500 updates, indicating that learning *bih* and *dih* when more experienced is possibly still harder than learning *lif* and *neem* at younger ages. This analysis indicates that with more experience the model is better able to represent the important differences between *bih* and *dih*.

Mapping to Distinctive Referents

A major goal of the current work was to examine the role of semantic similarity on lexical acquisition. In addition to

phonological similarity affecting acquisition it is likely the similarity of referents also affects word learning. To test this hypothesis, we created two new semantic patterns that were completely unique. Both patterns had 36 active semantic units, none of which overlapped. The units were chosen pseudo-randomly, and so patterns do not represent any real-world object. Using the same/switch method, we tested lexical acquisition of *bih* and *dih* and *lif* and *neem* paired with the distinct objects after 2500 updates. If semantic distinctiveness does not affect lexical acquisition, the interaction between test item type and label pair (*bih-dih* vs. *lif-neem*) should persist. Alternatively, if semantic distinctiveness can help to differentiate the label-object pairs, there should be no difference in the acquisition of *bih-dih* and *lif-neem*.

As seen in Figure 3, changing only the distinctiveness of the referents allows the model to learn *bih* and *dih* just as well as *lif* and *neem*. By making the referents of the two labels more distinct, similar-sounding labels are acquired as easily as distinctive sounding labels. A repeated measures 2 (test item type) x 2 (label pair) ANOVA was conducted to examine whether the acquisition of *bih-dih* differed from the acquisition of *lif-neem*, when they were mapped to distinct referents. While the significant main effect of test item type [$F(1,4)=482.437$, $p<.001$] persists, the interaction between test item type and label pair is no longer significant [$F(1,4)=.158$, $p=.711$]. Additionally, as seen in Table 2, hidden layer representations are further differentiated after training with distinct objects. This is true for both *bih-dih* and *lif-neem*.

Figure 3: Switch preference for three networks mapping to distinct objects and infants from Stager and Werker (1997). Difference in error for the networks is labeled on the left y-axis and difference in looking time in seconds for behavioral data is labeled on the right y-axis.

Conclusions

The natural world provides infants with strong correlations between linguistic structure and object properties. This structure supports the young child's difficult task of mapping labels to concepts and referents in their world.

In the present work we examined how structure among word forms and words referents can influence word learning. Word learning studies by Werker and colleagues (2004) suggested that high phonological density inhibits acquisition, while Storkel (2004) suggests that in some

contexts, phonological density should facilitate acquisition. Using a computational model of word learning, we explored the role that semantic referents of novel words may play in these findings.

Label	Training	Net 1	Net 2	Net 3
<i>bih-dih</i>	Prior to habituation	.832	.783	.78
<i>lif-neem</i>	Prior to habituation	2.01	2.02	2.11
<i>bih-dih</i>	Post habituation	2.43	2.57	2.53
<i>lif-neem</i>	Post habituation	3.8	3.93	3.36

Table 2: Euclidean distance between hidden representations of yoked label pairs when mapping to **distinct** referents.

The computational model examined effects of semantic and phonological similarity on the *process* of word learning. Using model analogs to habituation, we simulated the basic finding that it is difficult to learn similar sounding labels like *bih* and *dih*. By examining the hidden layer representations of these items we found that the surface similarity of the labels affected the model's ability to treat them as separate items. However, models were able to successfully map *bih* and *dih* to separate objects when the objects were completely distinct. Training with these distinct objects allowed the models to pull apart representations of words that had similar labels, as shown in Table 2.

Importantly, this simulation showed that the referents of labels, and their relationship to other items in the input, can affect word learning. This finding brings to light the need to consider the effects of semantic structure when studying word learning.

A SOM Model of First Language Lexical Attrition

Benjamin D. Zinszer (bdz107@psu.edu)

Ping Li (pul8@psu.edu)

Department of Psychology, Pennsylvania State University
University Park, PA 16802 USA

Abstract

First language lexical attrition remains a difficult phenomenon to study empirically, due to its long-term and dynamic effects. Based on observations from existing case studies, we propose a connectionist model to simulate the effects of first language lexical attrition. The model exhibits a plausible time-course for first language lexical comprehension, highlights the independence of productive and receptive attrition trajectories, and predicts an age of onset effect for early cases of L1 lexical attrition.

Keywords: language attrition, lexicon, modeling, self-organizing map, connectionism

Introduction

Many people learn and forget a second or third language during the course of their lifetimes. Less often, a major migration may cause someone to forget all or part of his native language. While a great deal of research has been dedicated to the first and second language acquisition, relatively little is known about language loss (hereafter, attrition) in the individual speaker.

Lexical Attrition

In the last decade, there has been an increasing amount of work devoted to the study of language attrition, specifically in L1 or first language attrition. Apparent age-related effects have been observed in the attrition of L1 phonology (Hyténstam et al, 2009; Pallier et al, 2003). However, long-term lexical attrition has remained largely undocumented, partly due to the lack of rigorous experimental methodologies for the study of lexical attrition.

Nonetheless, one could reasonably expect the long-term course of lexical attrition to differ from that of phonology. Previous research examining the interplay between language learning and cognitive functions has identified differing memory stores for lexical and phonological acquisition (Hernandez & Li, 2007; Ullman, 2001). To the extent that continued performance in the L1 depends on different memory representations, the effects of attrition on phonology and the lexicon may be independent.

The current body of L1 lexical attrition research provides some general observations about the relationship between age of onset (AoO)¹, length of residence (LoR) and the degree of attrition. A case study of letters written by an L1-

German immigrant to the United States revealed an ongoing process of lexical attrition even fifty years after AoO (Hutz, 2004). In another case study, an L1-German speaker with a similarly long LoR of 47 years in the United States demonstrated substantial lexical relearning in a natural conversational setting (Stolberg & Münch, 2010). That relearning is possible after such a long time raises the question of whether lexical attrition is truly a case of forgetting, in which L1 knowledge is destroyed in memory, or whether it is the access to L1 knowledge that is primarily affected by attrition.

The most evident problem in current L1 attrition research is the difficulty of reliably measuring change across time. As demonstrated in the case studies, loss of L1 abilities may be a slow and gradual process spanning years or decades. As a result, even longitudinal studies over a few years capture only a snapshot of a highly dynamic language system. The limited span of longitudinal data provided by any single study makes it extremely difficult or statistically impossible to identify the time course of development. While large samples with cross-section age variables (such as age of acquisition in the L2 literature) can mitigate these problems, advanced language users who experience L1 attrition are relatively scarce, making a cross-sectional sample nearly impossible.

One small-scale quantitative study has tested L2 lexical attrition through the relearning paradigm. De Bot, Martens, & Stossel (2004) found a relearning advantage in foreign language study for forgotten words over new words, revealing that the forgotten words, though inaccessible, persisted in memory. While this study found a general adherence to an exponential forgetting curve in which relearning savings are possible below the productive threshold, the findings are difficult to generalize due to the limited size of the vocabulary and the limited scope of the study.

Given the difficulties in systematic control of important learning variables (such as age, language proficiency, and L2 exposure), language attrition research has remained mostly a descriptive enterprise. Computational modeling may serve to turn language attrition research to an experimental science, due to its flexibility in parametric manipulation of the relevant variables and in testing relevant theoretical hypotheses. To date, very little work has been done in the computational modeling of language attrition. The goal of this study is to make a first attempt in providing a detailed computational account of the developmental time course of language attrition in the lexical domain.

¹ “Age of onset” here refers specifically to the beginning of attrition. Due to the difficulty of identifying this event, AoO is typically marked by the change of language environment (e.g., geographic migration), prior L2 exposure notwithstanding.

Computational Models

To our knowledge there has been only one computational model specifically designed to address lexical attrition. Meara's (2004) Boolean model of lexical attrition used a simple connectionist paradigm to simulate the effect of intra-lexical relationships on the time course of attrition. Meara's model exhibited self-organized criticality, that is, the wide-spread and sudden deactivation of lexical nodes at unpredictable intervals. This effect may be interpreted as largely a product of the inter-node dependencies inherent to Boolean models, but more importantly, Meara found that when the mean activation was taken across ten models, the resulting curve showed a gradual decline. This study highlights the troubling possibility that empirical research of lexical attrition in human subjects is hiding potential criticality effects. Increasingly sophisticated computational models may yet fill this gap.

Self-organizing feature maps (SOM) are a promising option in modeling lexical attrition. SOM is a connectionist modeling paradigm which represents data in a network of clustered nodes. Previous research has established the utility of SOM in producing cognitively plausible models of language development (see Li, 2009, for a review; see also Richardson & Thomas, 2008 and Mayor & Plunkett, 2010).

The potential for extending SOM to lexical attrition is suggested by its flexibility in simulating the effects of competing input sets. Age-related dynamic cross-linguistic competition in L2 learning has been demonstrated with other SOM-based models (Li & Farkas, 2002; Zhao & Li, 2007). Furthermore, effects of sensitive period or catastrophic interference have also been shown with the manipulation of learning parameters in SOM (Richardson & Thomas, 2008).

Computational modeling offers the possibility of a unified account of language learning, attrition, and relearning phenomena, integrating empirical research in these fields under more durable hypotheses. The present study aims to produce a SOM model: (1) to replicate the sustained gradual erosion of L1 lexical knowledge in both production and comprehension, (2) to compare the respective rates of attrition for comprehension and production, (3) to produce a plausible time course for long-term L1 lexical attrition, and (4) to reveal age of onset effects in L1 lexical attrition.

Method

In this study, a dual self-organizing feature map (SOM) model is trained in a first language (L1) and at varying ages of onset (AoO) in a second language (L2) while L1 training decreases or stops. Performances of the model in comprehension and production are tracked throughout training.

The Model

The self-organizing feature map (SOM) is a connectionist modeling paradigm wherein each node contains a vector of weights corresponding to each member of the input vector (see Kohonen, 2001 for a detailed explanation of SOM).

Node weights falling within a defined neighborhood around the input vector are adjusted towards the input based on their distance from it. Over many epochs of training, this adjustment results in topography-preserving orders, such that similar inputs are represented by nearby clusters of nodes in the map while dissimilar inputs by distinct and distant clusters. The typography-preserving characteristics of SOM are particularly well suited for examining the effects of cross-language lexical competition in a dynamically evolving system as in lexical attrition.

Architecture The model designed for this study employs two such SOMs (see Figure 1). The first SOM was trained on the phonological representations of words. This phonological map self-organizes according to the basic phonemic elements in a word, clustering words of a similar sound together. The phonological map was composed of 1600 nodes on a 40 by 40 rectangular grid. The second SOM was trained using the semantic representation of words. The semantic map clustered words of similar meaning, category, and part of speech. The semantic map was composed of 900 nodes arranged on a 30 by 30 rectangular grid. The semantic map was designed to be smaller than the phonological map because it received half as many unique input representations (see *Stimuli and Training*). The two maps were joined by Hebbian connections (see Hebb, 1949 for model and biological basis). A single Hebbian connection is represented by a weight that multiplies activation between the two nodes it connects. Every node on one map was connected to every node on the opposite map, for a total of 1.44 million (1600 x 900) Hebbian connections.

Functions and Parameters After the presentation of each input stimulus, the maps and Hebbian connections were updated according to a set of learning functions. These functions defined which sets of nodes and weights are adjusted and how much they are adjusted.

Figure 1: The model is composed of two self-organizing feature maps. Activation in each map is propagated to the other by means of Hebbian Connections.

On the phonological and semantic maps, the node whose weights most closely match those of the input set (measured as minimal Euclidean distance between input and each node) is designated as the Best Matching Unit or BMU. The nodes around the BMU are updated according to a neighborhood function approximating a Gaussian curve with a maximum value of one at the BMU.

The radius of the neighborhood is variable between trials and measured in terms of the Cartesian distances between nodes on the rectangular grid. In this study, the radius was initially set at one half the size of the smaller map (15) to allow maximum adjustment in early trials. With each epoch the radius was allowed to decrease by one if the quantization error was less than in the preceding trial. With this approach, performance of the model was not directly tied to a manipulation of the radius size, but rather the radius size and model performance were allowed to covary through early training stages.

Updates to SOM weights were proportional to a node's value on the Gaussian neighborhood curve, resulting in a smaller change for more distant nodes, and no change for nodes outside the neighborhood. All updates were also multiplied by the SOM's learning rate, a value between zero and one which limits the amount of change that can occur in a single trial. A learning rate of 0.2 was set for both maps. Hebbian connection adjustment was determined by co-activation in both maps. Activation for each node within the BMU's neighborhood was inversely proportional to Euclidean distance between the node's weights and the input vector. Each Hebbian connection was then adjusted by multiplying the activation of the nodes on each map and the Hebbian learning rate. The Hebbian learning rate was set to 0.1 in this model. Following each trial, Hebbian weights were normalized to values between zero and one.

Stimuli and Training

Two types of stimuli were provided to the model for training. Vectors containing phonological representations of words were presented one at a time to the phonological map. Simultaneously, vectors containing semantic representations of the same words were presented to the semantic map. This paired presentation allowed each map to organize around its respective input and then form connections between the phonological and semantic representations on their respective maps.

Phonological input vectors were generated using the PatPho system for English (Li & MacWhinney, 2002) and Mandarin Chinese (Zhao & Li, 2009). The dimension of each phonological vector was 63 units. Semantic vectors were obtained from the English stimulus set used to train the DevLex-II model. Each semantic input vector was 200 units long, derived from word co-occurrence patterns (see Li, Zhao, & MacWhinney, 2007 for details). In order to help the model discriminate between highly similar words (such as *red* and *blue* or *grandma* and *grandpa*) a nominal amount of noise was randomly added to the semantic data before training began for each model.

Most importantly, the English semantic representations were paired with both Chinese and English phonological representations during training. While emergentist models of bilingualism such as the Unified Competition Model have accounted for semantic and lexical transfer in second language acquisition (MacWhinney, 2005), prior computational models of language acquisition have failed to account for the largely shared conceptual space between two languages. Due to the importance of L2 negative transfer in L1 lexical attrition (Hutz, 2004; Schmitt, 2010) a computational account would be incomplete without a common semantic representation.

Words for the training set were selected from the MacArthur-Bates Communicative Developmental Inventories (English: Dale & Fenson, 1996; Chinese: Hao et al, 2008). Originally, 140 rough translation equivalents were obtained by comparing the English index with the English glosses in the Chinese index. Because intonation was not coded in the phonological representation, several words were eliminated as homophones. A few other words were removed because they could not fit the PatPho template for phonological encoding or did not have readily available co-occurrence data for semantic input. In total 116 English and 116 Chinese words were phonologically and semantically encoded for input to the model.

All instances of the model were trained for 500 epochs. The L1 (Chinese) was trained first, and at varying numbers of epochs (AoO) L1 input ceased and L2 (English) input began. AoO was varied in intervals of 50 epochs from 50 to 400. Ten models were trained for each of the eight AoOs.

Performance Tests

Following each training epoch, production and comprehension of the L1 was tested throughout the entire lifespan of the model.

For modeling purposes, comprehension was defined as the activation of the correct BMU on the semantic map when a phonological stimulus was presented to the phonological map. This activation was achieved by means of the Hebbian connections. After presentation of the stimulus, activation on the phonological map was calculated by the same method described in Functions and Parameters (above). Activation levels in the phonological map were then multiplied through their Hebbian connections. The incoming activation on the semantic map was summed for each node, and the most activated node on the semantic map was found. This most activated node was then compared to a list of semantic BMUs. If the most activated node was also the correct BMU, comprehension had occurred. If no BMU occupied the most activated node, the most activated node was compared to the closest BMU (by Cartesian distance) on the map. In the event that two or more BMUs on either map occupied the same node, all of these BMUs were disqualified from the comparison, preventing their corresponding words from passing the comprehension measure.

Figure 2: Mean comprehension scores in each AoO condition are graphed across the duration of the models (measured in training epochs). AoO values are also measured in training epochs, as depicted along horizontal axis.

Production was defined by the reverse process of comprehension. A stimulus input was provided to the semantic map, and activation was propagated by the same Hebbian connections to the phonological map, and the most activated unit was compared by the same criteria to the phonological BMUs. One important distinction in the case of production is that the most activated unit was only compared to the L1 BMUs to avoid inter-language confusion.

Results

L1 Comprehension

Mean comprehension curves were calculated across ten models for each AoO condition. Performance for each condition exceeded 92% by 50 epochs (the earliest AoO). AoO conditions later than 50 epochs exceeded 95% comprehension by 100 epochs. Maximum L1 comprehension after 100 epochs was 96.6% (112 out of 116 L1 words) for all models (un-averaged) with an AoO greater than 100. After AoO began, L1 comprehension decreased monotonically. Figure 2 shows the L1 comprehension curves for all eight AoO conditions. At the onset of L2 training, L1 comprehension seems to approximate an exponential decay for each AoO condition. Differences between L1 curves are described below (see section *Age of Onset Effects*).

L1 Production

L1 production declined severely and immediately for all AoO conditions. All models across all conditions performed below 5% correct productions within four epochs of the AoO and remained low throughout L2 training. Due to the low performance, no further analysis was applied to these data. See the *Discussion* section for a further treatment of this topic.

Age of Onset Effects

By visual inspection, AoO was inversely related to rate of attrition for the earlier AoO conditions. To quantify this relationship, the number of epochs required for each AoO condition to drop below 75% comprehension was calculated. Many models in the AoO 50 and 100 conditions did not reach maximum L1 comprehension performance by L2 onset. Therefore the performance calculation compensated by adding to performance measures the difference between each model's maximum L1 comprehension and the overall maximum (112) before calculating the number of epochs necessary to reach the threshold.

Figure 3 approximates the rate of attrition for each AoO by showing the number of epochs elapsed after L2 onset before the 75% L1 comprehension threshold was reached. Error bars indicate the two standard errors of the mean for

Figure 3: Mean number of epochs to reach 75% L1 comprehension or less, adjusted for incomplete learning. Error bars are two standard errors of the mean.

each AoO condition. ANOVA revealed a highly significant difference ($p < 0.001$) in mean decay rates between conditions. Post-hoc tests (Tukey, with a family alpha of 0.05) showed that the AoO 50 condition was significantly different than AoO 200-400 (but not 100 and 150), while AoO 100 was also significantly different from 200.

Discussion

While an examination of learning in connectionist models may be interesting in its own right, the results of this study are most informative with regard to the dynamic trajectories of human first language attrition. Prior studies in L1 attrition have found age effects in phonological attrition, but no such effect has been demonstrated for lexical attrition. Nonetheless, a review of the current L1 lexical attrition literature reveals that lexical attrition is a long-term and dynamic process.

Performance measures for L1 comprehension and production after AoO indicated great instability in the production while comprehension declined more gradually. A potential source of declining performance in both measures was the changing Hebbian weights. Because the weights were normalized with each trial, the magnitude of change to the Hebbian connections due to a stimulus is not strictly dependent on activation levels. This effect is analogous to a decay (or forgetting) rate, as all connection weights were reduced relative to the learning rate.

A major source of instability, and a probable driving factor behind the rapid decline in production, was the reorganization of the phonological SOM. The operational definition of comprehension assumed activation of the correct phonological representations (if present) and tested the consequent activation on the semantic map, rendering comprehension relatively resistant to changes in the phonological map. By contrast, production required that the static semantic representations correctly activate the highly plastic phonological representations. Faced with moving targets, productive performance was at a distinct disadvantage, even when activation was artificially restricted to L1 candidates and criteria were loosened to allow for “close enough” matches.

Although the degree and rate of decline for production may be exaggerated by the model, this finding does reinforce the dissociation of receptive versus productive abilities. Due to this dissociation, studies which primarily measure productive errors in speakers undergoing L1 attrition may overestimate the degree of loss. Stolberg and Münch (2010) found that lexical/semantic production errors decreased by approximately half over the course of 15 conversations in the subject’s L1. In light of the dissociation between comprehension and production, the degree to which these errors represent receptive L1 lexical attrition remains in question.

The relearning demonstrated in Stolberg and Münch’s study points to the possibility of persistent, though temporarily inaccessible L1 representations. Results from the described model suggest that these representations do

persist in memory, reactivated with relatively little practice long after becoming unavailable for production. De Bot et al (2004) confirmed the presence of latent lexical representations in the L2 through a short term relearning task. Foreign language students showed a relearning advantage for words to which they had been previously exposed but forgotten over learning new words. Our model stands to bridge these studies by demonstrating that these latent representations may also explain the observed L1 lexical attrition phenomena, further guiding L1 attrition studies toward seeking L1 representations that may have fallen below the threshold of retrieval for production.

The model also exhibited a highly plausible decay function for first language lexical comprehension. Previously only retrospective analyses, such as that by Hutz (2004), have been available for lexical attrition across a lifetime. Semantic transfer errors identified in Hutz’s case study (e.g. “*Das ist feine mit mir*” which is a literal translation of the English idiom “That’s fine with me”, rather than the equivalent German idiom “*damit bin ich einverstanden*”) grew at a diminishing rate over 55 years. The decay of comprehension in this model is highly compatible with Hutz’s findings in semantic transfer, indicating that the model’s performance curves may represent a component of the generalized time course for L1 lexical attrition.

Moreover, variation of age of onset revealed a possible inverse relationship with the rate at which the comprehension decay occurred. Particularly in the 50 AoO condition, we observed attrition occurring at a higher rate than for later AoOs. This rate, coupled with the slightly lower L1 pre-attrition performance (92% versus 97%), points to the effects of incomplete learning for early onset attrition. Empirical studies have shown that early rather than late exposure to L2 may lead to stronger influence from L2 to L1, causing certain elements of L1 to give way to L2 patterns more easily (e.g., in object naming patterns and categorization; see Pavlenko & Malt, in press). On the other hand, the stronger AoO effects at early stages may be accounted for by the substantial brain plasticity for new languages within the critical period (Pallier et al., 2003).

In the model, it is apparent that the importance of AoO is diminished in cases of later onset. The ostensible leveling-off may be attributable to the limitations placed on Hebbian entrenchment by the normalization. The strength of early AoO effects and high variability in later AoOs reflects Johnson and Newport’s (1989) observation of age-related effects in second language acquisition. Like Johnson and Newport’s data, our findings are at best ambiguous about the role of age in late second language onset. To what degree the performance of our model was due to incomplete L1 learning versus age-related acceleration of decay requires further investigation.

Conclusion

In empirical literature the study of language attrition has remained a qualitative and descriptive enterprise, due to the

lack of rigorous experimental methodologies for reliably measuring change across time. Coupled with the difficulty of finding a sufficient number of language users who experience L1 language attrition, the extant research makes it difficult to identify any time course of development. In this study, we provided a SOM-based computational model of lexical attrition as a first attempt to systematically investigate mechanisms of language attrition. Specifically, our model is able to produce a gradual decline in L1 lexical performance, suggesting a plausible course of decay in first language comprehension that is compatible with the observations of existing case studies. Furthermore, our model highlights the potential for independent effects on comprehension and production within a single language user. Finally, our model shows age of onset effects in relation to the rate of attrition and points to the possible role of incomplete L1 learning. Such effects are important for understanding the dynamic changes in the competition of two languages during learning.

Abstract

Using a novel enumeration task, we examined the encoding of spatial information during subitizing. Observers were shown masked presentations of randomly-placed discs on a screen and were required to mark the perceived locations of these discs on a subsequent blank screen. This provided a measure of recall for object locations and an indirect measure of display numerosity. Observers were tested on three stimulus durations (50, 200, 350 ms) and eight numerosities (2-9). Enumeration performance was high for displays containing up to six discs—a higher subitizing range than reported in previous studies. Error in the location data was measured as the distance between corresponding stimulus and response discs. Overall, location errors increased in magnitude with larger numerosities and shorter display durations. When errors were computed as disc distance from display centroid, results suggest a compressed representation by observers. Additionally, enumeration and localization accuracy increased with display regularity.

Keywords: spatial attention; enumeration; subitizing; visual indexing.

I. Introduction

When presented with a set of objects, humans can estimate quickly the set's numerosity with reasonable accuracy. This estimate of number supports various cognitive processes and assists decision-making and action-planning. Given the importance of such abilities, it would be reasonable to expect that a cognitive system employs several methods to obtain numerosity information. The challenge, however, lies in clearly identifying the possible mechanisms involved and determining the conditions under which they are employed.

The primary mechanism responsible for numerosity perception is the nonverbal mental magnitude system that also has been observed in animals and preverbal infants. Magnitudes are inferred mental entities that represent the numerosity or magnitude of things in the world via a mental "accumulator" or "number line" (Dehaene, 1992; Gallistel & Gelman, 1992). An accumulator mechanism is thought to enable the precise representations of duration and numerosity in rats by accumulating neural signals (Meck & Church, 1983). In humans, this accumulator system may represent discrete numerosities through an incrementing process that produces a preverbal count (Gallistel & Gelman, 1992, 2000). Although analog magnitudes are argued to underlie most numerical abilities, an alternate

mechanism may be employed for smaller numerosities. The term *subitizing* is used to describe the fast and accurate enumeration of 1-4 objects (Kaufman, Lord, Reese, & Volkman, 1949). Trick & Pylyshyn (1989, 1994) proposed that a *visual indexing* mechanism may be utilized for subitizing. Visual indexes are "pointers" that automatically pick out and stick to visual items displaying characteristics of "objecthood" (e.g., good continuation, cohesion). Each item that is to be tracked or enumerated is assigned an index in a bottom-up manner, enabling a simultaneous selection of four objects (Pylyshyn, 1989). Subitizing is thought to be the rapid enumeration of these active indexes. When a precise count is required for larger sets, this mechanism can be used to keep track of items that have been counted already, which increases the time required to make a numerosity judgment.

There are theoretical disagreements on the interpretation of the performance differences between small and large sets. Some studies attribute the change in the reaction times to the capacity limitations of information transfer into short-term memory (Cowan, 2001; Klahr, 1973) or a shifting of enumeration strategies (Mandler & Shebo, 1982). The rapid identification of small-set numerosity also can be attributed to the fast mapping of a label to the discrete increments on a mental magnitude (Gallistel & Gelman, 1991) or the fast counting of active indexes (Trick & Pylyshyn, 1994). Whether two systems are responsible for enumeration has yet to be determined conclusively, and this area of research continues to provide evidence supporting both perspectives.

Regardless of the mechanism responsible for subitizing, accurately enumerating a set requires the selection of each visual object. If an indexing mechanism is responsible for subitizing, observers would be able to report on four objects even under time constraints, but with poor memory for locations. Alternatively, if each object must be encoded into working memory for recall, then errors in enumeration and location recall should be similar. Numerosity perception has been studied extensively but little is known about the spatial information that is encoded when enumerating. To address this topic, the current study examines the location encoding that occurs in subitizing.

Studies on the spatial coding of object locations have shown that observers tend to remember locations by using spatial cues to categorize locations according to geometric "prototypes" (Huttenlocher, Hedges, & Duncan, 1991). When presented with a dot inside a geometric shape,

children remembered the location as being further away from the midline and edges of that shape—a bias towards the central tendency of the shape category, or prototype (Huttenlocher, Newcombe, & Sandberg, 1994). In adults, the representation of locations also was biased towards the prototype of spatial categories and these biases increased as memory became less certain over extended response delays (Spencer & Hund, 2002). These studies suggest that a single system for representing space is likely to serve both verbal and motor responses that are spatial in nature (Spencer, Simmering, & Schutte, 2006).

One potentially useful approach to understanding enumeration is to apply statistical and computational methods used in the study of visual perception. For example, one recent study used an information theoretic framework to model the human ability to learn statistical regularities from object features in visual displays, and tested whether observers used this information to enhance their ability to identify the locations of specific colors (Brady, Konkle, & Alvarez, 2009). The authors hypothesized that if there were more redundancies in the information input, then more content can be stored (as predicted by information theory). Their results indicate that more regular displays did in fact facilitate the encoding of information, which increased color recall performance in a way that could be predicted by a Bayesian learning model.

The primary goal of the current study is to characterize the spatial encoding during the enumeration of small sets of dots that were randomly placed on a computer screen and to determine if location and enumeration accuracy can be predicted by the statistical or geometric properties of these displays. To investigate this possibility, we devised an enumeration task that presented a display with randomly-placed small black discs. After a mask, observers marked the perceived location of each disc, which also served as their numerosity response (see Figure 1). Three stimulus durations (50, 200, or 350 ms) and eight numerosities (2-9) were tested. These stimuli were presented very briefly in order to prevent verbal counting and the response method allowed for a nonverbal report of numerosity and location (similar to a reporting methodology described in Dent & Smyth, 2006). *Enumeration accuracy* is measured as the percent of trials with an accurate numerosity report and the average (absolute) number of miscounts. For each trial, each disc on a response display was paired with a disc on the stimulus display to determine *location accuracy*, which is the distance between these corresponding discs.

The location data from this experiment was used to characterize observers' representations of objects selected for enumeration. The properties of the disc configurations in the test displays were compared to those in the observers' responses. This enabled quantitative comparisons between the actual stimulus and its representation. One testable prediction is that a display with more regularity would allow more content to be encoded more accurately into working memory, leading to better enumeration performance and object localization. Display regularity was obtained by

applying Delaunay Triangulation methods to identify "simplexes"—triangles with vertices comprised of display discs without other discs inside them (Kendall, 1989). This triangulation was applied to the elements in both the test and response displays, and the average area and side lengths of the resulting triangles were computed for each display. "Maximal circles", which connect the vertices of each triangle simplex, have also been used to study regularity in the spacing between dots (Fidopiastis, Hoffman, Prophet, & Singh, 2000). Similarly, maximal circles were identified and the average radii of these circles was computed and compared to observer responses. Another form of statistical summary examined was the centroid of disc configurations. Humans can estimate the center-of-mass of an array of randomly arranged dots on a display with high accuracy (Juni, Singh, & Maloney, 2008; Zhou, Chu, Li, & Zhan, 2006). The computation of this centroid estimate may prove to be crucial when representing individual locations. For each display, we computed the centroid and the distances of each element on the display from its centroid. We then compared the values between the stimulus and response data in order to estimate variability and compression.

The various regularity measures described above may be used to develop a model that predicts enumeration and localization performance. The current study aims to contribute to this goal by characterizing the spatial encoding during enumeration. This can lead to a better understanding of the nature of numerosity representations obtained under brief viewing conditions and help identify the mechanisms that contribute to this process. Using the characteristics of possible mechanisms—such as the Weberian nature of a magnitude mechanism or the set-based limitation of an indexing mechanism—we can test which model best explains the current data and identify the properties that are better predictors of accurate enumeration.

Figure 1. Schematic of this enumeration experiment.

II. Methods

Participants: 24 Rutgers University undergraduates participated in one session for course credit or payment.

Apparatus: The experiment was programmed in MATLAB with Psychophysics Toolbox 3.0.8 (Brainard, 1997) and presented using a desktop computer running Windows XP

(Intel Pentium 4 processor). The stimuli were displayed on a 19" color CRT monitor with a resolution of 1280 x 1024 pixels and a refresh rate of 70 Hz; contrast was set to 100% and brightness was set to 50%. The screen dimensions were approximately 35° by 27° in visual angle.

Stimuli: Test displays contained 2-9 identical black discs (35 pixels in diameter, or $\sim 1^\circ$) presented on a gray screen for 50, 200, or 350 ms. The discs were randomly placed on the screen with the following constraints: discs could not appear within 115 pixels ($\sim 3^\circ$) or more than 715 pixels ($\sim 20^\circ$) of each other, or within ~ 200 pixels of the screen edges. This produced an effective viewing display of 21° by 16° (768 x 614 pixels). Adequate separation of objects was emphasized to ensure "preattentive" object discriminability, since more attentional resources are required for accurate discrimination when separated by less than 1° (Bahcall & Kowler, 1999). The test display was masked using a random-dot texture created by randomly assigning a white or black value to a grid of 4 x 4 pixel squares.

General procedure: Observers sat approximately 60 cm from a computer screen in a darkened room. They were given instructions by the experimenter and performed six practice trials to ensure understanding of the task. Each trial began with a 2,500 ms presentation of a gray screen with a white central fixation cross. The stimulus screen was then flashed for a designated duration. A black screen appeared for one frame (16 ms) before a mask comprised of a random-dot texture was presented for 85 ms. Finally, a gray input screen with a crosshair pointer appeared and remained until observers made their responses by placing markers ("X") on each of the perceived disc locations. Pressing the space bar initiated the next trial. It was emphasized to the observers that the number of markers placed on the screen should represent the number of discs seen on the test display, even if they were unsure about the exact location. Response coordinates were recorded by the program. See Figure 1 for a diagram of a trial.

Processing the location data: The location data was comprised of two files, one for the stimulus display and another for the response display. In order to analyze the accuracy of location representations, stimulus and response coordinates (x-y values) were paired using the following procedure. When a trial had the same number of stimulus and response elements (i.e., correctly enumerated displays), a Procrustes analysis on the convex hulls of the element locations was used to identify the best fit of the response to the stimulus coordinates for each trial. Procrustes analysis determines the similarity between two shapes by estimating the best fit of one set of points to a comparison set by factoring out variations in scaling, rotation, and translation (Goodall, 1991). After applying the relevant scaling, rotation, or coordinate position transformations, Delaunay Triangulation and nearest-neighbor methods were used to identify stimulus-response pairs. For calculating pattern

regularity on a display, the mean and variance values were computed for the areas of triangle simplexes (identified by the triangulation), connecting edges, and the radii of the maximal circles that circumscribe the triangle simplexes. Trials with unpaired discs, which primarily occurred when displays were under- or over-counted, were not included in the location analysis (15% of possible data points).

III. Results

Enumeration Accuracy

The enumeration results replicate previous studies, with the highest accuracy observed in low numerosities. This range was maintained for six items—better than in previous studies where accuracy declines after four items. A follow-up experiment was conducted that included a control where numerosity was reported using Arabic numerals (Haladjian, Pylyshyn, & Gallistel, 2009). Observers performed better in the location-marking block (six items) than the control block (four items), supporting the current results.

Analysis of variance was conducted on the enumeration performance with observer included as a random variable. The largest numerosity condition of nine discs was excluded to control for anchoring effects. Analyzing the proportion of trials with perfect enumeration revealed main effects for display duration ($F=34.7(2,276)$, $p<.01$) and numerosity ($F=68.8(6,276)$, $p<.01$), with interactions ($F=7.7(12,276)$, $p<.01$). Analyzing the absolute value of miscounts for each condition also revealed main effects for display duration ($F=36.1(2,276)$, $p<.01$) and numerosity ($F=51.2(6,276)$, $p<.01$), with interactions ($F=11.8(12,276)$, $p<.01$). Figure 2 depicts the proportion of trials correctly enumerated and Figure 3 depicts the average absolute number of miscounts. Errors increased with larger numerosities but fewer errors were found with longer display durations. When observers made errors, they were generally underestimates (84% of errors were underestimates). Performance in the 50-ms display was significantly worse than the 200- and 350-ms durations for the 6-9 disc displays in both these analyses.

Figure 2. Proportion of trials with correct enumeration.

Figure 3. Average counting errors.

Location Accuracy

Location error is reported as the Euclidean distance between the coordinates of stimulus-response pairs for each trial. ANOVA results indicate main effects for display duration ($F=27.2(2,276)$, $p<.01$) and numerosity ($F=81.4(6,276)$, $p<.01$), with no interactions ($F=1.4(12,276)$, $p=.15$). Errors increased with larger numerosities and generally decreased with longer display durations (see Figure 4). The mean and variance of the following variables were computed to estimate display regularity: 1) area of Delaunay “simplex” triangles; 2) length of the triangle segments (shared edges were counted only once); 3) radii of the maximal circles that circumscribed the simplexes; 4) distance between each disc and the display centroid; and 5) radius of the enclosing “circumcircle” around the display elements (to estimate disc dispersion). Since performance was significantly worse in the 50-ms displays, only data from the 200- and 350-ms display durations (combined) are reported here.

The centroid (or center-of-mass) for each display was computed by calculating the mean x- and y-coordinate of all discs on a display. The compression measure is shown in Figure 5 as the average centroid-to-disc distances, that is, the average distance from discs on a display to the centroid. The substantially smaller distances in the observers’ responses suggests that their representation is compressed around the centroid of the display. The average dispersion (minimum enclosing circle radius) of the discs on a stimulus display ranged from 203 pixels ($SD=73$) in 2-numerosity displays to 358 pixels ($SD=19$) in 9-numerosity displays; for response data, this dispersion ranged from 185 pixels ($SD=73$) to 314 pixels ($SD=44$), indicating compression.

Display regularity was measured in terms of the variability in the size of the Delaunay simplexes and the size of the maximal circles that circumscribe these triangles. Here we report the effects of regularity as measured by the variability in the edge lengths of Delaunay simplexes; however, similar patterns of results were obtained with the area of the simplexes and the size of the maximal circles. Figure 6 depicts the average segment lengths and also suggests a compression of these representations. To

compare levels of display regularity, the standard deviation of the triangle segments in the test displays were grouped into quartiles, where 25% of the trials with least variation are in the first quartile and 25% of trials with the most variation are in the last quartile. This allowed us to plot location errors as functions of increasing variability (decreasing regularity) in Figure 7 and counting errors in Figure 8. These two charts show that displays with lower variability produce lower errors in both counting and localization (counting performance for displays <6 items are not shown since observers performed almost perfectly).

To compare the regularity of the test and response patterns, the overall compression in the response patterns was first undone using the scaling estimate from the Procrustes analysis. The variance in the simplex segment length for these “uncompressed” response patterns was then compared to, and found to be lower than, the variance in the corresponding stimulus patterns. This suggests that observers imposed regularity on the response patterns than there was not present in the stimulus patterns. Figure 9 plots stimulus and response data from two representative trials, which illustrates the imposed compression and regularity.

IV. Discussion

The visual system is thought to use redundancies from visual stimuli in order to encode information efficiently, as proposed by information theory applications to perception (Attneave, 1954). The current results showing better performance in displays with more regular patterns indicates a more efficient encoding of object locations that may be supported by an information theory of perception. When the triangle simplexes of a display have less variance, observers are more accurate in representing these more regular displays and exhibit better enumerating and localization performance. Additionally, there appears to be a tendency for compressing distances around the centroid. Even after factoring out the overall compression in the response patterns, these distances were found to be less variable in the response configurations than in the test configurations. This could indicate that observers are either assuming there is more regularity when they reconstruct the image, or representation errors are biased towards less variability or towards more “prototypical” representations of shape. This observed tendency to impose regularity on variable displays supports findings from previous studies (e.g., Taylor, 1961).

Increasing stimulus exposure durations from 50 ms to 200 ms produced more accurate enumeration for numerosities greater than six and more accurate location encoding for all numerosities. This suggests a coarse location-estimation process that occurs initially and is updated over time. The disassociation in enumeration and location performance for the smaller numerosity range also suggests that enumeration occurs independent of location-encoding: attention may be required to effectively encode locations but subitizing may be preattentive. This may indicate that visual indexes are responsible for subitizing, since location information does not need to be encoded initially to assign an index, but over time information can be bound to these indexes in order to build more accurate feature representations, including locations (Pylyshyn, 1989). The current results suggest that the indexing mechanism is implemented for smaller numerosities, but further experiments to support this conclusion are required.

The current experiment describes a novel methodology that implements a nonverbal report of numerosity, which appears to enable high enumeration accuracy of six items.

Allowing observers to enumerate by location may be a more accurate demonstration of selection abilities during fast enumeration, and this type of selection is sensitive to the geometric and statistical properties of the visual input. The observed location errors occur systematically and may benefit from inherent geometric regularities. Further analyses of these location data from a statistical perception or information theoretic perspective promise to reveal important information about the spatial nature of numerosity representations.

Abstract

Infants possess basic capabilities to assess various quantitative properties such as number, size, and time. Preverbal discriminations are approximate, however, and similarly limited by ratio across these dimensions. Here, we present the first evidence that redundant quantitative unisensory information—namely, simultaneous visual cues to both number and size—accelerates six-month-olds' quantitative competence. Using a habituation-dishabituation paradigm, results demonstrate that, when provided with synchronous visual cues to different quantitative properties, infants make more precise discriminations than when they receive information about a single cue alone. Such redundant conceptual information may be more salient than non-redundant information, which could better recruit attention and result in more precise learning and remembering than when such information is presented through only one cue.

Introduction

Even before they acquire language, infants are capable of perceiving various quantitative dimensions such as time, size, and number (e.g., Brannon, Lutz, and Cordes, 2006; Jordan, Suanda, and Brannon, 2008; Lipton and Spelke, 2003; Wood and Spelke, 2005; Xu and Spelke, 2000; Xu, 2003; Xu et al., 2005). This ability is approximate in that it follows predictions made by Weber's Law: infants' ability to distinguish between two magnitudes is a function of the ratio between the competing magnitudes (e.g., Xu, & Spelke, 2000; Bijeljac-Babic, Bertioncini, & Mehler, 1993; Brannon, Abbot, & Lutz, 2004; Gao, Levine, & Huttenlocher, 2000; Izard, Sann, Spelke, & Streri, 2009). For example, six month-olds successfully distinguish a 1:2 size change of a visual object, but fail to notice a 2:3 size change (Brannon, Lutz, & Cordes, 2006). Similarly, when tested with visual stimuli, six-month-old infants require a 1:2 ratio for successful discrimination of large numerical sets, failing to discriminate a 2:3 ratio change (e.g., Wood and Spelke, 2005; Xu and Spelke, 2000; Xu, 2003; Xu et al., 2005). By 9 months of age, however, infants successfully discriminate a 2:3 change in number (Lipton, & Spelke,

2003). This pattern suggests that discrimination abilities of infants show similar perceptual and cognitive limits across various dimensions of visual quantity.

When provided with redundant information about quantity through multiple sensory modalities, however, infants' discrimination abilities improve to a level previously thought attainable only after additional months of development. For example, although six-month-old infants fail to distinguish a 2:3 ratio change in number when provided with a single visual cue to number, they succeed when given cues simultaneously in both the visual and auditory modalities (Jordan, Suanda, & Brannon, 2008). Five-month-olds discriminate differing rhythmic patterns when presented audiovisually, but fail when presented only with a cue from the auditory or visual modality alone (Bahrick and Lickliter, 2000). Similarly, 3-month-olds are capable of discriminating differing tempos only when they are presented redundantly across multiple modalities (Bahrick, Flom, and Lickliter, 2002).

This tendency for infants' perceptual abilities to improve when provided with multiple synchronous sensory cues has been explained by the Intersensory Redundancy Hypothesis (see Bahrick and Lickliter, 2000 for review). The hypothesis states that redundant stimulation from multiple sensory modalities efficiently recruits infants' attention by providing overlapping sensory information, thereby causing the redundantly specified property to become perceptual "foreground", while other sensory stimulation remains "background". This, in turn, fosters perceptual differentiation, learning, and memory for redundant, amodal properties before other unisensory, modality-specific stimulus properties.

The effect of *intrasensory* redundancy on infants' cognitive abilities, however, remains to be empirically tested. Multisensory stimulation in the form of intersensory redundancy may not be the only way to boost infant quantitative competency; the multiple numerical cues provided by intersensory redundancy may be more important than the multisensory nature of the stimulation itself. Redundant conceptual information, regardless of

sensory modality, may be more salient than non-redundant information, which could better recruit attention and result in more precise learning and remembering than when such information is presented through only one cue. Here, we test the hypothesis that redundant *visual* stimuli will improve infants' quantitative discrimination abilities.

Methods

Participants

Twenty eight full-term six-month-old infants were tested (female= 14, mean age = 6 months 2 days; range: 5 months 15 days to 6 months 14 days). Participants were recruited from birth records obtained from the Utah Department of Health.

Design

Infants were randomly assigned to one of two conditions. Thirteen infants were habituated to a silent movie in which a ball bounced 8 times, while the remaining 15 infants were habituated to a silent movie in which a ball bounced 12 times. The size of the ball which bounced 8 times was exactly two-thirds the surface area of the ball that bounced 12 times. Following habituation, infants were tested with novel silent movies in which the ball bounced 8 or 12 times in alternation for six trials (order counterbalanced). The relative size difference of the balls bouncing 8 versus 12 times remained during test. Importantly, these stimuli closely mirror previous studies (see Jordan, Suanda, and Brannon, 2008 for test of 6-month-olds with these exact stimuli on number discriminations; see Brannon, Lutz, and Cordes, 2006 for test of 6-month-olds on discriminating this ratio of surface area), which demonstrated that 6-month-old infants fail to discriminate this ratio when either number or surface area are tested in isolation.

Stimuli

Infants were habituated to silent movie events of a ball that appeared to drop and then bounce up after making contact with a surface (see Jordan, Suanda, and Brannon, 2008). The size of the ball differed depending on its number of bounces: A ball which bounced 8 times (14.07 cm) covered exactly two-thirds of the total surface area as a ball which bounced 12 times (21.11 cm). The size of the individual ball was fixed and did not vary during the movie. Movies were constructed using Macromedia Flash and displayed on a computer within a 19 x 23 cm area.

Temporal parameters (Table 1) were controlled following Wood and Spelke (2005). During habituation, rate, duration, inter-event interval, and height of individual ball bounces were approximately equal for the 8- and 12-bounce sequences and were constant within trial but varied across trial. Therefore, on average during habituation 12-bounce sequences lasted longer and contained more motion than 8-bounce sequences. In contrast, during test sequences, total sequence duration, cumulative height of ball bouncing, and

total inter-event interval were approximately equal for the 8-bounce and 12-bounce sequence.

There were six distinct habituation sequences for 8- and 12- bounce events. During the habituation phase, the six movies in each condition repeated in random order for 16 trials, or until the infant met the habituation criterion. The six test trials consisted of novel 8- and 12-bounce movies shown in alternation, and occurred randomly without replacement for the first six habituation trials.

Table 1. Habituation and test trial parameters

	Bounce Duration (ms)	Interbounce Interval	Total Bounce Duration	Total Interbounce Interval	Total Duration of Sequence	Bounce Height (cm)	Total Bounce Height
<i>Test Trials</i>							
8	471	367	3768	2569	6337	10	80
12	315	233	3780	2563	6343	6.67	80
<i>Habituation Trials</i>

12	667	167	8004	2004	10008	14	168
<i>Mean</i>	367	250	4400	3000	7400	7.5	90

Surface area, circumference, and diameter remained constant within each trial type for 8 and 12 bounce videos respectively. Surface Area (8 = 14.07cm, 12 = 21.11cm); Circumference (8 = 13.30cm, 12 = 16.28cm); Diameter (8 = 4.23cm, 12 = 5.18cm).

Apparatus and Procedure

Infants sat on their guardian's lap approximately 60 cm away from a large monitor. Each test trial was initiated by the experimenter when the infant was looking in the direction of the monitor. Following the movie sequence, the last frame of the video was held fixed and remained on the screen for the remainder of the trial. Looking time to the fixed frame was recorded until the infant looked away for a continuous 2 seconds after looking at the fixed image for a minimum of 1 s, or after a maximum of 60 s. The habituation phase continued until the infant met the habituation criterion, defined as a 50% reduction in looking time over 3 consecutive trials relative to the first 3 trials that summed to at least 12 s, or until 16 trials were completed. The test phase consisted of silent movies, three of which

consisted of 8-bounce and three of which consisted of 12-bounce events.

A micro-camera monitoring the infant's face and a feed from the stimulus presentation computer were multiplexed onto a TV monitor and VCR. Each session was recorded for later reliability coding. Inter-rater reliability averaged 93.63% for all infants. Twenty-five percent of infants were coded by a single trained coder.

Results

An alpha of .05 was used for all comparisons. Infants required an average of 9.68 trials to reach habituation. Twenty five of the 28 infants reached habituation before all 16 habituation trials were complete. A paired-sample t test indicated that infants viewed the first 3 habituation trials significantly longer than the final 3 habituation trials, $t(27) = 9.46, p < .001$, Cohen's $d = 3.71$.

A $2 \times 2 \times 2$ repeated measures ANOVA was used to examine the relationship between the between-subject factors, gender and habituation condition (eight vs. twelve), and the within-subject factor, test trial type (novel vs. familiar). This analysis identified a significant main effect of test trial type, indicating that looking time within novel test trial types ($\mu = 6.92$ seconds) were significantly longer than looking times within familiar test trial types ($\mu = 4.62$ seconds; $F(1, 24) = 6.459, MSE = 12.02, p = .018$, Cohen's $d = .689$). No other main effects or interactions were significant.

A priori paired samples t test comparisons between pairs of novel and familiar test trials identified significant looking time differences between the first pair of novel and familiar test trials ($t(27) = 2.474, p = .02$, Cohen's $d = .970$), and the second pair of novel and familiar test trials ($t(27) = 2.196, p = .037$, Cohen's $d = .861$). However, looking time between novel and familiar test trials within the third pair of test trials were not significantly different ($t(27) = -.858, p = .399$, Cohen's $d = .336$). Infants looked significantly longer at novel test trials than the final three habituation trials ($t(27) = 3.26, p = .003$, Cohen's $d = 1.28$). However, looking times for familiar test trials did not differ from the

final three habituation trials ($t(27) = .641, p = .527$, Cohen's $d = .251$).

Binomial sign tests indicate that the number of infants who looked longer at novel test trial types ($n = 19$) was significantly larger than the number of infants who looked longer at familiar test trial types ($n = 9$) (sign-test, $p = .043$).

Discussion

These results demonstrate that infants' quantitative visual discriminations do not adhere to one strict ratio limit. With visual stimuli providing two simultaneous quantitative cues, six-month-old infants make more precise discriminations than previously reported in other studies when they received information about either number or surface area alone (Jordan, Suanda, and Brannon, 2008; Brannon, Lutz, and Cordes, 2006)). Our experiment is therefore the first to demonstrate an increase in quantitative precision resulting from redundant information provided by synchronous visual cues.

Past research has demonstrated that multiple sources of information presented across sensory modalities must be synchronous in order to be beneficial to infant learning in various domains (Bahrick, & Lickliter, 2000). In the current experiment, the change in number and surface area occurred in synchrony; however, the change did not occur across sensory modalities. Thus, multisensory stimulation in the

form of intersensory redundancy is not the only way to boost infant quantitative competence (Jordan et al., 2008). Instead, the multiple numerical cues provided by intersensory redundancy may be more important than the multisensory nature of the stimulation itself. Redundant conceptual information, regardless of sensory modality, may be more salient than non-redundant information, which could better recruit attention and result in more precise learning and remembering than when such information is presented through only one cue.

The exact mechanism through which infants accomplish this feat remains unknown. Recent epigenetic theories suggest that infants are endowed with basic capabilities to detect and process intersensory stimuli at birth, but that experiences throughout development are necessary to enhance these abilities (Lewkowicz, 2000). These experiences may begin in utero (Kisilevsky, 1995; Schaal, Orgeur, & Rognon, 1995; Bekoff, 1995), and continue throughout infancy and into childhood (Milner, & Bryant, 1968). However, as suggested by Lewkowicz (2000) only relatively recently have studies begun acknowledging and investigating the pervasive effects of multimodal stimulation on infants' perceptual abilities.

One area that has until recently been largely overlooked are infants' abilities to learn from synchronous stimulation within a single sensory modality. In their everyday environments, it is possible that infants experience synchronous unisensory stimulation no less often than they experience synchronous multisensory stimulation. Therefore, given the proposed importance of experience on the development of perceptual capabilities, the capacity of infants to perceive synchronous unisensory cues may be similar to their capacity to perceive synchronous multisensory cues in many domains. The current results mark an initial step in better understanding how infants utilize multiple temporally and spatially synchronous cues from the same sensory modality.

Our results are the first to indicate that infants' abilities to discriminate between quantities are improved by the presentation of redundant *intrasensory* cues. Redundant visual stimulation may cause more effective encoding of quantity by selectively recruiting infants' attention to visual properties of magnitude, thereby resulting in increased neural responsiveness to synchronous, redundant quantitative information. Therefore, when given multiple synchronous intrasensory cues, infants may have experienced greater signal strength and decreased variance for their ratio-dependent quantitative representations in memory.

It is necessary, however, to investigate the physiological bases of this enhanced quantitative ability in order to clarify potential causes and correlates. Recent findings have shown promise in identifying patterns of brain activation specifically involved in numerical understanding, even in infancy (Libertus, Pruitt, Woldorff, & Brannon, 2009). It has been hypothesized that there may be similar mental algorithms and neural areas devoted to common magnitude

processing, as opposed to completely discrete, compartmentalized areas responsible for processing specific quantitative properties individually (e.g., Cantlon et al., 2009).

Much work is still needed now to determine the extent of these findings. For instance, what other synchronous visual stimulation is capable of improving infants' quantitative abilities? Do these findings generalize outside of the domain of quantity, across other amodal properties? Does discrimination of properties in other sensory modalities such as audition benefit from synchronous intrasensory presentation? To better understand the role of synchrony in producing such effects, it would also be informative in the future to provide infants with the same overall amount of information about size and number changes, but to present these changes asynchronously. These questions should be addressed before we can begin to understand the limits of infant intrasensory processing capabilities.

Abstract

Absolute identification exposes a fundamental limit in human information processing. Recent studies have shown that this limit might be extended if participants are given sufficient opportunity to practice. An alternative explanation is that the stimuli used – which vary on only one physical dimension – may elicit psychological representations that vary on two (or more) dimensions. Participants may learn to take advantage of this characteristic during practice, thus improving performance. We use multi-dimensional scaling to examine this question, and conclude that despite some evidence towards the existence of two dimensions, a one dimensional account cannot be excluded.

Keywords: absolute identification; unidimensional stimuli; multidimensional scaling; MDS; learning

A typical Absolute Identification (AI) task uses stimuli that vary on only one physical dimension, such as loudness, brightness, or length. These stimuli are first presented to the participant one at a time, each uniquely labeled (e.g. #1 through to n). The participant is then presented with random stimuli from the set, without the label, and asked to try and remember the label given to it previously.

This seemingly simple task exhibits many interesting benchmark phenomena. The one of most concern for the current paper is the apparent limitation in performance. The maximum number of stimuli that people were previously thought to be able to perfectly identify was only 7 ± 2 (Miller, 1956). Performance was thought to improve slightly with practice and then reach a low asymptote (Pollack, 1952; Garner 1953).

This finding was particularly surprising given that this limit appeared to be resistant to practice (Garner, 1953; Weber, Green & Luce, 1977), and was generally consistent across a range of modalities (e.g. line length: Lacouture, Li & Marley, 1998; tone frequency: Pollack, 1952; Hartman, 1954; tone loudness: Garner, 1953; Weber, Green & Luce, 1977). In addition, this limitation appears to be unique to unidimensional stimuli. For example, people are able to

remember hundreds of faces and names, and dozens of alphabet shapes. It is generally accepted that this is because objects such as faces, names, and letters vary on multiple dimensions. Performance generally increases as the number of dimensions increase (Eriksen & Hake, 1955). This makes intuitive sense when one considers the individual dimensions on a multidimensional object. For example, if people are able to learn to perfectly identify 7 lengths, and 7 widths, they could potentially learn to identify 49 rectangles formed by a combination of lengths and widths.

Despite decades of research confirming this limit in performance for unidimensional stimuli, more recent research has suggested that we may be able to significantly increase this limit through practice (Rouder, Morey, Cowan and Pfaltz, 2004; Dodds, Donkin, Brown & Heathcote, submitted). For example, given approximately 10 hours of practice over 10 days, Dodds et al.'s participants learned to perfectly identify a maximum of 17.5 stimuli (out of a possible 36), a level significantly beyond the 7 ± 2 limit suggested by Miller (1956). From 58 participants that took part in a series of AI tasks, 22 exceeded the upper end of Miller's limit range (nine stimuli).

Other Stimulus Dimensions

The results from Dodds et al. (submitted) were not limited to the identification of lines varying in length. Dodds et al. also used a wide range of other stimuli, and found similar learning effects. For example, dots varying in separation, lines varying in angle and tones varying in pitch all demonstrated similar results. Participants learned to perfectly identify a maximum of 12.6 stimuli using dots varying in separation, 10.4 using lines varying in angle and 17.5 using tones varying in frequency, all exceeding Miller's (1956) upper limit of 9 stimuli.

The learning effects from Rouder et al. (2004) and Dodds et al. (submitted) may be attributed to the type of stimuli employed. The existence of severe limitations in

performance is unique to unidimensional stimuli, and since multiple dimensions are commonly associated with improved performance (Eriksen & Hake, 1955) it may be argued that the stimuli vary on multiple dimensions. Tones varying in frequency for example, are generally viewed as multidimensional. While Dodds et al. employed *pure* tones, leaving the stimuli to vary on only one *physical* dimension (wavelength), our perception of loudness increases as a function of increasing frequency. Therefore as frequency increased, participants would perceive the tones as being of different loudness, creating a greater number of perceived dimensions. This is not an uncommon phenomenon, as a similar effect is found in colour perception. Different colours are generated by a manipulation which is *physically* unidimensional (wavelength change), but the psychological representation of colour is generally considered to consist of three dimensions (e.g., MacLeod, 2003). Therefore it may be possible that the internal psychological representation of different line lengths used in both Rouder et al. (2004) and Dodds et al. (submitted) varied on more than one dimension.

In order to examine this theory using the same stimuli employed by Dodds et al. (submitted), we use Multidimensional Scaling (MDS) methods to examine the structure of similarity ratings generated using these stimuli. MDS refers to a broadly used range of statistical techniques, designed to allow the examination of relationships between objects of interest. Given a matrix of proximity data, MDS uncovers a spatial arrangement of objects in a manner that best reconstructs the original proximity data. For example, given a matrix of data with the distances between *n* cities, MDS analysis would present a spatial ‘map’ that would arrange the cities in the most likely location, given the distances provided by the data. Because we use subjective “similarity ratings”, rather than actual measured distances, we employ non-metric MDS, which does not assume a linear mapping between similarity ratings and distances.

Typically, MDS is employed after one has already assumed the number of dimensions on which the stimuli might vary. In the current experiment however, we use MDS to determine the number of dimensions that best describe Dodds et al.’s (submitted) stimuli.

Method

Participants

The 27 participants, recruited from an introductory psychology course at the University of Newcastle, Australia, took part in exchange for course credit.

Stimuli

Stimuli were 16 lines varying in length (Figure 1). See Table 1 for pixel lengths. Lines were 11 pixels in width and were black, presented on a white background. Stimuli were log spaced, and were separated by a distance substantially greater than the Weber fraction for length (2%; Laming, 1986; Teghtsoonian, 1971).

Figure 1. Unidimensional stimuli (line lengths) used in the Experiment. On any single trial, two of these stimuli were presented consecutively. All possible pairs of stimuli, including identical stimuli, were presented twice during the Experiment.

Table 1. Pixel lengths of the 16 lines used as stimuli

Pixel Lengths							
15	18	22	27	33	41	50	61
74	90	110	134	164	200	244	298

Procedure

Participants were instructed to rate the similarity of two stimuli that appeared on a computer monitor, on a scale of 1 to 100. On each trial, a single line would appear on the screen for 1 sec, followed by another line for 1 sec. The position of each line was jittered randomly on every presentation. After the two stimuli had been removed from the screen, a slider panel appeared at the bottom of the screen, allowing the participant to move a scrolling bar along a scale of 1 to 100 (where 1 = *dissimilar* and 100 = *similar*). Every possible pair of stimuli from the set, including identical pairs were presented twice. This resulted in 8 blocks of 64 trials, or a total of 512 trials (i.e., where $n=16$ stimuli and $r=2$ replications, number of trials = rn^2). A mandatory 30 sec break was taken between each block.

Each participant was given five practice trials at the beginning of the experiment, where they were asked to complete an identical task to the one above, with the exception that the stimuli were circles varying in diameter. The purpose of the practice trials was only to familiarize the participant with the response method. Different stimuli were used to prevent additional exposure to experimental stimuli.

Results

The main objective of our analysis is to determine whether the stimuli used by Dodds et al. (submitted) are represented internally by one or multiple dimensions. Initial descriptive analysis suggested that the data were consistent with a one-dimensional explanation: Figure 2 shows the average similarity ratings across participants, plotted as function of stimulus magnitude for each stimulus in the rating pair. Note that identical stimuli are rated as very similar (along the central diagonal), and rated similarity decreases monotonically with the rank-distance between the stimuli (at the left and right corners).

Figure 2. 3D structure of similarity ratings of all 16 stimuli.

Although Figure 2 indicates that the similarity ratings are consistent with a 1D psychological representation, they could nevertheless hide very subtle effects in the data, or large effects for individuals that average out in the group. In order to test this, we calculated non-metric MDS analyses for individual data. Each participant's data were transformed into a single symmetric dissimilarity matrix by subtracting the average similarity rating for each pair of items from 100 and averaging across reversed presentations (e.g., stimulus pair #1-#7 with stimulus pair #7-#1). This matrix was submitted for MDS analyses using both 1D and 2D representations for the data.

Deciding which of the 1D and 2D MDS analyses provides the best account of the data is not trivial. Various ad hoc methods have been used, including examining a goodness of fit measure, or examining the spatial arrangement the points in proximity plots. We applied both methods to our data. In MDS, goodness of fit between the reconstructed and observed dissimilarity matrices is typically measured by sum-squared error, which is called the *stress* value. Smaller stress indicates a better fit; however the MDS models are *nested* meaning that stress must always decrease as more dimensions are included. This means that stress must always be smaller for the 2D than the 1D model. Statistical tests on the magnitude of decrease in stress are not easily constructed, because the key properties of non-metric MDS make it difficult to assume a distributional model for the

data. Figure 3 graphs the average stress value, across participants, for MDS fits with dimensions from 1 to 10 (a *scree plot*).

Figure 3. Scree plot showing the decrease in stress value as the number of dimensions increase.

Some authors recommend determining the number of dimensions from a scree plot by finding its “elbow”; a sharp drop in stress value, followed by a relatively flat continuation. Such a pattern could suggest that the latter dimensions fail to provide sufficiently better fit to warrant adding more dimensions to the model. Unfortunately, this method fails to provide any insight into the number of dimensions that best describe the stimuli, as there is no obvious elbow in the scree plot. This is a common problem (e.g., Grau & Nelson, 1988; Lee, 2001). In addition, the use of such methods has been criticized as placing unreasonable emphasis on a numerical measurement. Such methods to determine dimensionality are often used to the exclusion of other, more meaningful aspects of analysis, such as simply the interpretability of results (Shepard, 1974).

A more appropriate method to determine whether a two dimensional model provides a sensible description of the stimuli might be to examine the spatial relationship between objects in the purported 2D psychological space. This can be investigated with a “proximity plot”, where each of the points provided in the similarity matrix are physically arranged in a manner that best satisfies the distances (or similarities) provided in the original data. Figure 4 shows two examples of these proximity plots, for two participants, from MDS analyses with two dimensions.

The philosophy of using MDS to recover internal structure relies on the assumption that, if the psychological representation of the stimuli was truly two dimensional, these 2D MDS proximity plots should reconstruct the internal representation. Because of the nature of the models under consideration (e.g. of categorization and absolute identification), this internal representation should have some relatively smooth and systematic shape. On the contrary, if the internal representation of the stimuli is truly one dimensional, these 2D MDS proximity plots should

Figure 4. Two proximity plots of individual fits of a two dimensional model. Each of these graphs is the resulting proximity plot from a single participant in the Experiment. Each point represents a single stimulus in 2D space. Lines connect adjacent stimuli in the set. The value at the top of each graph is the stress value, a goodness of fit measure.

illustrate the 1D structure (a straight line) possibly along with some meaningless noise.

However, these interpretations of the proximity graphs are only appropriate when examining the results of metric MDS analyses (using true, quantitative distances). In the current case, where non-metric MDS analyses must be used, patterns that may normally suggest a two dimensional internal representation, might actually arise from data that are truly *one dimensional*. This problem stems from the monotone transformations allowed by non-metric MDS, between the observed similarity data and the internal psychological distances (as noted originally by Shepard, 1974). Since non-metric MDS analyses only preserve the rank order of the similarity ratings, leaving the exact similarity values to vary in systematic ways that best suit the data, there is considerable flexibility in the spatial arrangements that might arise from a single underlying dimension. Therefore both Figure 4a and Figure 4b could be construed as evidence favouring a single underlying dimension. Whilst the two proximity plots demonstrate distinctly different patterns, both provide evidence to suggest that our stimuli vary on only a single dimension.

Even though smooth C- or U-shaped proximity plots are *consistent* with one dimensional internal representations, they are also consistent with two dimensional internal representations – that is, truly C- or U-shaped underlying structures. We attempt to resolve this ambiguity using a simulation study comparing MDS outputs from 1D and 2D fits to truly 1D data, in the presence of noise. These simulations provide a metric for interpreting the stress values from our fits to data.

Simulation Study

We investigated this problem of dimensionality with a simulation study. We generated synthetic data from a similarity matrix that was truly one dimensional (the rated distance between each stimulus was a linear function of their ranked difference in the set). We scaled this generating similarity matrix to be as similar to the observed data as

possible; we used 16 stimuli, with maximum and minimum similarity ratings of 95.91 and 6.88, respectively. Similarity between stimuli i and j could then be set as:

$$\text{sim}_{\max} - (\text{sim}_{\max} - \text{sim}_{\min}) * (\text{abs}(i-j)/15)$$

From this true similarity matrix, we generated synthetic data sets that matched the characteristics of the real data. Noise was added to the matrix using a normal distribution with standard deviation 12.18, and sampled similarity values outside $[0,100]$ were truncated. These settings resulted in synthetic similarity matrices that were nearly identical to the human data, on average, for the range and variance of similarities, and also for the variance of similarity values across participants, conditioned on each stimulus pair.

We generated 1000 such matrices, and fit each with MDS using both 1D and 2D settings. The lower panel of Figure 5 shows the difference in stress values between these two fits for each simulated data set (negative values indicate a better fit for 2D than 1D).

Figure 5. Difference in stress values for between 2D and 1D fits of the original data (top panel) and the true 1D data (bottom panel)

The upper panel of Figure 5 shows the difference between 2D and 1D stress values for the fits to our human data. The important thing to take from these graphs is that the decrease in stress generated by moving from a 1D to a 2D fit is about the same for our human data as it is for our synthetic data. Since the synthetic data were generated by a truly 1D process, this means that the stress values calculated for our human data are entirely consistent with a 1D

account. This provides further support to the evidence provided by the MDS analysis of our own data – that our stimuli may vary on only a single dimension.

Discussion

The purpose of the current experiment was test line-length stimuli commonly used in AI and always assumed to be unidimensional (e.g., Dodds et al., submitted; Rouder et al., 2004; Lacouture & Marley, 1995; Lacouture, 1997). Dodds et al. found that contrary to previous research, their participants were able to substantially improve their performance at the task when given significant practice. Although the stimuli used in their experiment varied on only one physical dimension, the results were more reminiscent of experiments using multiple dimensions, where it is more common to find substantial improvement with practice.

Although the stimuli used in Dodds et al. (submitted) varied on only one physical dimension, it is possible that they may vary on multiple psychological dimensions. In order to examine how many psychological dimensions underpin these stimuli, we used two methods; 1) using MDS techniques we examined similarity data taken using these same stimuli and 2) compared the structure of our data to simulated one dimensional data. MDS proximity graphs suggested that the stimuli may vary on a single dimension, and our simulation study provided further support for this, showing that these fits could be consistent with a one dimensional data generating process, when noise is added.

When examining individual proximity graphs taken from MDS analysis assuming two dimensions, a C (or U) shaped pattern often emerged, which is commonly assumed to provide evidence towards a 2D solution (Shepard, 1974). While this may be appropriate for a metric MDS analysis, the monotonic transformations unique to *non-metric* MDS allow some flexibility in the position of the objects in the final proximity graph. Despite this difference required in interpretation of metric vs. non-metric proximity graphs, it is possible that the two types of proximity graphs generated by our data (Figure 4) were genuinely representative of one vs. multiple dimensions, and that the action of specifying the number of dimensions to examine, forces the model to fit, sporadically producing evidence for and against a two dimensional solution. In support of a one dimensional solution however, our simulated data demonstrate a similar structure to our original similarity data, suggesting that the stimuli used in Dodds et al. (submitted) vary on only a single dimension.

Therefore it appears that the interpretation of MDS output for the number of underlying dimensions in the data is difficult. While we were able to gather evidence using a variety of techniques to suggest that our data were consistent with a single dimension, MDS could not provide a definitive answer. Lee (2001) showed that it is possible to reliably determine dimensionality from MDS analysis, but only when the determination is between larger numbers of dimensions. Like us, he found much poorer reliability when the choice was between lower numbers of dimensions.

Hence, the task of choosing between a low number of dimensions remains very subjective, and users should take care not be misled by “overfitting”, where a complex model imitates data from a simpler underlying data generating process. Furthermore, in the case of determining dimensionality, one should take care not to focus solely on quantitative results such as the stress value, but also take into consideration the pattern of data in the original similarity matrix (such as in Figure 2) or even simply the interpretability of results (Shepard, 1974).

Both the MDS analysis of the similarity data for Dodds et al.’s (submitted) lines of varying length and our simulation study were consistent with a 1D psychological representation. This finding makes it less likely that the substantial improvement with practice observed by Rouder et al. (2004) and Dodds et al. (submitted) in absolute identification of line lengths was due to participants learning to take advantage of a multi-dimensional psychological representation. This finding may also extend to the other stimuli that Dodds et al. employed. Similar learning effects to that of lines varying in length suggest that modality, or specifically, the number of dimensions that stimuli vary within, cannot be the sole cause of the improvement in performance. Hence, investigation of alternative explanations for the improvement they observed seems warranted.

Abstract

A central challenge in cognitive science is to measure and quantify the mental representations humans develop – in other words, to ‘read’ subject’s minds. In order to eliminate potential biases in reporting mental contents due to verbal elaboration, subjects’ responses in experiments are often limited to binary decisions or discrete choices that do not require conscious reflection upon their mental contents. However, it is unclear what such impoverished data can tell us about the potential richness and dynamics of subjects’ mental representations. To address this problem, we used ideal observer models that formalise choice behaviour as (quasi-)Bayes-optimal, given subjects’ representations in long-term memory, acquired through prior learning, and the stimuli currently available to them. Bayesian inversion of such ideal observer models allowed us to infer subjects’ mental representation from their choice behaviour in a variety of psychophysical tasks. The inferred mental representations also allowed us to predict future choices of subjects with reasonable accuracy, even in tasks that were different from those in which the representations were estimated. These results demonstrate a significant potential in standard binary decision tasks to recover detailed information about subjects’ mental representations.

Introduction

Cognitive science studies the mental representations humans (and other animals) develop and the way these representations are used to perform particular tasks. A central challenge is to measure and quantify such mental representations experimentally – in other words, to ‘read’ subjects’ minds. A classical approach to this is to ask subjects directly to report their mental contents verbally. Unfortunately, this procedure is prone to introducing biases arising from verbal processing, and from the educational and cultural backgrounds of subjects (Ericsson & Simon, 1980; Russo et al., 1989). In order to eliminate these biases, an alternative approach is to limit subjects’ responses to simple binary decisions or discrete choices that do not require conscious reflection upon their mental contents. However, it is unclear what such impoverished data can tell us about the potential richness and dynamics of subjects’ mental contents.

A powerful computational framework formalises the goal of learning as estimating the probability distribution or density of stimuli (Hinton & Sejnowski, 1986; Dayan & Abbott, 2001). This motivates many formal theories

of human learning and cognition to model the relevant mental content of a subject either implicitly or explicitly as a ‘subjective’ distribution over possible stimuli (Chater et al., 2006; Sanborn & Griffiths, 2008). In this study we adopted this representation, and our goal was to estimate subjects’ subjective distributions solely from their responses in simple binary decision tasks without making any assumptions about the process by which those subjective distributions were acquired, i.e. learning.

Ideal observer models are widely used for explaining human behaviour in various psychophysics tasks (Geisler, 2003). They formalise (quasi-)optimal decision making strategies given the information available to subjects and their background knowledge about the task, which in our case includes their subjective distributions. While previous studies mostly used ideal observer models to determine optimal performance in particular tasks to which human performance could then be compared, we treat them as stochastic models formalising the link between subjective distributions (the unobserved variable), and test stimuli and responses (the observed variables). Our main observation is that such models can be used to provide the likelihood in a Bayesian statistical analysis of subjective distributions, thus enabling one to infer mental contents from task responses in a principled way.

We term our approach *doubly Bayesian*, as we assume that subjects act as quasi-ideal observers, which entails Bayesian inference on their side; and then we use these ideal-observer models in a Bayesian framework to infer a posterior distribution of possible subjective distributions.

Inferring subjective distributions

The graphical model (Koller & Friedman, 2009) in Fig. 1A describes our model of a subject’s behaviour in a session of a psychophysics experiment. We assume that the subject entertains a subjective distribution \mathcal{P} over possible stimuli, and that this distribution does not change over the analysed session. In trial i of the experiment, the subject is presented a set of test stimuli \mathcal{S}_i and gives a response r_i . The value of r_i depends on the current stimuli \mathcal{S}_i , the subjective distribution \mathcal{P} , and ‘link’ parameters $\Theta_{\mathcal{O}}$ describing further aspects of observation and decision making, such as attention, perceptual noise, etc.

Figure 1: **A**, Graphical model describing the subject’s behaviour in an experimental session of N consecutive trials. We assume that the subject represents a subjective distribution, \mathcal{P} , over possible stimuli, and in trial i their response r_i depends on the currently observed test stimuli \mathcal{S}_i , their subjective distribution, \mathcal{P} , and some other parameters influencing their responding, $\Theta_{\mathcal{O}}$. Our goal is to infer \mathcal{P} and $\Theta_{\mathcal{O}}$ from the observed sequence of stimulus-response pairs. **B-D**, Generative models for the three task types (CAT, DISC, and PREF, see descriptions under ‘Experimental data sets’). Subjects assume that their observations, s , are perceptual noise-corrupted versions of the ‘true’ stimuli, s^* , sampled by the experimenter from a distribution that is the same as their subjective distribution, \mathcal{P} , or an alternative distribution, \mathcal{Q} (which is assumed to be uniform for tractability), depending on the particular hypothesis, \mathcal{H} .

In order to quantify the dependence between subjects’ choices and their subjective distributions, response probabilities, $p(r_i|\mathcal{S}_i, \mathcal{P}, \Theta_{\mathcal{O}})$, were specified by quasi-ideal observer models. These models formalise subjects’ choices as functions of the posterior probabilities of the two hypotheses corresponding to either response being correct.

Each hypothesis amounts to a different model of how stimuli might have been generated, and so the posterior over hypotheses is inferred by a Bayesian inversion of these generative models. Fig. 1B-D shows such generative models in three tasks considered later in this paper (for more detail, see the supplementary material¹). Once posterior probabilities are available, the statistically optimal, although psychologically unrealistic, strategy would be to deterministically choose the response with the max-

imal posterior probability. As a more realistic model of human decision making we used a soft-max function (parametrised by $\Theta_{\mathcal{O}}$) of log posterior probabilities, that describes quasi-optimal decision making (Sanborn & Griffiths, 2008; Orbán et al., 2008).

Our goal is to estimate latent parameters \mathcal{P} and $\Theta_{\mathcal{O}}$ from a series of stimulus-response pairs $\{\mathcal{S}_i, r_i\}_{i=1}^N$. As responses given in subsequent trials of the experimental session are assumed to be conditionally independent, the likelihood of latent parameters becomes

$$p(r_{1:N}|\mathcal{S}_{1:N}, \mathcal{P}, \Theta_{\mathcal{O}}) = \prod_{i=1}^N p(r_i|\mathcal{S}_i, \mathcal{P}, \Theta_{\mathcal{O}})$$

To allow for full Bayesian inference we specified prior distributions over the subjective distribution, \mathcal{P} , and link parameters, $\Theta_{\mathcal{O}}$. We chose to model subjective distributions as mixtures of Gaussians (MoG’s). This parametric family of distributions is flexible enough to model complex subjective distributions in low dimensional feature spaces and allows for analytical computation of likelihood ratios in the binary tasks considered here. Importantly, this prior reflected no information about the distribution of stimuli with which subjects were trained (i.e. the distribution to which their subjective distributions could be expected to be close), except for the general domain of possible stimulus values. The MoG representation is not a vital part of our general approach: other representations and priors may be more appropriate in some cases.

Given the prior and the likelihood defined above, we inferred a posterior over \mathcal{P} and $\Theta_{\mathcal{O}}$ via Bayes’ rule:

$$p(\mathcal{P}, \Theta_{\mathcal{O}}|r_{1:N}, \mathcal{S}_{1:N}) \propto p(\mathcal{P})p(\Theta_{\mathcal{O}}) \prod_{i=1}^N p(r_i|\mathcal{S}_i, \mathcal{P}, \Theta_{\mathcal{O}})$$

Unfortunately, calculating the posterior exactly is intractable, so we have to resort to approximate inference techniques, for which we implemented a Hamiltonian Monte Carlo algorithm (Neal, 2010).

Experimental data sets

Two experimental data sets were analysed, each collected using simple visual stimuli and requiring binary responses from subjects.

One-dimensional feature space The first set of experimental data was the fish categorisation data set collected by Sanborn & Griffiths (2008). In this experiment, the stimuli used were schematic images of fish of fixed length and variable height, i.e. the relevant feature space was one dimensional (see Fig. 2A). Subjects were trained (with corrective feed-back) in a supervised binary categorisation task (CAT) to distinguish fish drawn from a Gaussian training distribution from fish drawn from a uniform distribution. The mean and variance of the

¹available online at mlg.eng.cam.ac.uk/ferenc/mindreading

training distribution was varied across four conditions (Fig. 2B, red curves), with 9-11 subjects in each condition. Subjects also performed a stimulus preference task (PREF), in which they had to choose the stimulus which seemed more likely to be drawn from the training distribution. In this task, no feedback was provided. The experiment started with an initial block of 120 CAT trials (to train subjects) followed by four blocks of PREF task alternating with four blocks of CAT task, each block consisting of 60 trials. In a final block of CAT trials, no feedback was provided. For our analysis we neglected the initial training session. We used the next 180 PREF and 180 CAT trials to infer subjects' subjective distributions and reserved the last 60 PREF and 60 CAT trials for cross-validation.

Three-dimensional feature space The stimuli in the second experiment were trapezoids with three features varying systematically: colour (gray-scale), size, and shape (ratio of parallel sides), each parametrised by continuous values between 0 and 1 (Fig. 3A). This experiment involved one-back discrimination (DISC) and stimulus preference tasks (PREF). During DISC trials, which also served to train subjects on a particular distribution of stimuli, subjects were presented with one stimulus per trial, and had to judge (without feedback) whether it was the same or different than the one presented in the previous trial. In actuality, 10% of stimuli were exact repetitions of stimuli presented in the previous trial, the rest was sampled independently from the training distribution. Two different training distributions were used in the two conditions (Fig. 3B, left panels), with six subjects in each condition. During PREF trials subjects had to choose (without feedback) the stimulus which appeared to be more familiar based on the stimuli they had seen during training. The experiment started with 300 DISC training trials, followed by 100 PREF trials and another 200 DISC trials. In our analysis we neglected the first 100 DISC trials, used 300 DISC and 50 PREF trials to infer subjective distribution and preserved 100 DISC and 50 PREF trials for cross-validation.

Results

Inferring subjective distributions After extensively validating our method on synthetic datasets (supplementary material¹), we inferred human subjective distributions from the two experiments described earlier. Fig. 2B shows results on the experiment with a one-dimensional feature space. The inferred subjective distributions reflected qualitative aspects of the distributions of stimuli on which subjects were trained in different conditions. This match between inferred and training distributions became especially clear in the categorisation task.

Fig. 3B shows results on the experiment with a three-dimensional feature space. These results suggest that

subjects did not learn the training distribution in this experiment very well (see also below), although some resemblance between training and inferred subjective distributions were recovered for a few subjects (e. g. subjects 1, 4, 11 and 12). The subjective distributions inferred for the same subject in the two different tasks also revealed some consistency of these distributions.

Figs. 2-3B illustrate the primary goal of our study: to provide a method for inferring and visualising subjective distributions based on subjects' responding in psychophysics experiments. However, as subjective distributions cannot be observed or measured directly, there is no obvious way to assess the degree to which these inferences are 'correct'. One possibility, pursued above, is to compare the inferred distributions to the distributions subjects were trained on (assuming that subjects are approximately ideal learners and decision makers). While a match between the inferred subjective distribution and the training distribution (Fig. 2B) can be taken as indicative of valid inferences, a lack of match (Fig. 3B) is harder to interpret. In particular, one cannot distinguish between the algorithm giving incorrect results or subjects behaving sub-optimally (because of a failure to learn, or a failure to use learned information to direct choices). Therefore we sought to establish the quality of the inferences of our method in a more reliable way.

Predicting human behaviour A standard way to assess the quality of a statistical model of a data set is to test its predictive performance in cross-validation: infer its parameters (hidden variables) based on a subset of the data, and measure how well it predicts the held-out part of the data set. Our method is readily amenable to this cross-validation approach since it defines an explicit statistical model for predicting subjects' responses based on the stimuli they see (Fig. 1A). Making such predictions is not only important for validation purposes in the context of the present study, but may also be relevant in its own right in applications in which e. g. customer choices need to be predicted based on their previous choices.

For cross-validation, we inferred subjects' subjective distributions and link parameters from the first blocks of trials of a task and based on the inferred model predicted their responses in the final block of trials in the same task (Fig. 4, *double Bayes*). Ideally, subjective distributions are independent of the type of task subjects are performing, and hence one would even expect to be able to infer the subjective distribution from behaviour in one task and, based on that, predict choices in an other task. Thus, we also performed a stronger cross-validation test in which we measured such across-task predictive performance (Fig. 4, *double Bayes-CT*).

Subjects' responding is inherently stochastic, therefore the absolute predictive performance of our model is not particularly informative in itself. In order to establish some relevant baseline performance, we implemented al-

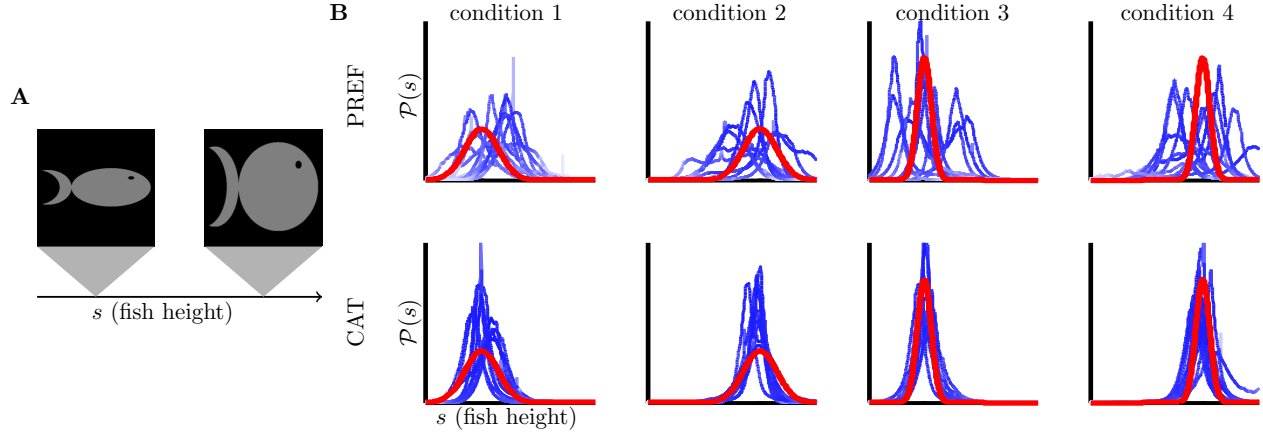

Figure 2: **A**, One dimensional stimuli used in the first set of experiments. **B**, Subjective distributions in a one-dimensional feature space. *Rows* correspond to task types, *columns* correspond to experimental conditions using training distributions with different means (1 & 3 vs. 2 & 4) or variances (1 & 2 vs. 3 & 4). *Red lines* show training distributions, *blue lines* show the posterior mean subjective distribution of each subject. *Shading of blue lines* indicates point-wise marginal posterior uncertainty: lighter means higher uncertainty (s.e.m. divided by the mean).

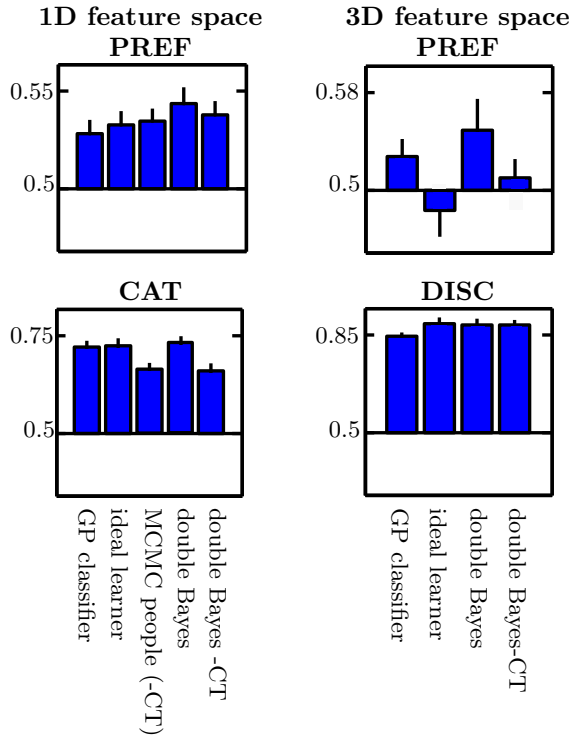

Figure 4: Predicting human responses by alternative methods. *Bars* show across-subject averages (\pm s.e.m.) of probabilities of correct predictions. In the PREF tasks our method *double Bayes* significantly outperformed both the *GP classifier* and the *ideal learner* in both experiments and also *MCMC people* in the 1D experiment ($p < 0.05$). In the CAT task, the *MCMC people* method was used for across-task predictions (-CT).

ternative models for predicting subjects' responses. Since the task of predicting responses based on the stimuli that subjects see is formally equivalent to a binary classification task (see supplementary material¹), we implemented a Gaussian process classifier (Fig. 4, *GP classifier*) (Rasmussen & Williams, 2006). The GP classifier is a particularly powerful algorithm applicable for such classification tasks, but it is also a black-box model in the sense that it has no explicit notion of subjective distributions. Therefore, it provides an interesting baseline by giving about the best predictive performance that can be achieved without modelling subjects' mental representations.

As an alternative method that did have an explicit notion of subjective distributions, we implemented an 'ideal learner' version of our model, which has the training distribution as its subjective distribution for all subjects, but its link parameters (parametrising stochasticity in decision making) are still fitted to each subject's data individually (Fig. 4, *ideal learner*). This model controls for the importance of individual differences in the inferred subjective distributions in our method, and also tests the validity of the assumption that subjects act as ideal learners in these experiments.

Finally, we also implemented as an alternative method a previously published algorithm ('MCMC with people') to infer subjective distributions (Sanborn & Griffiths, 2008). Although this algorithm can only be applied to specifically designed stimulus preference experiments, one of our data sets includes data from such an experiment, so we tested the performance of the algorithm on that data set by performing both within-task and across-task cross-validation (Fig. 4, *MCMC people* (-CT)).

Figure 3: **A**, Stimuli used in the second experiment had three continuous features, size, colour and shape. **B**, Subjective distributions in the three-dimensional feature space. *Left, in red*: training distributions; *right, in blue*: posterior mean subjective distributions (*blue*) for each subject individually (*columns, S1-S12*). Rows correspond to different conditions, using different training distributions, and different task types to test subjects’ subjective distributions. In the discrimination task, subjects 7 and 8 responded irrespective of stimuli.

Fig. 4 shows the predictive performances of these methods. The absolute difficulty of predicting responses greatly varied across tasks, the discrimination task and the categorisation tasks being considerably easier than the preference task, but the relative performances of the different methods showed consistent patterns across the different experiments and tasks. When comparing within-task predictive performances, our method was the best, or among the best, in all tasks. Notably, it outperformed the ‘MCMC with people’ method even in the case when that method was applicable at all.

In most cases, the three subjective distribution-based methods (*double Bayes*, *ideal learner*, *MCMC people*) outperformed the GP classifier, showing that making predictions about subjects’ responding benefits substantially from representing and inferring subjective distributions explicitly. This is especially true in across-task cross-validation which is impossible with a GP classifier in lack of any parameter that could be shared between tasks. Yet, in two out of four cases our method had higher accuracy even when comparing its across-task performance against within-task performance of the GP classifier.

Methods using subject-specific subjective distributions (*double Bayes*, *MCMC people*) also performed at least as well as the ideal learner, confirming the validity of the individual differences in subjective distributions these methods inferred, and showing that the poor match found between training and subjective distributions in some cases (Fig. 3B) were real and not a failure of our algorithm to recover ‘better looking’ subjective distributions.

Discussion

We have presented a new computational method for inferring subjects’ mental representation of stimuli from their responses on simple binary decision tasks. Since Bayesian inference was intractable, we implemented a Hamiltonian Markov chain Monte Carlo method for numerical analysis, which we have extensively validated and tested on real-world data sets. We found that the method was able to recover subjective distributions of humans when they were trained on stimuli with known structure and to predict future responses better than other model-based and ‘black-box’ methods. We have also shown that – using our method – information gained in one type of task could be transferred and applied to predict responses in another task which we take as further evidence for the veridicality and task-invariance of the mental representations we inferred. These results also offer a way to reconcile cognitivism with behaviourism inasmuch as they demonstrate that even when the only goal is to predict responses from stimuli, modelling mental representations explicitly is quantifiably useful.

There is a long tradition in experimental psychology and cognitive science to use simple statistics of task performance, such as percent correct rates, or reaction times, as indices of learning (Gallistel, 1993). These ‘naïve’ methods, even in their statistically most sophisticated forms (Gallistel et al., 2004; Kakade & Dayan, 2002; Smith et al., 2005; Preminger et al., 2009; Katkov et al., 2007), boil down to estimating a single (time-dependent) scalar measure of memory strength, i.e. the degree of

match between subjects' mental representations and that required by the experimenter (which would presumably allow subjects to perform perfectly). However, by reducing mental contents to simple memory strength measures, these methods fail to provide a detailed picture of structured mental representations which is what we aimed to achieve in the present study.

While structured probabilistic models of cognition have become mainstream more recently (Chater et al., 2006), they have mostly been used in normative theories to account for general, qualitative principles of learning (e.g. patterns of generalisation) rather than to quantitatively estimate individual subjects' mental representations in specific experiments. Our approach is complementary to these as it makes no assumptions about learning itself.

Our work is most closely related to more recent work by Paninski (2006) and Sanborn & Griffiths (2008) who both used ideal observer models to infer subjective distributions. In the paper by Paninski (2006) continuous decision tasks were considered (in which subjects' responses are analogue rather than discrete), and the method developed there does not seem to generalise well to the binary decision tasks considered here (and used extensively in experimental psychology), because the linear programming problem that needs to be solved becomes seriously under-constrained. Our analysis of the preference task is taken from previous work by Sanborn & Griffiths (2008), but they used it to construct a particular kind of stimulus preference task in which subjects' responding itself implements a Markov chain Monte Carlo sampler. This is a most elegant idea, but does not translate in any obvious way to other task types, or indeed to preference tasks which were not constructed according to their particular rules. Our method does not suffer from these limitations because of its doubly Bayesian nature: once ideal observer behaviour based on Bayesian analysis is formalised, the method offers an automatic and principled way of inferring subjective distributions.

A natural way to extend our work in the future will be to consider dynamical priors over subjective distributions in order to track their temporal evolution, inferring changes brought about by learning. The machine learning literature offers powerful tools for carrying out inference in such dynamical models.

Acknowledgements

We thank P. Dayan, C. Rasmussen, and A. Sanborn for useful discussions and K. Jucicaite and S. Ölschläger for help with acquiring psychophysics data. We are grateful for A. Sanborn and T. Griffiths for providing access to their experimental data. This project was supported by the Wellcome Trust (FH, ML), the Gatsby Charitable Foundation (FH), and the Max Planck Society (UN).

Abstract

In two experiments, we investigated the development of cross-sectioning ability using either three-dimensional (3D) or two-dimensional (2D) stimuli. Three to 9 year old children visualized cross-sections of either real 3D geometric shapes (Experiment 1) or 2D photographs of the shapes (Experiment 2). Performance on the 3D task was also analyzed to determine to what extent cross-sectioning ability is related to performance on more widely used spatial tasks including mental rotation and the water-level task. We found that performance on the cross-sectioning and mental rotation tasks were significantly correlated, and the 2D and 3D tasks were both successful in assessing cross-sectioning ability in young children. As expected, we also found a significant increase in cross-sectioning performance across age groups.

Key Words: spatial development; cross-section; education.

Introduction

Spatial ability is important for success across a variety of academic subjects, particularly in the science, technology, engineering, and mathematics (STEM) disciplines. Spatial ability is also related to choosing technological and science-related careers and predicts the choice of math and science as college majors (Shea, Lubinski, & Benbow, 2001), as suggested by the fact that individual differences across verbal, quantitative, and spatial abilities at age 13 were predictive of educational and vocational group membership 20 years later. However, despite the importance of spatial ability, spatial training is not a regular part of school curricula and there are no national or state standards for spatial intelligence. Consequently, many students have difficulty with spatial tasks and lack the opportunity to improve their spatial reasoning skills.

Spatial ability can refer to a wide range of skills, some of which focus on how individuals perceive and act on objects in space while others focus on how individuals orient and navigate within space. One category of spatial ability of particular interest is spatial visualization, or the ability to understand, mentally encode, and manipulate 3D forms (Carroll, 1993; Hegarty & Waller, 2004).

Cross-sectioning, also referred to as “penetrative” thinking (Kali & Orion, 1996) is a particular spatial visualization skill that involves inferring a 2D representation of a 3D structure, and vice versa (Cohen & Hegarty, 2007).

This imaginary slicing of a 3D object to a 2D plane is an essential skill for many of the sciences, ranging from anatomical cross-sections in biology and neuroscience to cross-sections of landforms in geology (Cohen & Hegarty, 2008). Conversely, in order to understand what is under a microscope, students must also be able to mentally reconstruct a 3D object from a given 2D image.

Spatial visualization requires performing multistep manipulations of spatial representations, such as a paper-folding task that requires the ability to work quickly, rotate figures, and keep track of multiple operations. This is thought to be distinct from other spatial tasks such as spatial perception and mental rotation (Linn & Petersen, 1985). For example, the water-level task, which requires subjects to draw a horizontal line in a tilted bottle where they believe the water level would be, is categorized as a spatial perception task because it requires determining spatial relationships with respect to a given frame of reference. Linn and Petersen define mental rotation as a Gestalt-like analogue process that involves accurately mentally rotating a 2D or 3D figure. However, the development of cross-sectioning ability has not been compared to these other measures of spatial ability, in part because of a lack of adequate measures and the unknown age at which this ability emerges. Thus, we do not know whether it is more related to spatial visualization, spatial perception, or mental rotation.

Cross-Sectioning Ability of Young Children

There is disagreement about the age at which children are able to reason about cross-sections of 3D objects. In contrast to Piaget and Inhelder’s (1956) view that children should have achieved mastery of geometric sectioning by 12 years old, many studies have found that spatial visualization involving cross-sections does not develop until the teenage years. For example, most students do not accurately predict the appearance of a geometric plane intersecting a simple cone or sphere until sometime between the ages of 11 and 15 (Russell-Gebbett 1984, 1985), while even students in grades 8, 10, and 12 have difficulty accurately choosing a cross-section of simple geometric line drawings (Boe, 1968; Davis, 1973).

The difficulty older children and adolescents have with these assessments may be in the presentation of the test

items themselves rather than a lack of underlying cognitive processes supporting cross-sectioning skills. Assessments involving cross-sections are often based on 2D diagrams and complex figures that represent 3D objects. Although these have been shown to successfully measure spatial visualizations of cross-sections among adults (e.g., Santa Barbara Solids Test, Cohen & Hegarty, 2007) and adolescents (e.g., Mental Cutting Test “Schnitte,” Quaiser-Pohl, 2003), these assessments are too advanced for use with younger children.

One factor impacting success when measuring other spatial skills in young children has been using more familiar, salient, and concrete stimuli. For example, tasks have used pictures of humans and animals to successfully measure mental rotation ability in young children (Quaiser-Pohl, 2003; Wiedenbauer & Janesen-Osmann, 2008). Similarly, by using basic 2D geometric shapes, Levine and colleagues (1999) were able to successfully assess mental transformation ability in preschool children.

In the present study, we created a new method for assessing cross-sectioning skills in young children by using brightly colored foam shapes as the stimuli. We contrasted this 3D method with a 2D method using photographs of the actual shapes. Thus, we aimed to successfully measure children’s cross-sectioning skills to determine a) how cross-sectioning skills develop between the ages of 3 and 9 years, b) the association between cross-sectioning skills and other spatial reasoning tasks, and c) how the method of assessment impacts performance.

We expected that using salient and familiar objects, such as the foam shapes, would make the task accessible for preschool to early elementary children. We also predicted that there would be an increase in spatial ability across the age range. We explored the relation between cross sectioning and two other measures of spatial ability that would engage similar yet categorically distinct spatial operations (see Linn & Petersen, 1985): mental rotation and the water-level task. We predicted that cross-sectioning would correlate with these more established measures of spatial reasoning but that the strength of the correlations would vary depending on the spatial processes required. Specifically, given that cross-sectioning involves manipulating mental images and possibly rotation, we predicted that performance on the cross-sectioning tasks would be significantly correlated with performance on a mental rotation task. However, as the water-level task has been shown to demonstrate distinctly different spatial operations from spatial visualization tasks (see meta-analysis by Linn & Petersen, 1985), we expected this task might not correlate as strongly with cross-sectioning as mental rotation.

Additionally, spatial ability has been shown to develop even through early adolescence (Vasta & Liben, 1996). Therefore, we expected to find an effect of age such that performance on cross-sectioning improves over time. Interestingly, using 3D objects adds complexity, which some researchers have shown negatively impacts

performance on mental rotation tasks (e.g. Rosser, 1980). Since cross-sectioning ability involves the interface of 2D and 3D representations we might expect that this task would be more difficult for young children because of the increased complexity of the stimuli. Consequently, in Experiment 2 we contrasted the presentation of the stimuli between actual three-dimensional geometric shapes (3D) and photographs of the real shapes (2D). Our expectation was that young children would be more successful when they were presented with problems involving cross-sections of actual 3D objects than when these same cross-sectioning problems were presented as photographs on a computer screen.

Experiment 1

In this study, we developed an assessment of cross-sectioning ability to determine if this task was suitable for young children. Experiment 1 used real objects (e.g., geometric foam shapes) and compared performance on the 3D cross-sectioning task to performance on two other standard measures of spatial ability (mental rotation and the water-level task) to determine the trajectory of cross-sectioning development during the early elementary years in relation to other spatial skills.

Method

Participants. Fifty-one elementary students (17 boys, 34 girls) ranging in age from 5 years 0 months to 9 years 0 months ($M=7.35$ years, $SD=1.16$), were recruited from the Chicago area. Participants were compensated \$10 for their time and travel and were also given a t-shirt for participating. We constructed four age groups from the data collected: 5 year olds ($n=8$, $M=5.58$ years, $SD=0.32$), 6 year olds ($n=11$, $M=6.43$ years, $SD=0.31$), 7 year olds ($n=16$, $M=7.32$ years, $SD=0.32$), and 8 to 9 year olds ($n=8$, $M=8.69$ years, $SD=0.27$).

Apparatus and materials. Stimuli for the cross-sectioning task consisted of six solid foam geometric shapes. Each solid had a base edge length or diameter of 7cm and a height of either 7cm (sphere, pyramid) or 14cm (cone, cylinder, rectangular prism, triangular prism).

Figure 1. The sample cross-sectioning item, showing a sphere bisected by an intersecting plane. Participants were asked to choose among four options to identify the resulting cross-section.

To create the 12 test items, each shape was bisected with an intersecting plane of sturdy, gray stock paper (see Figure 1).

Design and Procedures.

Participants were tested on three spatial reasoning tasks in a set order: cross-sectioning, mental rotation, and the water-level task. All participants were tested individually in a laboratory at the University of Chicago.

Participants first completed a cross-sectioning task adapted from Piaget and Inhelder (1956) and Boe (1968). In this task, children were presented with one sample item and twelve test items composed of familiar, colorful 3D foam shapes that were cross-sectioned by an intersecting plane. A sphere was used as the sample item and five different shapes (a cone, cylinder, pyramid, rectangular prism, and triangular prism) were used to construct the test items. Each shape was used twice, with one test item depicting a cut along the horizontal axis and the other along the vertical axis. An additional horizontal cut cone and vertical cut rectangular prism of different colors were used to complete the 12 test items.

The experimenter first showed each solid foam shape to the child, rotating the object so they could view all sides of the object, and then identified it (e.g., “This is a cylinder”) in order to familiarize the child with the stimuli. Next, the experimenter showed the sample item. A sphere was bisected with a piece of sturdy stock paper between the two halves demonstrating where and how the object had been cut (see Figure 1). The participant was told to imagine what the inside of the sphere would look like if we were to pull it apart at the cut point. The experimenter stated that the cut side would be flat and may make a shape that is different than the shape of the whole object that we see. The participants were then asked to point to the resulting cross-section shape from an array of four 2D shape choices. All shapes were cut either symmetrically (i.e., along the center) or asymmetrically along the longitudinal or horizontal axis. The stimuli were shown to the participants from one of two orientations: half of the participants viewed the objects so that they were looking at the intersecting plane from an approximate 90 degree angle (e.g., the plane of the paper was parallel to the ground such that the edges were more visible, see Figure 1) and the other half viewed the intersecting plane face-on (e.g., the paper was perpendicular to the ground such that the surface around was fully visible).

Participants also completed the Primary Mental Abilities (PMA) spatial relations test (Thurstone & Thurstone, 1963), where they were asked to pick from a four-choice array the shape that would make a square if it were put together with the target shape. Participants were instructed that this task was like a puzzle where shapes could be rotated to fit but could not be flipped over.

Then, participants performed the water-level task adapted from Piaget and Inhelder (1956). In this task, participants were presented with a line drawing of a half-full bottle of water. They were then given four pictures of empty bottles tilted upright, to the left or to the right, 30°, 45°, and 60°

from horizontal. Participants were asked to draw the resulting water line if the bottle was half full and was tilted.

The cross-sectioning and mental rotation tasks were scored such that each participant received an accuracy score (e.g., mean proportion correct), whereas the water-level task measured the angular disparity from 0 degrees (e.g., mean error). First, we present our analysis on the cross-sectioning task as a new method to assess spatial visualization skill in young children. Then, we compare performance across the three tests.

Results

Table 1 presents the mean performance for each spatial task by age group. Note, for the cross-sectioning task, there was no significant difference based on the viewing orientation of the test items (90 degrees: $n=26$, $M=.69$, $SD=.21$; facing: $n=25$, $M=.76$, $SD=.18$). Thus, we collapsed across this factor in our analysis.

For the cross-sectioning task, a 2x4 ANOVA (gender by age group) revealed a significant effect of age group, $F(3,43)=7.98$, $p<.001$, but no effect of gender, $F(1,43)=0.07$, $p=.79$, and no interaction, $F(3,43)=1.79$, $p=.16$. Specifically, cross-sectioning performance significantly improved at each age compared to the last, except for between ages 6 and 7 years (all p 's < .02, using Bonferroni adjustment). This reflects a developmental trend, such that participants improve with age, starting at 5 years old, and attain very good performance on this task (88% correct) around 8 years of age.

We conducted an item analysis to determine item difficulty. The most difficult test items across the entire sample were generally those where the cross-section resulted in a different shape from the whole, which we call

Table 1. Mean performance on spatial tasks by age group.

	Triangular Prism	Rectangle	49
	Cone	Circle	39
	Pyramid	Square	31
Mean Total			56.6 (10.8)

incongruent cross-sections (Table 2). For example, performance on the pyramid cut horizontally to reveal a square cross-section was the most difficult item (31% accuracy rate overall). Conversely, shapes with congruent cuts were much easier for children to grasp (e.g., the pyramid cut vertically to reveal a triangle, 59% answered correctly). Overall, children scored significantly higher on the congruent items than the non-congruent items, $t(50)=3.72, p=.001$.

For the mental rotation and water-level tasks, we conducted an analysis of variance (ANOVA) with the mean proportion correct (or the mean deviation score in the case of the water level test) by gender and age group. We found a significant age group effect for the mental rotation task, $F(3,43)=8.26, p<.001$, and the water-level task, $F(3,43)=3.10, p=.04$.

The cross-sectioning and mental rotation tasks were significantly correlated across the entire sample, $r(49)=.47, p=.001$. However, when controlling for age (in months), a multiple regression model revealed that mental rotation score was not a significant predictor for cross-sectioning performance, $\beta = .23, p = .09, R^2 = .40, \Delta R^2 = .04$. Further, when collapsing across age groups, we found no significant correlation between cross-sectioning and water-level task performance, $r(49)=.20, p=.23$.

In summary, children successfully completed the cross-sectioning task, suggesting that children as young as 5 years old are capable of performing basic cross-sections given the appropriate stimuli. Further we found an increase in performance with age. Difficulty of test items generally represented two categories: congruent items were easier in that the cross-section resulted in a similar shape to the

overall object, whereas incongruent items were harder due to the cross-section resulting in a different shape than the overall object. Positive correlations between the mental rotation and cross-sectioning tasks were present across the 5 to 8 year age range. However, when controlling for age, mental rotation was not a significant predictor of cross-sectioning performance, which suggests these tasks are not measuring *identical* skills but rather related spatial skills, particularly in children younger than 8 years old. Further, there was no significant correlation between performance on the cross-sectioning and water-level tasks. Thus, cross-sectioning ability is somewhat independent of both spatial perception and mental rotation. We are currently examining cross-sectioning performance in relation to another spatial visualization task using a paper folding task that is appropriate for young children.

Experiment 2

In order to examine the effects of presentation on cross-sectioning ability, we contrasted performance using 3D and 2D stimuli. Hence, half of the participants saw real three-dimensional geometric shapes (3D), while the other half of participants viewed 2D photographs of the shapes on a computer screen. We also investigated whether preschool children as young as 3 years old would succeed at the task. If successful, the cross-sectioning assessment would be useful in a variety of settings outside of a laboratory, as well as with a greater age range.

Method

Participants. Sixty-nine elementary students (37 boys, 32 girls) ranging in age from 3 years 1 month to 9 years 3 months ($M=5.82$ years, $SD=1.66$) were recruited as previously described and randomly assigned to two groups: 3D stimuli (19 boys, 16 girls; age, $M=5.72$ years, $SD=1.67$, range 3yrs1mos to 8yrs1mos) and 2D stimuli (19 boys, 16 girls; age, $M=5.47$ years, $SD=1.74$, range 3yrs1mos to 9yrs3mos).

Apparatus, Design and Procedures. All participants received the same familiarization and testing procedure for the cross-sectioning task only as described in Experiment 1. However, participants were randomly assigned to either the 3D or 2D stimuli group, which determined the type of objects they saw during the cross-sectioning test (either real 3D foam shapes used in Experiment 1 or 2D photographs of the shapes, see Figure 1). Additionally, as viewing orientation did not impact performance in Experiment 1, all stimuli were held by the experimenter (for 3D) or presented on a computer screen (for 2D) such that the intersecting plane was at an approximate 90 degree angle to the child.

Results

Table 3 presents the mean proportion correct across age groups within the 2D and 3D conditions. A 2x2x6 ANOVA (condition by gender by age group) revealed a significant interaction between condition and age group, $F(5,46)=5.16$,

3D	<i>M</i>	<i>SE</i>	<i>n</i>	2D	<i>M</i>	<i>SE</i>	<i>n</i>	<i>p</i>
3 years	0.47	0.05	6	3 years	0.50	0.05	5	.70
4 years	0.45	0.08	8	4 years	0.54	0.05	6	.35
5 years	0.65	0.06	6	5 years	0.52	0.02	7	.043
6 years	0.72	0.03	6	6 years	0.48	0.08	7	.016
7 years	0.80	0.03	5	7 years	0.63	0.05	4	.023
8-9 years	0.75	0.10	4	8-9 years	0.92	0.04	5	.12
Total	0.62	0.03	35	Total	0.58	0.03	34	.20

Table 3. Mean proportion correct (standard error) on the cross-sectioning task for each condition (2D vs. 3D) by age group.

$p=.001$. Specifically, there was a benefit for those in the 3D condition in the 5, 6 and 7 year age groups (see Table 3), but not in 3-4 year olds or 8-9 year olds. There was also a main effect of age, $F(5,46)=8.42$, $p<.001$, such that performance significantly increased with age overall, from early (4 years) to late (8 years), $p<.01$ Bonferroni (3 yrs=48% correct, 4 yrs=49%, 5 yrs=58%, 6 yrs=59%, 7 yrs=72%, and 8-9yrs=84%). This replicates the developmental trend found in Experiment 1 that children improve basic understanding of cross-sections over time, and extends the earliest age tested successfully to 3 years old.

Additionally, we compared performance on individual test items between the 3D and 2D versions of the task (Table 4). Again, the most difficult test items were incongruent cross-sections (e.g. the pyramid cut horizontally

to reveal a square cross-section), while shapes with congruent cuts were much easier for children to grasp (e.g., the pyramid cut vertically to reveal a triangle). A 2x2 ANOVA (condition by item type), revealed significantly higher performance for congruent compared to incongruent items, $F(1, 67)=107.21$, $p<.001$, but no effect of condition ($p=.34$) or interaction between condition and item type, ($p=.17$).

Discussion

In the present experiments we found that young children do reason about cross-sections and this ability can be assessed successfully using a task that involves either three-dimensional simple geometric shapes or two-dimensional photographs of simple geometric shapes. This ability develops over time, such that basic understanding of cross-sections improves from 3 to 8 years of age. Further, cross-sectioning ability is independent from other spatial skills, but is related to mental rotation more so than the water-level task.

According to Linn & Petersen (1985), spatial visualization tasks require maintaining mental representations and performing multistep manipulations on them. Thus, cross-sectioning skills, which involve such complex mental operations and rotations, would likely be categorized as a spatial visualization skill. As such, we found that cross-sectioning is distinct from mental rotation, as assessed by the Thurstone mental rotation test, and spatial perception, as assessed by the water-level task. Although some studies have not successfully measured cross-sectioning ability in children younger than adolescence, we found that a basic understanding of cross-sections emerges as young as preschool.

Further, it is possible to assess cross-sectioning ability in children using either real objects or photographs of real objects. Although using 3D objects provided a significant advantage for children between 5 and 7 years of age, performance across the 2D group was still above chance levels. The absence of a 3D advantage in the youngest children (3 and 4 year olds) may be due to the use of a simple shape matching strategy for both 3D objects and 2D

Table 4. Mean percent correct (standard error) of cross-section task items for 3D ($n=34$) and 2D ($n=35$) stimuli.

Item type	Item Shape	Cross-section	3D	2D
Congruent	Triangular Prism	Triangle	66	65
	Cylinder	Circle	77	76
	Rectangular Prism (2)	Rectangle	86 67	87
	Cone (2)	Triangle	74 77	71
	Pyramid	Triangle	89	88
	Total		76.7 (4.3)	77.7 (3.5)
Incongruent	Rectangular Prism	Square	77	53
	Cylinder	Rectangle	60	53
	Triangular Prism	Rectangle	43	18
	Cone	Circle	34	26
	Pyramid	Square	11	9
	Total		41.1 (4.3)	31.2 (3.3)

photographs. For example, the triangular shaped cone matches the isosceles triangle. However, we included at least one foil item that had a similar shape as the correct answer to prevent this strategy always leading to the answer. In contrast, the absence of a 3D advantage in 8-9 year olds may reflect the development of the ability to think about 2D images as 3D objects. When asking about cross-sections of any stimuli presented in 2D, one must successfully infer the object as 3D prior to performing mental operations. However, if children are unable to accurately process 2D information into 3D structures, they are already starting at a disadvantage. Further study is needed to examine possible strategy differences in children with lower cross-sectioning ability compared to those with more advanced skills. Also, we aim to assess various methods for improving cross-sectioning ability across the preschool to early elementary ages.

Abstract

Numerous studies have shown that the gist in photorealistic pictures of scenes is extracted after very short presentation times. So far, the investigation of gist extraction has been limited to pictures of scenes. The present study investigated whether the gist in pictures of causal systems, which are typically used as instructional material, is extracted as fast as the gist in pictures of scenes, and whether more than just the gist is rapidly extracted from a causal system (i.e., information concerning its details and functioning). Schematic and photorealistic pictures of scenes and causal systems were presented to subjects ($N = 24$) at different presentation times. Results showed that the gist in causal systems is extracted as fast as in scenes, and that an initial understanding of the functioning of schematic causal systems is also rapidly acquired. Results are discussed in the light of their implications for learning from text and pictures.

Keywords: Gist; Scene Perception; Causal Systems; Learning from Text and Pictures

Learning from Text and Pictures

In multimedia research it is a well known finding that learning from text and pictures leads to better retention and recall than learning from text alone (Levie & Lentz, 1982). Moreover, when students have to learn about causal systems, they are better able to apply their knowledge to produce creative solutions to problem-solving questions after learning from text and pictures than after learning from text alone (Mayer, 1989). Accordingly, learning from both text and pictures leads to higher comprehension than learning from text alone. Despite the fact that the beneficial effects of pictures for learning are well established in the research literature, far less is known concerning how the pictorial information is processed during learning.

An exception is an early study by Hegarty and Just (1993), in which comprehension was assessed via questions about the kinematics of different pulley systems. Students were better able to infer motion in the pulley system when previously learning from text and pictures than when learning from text alone or picture alone. Eye tracking data

furthermore revealed that during learning from text and pictures of pulley systems, subjects first processed text information, and then switched to the picture in order to integrate the information from both sources.

Unlike Hegarty and Just (1993), various studies showed that when subjects were confronted with information from text and pictures, they often initially looked at the picture for a short time before they started to read the text. This pattern of processing has been shown for advertisements (Rayner et al., 2001), comics (Carroll, Young, & Guertin, 1991), real-world scenes (Underwood, Jebbett, & Roberts, 2004), and biology schoolbooks (Mak, 2008). In a study by Stone and Glock (1981), in which subjects had to learn how to build a cardboard loading cart from text and schematic pictures, subjects first looked at the picture for 1000 to 2000 ms, before they started to read the text. According to the authors, subjects initially looked at the picture in order to get a first impression (i.e., gist) of what the material was about. However, it is yet unclear what role looking briefly at a picture prior to reading a text may play for understanding the presented content. At least this phenomenon has not been directly addressed in research on learning from text and pictures. However, there has been ample research in basic cognitive psychology about the extraction of information from briefly looking at pictures of scenes.

Extraction of Information from Scenes

In an early study of Biederman and colleagues (1974), subjects had to select one out of two labels, which they judged to better describe a picture of a jumbled vs. coherent scene. In coherent scenes, when the two labels were similar (e.g., “shopping plaza” vs. “busy road and stores”), accuracy of selecting the right label was at 100% for the majority of subjects after 300 ms of presentation. When the two labels were dissimilar, a ceiling effect in accuracy of selecting the right label occurred after only 100 ms. The authors concluded that information about the gist of a scene is already extracted after a single fixation, which enabled subjects to perform the task correctly. This is in line with

the findings from Henderson and Hollingworth (1999), who state that the average fixation duration during scene viewing is about 330 ms.

Similarly, Loftus, Nelson, and Kallman (1983) conducted a study in which subjects were asked to decide whether the picture of a scene had already been presented or not. Subjects were told to base their decision either on general properties of the picture or on detail information. When the decision was based on general properties of the picture, performance increased much less between 250, 500, and 1000 ms presentation time than when the decision was based on detail information. The authors concluded that most holistic information in scenes is extracted from the first fixation (about 330 ms; Henderson & Hollingworth, 1999) and subsequent fixations have the primary purpose of identifying relevant details.

Castelhano and Henderson (2008) also provided evidence for a rapid extraction of holistic information from pictures of scenes by presenting photos of scenes to subjects for a short time (25 – 250 ms) and later asking them whether a specific detail had been depicted in the scene. The detail in question was either consistent (e.g., fire hydrant) or inconsistent (e.g., tea set) with the gist of the scene (e.g., street scene) but was never actually present. Between 42 and 250 ms presentation time, subjects more often affirmed that the detail in question was present in the scene when the detail was consistent than when it was inconsistent with the gist of the scene. The authors concluded that a rapidly acquired (42 – 250 ms) scene gist was responsible for more affirmative responses to details consistent with scene gist by activating information about the scene's content and basic-level category.

To conclude, studies in basic cognitive psychology consistently demonstrate that information about the gist (e.g., general topic) in photos of scenes is extracted within the first fixation. Later fixations are presumably made to scan the scene for details.

Aims of the Current Study

The aim of the current study was to apply and compare findings from basic cognitive research on gist extraction from scenes to learning from text and pictures to better understand the role that pictures might play during the latter.

Unlike with scenes, there has yet not been much research about the extraction of information from instructional material. As mentioned before, in the study from Stone and Glock (1981), looking at the picture for 1000 to 2000 ms was interpreted as the time it took subjects to extract the gist. This is much longer than the time it takes subjects to extract the gist from scenes (< 250 ms). However, Stone and Glock interpreted the time subjects initially looked at the picture before reading the text as the time required to extract its gist. Subjects could also have extracted the gist within the first fixation (about 330 ms) as in scenes and looked at the picture up to 2000 ms only in order to scan it for details. Thus, it is still unclear when information about the gist and details is extracted in pictures of instructional material.

Information extraction in pictures of causal systems was investigated, since they are often used as instructional material in studies on learning from text and pictures (e.g., Hegarty & Just, 1993; Mayer, 1989). It was expected that once the gist of a causal system has been extracted, subjects would use the remaining time to understand the functioning of the depicted system. Hence, with longer presentation times knowledge about the functioning of the system should improve. In the aforementioned studies on learning about causal systems (e.g., Mayer, 1989), mostly schematic pictures of causal systems have been used (e.g., line drawings). On the other hand, gist extraction from scenes has been investigated by presenting photorealistic pictures to subjects (e.g., Castelhano & Henderson, 2008). In the present study, it was investigated whether these findings on gist extraction could be extended to schematic pictures of causal systems from studies on learning from text and pictures (e.g., Hegarty & Just, 1993). To overcome the confound that in previous research mostly photorealistic pictures of scenes and schematic pictures of causal systems were used, schematic and photorealistic depictions of both, scenes and causal systems were directly compared to each other in the current study. The degree of realism is considered to be a continuum with schematic line drawings on the one end and photos of natural objects on the other end. The less similar an illustration is to its real-world referent with respect to shape, details, color, and texture the more schematic it is. It can be expected that in general information will be extracted more easily from schematic depictions than from realistic ones, because the prior do contain fewer elements which can be recognized more easily due to better contrasts etc. However, effects of realism were not the focus of the study; rather this variable was solely introduced to bridge the gap between prototypical materials used in scene perception research (photorealistic scenes) and research on learning from text and pictures (schematic depictions of causal systems).

Hence, the current study addressed the question whether the gist in causal systems would be extracted as fast as the gist in scenes. Further, details were assumed to be better extracted at longer presentation times compared to shorter ones. Finally, it was investigated whether the functioning of causal systems would be understood and whether this depended on presentation time.

Method

Participants and Design

Twenty-four students (15 female, 9 male, average age: $M = 23.83$ years, $SD = 3.50$) from the University of Tuebingen, Germany, took part in the experiment for either payment or course credit. The experiment followed a $2 \times 2 \times 4$ design, with *Type* (scene vs. causal system), *Realism* (schematic vs. realistic) and *Presentation Time* (150 vs. 600 vs. 2000 vs. 6000 ms) serving as within-subjects factors.

Materials and Procedure

The materials in the experiment comprised 80 pictures of scenes and 80 pictures of causal systems. In a pilot study, subjects had to rate the number of objects in each picture, and to categorize the pictures with respect to their degree of realism and type (scene vs. causal system); the rated number of objects was the same for realistic and schematic pictures, and only unambiguous illustrations were used in the study. A scene depicted an everyday situation. A causal system always had a certain purpose (e.g., pulling weight). It consisted of multiple components, where at least one component was influenced by another – hence, removing one component would have changed the functioning of the system. In the experiment, for both scenes and causal systems, half of the pictures were schematic, the other half realistic. This led to four different categories of pictures in the experiment (see Figure 1). Each picture appeared in the center of the computer screen and covered nearly the whole screen size. An experimental session consisted of 8 training trials and 160 experimental trials.

	schematic	realistic
Causal systems	a) 	b) 
Scenes	c) 	d) 

Figure 1: Categorization of pictures used in the experiment. Pictures could either depict a scene or a causal system and could be either schematic or realistic.

Each experimental trial started with the presentation of the word “ready?”, which remained on the screen until a key was pressed. After pressing a key, the word “ready?” was replaced by the fixation cross, which was displayed for 800 ms. Then a picture (scene vs. causal system, schematic vs. realistic) appeared for either 150, 600, 2000 or 6000 ms, respectively, and was immediately masked afterwards. Both pictures and presentation times were presented in a randomized order. After each picture, a statement about the gist, then about details, and then about the functioning of the picture was presented and students were asked to respond to these statements (see Measures section for details). The statement concerning the functioning was presented only after pictures of causal systems. After responding to the last statement (detail or functioning), the trial was over and the word “ready?” reappeared, which marked the beginning of a new trial. An experimental trial for a single picture lasted about 15 seconds. The whole experimental session lasted approximately 45 minutes.

Measures

After viewing each picture, participants had to respond to either two or three statements about the picture depending on the experimental condition. All statements were in a two-alternative-forced-choice format, where students had to choose between a “yes” and a “no” response by pressing one of two keys on a keyboard. In half of the trials, “yes” was the correct response, in the other half of the trials “no” was correct. The first statement was about the gist of the picture. For instance, students were asked to decide whether a scene could be identified as “happy people” (see Figure 1d) or whether a causal system could be identified as “electric circuit” (see Figure 1b). Statements about the gist always consisted of only one to three words. In the second statement, participants had to judge whether specific details had been present in the scene (e.g., “presents are lying under the tree”; see Figure 1c) or in the causal system (e.g., “an eye is depicted”; see Figure 1a) just seen. Details were not relevant to either the meaning of the scene or the functioning of the causal system. Moreover, details were depicted in the periphery rather than in the center of the picture so that they were less likely to be seen within the first fixation. The third statement was presented only after pictures of causal systems, and was about the functioning of the depicted system. In order to be able to answer statements about the functioning correctly, inferences were required (e.g., “If the block is pulled out of the test tube, then liquids are at the same level in both test tubes”; see Figure 1a). It is important to note that statements concerning the functioning could be answered correctly only by relating multiple objects from the picture to each other; they could not be answered correctly solely based on prior knowledge that might have been activated once the causal system had been recognized correctly. The detail and functioning statements consisted of one sentence each.

As the main dependent variable, the percent correct was computed. Each correct response (both hits and correct rejections) was coded with 1, each incorrect response with 0. Multiplied by 100, percent correct was 100% at maximum and 50% at chance level and was computed separately for the three types of statements (gist, details, and functioning). Mean reaction times (RT) for responses to the different statements served as a second dependent variable in the experiment. Eye tracking data were assessed as well, but will not be reported here for space reasons.

Results

Overall, results revealed that there was no speed-accuracy trade-off, since there was no significant negative correlation between accuracy and RT ($r = .24, p = .26$). Thus, only accuracy to statements about the gist, details, and the functioning will be analyzed here.

Gist

T-tests revealed that both in scenes ($t(23) = 31.32, p < .001$) and in causal systems ($t(23) = 11.42, p < .001$), accuracy to

gist statements was above chance level at the shortest presentation time (150 ms), which speaks in favor of an early extraction of gist from both, scenes and causal systems (see Figure 2).

Figure 2: Accuracy to statements about the gist in schematic and realistic pictures of scenes and in schematic and realistic pictures of causal systems.

A 2 (*Type*: scenes vs. causal systems) \times 2 (*Realism*: realistic vs. schematic) \times 4 (*Presentation Time*: 150 vs. 600 vs. 2000 vs. 6000 ms) repeated-measures ANOVA was conducted to analyze accuracy for statements about gist. There was a significant main effect of *Type*, indicating that statements about the gist were answered more accurately ($F(1, 23) = 96.68, p < .001$) in scenes than in causal systems (see Figure 2), which is probably due to a higher difficulty in recognizing the general topic of causal systems. There were also significant main effects of *Realism* ($F(1, 23) = 8.41, p = .01$) and *Presentation Time* ($F(3, 69) = 17.51, p < .001$) meaning that gist extraction was better in realistic than in schematic pictures, and improved with longer presentation times. There were no interactions (all $p_s > .05$).

Details

T-tests revealed that both in scenes ($t(23) = 5.04, p < .001$) and in causal systems ($t(23) = 2.31, p = .03$), accuracy to statements about details was above chance level at 150 ms (see Figure 3).

A 2 (*Type*) \times 2 (*Realism*) \times 4 (*Presentation Time*) repeated-measures ANOVA revealed significant main effects of *Type* ($F(1, 23) = 25.63, p < .001$) and *Presentation Time* ($F(3, 69) = 12.46, p < .001$) on accuracy to detail statements. As expected, details were recognized more accurately at longer presentation times both in scenes and in causal systems. While there was no main effect of *Realism* ($F(1, 23) = 1.79, p = .19$) it interacted significantly with *Type* ($F(1, 23) = 13.08, p < .001$). Bonferroni tests showed that detail extraction was better in realistic than in schematic pictures of scenes ($p = .03$), whereas it tended to be worse in realistic than in schematic pictures of causal systems ($p = .065$). There were no further interactions (all $F_s < 1$).

Figure 3: Accuracy to statements about details in schematic and realistic pictures of scenes and in schematic and realistic pictures of causal systems.

Functioning

T-tests revealed that accuracy to statements about the functioning of realistic pictures of causal systems was at chance level for 150, 600 and 2000 ms (all $p_s > .05$). Only at the longest presentation time of 6000 ms, accuracy was above chance level ($t(23) = 5.29, p < .001$). On the other hand, accuracy to statements about the functioning of schematic causal systems was already above chance level ($t(23) = 3.86, p = .001$) at 600 ms presentation time (see Figure 4). Only at the shortest presentation time of 150 ms, accuracy was at chance level ($p > .05$).

Figure 4: Accuracy to statements about the functioning in schematic and realistic pictures of causal systems.

A 2 (*Realism*) \times 4 (*Presentation Time*) repeated-measures ANOVA revealed a significant main effect of *Presentation Time* ($F(3, 69) = 9.20, p < .001$) and a significant interaction *Realism*Presentation Time* ($F(3, 69) = 3.13, p = .03$), meaning that for realistic pictures of causal systems the functioning was understood better at longer presentation times, which was not the case for schematic ones.

Bonferroni comparisons confirmed that in schematic causal systems, longer presentation times (2000, 6000 ms)

did not lead to further improvements in understanding of the functioning (both $p_s > .05$) compared to 600 ms presentation time. Thus, it can be concluded that in schematic causal systems, an initial understanding was rapidly acquired (at 600 ms), and at longer presentation times schematic causal systems might have solely been scanned for details. In realistic pictures of causal systems there was no understanding of the functioning but at the longest presentation time of 6000 ms. Bonferroni tests showed that understanding of the functioning still improved between 2000 and 6000 ms ($p = .02$). Thus, it took subjects longer to understand the functioning of realistic pictures of causal systems (6000 ms) than to understand the functioning of schematic ones (600 ms). Subjects probably still attended to realistic pictures of causal systems at 6000 ms in order to extract their functioning. This possibly led to less attention to details at 6000 ms, which could have resulted in the marginally lower performance in detail extraction ($p = .054$) for realistic compared to schematic pictures of causal systems after 6000 ms presentation time.

Discussion

The present study aimed at investigating the extraction of different information (gist, details, and the functioning) from briefly attending to schematic and realistic pictures of scenes and causal systems.

The results demonstrate that the gist was rapidly extracted (< 150 ms) in both scenes and causal systems, confirming prior research from gist extraction in scenes (e.g., Castelano & Henderson, 2008) and expanding it to instructional material. Moreover, details were recognized more accurately at longer presentation times, which is in line with prior research from detail extraction in scenes (Loftus et al., 1983). Comprehension of the functioning quickly reached an asymptote in schematic pictures of causal systems (at 600 ms). In realistic pictures of causal systems, however, subjects needed more time to understand the functioning, which might have impaired detail extraction at longer presentation times because subjects might have split their attention between details and objects that they assumed to be relevant for understanding the functioning of the system. The analysis of the eye tracking data will reveal whether these assumptions hold true.

Influences on Comprehension of the Functioning of Causal Systems

More familiarity can possibly account for the faster comprehension of the functioning in schematic than in realistic pictures of causal systems. Schematic causal systems often appear in textbooks, but students are seldom faced with and almost never learn from photorealistic pictures of causal systems. Hence, a lack of familiarity with realistic pictures of causal systems could explain why understanding of schematic causal systems reached an asymptote very quickly (600 ms), whereas understanding of realistic pictures of causal systems was still at chance level at 600 ms and at 2000 ms presentation time.

Moreover, there might be an influence of domain-specific knowledge on comprehension of the functioning of causal systems. Unfortunately, in the present study no prior knowledge test could be administered, because causal systems were from many different domains (biology, chemistry, physics, engineering, and mechanics) and thus a prior knowledge test for each domain would have been too long. However, a demographic questionnaire was presented to participants that assessed their prior knowledge with regard to their last school grades in the respective school subjects and their general interest in the different domains. No participant had both very good school grades and a high interest in each of the aforementioned domains. Thus, it is highly unlikely that a participant could answer to all statements about the functioning of causal systems solely by relying on high prior knowledge. To test the influence of prior knowledge on the comprehension of causal systems in the respective domain on a more fine-grained level, further studies will be conducted.

Does the Gist of Causal Systems Help in Learning from Subsequent Text?

Studies that experimentally varied the sequence of presenting a text and a corresponding picture (Kulhavy et al., 1993; Ullrich & Schnotz, 2008) have shown that processing of a picture before the corresponding learning text can foster learning. Kulhavy and colleagues (1993) obtained better learning outcomes when a map was presented before a text. According to the authors, the structure of the map helped subjects in learning from subsequent text. However, in these studies, a picture was presented for either three to five minutes, or even without time constraints, which presumably led to a detailed mental model of the picture that was later integrated with the text and thus resulted in higher learning outcomes.

Results of the present study suggest that the gist in causal systems is extracted after very short presentation times (< 150 ms). It is unlikely that the short presentation (150 ms) of a picture already leads to a detailed mental model of the picture. Presumably, it rather acts as a scaffold (Friedman, 1979). Friedman (1979) assumed that subsequent information can then be added to that scaffold, thereby facilitating incremental mental model construction from pictures (and text, cf. Hegarty & Just, 1993). Moreover, Castelano and Henderson (2007) suggested that gist extraction leads to priming of the spatial structure of a picture, and this spatial structure “lingers in memory and can facilitate later perceptual and cognitive operations and behavior” (p. 760). If the gist already provided a scaffold of a picture that can be held in memory for some time, then later information from the text could be added to that scaffold, which could result in better learning. To test this assumption, we further plan to conduct studies, in which the picture of a causal system is presented for a short time (e.g., 150 ms) before a subsequent learning text.

Does Comprehension of the Functioning of Causal Systems Help in Learning from Subsequent Text?

The current results suggest that 600 ms can be enough to gain a preliminary comprehension of the functioning of schematic causal systems. As mentioned before, Stone and Glock (1981) showed that when subjects learned from text and pictures, they first attended to the picture for 1000 to 2000 ms before they started to read the text. Thus, this initial attention on the picture was probably long enough not only to extract the gist but also to gain a preliminary comprehension of the pictures' functioning, which in turn could have led to better learning from subsequent text.

However, it is not yet clear whether subjects in the study from Stone and Glock (1981) actually gained a preliminary comprehension of the picture after initially attending to. Subjects could also have attended to the picture in the first place because it merely was more visually appealing than the text. In this case, the initial attention to the picture possibly might not have been helpful for learning. Thus, further studies will have to investigate whether attending to a causal system for the time necessary to understand its functioning (i.e., 600 ms) fosters learning from subsequent text when subjects are instructed to attend to the system to understand its functioning versus when they are not.

From Basic Cognitive Research to Educational Settings

The study demonstrated that a well established effect in basic cognitive research (rapid gist extraction in scenes) can be found with instructional material as well, thereby providing further insights into the roles that pictures may play in learning from text and pictures. As such, this study can be considered as a starting point of an interdisciplinary approach that tries to better understand the processes that take place during learning from pictures and text through systematically applying findings from basic cognitive psychology to educational scenarios. Besides leading to a better understanding of the learning process, in the long run this approach may also provide recommendations for efficient instructional designs in educational settings.

Abstract

The reported study examined whether the processing of spatial verbal information interferes in the visuo-spatial sketchpad with the execution of eye movements, associated with viewing pictures and reading. Seventy-four students were randomly assigned to six groups, resulting from a 2×2 mixed design, with spatial secondary task (with vs. without), text contents (visual vs. spatial), and text modality (spoken vs. written) as independent variables. Consistent with our assumptions, learners with text containing spatial contents showed worse recall performance than those with text containing visual contents. Furthermore, written presentation of text containing spatial contents loaded the visuo-spatial sketchpad to a higher extent than spoken presentation. Implications of these results for learning with multimedia are discussed.

Keywords: multimedia; working memory; modality effect; spatial verbal information; secondary task

Introduction

In the last two decades, a lot of research has been conducted on how people learn from multimedia, that is, from the presentation of texts together with pictures (Mayer, 2009).

The Cognitive Theory of Multimedia Learning (CTML; Mayer, 2009) is one of the most important theories concerning multimedia learning. One of its theoretical foundations is an older version of Baddeley's working memory model (1992). According to this model, working memory consists of three systems: The phonological loop (PL), where all verbal information is processed, the visuo-spatial sketchpad (VSSP), where visual and spatial information is processed, and the central executive, which governs the functioning of the phonological loop and the VSSP. Accordingly, the CTML assumes that texts are processed in the phonological loop, whereas pictures are processed in the VSSP. The working memory systems are limited in the amount of information that can be processed in parallel. Accordingly, processes accomplished within the same system can interfere with each other and hinder learning. Therefore, text-picture presentations should be designed in a way that a learner can make optimal use of the

cognitive resources so that an overload in one or both systems can be avoided.

However, since Baddeley's first comprehensive descriptions of his model there have been numerous new findings concerning the functioning of working memory that have been considered in newer versions of the Baddeley model, but have not yet been incorporated into the CTML. In particular, the structure of the VSSP has been further specified. According to our view, these specifications may play an important role in multimedia learning. Thus, the aim of this paper is to have a closer look at the VSSP and its implications for learning with multimedia.

A Closer Look at the Visuo-spatial Sketchpad

According to Logie (1995), the VSSP can be divided into a visual and a spatial part. Whereas the visual part deals with information like an object's color or form, the spatial part handles information like spatial sequences or spatial configurations (e.g., Darling, Della Sala, & Logie, 2007; Della Sala et al., 1999). Whereas Logie and colleagues focused on pictorial stimuli, other researchers have addressed the question whether the VSSP may also be involved in the processing of text. This research suggests that if text contains information about spatial and/or visual configurations, it will not be processed only in the PL but also in the respective part of the VSSP, whereas if it contains more abstract information, it will be processed in the PL alone (De Beni et al., 2005; Deyzac, Logie, & Denis, 2006). Another line of research on the spatial VSSP has also shown that this structure is not responsible only for the processing of spatial information but also for the control of movements, for example arm or eye movements (e.g., Postle et al., 2006).

Although from a theoretical perspective the VSSP should play a crucial role in multimedia learning, its involvement has not often been considered empirically in multimedia learning. One method to measure the involvement of the spatial VSSP in task performance is the secondary task paradigm. In this paradigm, two tasks are combined, a primary and a secondary task. The primary task is the main

task, for example a multimedia learning task, whereas the secondary task is a task that loads one of the working memory systems. If both tasks rely on the same working memory systems, they will compete for its limited resources. As a consequence, primary task and/or secondary task performance will decrease compared to a control condition in which participants perform the two tasks separately. A secondary task that is assumed to load the spatial VSSP is the spatial tapping task. In this task, participants have to press buttons in a predefined order on a keyboard, which is hidden from view (e.g., Della Sala et al., 1999). Because the spatial VSSP controls the execution of movements, the continuous tapping interferes with the processing of spatial information (Farmer, Berman, & Fletcher, 1986).

Another way of assessing the involvement of the VSSP focuses on determining the learner's capacity of the spatial and visual VSSP and relating them to learning outcomes. Two tasks have been used to measure the capacities of the spatial and the visual VSSP, respectively, the Corsi block task (Milner, 1971) and the Visual Pattern Test (VPT; Della Sala et al., 1997), respectively. In the Corsi block task, the instructor taps fixed spatial sequences of cubes on a wooden board, which the participant has to recall afterwards. In the VPT, the participant has to recall abstract visual patterns. These patterns are presented in two-dimensional matrices in which a random selection of half of the cells is colored black.

Implications for Multimedia Learning

Figure 1 shows which parts of the VSSP are needed to represent different combinations of pictures and text contents, different amounts of eye movements, and a spatial secondary task. Whereas pictures are assumed to be processed in the visual and spatial VSSP because they contain visual as well as spatial information, texts load the visual or spatial VSSP as a function of their contents. Text containing no visuo-spatial information loads neither the visual nor the spatial VSSP, whereas text containing visual contents loads the visual VSSP (Figure 1, upper row), and text containing spatial contents loads the spatial VSSP (Figure 1, bottom row). Furthermore, as the spatial VSSP controls the execution of eye movements, viewing pictures and reading written text will result in an additional load of the spatial part (Figure 1, b, d, f, h). Moreover, the load of the spatial VSSP can be increased by implementing a spatial secondary task (Figure 1, right column).

In the current paper we focus on three implications that result from this analysis and that will be outlined in the following.

First implication: A Spatial Secondary Task Interferes with Picture Processing, Text Containing Spatial Contents, and Eye Movements. The first implication of the preceding analysis refers to the effects of a spatial secondary task on learning. It is presupposed that the spatial secondary task loads the spatial VSSP but not the visual VSSP (Figure

1, compare left vs. right column). Therefore, the spatial secondary task should interfere with the processing of the picture, the processing of text containing spatial contents, and the execution of eye movements associated with reading. On the other hand, it should not interfere with the processing of texts containing visual contents, and it should interfere less with spoken than with written text, because no eye movements are required to listen to text.

Second Implication: Text Containing Spatial Contents interferes with Picture Processing. When presenting pictures together with text containing spatial contents, one would expect interference in the spatial VSSP, because the processing of the spatial picture and spatial text contents as well as the control of eye movements both take place here (see Figure 1, bottom row). When presenting pictures together with text containing visual contents, one would expect less interference because the load is distributed more equally (see Figure 1, upper row). Accordingly, pictures presented together with text containing spatial contents should result in worse learning outcomes than pictures presented together with text containing non-spatial contents. A study conducted by Schmidt-Weigand and Scheiter (2008) confirms this assumption by showing that pictures are helpful for learning only, when they accompany text with a low degree of spatial information compared to text with a high degree of spatial information.

Third Implication: Written Text Containing Spatial Contents Interferes more with Picture Processing than Spoken Text Containing Spatial Contents. A third implication of the preceding analysis refers to the modality of the text: Because eye movements are not needed only for picture inspection, but also for reading, one might expect worse performance with written text than with spoken text when processing text containing spatial contents. Figure 1 (bottom row) shows that the spatial part is less loaded with spoken text containing spatial contents than with written text containing spatial contents, because more eye movements are required to read the text and to switch between text and picture. This load difference might result in worse learning outcomes for written text containing spatial contents than for spoken text containing spatial contents. For text containing non-spatial contents the difference between written text and spoken text is not expected to be equally harmful, because the text contents are not processed in the spatial VSSP and therefore no interference with the control of eye movements is expected. Note that a general superiority of spoken over written text presentations has been acknowledged for a long time already in multimedia research (i.e., modality effect, Moreno & Mayer, 1998); however, its explanation is different from the one presented here and in particular does not depend on the text content. Hence, we will not address this effect here any further.

		Without Secondary Task		With Secondary Task	
		Spoken Text	Written Text	Spoken Text	Written Text
Text Containing Visual Contents	a)	VSSP visual spatial Visual Text Content Spatial Text Content Visual Pictorial Information Spatial Pictorial Information Eye movements Spatial SecTask		VSSP visual spatial Visual Text Content Spatial Text Content Visual Pictorial Information Spatial Pictorial Information Eye movements Spatial SecTask

Figure 1. The load (grey color) of the VSSP as a function of the processing of pictures, the processing of different text contents, the processing of a spatial secondary task (Spatial SecTask), and the control of eye movements.

There is some evidence for the prediction that the text contents may moderate the modality effect. Kürschner, Schnotz, and Eid (2007) showed modality effects only with spatial information but not with non-spatial information. One purely text-based study (Glass et al., 1985) explicitly examined the influence of text modality on the processing of text containing visual versus spatial contents. Whereas with regard to sentences about spatial relations a modality effect occurred, this was not the case with regard to sentences about visual characteristics like color.

Experiment

The aim of the current study was to investigate whether processing texts containing spatial contents would interfere with picture processing and whether reading written text containing spatial contents would interfere more with picture processing than listening to the same text. Furthermore, it was investigated whether a spatial secondary task would interfere with the processing of pictures, text containing spatial contents, and eye movements.

Method

Participants and Design. Seventy-four students of the University of Tuebingen (62 female, average age: $M = 21.89$ years, $SD = 3.08$ years, 6 left-handed) participated in the study. They were randomly assigned to one of four conditions, which resulted from a $2 \times 2 \times 2$ mixed design, with spatial secondary task (with vs. without) and text contents (visual vs. spatial contents) as between-subject factors and text modality (spoken vs. written text) as within-

subject factor. Due to the mixed design, between 18 and 19 students were assigned to one cell (see Table 1).

Materials. The materials were presented in a computerized learning environment. The system-paced learning phase consisted of six static pictures of fictitious fish accompanied by six corresponding texts. Each fish was presented on a single slide. The pictures were identical in all groups, whereas the texts differed with regard to contents and modality as a function of the experimental condition. The lengths and the Flesch reading ease scores (Flesch, 1948) of the two text versions were equivalent indicating that there were no differences in text difficulty across the two versions. The pace of presentation was determined by the duration of the spoken text conditions.

The independent variables were varied between groups in the learning phase as follows: Learners with secondary task had to press different buttons in a predefined order on a keyboard hidden from view during learning. Learners without secondary task learned without performing a secondary task. Learners with text containing visual contents received information about visual features of the depicted fish species, that is, the color or form of specific body parts (e.g., “The pectoral fin has the same light brown color as the dorsal fins”). Learners with text containing spatial contents received information about spatial features of the fish species, that is, the location of a body part or its spatial relation to other parts (e.g., “The pectoral fin lies between the two dorsal fins”). Text modality was varied within the learning environment. Three of the six fish were accompanied by spoken text, the other three fish by written

text (partially balanced design). In the conditions with spoken text, learners listened to the text while the picture was presented on the screen. In the conditions with written text, the text was presented below the picture (see Figure 2).

Figure 2: Presentation of the learning materials with spoken (left) and written (right) texts.

Measures. The test phase consisted of four open recall questions, which measured text or picture recall. To measure text recall, learners had to write down everything they remembered from the texts regarding two of the presented fish. To measure picture recall, learners had to draw two of the fish (only information not mentioned in the text was analyzed). Two independent raters blind for experimental condition scored the open recall questions afterwards with an interrater reliability of Cohen's kappa = .79 for text recall and Cohen's kappa = .73 for picture recall. With regard to picture recall, we distinguished between the recall of visual versus spatial picture information. Additionally, the VPT (Della Sala, et al., 1997) to measure the capacity of the visual VSSP and the Corsi Block test (Milner, 1971) to measure the capacity of the spatial VSSP were administered.

Procedure. Participants were tested individually. First, participants were given a short written instruction about the experiment (i.e., about the learning domain as well as the procedure of the experiment). Second, participants in the secondary task conditions were introduced to the task and practiced it for two minutes. Third, all participants entered the system paced learning phase that was subject to experimental manipulation. Fourth, they responded to the open recall questions. Finally, they performed the VPT and Corsi block test. A single experimental session lasted about 60 minutes.

Results

Because it could not be excluded that gender or handedness

interacted with the processing of spatial information, we conducted prior analyses in a first step. For gender, no significant interactions were observed, indicating that gender did not influence learning outcomes. Regarding handedness, the corresponding analyses were not possible because of an insufficient number of left-handed participants. However, due to the small number of left-handed participants we did not expect an influence on learning outcomes.

Because of the results of the prior analyses, we collapsed across gender and handedness for the following analyses. For text recall, an ANOVA was conducted. For spatial and visual picture recall, the corresponding variables were analyzed by means of a MANOVA. In all analyses, secondary task and text contents were incorporated as between-subject factors and text modality was incorporated as within-subject factor. To control for individual differences in the capacity of the visual and spatial VSSP, the Corsi block scores and VPT scores were incorporated as covariates. Note that there were no interactions between the two capacity measures and any of the experimental factors. In the following, the statistical details are only reported for significant results, because of space limitations. Adjusted marginal means and standard errors corrected for the influence of the visual and spatial VSSP capacity are reported in Table 1.

With regard to *text recall*, the results showed an effect of the VPT, $F(1, 68) = 4.11, p = .047, \eta^2_p = .06$: The higher the capacity of the visual VSSP was, the better learners recalled the text information ($r = .21, p = .08$). Furthermore, in line with the second implication, learners with text containing visual contents ($M = 32.82\%, SE = 3.37$) outperformed learners with text containing spatial contents ($M = 18.95\%, SE = 3.36$), $F(1, 68) = 8.29, p = .01, \eta^2_p = .11$. This indicates that text containing spatial contents and picture processing interfere in the spatial VSSP, resulting in worse learning outcome for the recall of spatial text information compared to visual text information.

With regard to *picture recall*, the MANCOVA showed a significant difference between learners with texts containing visual and spatial contents, $V = .46, F(3, 67) = 28.20, p < .001$, and an influence of the secondary task on learning outcomes, $V = .09, F(3, 67) = 3.21, p = .046$. Also the three-way interaction text modality \times text content \times secondary task was significant, $V = .09, F(3, 67) = 3.26, p = .045$.

Table 1: Adjusted marginal means and standard errors as a function of the experimental condition.

	text containing visual contents				text containing spatial content			
	without secondary task		with secondary task		without secondary task		with secondary task	
	spoken $n = 18$	written $n = 18$	spoken $n = 19$	written $n = 19$	spoken $n = 18$	written $n = 18$	spoken $n = 19$	written $n = 19$
Recall of text information (%)	35.91 (7.08)	35.30 (6.50)	30.32 (6.69)	29.79 (6.14)	20.48 (6.85)	20.12 (6.30)	15.82 (6.87)	19.37 (6.31)
Recall of visual picture information (%)	57.52 (4.79)	49.97 (4.37)	52.09 (4.52)	46.83 (4.13)	32.90 (4.63)	33.24 (4.23)	36.61 (4.64)	27.90 (4.24)
Recall of spatial picture information (%)	53.32 (5.43)	44.59 (5.87)	38.80 (5.13)	42.63 (5.54)	42.45 (5.26)	58.04 (5.68)	44.81 (5.27)	34.58 (5.69)

Follow-up three-way ANCOVAs confirmed the expected main effect of text content with regard to the recall of visual picture information: Learners with text containing visual contents ($M = 51.60\%$, $SE = 2.06$) recalled the visual aspects of the pictures (like color or form) better than learners with text containing spatial contents ($M = 32.67\%$, $SE = 2.06$), $F(1, 68) = 41.16$, $p < .01$, $\eta_p^2 = .38$). This confirms the second implication that text containing spatial contents interferes with picture processing, whereas text containing visual contents does not. With regard to the recall of spatial picture information the effect of the secondary task, $F(1, 68) = 6.24$, $p = .02$, $\eta_p^2 = .08$, as well as the three-way interaction, $F(1, 68) = 5.76$, $p = .02$, $\eta_p^2 = .08$, were confirmed: In line with the first implication, learners, who performed a spatial secondary task during learning, recalled the spatial picture information ($M = 40.21\%$, $SE = 2.58$) worse than learners who did not perform a secondary task ($M = 49.60\%$, $SE = 2.65$). This indicates that the spatial picture contents are processed in the spatial VSSP. However, the Bonferroni tests of the three-way interaction text modality \times text content \times secondary task, showed that this main effect of the spatial secondary task on spatial picture recall was due to interference between the spatial secondary task and the processing of written text containing spatial contents ($p = .01$, see Figure 3). This result supports the third assumption, because it indicates a higher load of the spatial VSSP with written than with spoken text presentation, when spatial text contents are presented.

Figure 3: The pattern of results for spatial picture recall (adjusted means). $*p < .05$

Summary and Discussion

One purpose of the reported study was to examine whether pictures, text containing spatial contents as well as eye movements load the spatial VSSP. Furthermore, the hypotheses were tested that text containing spatial contents would interfere with picture processing and that this interference would be affected by the modality of the presented text.

The first assumption concerning interference between the spatial secondary task and the processing of pictures, text containing spatial contents as well as the execution of eye movements was only partially confirmed. Performance decrements while conducting a spatial secondary task were observed with regard to the recall of spatial picture information, especially for learners with written text containing spatial contents (see Figure 3). As mentioned before, the load of the VSSP is assumed to be extremely high in this specific case (see Figure 1, h). This may explain why the secondary task interfered particularly with the recall of spatial picture information accompanied by written text containing spatial contents. Contrary to our assumptions, the secondary task did not hinder the recall of spatial verbal information or the recall of written text in general. These findings imply that the processing of text containing spatial contents and the control of eye movements in general did not load the spatial VSSP to such a high degree that interference with a secondary task was observed.

The second assumption concerning worse learning outcomes with pictures accompanied by text containing spatial contents as compared to text containing visual contents was confirmed: Learners, who received pictures together with text containing spatial contents, showed overall worse performance in recalling text-based and visual picture-based information. Furthermore, learners with text containing visual contents recalled spatial picture-based information to the same extent as did learners with text containing spatial contents. Thus, text containing spatial contents did not support the recall of spatial picture information: These results indicate that learners with text containing visual contents processed the picture more thoroughly than learners with text containing spatial contents. How can these results be explained? In the theoretical part of the paper we assumed that text containing spatial contents leads to an additional load of the spatial VSSP, resulting in worse learning outcomes for text and picture recall. However, in total, the secondary task did not reduce the performance of learners with text containing spatial contents, which may indicate that spatial text contents do not increase the load of the spatial VSSP. Instead, as mentioned above, the secondary task interfered with the processing of spatial picture information only when the load of the spatial VSSP was assumed to be extremely high (see Figure 3). Thus, it cannot be definitely concluded that the observed performance decrement with text containing spatial contents is due to a higher load of the spatial VSSP. Rather, it is also possible that a spatial secondary task does not reduce performance when the spatial VSSP gets simply loaded but only if it gets overloaded.

An alternative explanation for the found performance decrement with text containing spatial contents might be the text difficulty. With regard to recall of text contents, one might argue that text containing visual information, that is, information about color and form, is easier to

recall than text containing spatial information, that is, information about spatial relationships or the position of a certain characteristic. Thus, the fact that learners with text containing visual contents performed better, when they had to recall text-based information might potentially be simply explained by differences in text difficulty and not by interference in the spatial VSSP. On the other hand, the Flesch scores indicated the same reading ease for both texts. Furthermore, one may ask why text difficulty should influence the processing of the pictures, which were the same in all groups. One might argue that because text containing spatial contents is more difficult to process, learners might concentrate more on the text and neglect the picture. This in turn might result in worse recall performance for pictures. However, a further study where we used eye tracking methodology to assess the amount of attention devoted to text and pictures showed no differences between learners with different text contents with regard to their viewing behavior. Thus, it seems as if text difficulty is not responsible for the results.

The third assumption concerning a modality effect that would occur only with text containing spatial contents was confirmed for the recall of spatial picture information, when learners additionally performed a secondary task. Thus, under extreme load conditions the eye movements necessary to read the text interfered with picture processing. This implies that written text can decrease performance when the load of the spatial VSSP is already high.

To conclude, these results show that the presentation of text containing spatial contents together with pictures might be detrimental to learning under certain circumstances such as restricted learning time or system-paced presentations. Under these conditions it might be better to convey spatial information only through visualizations, because visualizations are more efficient than texts for accomplishing tasks that require the processing of visuo-spatial properties (Larkin & Simon, 1987). If it is not possible to convey the spatial information only via picture, we recommend presenting spoken texts, because otherwise the eye movements associated with reading may decrease performance when the load of the spatial VSSP is high.

To get deeper insights into the interplay of working memory and multimedia learning, further research is needed that addresses more fine-grained processing aspects (e.g., measuring the amount of eye movements and relate it to spatial text processing). This is in line with our conviction that more cognitive basic research is needed to develop more precise theoretical frameworks for explaining how multimedia learning works.

Abstract

Though several studies have demonstrated the usefulness of pictures in multimedia learning, memory, cognitive load and visual search, there have been very few attempts to study their impact in the web-navigation scenario. Also, cognitive models of web-navigation (like CoLiDeS, CoLiDeS+) ignore the information from visual modality and focus solely on the information from text. We conducted an experiment to study the extent to which providing icons next to hyperlinks facilitates information retrieval tasks on the web. Three different versions of navigation styles were created: Hyperlinks with Icons, Hyperlinks alone and Icons alone. Users took significantly less time, were significantly less disoriented and made fewer clicks to finish their tasks when icons were provided along with hyperlink text. These results suggest that it is important for a cognitive model on web-navigation to include information from pictures. An important practical implication is to provide meaningful icons next to hyperlinks for better navigation.

Keywords: Web-navigation, text, pictures, icons, web-usability, cognitive model

Introduction

With the advancement of web-technology, the World Wide Web (WWW) now has evolved into a complete hypermedia environment, i.e. information is spread across all modalities – text, picture, audio and video. This adds to the complexity and the *lost in hyperspace* phenomenon of the users (Conklin, 1987). Pirolli and Card (1999) found that a user always follows the path that gives highest *information scent*; i.e., a user estimates the cost and value of taking a particular action like clicking on a hyperlink, and comparing several such actions always picks the action that has the highest value or information scent (Chi *et al.*, 2000, 2001).

Inspired by this information scent model, several cognitive models of web-navigation (CoLiDeS, CoLiDeS+, SNIF-ACT and MESA) have been developed. Comprehension based Linked model of Deliberate Search

(CoLiDeS) developed by Kitajima, Blackmon and Polson (2000) divides the process of navigating a website into four steps – *parsing, focusing, comprehension and elaboration and selecting*. A user first parses the web page into 5-10 top-level schematic regions, focuses on one of the sub-regions, comprehends and generates an elaborated representation of each object in the sub-region based on his or her background knowledge and finally selects one object in that sub-region. This final step of selection is based on the computation of semantic similarity between the user's goals and the elaborated representations developed by the user.

CoLiDeS+ developed by Juvina and Oostendorp (2005, 2008) improved CoLiDeS by incorporating contextual information, i.e. information from previously visited web pages. It computes *path adequacy* as the semantic similarity between the user goal and the navigation path. CoLiDeS+ selects the incoming information only if it increases path adequacy. When the incoming hyperlink does not increase path adequacy, other hyperlinks with lower information scent are considered. Further, it considers backtracking to other regions in the same page and then to other pages.

Miller and Remington (2004) proposed a *Method for Evaluating Site Architectures* (MESA). This model focuses on the quality of link labels and the effectiveness of various link-selection strategies. By varying the link quality and using links that are not fully descriptive of the target goals, user behaviour is modelled. The common condition when the user is not sure of his goal or is not knowledgeable enough to assess the relevance of the link texts to the goal is also modelled.

SNIF-ACT (*Scent based Navigation and Information Foraging in the ACT Architecture*) developed by Pirolli and Fu (2003), predicts user-navigation behaviours when they perform unfamiliar information retrieval tasks. It also predicts that users would leave a site when the information scent falls below a threshold value. SNIF-ACT is based on an algorithm called Web User Flow by Information Scent

(WUFIS) developed by Chi *et al.* 2001. It combines both information retrieval and spreading activation techniques to arrive at the probabilities associated with each hyperlink that specify the proportion of users who will navigate through it.

All these models compute information scent by calculating the semantic similarity between the user goal and the hyperlink text. Although a web page contains much more information than just hyperlink text, the models ignore all of it. Actually, there has been very little research on the impact of such complex hypermedia environments on navigation in such web scenarios. However, extensive research from the fields of multimedia learning, memory, cognitive load and visual search give us an insight into the positive impact of multimodal representations, and potentially on web-navigation. We will present a study that examines the extent to which providing icons next to hyperlinks facilitate information retrieval.

Overview of research on impact of pictures

Mayer and Moreno (2003a, 2003b, 2004) demonstrated that meaningful learning that involves attending to important aspects of material, organizing it into a coherent structure, comprehending and understanding it and integrating with already known knowledge can happen better with content that has both visual and verbal format. Their theory is based on the dual-channel assumption of Paivio (1986), according to which humans possess separate channels for processing verbal and visual material, and the working memory theory of Baddeley (1998), which states that only a limited amount of processing can take place in any channel at any point of time. Of the seven principles that Mayer came up with, three are relevant to the web-scenario as well: coherence principle (present relevant pictures and avoid unnecessary information), spatial contiguity principle (present on-screen text nearer to the corresponding picture) and personalization principle (use words that are familiar to the user).

Larkin and Simon (1987) differentiate between diagrammatic and textual representations. They demonstrated that by preserving topological and spatial relations, diagrammatic representations make it easier to solve certain geometric problems. Scaife and Rogers (1996) proposed that graphical representations bring advantages for learning by reducing the amount of effort required to solve a problem and reducing ambiguity by limiting the range of inferences that can be drawn. It is known that students develop deeper understanding of material through self-explanations. Ainsworth and Loizou (2003) showed that this phenomenon is stronger when material with diagrams is presented. Sweller and Chandler (1994) showed that by physically integrating text and corresponding pictures, working memory load is reduced as it reduces redundancy and the effort in integrating information from various sources. Levie and Lentz (1982) have shown that information is remembered and retrieved better when accompanied by relevant pictures.

An eye tracking study by Namatame *et al.*, 2008 showed that for a directory-based search in a computer, fixation time and number of saccades are the least for labelled pictogram condition. This is also evident from the research on visual attention (Desimone and Duncan, 1995, Treisman and Galade, 1980), which demonstrated that any object significantly different from its surrounding objects along intensity, colour, orientation, and motion direction will be perceived by the human brain at very early stages of visual processing. Pictures, being the most salient objects on a web page, are thus attended to by the user before text. Although all this literature points to the positive influence pictures have on learning, memory and cognitive load, little effort has been put to study their impact in the domain of web-navigation.

Impact of graphics on web-navigation

Finding information on the web can at times be a daunting task given its vastness and non-linear nature. Further, recent research by Ruddle (2009) showed that even frequent visitors remember very little of the content and structure of a website. This further warrants the need to study factors affecting web-navigation behavior in detail. It has been found by Carnot *et al.*, (2001) that using a concept-map-based browser, which is a hierarchical organization of a set of concepts and relations between the concepts gives much more accurate search performance compared to a normal browser. The position of the navigation bar was found to significantly affect the mean time spent on a page (Petrie *et al.*, 2009).

Hinesley (2005) studied the impact of graphics in locating web page widgets by taking two versions of a page – one with original text intact and the other with all text replaced with character 'X' (greeked pages). She found that it was more difficult to find textual widgets on greeked pages than graphical widgets. Also, Hinesley and Blackmon (2008) investigated the interaction between location expectations and graphics with greeked pages. They found yet again that the performance detriment for graphical widgets was less when location expectations were violated. Hinesley thus claimed that it is graphics that play an important role in identifying web page widgets.

We scrutinized this claim in Karanam *et al.*, (2009) by examining the interaction of text and graphics completely. While Hinesley manipulated text with graphics intact in the first experiment, she manipulated graphics on greeked text in the second. We took four versions of each web page by systematically varying text and graphics. Our major result was that in the absence of graphics, having textual information was better than having no text. When there were no graphics, textual information significantly reduced the user's efforts in finding a widget. Thus, we argued that both text and graphics play an equally important role in a web page and it is important for cognitive models of web-navigation to take this into account.

Both Hinesley and Karanam restricted the tasks in their experiments to locating a widget on a web page. They did not involve any navigation or information retrieval. All that the user had to do was to locate the widget and click on it. What is the impact of graphics on navigation performance? Do graphics and text influence navigation for some information retrieval in the same way as they influence the task of locating a widget? Generally, we assume that users would visit a website with a predefined goal in mind. Thus, what would be the impact on their accuracy of finding the correct target page? This formed the starting point of our next study in which we wanted to investigate if providing meaningful icons next to hyperlinks would aid the user in navigating better. Would it help the user in finding their answers to their goals quicker? Van Oostendorp and Holzle (2005) for instance did find that presenting icons of the participants next to labels of messages on a bulletin board during collective problem solving had a positive effect on communication and performance. We will examine these questions by presenting participants with three different navigation structures – hyperlinks with icons, only hyperlinks and only icons. We will measure the influence of these three different structures on task completion times, number of clicks, task accuracy and user disorientation.

Method

Participants

Forty-five graduate and undergraduate students from Mahatma Gandhi Institute of Technology participated in this experiment. The mean age of the participants was 23. A pre-test was administered before the experiment on the content of the materials used. Three questions each on the country “Georgia” and “Musical Instruments” were given. Each question had four multiple choices, and the participants had to choose one of them as the answer. Correct answers were scored as 1 and wrong answers as 0. For each participant, total score was then calculated by taking the sum of individual scores of each question. All participants scored low on the final scores. ($M=1.31$, $SD=1.05$). It can be inferred that their prior knowledge of the subject was quite low.

Material and Apparatus

Website We used two topics for our websites: “Encyclopaedia of Georgia” (25 pages) and “Musical Instruments” (31 pages). Website on Georgia had content describing its geography, society, culture and religion. Website on Musical Instruments had content on different methods of classifying musical instruments – the Western System, the Hornbostel Sachs system and classification by Nationality.

Each website was 4 levels deep. Three versions of each website were created based on three different navigational styles: only hyperlink text (L), hyperlink text with icons (LI) and only icons (I), as shown in figure 1. For each hyperlink,

at least five icons were collected, and two authors of this paper scored them for relevancy on a 7-point Likert scale. The icons with highest scores for relevancy were chosen as icons.

Figure 1: Three versions of a webpage with different navigational styles

Information Retrieval Tasks A total of eight user goals were generated: four for each website, one for each level. An example user goal for Georgia website could be – “A traditional Georgian confection made of caramelized nuts, usually walnuts, fried in honey, is served exclusively on New Year’s Eve and Christmas. Name it”.

Table1: Information Retrieval Tasks

“Georgia” Website	
Level	Task
1	The Georgian school system is divided into four stages, what are they?
2	Name two traditional Georgian feast songs.
3	A traditional Georgian confection made of caramelized nuts, usually walnuts, fried in honey, is served exclusively on New Year’s Eve and Christmas. Name it.
4	Name three trees that cover the northern slope of Greater Caucasus Mountains?
“Musical Instruments Website	
Level	Task
1	According to Hornbostel Sachs system of Musical Instruments Classification, which mode of sound production do Idiophones use?
2	In the ancient system of musical instruments classification, xylophone belongs to which category of percussion instruments?
3	The Russian musical instrument – ‘Ghusli’ has similarities with other instruments in China, Japan and Baltic countries. What are they?

4	In Ancient system of classifying musical instruments, saxophone is categorized as woodwind instrument and not brass instrument. Why?
---	--------------------------------------------------------------------------------------------------------------------------------------

Measures Our dependent variables were mean task-completion time, number of clicks, task accuracy and disorientation.

Mean Task-Completion Time: The time taken by the user to finish the task was measured. There was a time limit of 5 minutes for each task.

Number of clicks: The number of clicks made by the user before reaching the target page.

Task Accuracy: Task accuracy was measured by scoring the answers given by users. A correct answer from correct page was scored 1. A wrong answer from correct page was scored 0.5. Wrong answers from wrong pages and answers beyond time limit were scored 0.

Disorientation: An objective measure of disorientation was used: It was computed using Smith (1996)'s L measure.

$$L = \sqrt{(N/S - 1)^2 + (R/N - 1)^2}$$

Where:

R = number of nodes required to finish the task successfully (thus, the number of nodes on the optimal path);

S = total number of nodes visited while searching;

N = number of different nodes visited while searching.

Design

We used a between-subjects design with fifteen participants in each group. Every participant answered all eight questions. The order of questions was randomized.

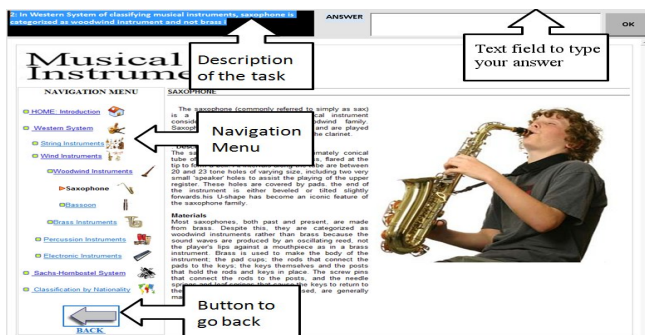

Figure 2: Layout presenting information retrieval tasks

Procedure

After the pre-test to check their prior knowledge about the domain, participants were presented with eight information retrieval tasks on the two different websites in random

order. Their task was to locate the target page that contains the answer to these questions; type the answer in the box provided and proceed to the next task. Figure 2 shows the layout of the screen presenting information retrieval tasks. Participants first saw the task description on the screen and then the website was presented in a browser. The task description was always present in the top-left corner, in case the participant wished to read it again.

Results

We did not find a significant impact of condition on task accuracy ($p > .05$) and therefore we only report the results on other variables – task-completion time, clicks and disorientation.

We first did a mixed ANOVA analysis with our experimental condition as a between-subjects variable and Website as a within-subjects variable. We got a very strong main effect of website for all three of our measures but the interaction effect was not significant. We interpret that the website on musical instruments was relatively unfamiliar and new compared to the website on Georgia, to most of our participants and therefore they took more time, more clicks and were more disoriented in performing their tasks.

Task-Completion Time The number of time-outs in each of the three conditions was computed. The time-out percentages were: Hyperlinks with icons (7.5%), only hyperlinks (10%) and only icons (12.5%). We considered only the tasks for which participants gave correct answers for this analysis. A between-subjects one-way ANOVA with the three experimental conditions as independent variable and mean task completion time as dependent variable was conducted. Results show a main effect of condition ($F(2,36) = 4.427, p < .05$). Figure 3 shows the means plot.

Figure 3: Mean Task-Completion Times

Post-hoc tests reveal significant differences between the groups – (LI)-(I) $p < .01$. That is, the task-completion times were significantly less when both links and icons were together when compared to only icons. The difference between (L) and (I) groups was not significant $p > .05$.

Number of Clicks A similar between-subjects one-way ANOVA with the three experimental conditions as independent variable and the number of clicks taken to find the target page with correct answer as dependent variable was conducted. The main effect of Condition is highly significant ($F(2,36) = 43.239, p < .001$). Figure 4 depicts this relationship for average number of clicks.

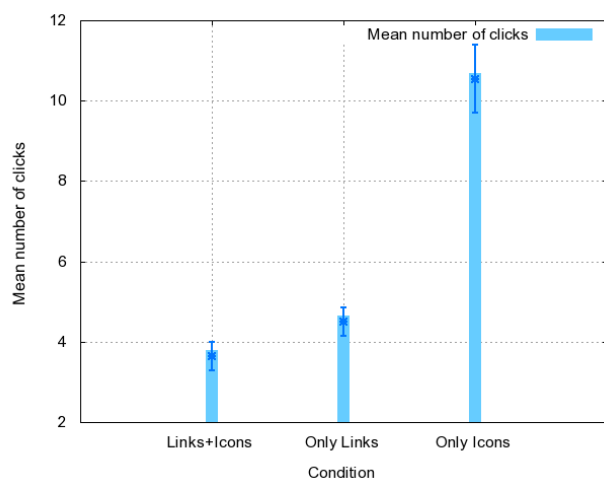

Figure 4: Mean number of clicks

Post-hoc tests reveal significant differences between (LI)-(I) $p < .05$ and (L)-(I) $p < .05$ groups. The number of clicks users took when there were both icons and hyperlink text was significantly less than when there were only icons. Similarly, the number of clicks users took to finish their tasks when there was only hyperlink text was also significantly less than when there were only icons. In other words, having only icons took the maximum number of clicks to finish the tasks, suggesting that only icon-based navigation might not be advisable. The difference in number of clicks between (LI) and (L) groups was not significant ($p > .05$).

Disorientation A between-subjects one-way ANOVA with the experimental condition as independent variable and mean objective disorientation measure as dependent variable was conducted. Results reveal a very significant main-effect of condition $F(2,36) = 33.598, p < .001$.

Post-hoc tests reveal significant differences between the pairs – (LI)-(I) $p < .05$ and (L)-(I) $p < .05$. Having only icons induced the maximum disorientation in users. Users deviated from the optimum path the most under this condition. They took the maximum number of de-tours and returned to the same page visited earlier frequently. Their disorientation significantly reduced when icons were replaced with corresponding hyperlink text. Users could navigate much better compared to the condition when there were only icons. Further, when both hyperlink text and

icons were provided, there was even more significant decrease in disorientation. Figure 5 shows the graph.

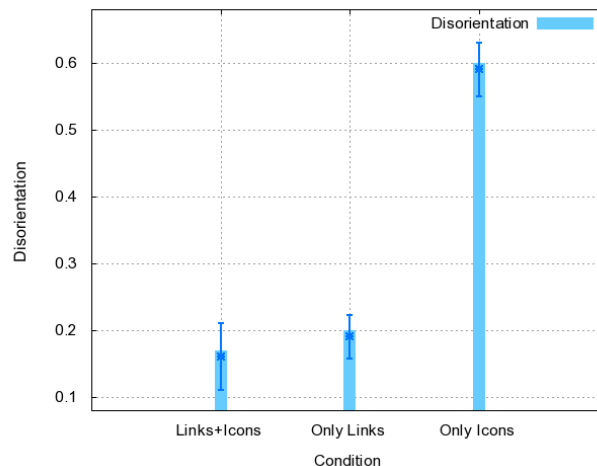

Figure 5: Disorientation

Discussion

In this research, we focused on the impact of providing icons next to hyperlink text in the main navigation menu of a page on user's search and information retrieval performance. Overall, we found that providing icons next to hyperlink text is very helpful for users in reducing the amount of time they take to finish their task, number of clicks they take to reach their target page and in optimizing the path they take to the target page.

It has been found that users take significantly less time when both hyperlink text and corresponding icons are provided compared to the conditions when only hyperlink text or only icons are present. Number of clicks also shows a similar pattern: Users take significantly less number of clicks to find their target pages with icons and hyperlink text present when compared with the pages with only hyperlinks or only icons. Users were disoriented the most when there were only icons present. It was hard to navigate with only icons. This phenomenon of disorientation decreased significantly when there was only hyperlink text and further decrease was effectuated by placing meaningful icons next to the text.

In general, our results support the positive impact of pictures found elsewhere in other domains like multimedia learning, cognitive load and visual search. We have shown that pictures / graphical information together with textual information play an important role in improving overall user-performance in not only locating their target on a web page but also navigating through a website and finding their target pages.

One practical implication of this study is to use meaningful icons next to hyperlink text to improve the overall usability of a website. Also, on basis of this study and our previous study (Karanam *et al.*, 2009), we argue strongly for inclusion of pictorial and graphical information in cognitive models of web-navigation. We have already

shown that semantic information derived from pictures can be included into CoLiDeS (Karanam *et al.*, 2009). We also demonstrated that such a model would predict the correct hyperlink more frequently and more accurately.

Abstract

We present an algorithmic model for the development of children’s intuitive theories within a hierarchical Bayesian framework, where theories are described as sets of logical laws generated by a probabilistic context-free grammar. Our algorithm performs stochastic search at two levels of abstraction – an outer loop in the space of theories, and an inner loop in the space of explanations or models generated by each theory given a particular dataset – in order to discover the theory that best explains the observed data. We show that this model is capable of learning correct theories in several everyday domains, and discuss the dynamics of learning in the context of children’s cognitive development.

Introduction

As children learn about the world, they learn more than just a large stock of specific facts. They organize their knowledge into abstract coherent frameworks, or *intuitive theories*, that guide inference and learning within particular domains (Carey, 1985; Wellman & Gelman, 1992). Much recent work in computational cognitive modeling has attempted to formalize how intuitive theories are structured, used and acquired from experience (Tenenbaum, Griffiths, & Kemp, 2006), working broadly within a hierarchical Bayesian framework shown in Figure 1 (and explained in more detail below). While this program has made progress in certain respects, it has treated the problem of theory acquisition only in a very ideal sense. The child is assumed to have a hypothesis space of possible theories constrained by some “Universal Theory”, and to be able to consider all possible theories in that space, in light of a given body of evidence. Given sufficient evidence, and a suitably constrained hypothesis space of theories, it has been shown that an ideal Bayesian learner can identify the correct theory underlying core domains of knowledge such as causality (Goodman, Ullman, & Tenenbaum, 2009), kinship and other social structures (Kemp, Goodman, & Tenenbaum, 2008). These Bayesian computational analyses have not to date been complemented by working algorithmic models of the search process by which a child can build up an abstract theory, piece by piece, generalizing from experience. Here we describe such an algorithmic model for Bayesian theory acquisition. We show that our algorithm is capable of constructing correct if highly simplified theories for several everyday domains, and we explore the dynamics of its behavior – how theories can change as the learner’s search process unfolds as well as in response to the quantity and quality of the learner’s observations.

At first glance, the dynamics of theory acquisition in childhood look nothing like the ideal learning analyses of hierarchical Bayesian models – and may not even look particularly

rational or algorithmic. Different children see different random fragments of evidence and make their way to adult-like intuitive theories at different paces and along different paths. It seems unlikely that children can simultaneously evaluate many candidate theories at once; on the contrary, they appear to hold just one theory in mind at any time. Transitions between theories appear to be local, myopic, and semi-random, rather than systematic explorations of the hypothesis space. They are prone to backtracking or “two steps forward, one step back”. We suggest that these dynamics are indicative of a stochastic search process, much like the Markov chain Monte Carlo (MCMC) methods that have been proposed for performing approximate probabilistic inference in complex generative models. We show how a search-based learning algorithm can begin with little or no knowledge of a domain, and discover the underlying structure that best organizes it by generating new hypotheses and checking them against its current conceptions of the world using a hierarchical Bayesian framework. New hypotheses are accepted probabilistically if they can better account for the observed data, or if they compress it in some way. Such a search-based learning algorithm is capable of exploring a potentially infinite space of theories, but given enough time and sufficient data it tends to converge on the correct theory – or at least some approximation thereof, corresponding to a small set of abstract predicates and laws.

The plan of the paper is as follows. We first introduce our framework for representing and evaluating theories, based on first-order logic and Bayesian inference in a hierarchical probabilistic model that specifies how the theory’s logical structure constrains the data observed by a learner. We then describe our algorithmic approach to theory learning based on MCMC search, using simulated annealing to aid convergence. Finally we study the search algorithm’s behavior on two case studies of theory learning in everyday cognitive domains: the taxonomic organization of object categories and properties, and a simplified version of magnetism.

Formal framework

We work with the hierarchical probabilistic model shown in Figure 1, based on those in (Katz, Goodman, Kersting, Kemp, & Tenenbaum, 2008; Kemp et al., 2008). We assume that a domain of cognition is given, comprised of one or more systems, each of which gives rise to some observed data. The learner’s task is to build a theory of the domain: a set of abstract concepts and explanatory laws that together generate a hypothesis space and prior probability distribution over candidate models for systems in that domain. The laws and

Figure 1: A hierarchical Bayesian framework for theory acquisition concepts are written in logical form, a “language of thought”, typically a subset of first-order logic. The learner’s model of a system specifies what is true of that system, and thereby generates a probability distribution over possible observations that can be made for that system.

For example, consider a child learning about the domain of magnetism. She might begin by playing with a few pieces of metal and notice that some of the objects interact, exerting strange pulling or pushing forces on each other. She could describe the data directly, as “Object i interacts with object f ”, “Object i interacts with object j ”, and so on. Or she could form a simple theory, in terms of abstract concepts such as magnet, magnetic object and non-magnetic object, and laws such as “Magnets interact with other magnets”, “Magnets interact with magnetic objects”, and “Interactions are symmetric” (but no other interactions take place). Systems in this domain correspond to specific subsets of objects, such as the set of objects $\{a, \dots, i\}$ in Figure 1. A model of a system specifies the minimal facts needed to apply the abstract theory to the system, in this case which objects are magnetic, which are magnets, and which are non-magnetic. From these core facts the laws of the theory determine all other true facts – in our example, this means all the pairwise interactions between the objects: e.g., objects i and j , being magnets, should interact, but i and e should not, because e is non-magnetic. Finally, the true facts generate the actual data observed by the learner via a noisy observation process.

While the abstract concepts in this simplified magnetism theory are attributes of objects, more complex relations are possible. Consider for example a domain of taxonomy, as in Collins and Quillian’s classic model of semantic memory as an inheritance hierarchy (Collins & Quillian, 1969). Here the abstract concepts are is_a relations between categories and has_a relations between categories and properties. The theory underlying taxonomy has two basic laws: “The has_a relation

inherits down is_a relations” and “The is_a relation is transitive” (laws 3 and 4 on the right side of Figure 1). A system consists of a specific set of categories and properties, such as salmon, eagle, breathes, can fly, and so on. A model specifies the minimal is_a and has_a relations, typically corresponding to a tree of is_a relations between categories with properties attached by has_a relations at the broadest category they hold for: e.g., “A canary is a bird”, “A bird is an animal”, “An animal can breathe”, and so on. The laws then determine that properties inherit down chains of is_a relations to generate many other true facts that can potentially be observed, e.g., “A canary can breathe”.

Equipped with this hierarchical generative model, a learner can work backwards from observed data to multiple levels of latent structure. Given the correct theory, the learner can infer the most likely model underlying a set of noisy, sparse observations and predict facts that have not been directly observed (Katz et al., 2008; Kemp et al., 2008). If the true theory is unknown, the learner can consider a hypothesis space of candidate theories, generated by higher-level “Universal Theory (UT)” knowledge. UT defines a distribution over the space of possible theories, $P(T|UT)$, which can then be used by a learner to infer the correct theory describing a domain, according to the standard Bayesian formulation:

$$P(T|D, UT) \propto P(D|T)P(T|UT) \quad (1)$$

Bayes’ rule here captures the intuition of Occam’s razor. The theory that best explains the data, or has highest posterior probability $P(T|D, UT)$, should be based on two considerations: how well the theory fits the data, as measured by the likelihood $P(D|T)$, and how simple or short is the theory, as measured by the prior $P(T|UT)$. We now define these hypothesis spaces and probabilities more formally, and then describe a learning algorithm that searches the space of theories by proposing small random changes to the current theory and accepting changes stochastically based on whether they are likely to lead to higher overall probability.

A language for theories. Following (Katz et al., 2008) we represent the laws in a theory as Horn clauses: logical expressions of the form $t \leftarrow (p \wedge q \wedge \dots \wedge r)$. Horn clauses express logical implications – a set of conjunctive conditions under which t holds – but can also capture intuitive causal relations under the assumption that any propositions not generated by the theory are assumed to be false. In our formulation, the clauses contain two kinds of predicates: “core” and “surface”. Core predicates are a minimal set of predicates that determine all other predicates when combined with the theory’s laws. Surface predicates are derived from other predicates, either surface or core, via the laws. Predicates may or may not be directly observable in the data. The core predicates can be seen as compressing the full model into just the minimal bits necessary to specify all true facts. In the magnetism example above, the core could be expressed in terms of two predicates $p(X)$ and $q(X)$. Based on an assignment of truth values to these core predicates, the

learner can use the theory’s laws such as $\text{interacts}(X, Y) \leftarrow p(X) \wedge q(Y)$ to derive values for the observable surface predicate $\text{interacts}(X, Y)$. Notice that $p(X)$ and $q(X)$ are abstract predicates, which acquire their meaning as concepts picking out magnets or magnetic objects respectively in virtue of the role they play in the theory’s laws. In constructing such a theory the learner essentially creates new concepts (Carey, 1985). Entities may be typed and predicates restricted based on type constraints: e.g., in taxonomy, $\text{has.a}(X, Y)$ requires that X be a category and Y be a property, while $\text{is.a}(X, Y)$ requires that X and Y both be categories. Forcing candidate models and theories to respect these type constraints provides the learner with a valuable and cognitively natural inductive bias.

The theory prior $P(T|UT)$. We posit UT knowledge in the form of a probabilistic context-free Horn clause grammar (PHCG) that generates the hypothesis space of possible Horn-clause theories, and a prior $P(T|UT)$ over this space (Figure 2). This grammar and the Monte Carlo algorithms we use to sample or search over the theory posterior $P(T|D, UT)$ are based heavily on Goodman, Tenenbaum, Feldman, and Griffiths (2008), who introduced the approach for learning single rule-based concepts rather than the larger theory structures we consider here. We refer readers to Goodman et al. (2008) for many technical details. Given a set of possible predicates in the domain, the PHCG draws laws from a random construction process (Law) or from law templates (Tem; explained in detail below) until the Stop symbol is reached, and then grounds out these laws as horn clauses. The prior $p(T|UT)$ is

$P(X, Y) \leftarrow P(X, Z) \wedge P(Z, Y)$	$P(X, Y) \leftarrow P(X) \wedge P(Y)$
$P(X, Y) \leftarrow P(Z, X) \wedge P(Z, Y)$	$P(X, Y) \leftarrow P(Y, X)$
$P(X, Y) \leftarrow P(X, Z) \wedge P(Y, Z)$	$P(X, Y) \leftarrow P(X, Y)$
$P(X, Y) \leftarrow P(Z, X) \wedge P(Y, Z)$	$P(X) \leftarrow P(X)$
$P(X, Y) \leftarrow P(X, Y) \wedge P(X)$	$P(X) \leftarrow P(X, Y) \wedge P(X)$
$P(X, Y) \leftarrow P(Y, X) \wedge P(X)$	$P(X) \leftarrow P(Y, X) \wedge P(X)$
$P(X, Y) \leftarrow P(X, Y) \wedge P(Y)$	$P(X) \leftarrow P(X, Y) \wedge P(Y)$
$P(X, Y) \leftarrow P(Y, X) \wedge P(Y)$	$P(X) \leftarrow P(Y, X) \wedge P(Y)$

Figure 3: The list of templates available to in the PHCG.

the product of the probabilities of choices made at each point in this derivation. All these probabilities are less than one, so overall the prior favors simpler theories with shorter derivations. The precise probabilities of different rules in the grammar are treated as latent variables and integrated out, favoring re-use of the same predicates and law components within a theory (Goodman et al., 2008).

Law templates. We make the grammar more likely to generate useful laws by equipping it with templates, or canonical forms of laws that capture structure likely to be shared across many domains. While it is possible for the PHCG to reach each of these law forms without the use of templates, their inclusion allows the most useful laws to be invented more readily. They can also serve as the basis for transfer learning across domains. For instance, instead of having to re-invent transitivity anew in every domain with some specific transitive predicates, a learner could recognize that the same transitivity template applies in several domains. It may be costly to invent transitivity for the first time, but once found – and appreciated! – its abstract form can be readily re-used. The specific law templates used are described in Figure 3. Each “ $P(\cdot)$ ” symbol stands for a non-terminal representing a predicate of a certain -arity. This non-terminal is later instantiated by a specific predicate. For example, the template $P(X, Y) \leftarrow P(X, Z) \wedge P(Z, Y)$ might be instantiated as $\text{is.a}(X, Y) \leftarrow \text{is.a}(X, Z) \wedge \text{is.a}(Z, Y)$ (a familiar transitive law) or as $\text{has.a}(X, Y) \leftarrow \text{is.a}(X, Z) \wedge \text{has.a}(Z, Y)$ (the other key law of taxonomy, stating that “has.a is transitive over is.a”).

The theory likelihood $P(D|T)$. An abstract theory makes predictions about the observed data in a domain only indirectly, via the models it generates. A theory typically generates many possible models: even if a child has the correct theory and abstract concepts of magnetism, she could categorize a specific set of metal bars in many different ways, each of which would predict different interactions that could be observed as data. Expanding the theory likelihood,

$$P(D|T) = \sum_M P(D|M)P(M|T) \quad (2)$$

we see that theory T predicts data D well if it assigns high prior $P(M|T)$ to models M that make the data probable under the observation process $P(D|M)$.

The model prior $P(M|T)$ reflects the intuition that a theory T explains some data well if T requires few additional degrees of freedom beyond its abstract concepts and laws to make its predictions. That is, few specific and contingent facts about the system under observation are required

in addition to the theory’s general prescriptions. This intuition is captured by a prior that encourages the core predicates to be as sparse as possible, penalizing theories that can only fit well by “overfitting” with many extra degrees of freedom. Formally, following (Katz et al., 2008), we model all values of the core predicates as independent Bernoulli random variables with conjugate beta priors encouraging most variables to have the same value (on or off). We assume that any proposition potentially in the model M is false unless it is a core predicate turned on by this Bernoulli process or is derived from the core predicates through the theory’s laws (the *minimal model* assumption of logic programming).

Finally, the model likelihood $P(D|M, T)$ comes from assuming that we are observing randomly sampled true facts (sampled with replacement, so the same fact could be observed on multiple occasions), which also encourages the model extension to be as small as possible.

Stochastic search in theory space: a grammar-based Monte-Carlo algorithm. Following Goodman et al. (2008), we use a grammar-based Metropolis-Hastings (MH) algorithm to sample theories from the posterior distribution over theories conditioned on data, $P(T|D, UT)$. This algorithm is applicable to any grammatically structured theory space, such as the one generated by our PHCG. The MH algorithm proceeds by randomly proposing changes to the current theory, and accepting or rejecting these changes. Each proposed change to the current theory corresponds to choosing a grammatical constituent of the theory then regenerating it from the PHCG. For example, if our theory of magnetism includes the law $\text{interacts}(X, Y) \leftarrow p(X) \wedge q(Y)$, the MH procedure might propose to add or delete a predicate (e.g., $\text{interacts}(X, Y) \leftarrow p(X) \wedge q(Y) \wedge p(Y)$ or $\text{interacts}(X, Y) \leftarrow p(X)$), to change one predicate to an alternative of the same form (e.g., $\text{interacts}(X, Y) \leftarrow p(X) \wedge p(Y)$) or a different form if available (e.g., $\text{interacts}(X, Y) \leftarrow p(X) \wedge r(X, Y)$); to resample the law from a template (e.g., $\text{interacts}(X, Y) \leftarrow r(X, Z) \wedge r(Z, Y)$); or to add or delete a whole law.

These proposals are accepted with probability equal to the minimum of 1 and the MH acceptance ratio,

$$\frac{P(T'|D, UT) \cdot Q(T|T')}{P(T|D, UT) \cdot Q(T'|T)} \quad (3)$$

where T is the current theory, T' is the new proposed theory, and $Q(\cdot|\cdot)$ is the transition probability from one theory to the other, derived from the PHCG (Goodman et al., 2008). To aid convergence we raise the posterior ratio to a power greater than 1, which we increase very slightly after each MH step in a form of simulated annealing. The learner initially explores alternative theories freely, but with time becomes increasingly likely to reject theory changes unless they lead to an improved posterior probability.

While this MH algorithm could be viewed merely as a way to approximate the calculations necessary for a hierarchical

Bayesian analysis, we suggest that it could also capture in a schematic form the dynamic processes of theory acquisition and change in young children. Stochastic proposals to add a new law or change a predicate within an existing law are consistent with some previous characterizations of children’s theory learning dynamics (Siegler & Chen, 1998). These dynamics were previously proposed on purely descriptive grounds, but here they emerge as a consequence of a rational learning algorithm for effectively searching an infinite space of logical theories.

Approximating the theory score. Computing the theory likelihood $P(D|T)$, necessary to compare alternative theories in Equation 3, requires a summation over all possible models consistent with the current theory (Equation 2). Because this sum is typically very hard to evaluate exactly, we approximate $P(D|T)$ with $P(D|M^*)P(M^*|T)$, where M^* is an estimate of the maximum a-posteriori (MAP) model inferred from the data: the most likely values of the core predicates. The MAP estimate M^* is obtained by running a Gibbs sampler over the values of the core predicates, as in (Katz et al., 2008), annealing slightly on each Gibbs sweep to speed convergence and lock in the best solution. The Gibbs sampler over models generated by a given theory is thus an “inner loop” of sampling in our learning algorithm, operating within each step of an “outer loop” sampling at a higher level of abstract knowledge, the MH sampler over theories generated by UT knowledge.

Case Studies

We now explore the performance of this stochastic approach to theory learning in two case studies, using simulated data from the domains of taxonomy and magnetism introduced above. We examine the learning dynamics in each domain and make more explicit the possible parallels with human theory acquisition.

Taxonomy

Katz et al. (2008) defined a similar hierarchical Bayesian framework and showed that a theory of taxonomic reasoning about properties and categories in an inheritance hierarchy could be correctly selected from among several alternatives, on the basis of data. However, they did not address the harder challenge of constructing the theory from the ground up, or selecting it from an effectively infinite hypothesis space of theories (which could be used to describe many other domains). That is our goal here. Following Katz et al. (2008), we take the correct theory to have two unobservable core predicates, $g(X, Y)$ and $f(X, Y)$, and two observable surface predicates, $\text{is_a}(X, Y)$ and $\text{has_a}(X, Y)$. There are four laws:

- Law 1: $\text{has_a}(X, Y) \leftarrow f(X, Y)$
- Law 2: $\text{is_a}(X, Y) \leftarrow g(X, Y)$
- Law 3: $\text{has_a}(X, Y) \leftarrow \text{is_a}(X, Z) \wedge \text{has_a}(Z, Y)$
- Law 4: $\text{is_a}(X, Y) \leftarrow \text{is_a}(X, Z) \wedge \text{is_a}(Z, Y)$

Laws 1 and 2 set up the core predicates to represent the mini-

Figure 4: Log posterior score for representative runs of theory learning in Taxonomy. Dashed lines show different runs. Solid line is the average across all runs. Node 1 marks the acquisition of law 3, node 2 marks the acquisition of law 4.

mal is *a* and has *a* links, on top of which are defined the laws of property inheritance (Law 3) and transitive category membership (Law 4). We take laws 1 and 2 as given, assuming the structure and meaning of the core predicates as Katz et al. did, and ask whether a learner can successfully construct laws 3 and 4. Following Katz et al., we consider a concrete domain with 7 categories and 7 properties in a balanced taxonomy, as shown in Figure 1. Observations include all positive facts asserting that a property is true of a category, as in “An eagle has claws”. (The data used for this section and the following case study can be found at <http://web.mit.edu/tomeru/www/tlss/>.) We ran 10 simulations for 1300 iterations of the outer MH loop. Learning curves for representative runs as well as the average over all runs are shown in Figure 4. Out of 10 simulations, 8 found the correct theory within the given number of iterations, and 2 discovered a partial theory which included only law 3 (property inheritance). Several observations are worth noting.

Abstract learning is possible. Using only stochastic local search moves, a learner can navigate the space of potential theories to discover the laws underlying the domain. Even a relatively small dataset (with 7 categories and 7 properties) is sufficient to learn the correct abstract domain theory.

Individual learning curves show sudden changes and high variability in what is learned when, while on average learning is smooth and follows a characteristic timescourse. The learning algorithm’s local dynamics are highly stochastic and variable across runs, because of the randomness in what theory changes are proposed when, and the fact that a small theory change can make a big difference in predictive power. Yet there is still a meaningful sense in which we can talk about “typical” learning behavior, even though any one learner may not look much like this average. If stochastic local search is a key component in children’s theory construction, it could explain why cognitive development shows this same dual nature: systematic and graded progression at the population level, despite random, discontinuous and highly variable learning rates in any one child.

Although proposals are random, there is a systematic and rational order to learning. While there are many routes

through theory space to a given endpoint, a sequence of random MH proposals may still prefer some orders of knowledge acquisition over others. Here, when law 4 is discovered (on 8/10 runs), it is always acquired after law 3. This is because law 4 (transitivity of category membership) provides much more explanatory power – and hence is more stable under our stochastic theory-learning dynamics – given law 3 (property inheritance) and a reasonable domain model specifying which properties hold for which categories. This order is also consistent with the order of acquisition in human cognitive development (Wellman & Gelman, 1992): children learn to generalize properties of biological categories to instances well before they learn that categories can be arranged in a multilevel hierarchy supporting transitive inferences of category membership.

Magnetism

After showing that stochastic search can learn the correct laws in a domain theory, we now consider a second case study in which the acquisition of new laws corresponds to a shift in the meaning of the core predicates, and new (i.e., previously unassigned) core predicates are introduced during learning – akin to some of the conceptual changes described by Carey (1985). Our domain here is the simple version of magnetism described above, with two unobservable core predicates: $p(X)$ and $q(X)$, and one observable surface predicate: $\text{interacts}(X, Y)$. There are three laws:

- Law 1: $\text{interacts}(X, Y) \leftarrow p(X) \wedge p(Y)$
- Law 2: $\text{interacts}(X, Y) \leftarrow p(X) \wedge q(Y)$
- Law 3: $\text{interacts}(X, Y) \leftarrow \text{interacts}(Y, X)$

We consider a concrete system with 3 magnets, 5 magnetic objects and 2 non-magnetic objects. These concepts are initially unknown to the learner. The core predicates $p(X)$ and $q(X)$ are completely abstract and initially uninterpreted. They will acquire their meaning as concepts picking out magnets and magnetic objects respectively in virtue of the role they play in the theory’s laws, specifying that objects in one subset (the p ’s) interact with each other and with objects in a second set (the q ’s), but q ’s do not interact with each other. In constructing a theory, the learner introduces these abstract predicates via new laws, or new roles in existing laws, and thereby essentially creates these concepts where she did not have them before (Carey, 1985).

We ran 10 simulations for 1600 iterations of the outer MH loop. Representative runs are displayed in Figure 5, as well as the average over all the runs. The results were similar to the taxonomy case study in several respects, which we also expect to hold for a variety of other domains. The correct theory was usually learned, with some variation: 9/10 simulations found the correct theory or a variant of it, and one discovered a partial theory containing only law 1. Only some runs learned the exact form of law 3, asserting that interactions are symmetric. Others found variants that were extensionally equivalent to symmetry in this domain, but slightly more

Figure 5: Representative runs of theory learning in Magnetism. Dashed lines show different runs. Solid line is the average across all runs. Node 1 marks the acquisition of law 1 and the confounding of magnets with magnetic objects. Lower right panel zooms into the end of the simulation, showing acquisition of the final correct theory.

complex in their logical form. Individual runs of learning showed discrete jumps with high variability, while average-case behavior was smooth, with systematic order effects. Law 3 is never learned first, because alone it has no explanatory power. Either law 1 or the combination of laws 2 and 3 tend to be learned first, followed by the other, although sometimes laws 1 and 2 are learned first, followed by law 3. Law 1 tends to be learned first overall because it is most likely under the prior (which is also the proposal distribution for local search moves), and also because, as explained below, it represents a reasonable first approximation to the domain's structure.

The algorithm's learning dynamics in this case study are particularly interesting for how they parallel key transitions in childrens' cognitive development: restructuring or construction of new concepts, as when one concept differentiates into two (Carey, 1985). When our simulations of learning about magnetism construct law 1 first, without laws 2 and 3, they find a simpler theory capturing many of the observed facts at the cost of over-generalizing. That is, under law 1 alone, the optimal setting of the core predicates – the most probable model – equates magnets and magnetic objects, making $p(X)$ true for both. This is a good first approximation, even as it collapses two categories of objects with fundamentally different causal properties: the generators of magnetic force (the “magnets”) and the objects on which that force acts (the “magnetic objects”). Only once all three laws have been constructed does the learner come to distinguish between magnets and magnetic objects, reflected in the difference between the roles played by the two core predicates $p(X)$ and $q(X)$. Only once law 2 is available does the learner have reason to restrict the extension of $p(X)$ to just magnets, excluding other magnetic objects.

Conclusion and Future Directions

We have presented an algorithmic model of theory acquisition as stochastic search in a hierarchical Bayesian framework and explored its dynamics in two case studies. We were encouraged by the general pattern of successes on these examples and by several qualitative parallels with phenomena of hu-

man cognitive development. These results suggest that previous ideal learning analyses of Bayesian theory acquisition can be realized approximately by algorithms that are cognitively plausible for child learners, and indeed potentially descriptive of the dynamics of development.

Previous hierarchical Bayesian analyses of learning abstract knowledge have focused on the role of accumulating data in driving changes to the learner's hypotheses (Kemp & Tenenbaum, 2008). In contrast, here we have focused on how changes to the learner's theories and abstract concepts are driven by a different source, the stochastic dynamics of the learning algorithm. Data-driven and algorithm-driven theory change can have a similar character, first discovering simpler, rougher approximations to reality and then refining those to more complex, accurate representations; sometimes changing by adjusting small details, but other times by making large qualitative transitions or discoveries. In future work we plan to explore further the similarities, differences and interactions between these two drivers of learning dynamics, both in computational analyses and experimental work. We hope to establish tighter quantitative correspondences with human learning curves in development, as well as with controlled laboratory studies of theory learning in adults, where some of the same mechanisms might be at work. We will also consider a broader range of algorithmic approaches, stochastic as well as deterministic, evaluating them both as behavioral models and as effective computational approximations to the theory search problem for larger domains.

Is it me or the world? 16-month-olds distinguish competing hypotheses about the cause of failed interventions

Abstract

When an agent fails to make an object function properly, there are two possibilities: the agent did something wrong or something is wrong with the object. As in all problems of confounding, these hypotheses can be disambiguated by varying one factor and holding the other constant: in this case, either by holding the object constant and varying the agent (e.g., by asking for help from others) or by holding the agent constant and varying the object (e.g., by trying another object). Here we show that 16-month-old infants engage in distinct patterns of behavior depending on the relative probability of the competing hypotheses: they ask for help more often when they (rather than the object) are the probable cause of failure; they reach for a new object more often when the object (rather than themselves) is the probable cause of failure.

Keywords: infants, confounding, exploratory behavior, ambiguous evidence, asking for help.

Imagine that you are trying to get into a new office but the key doesn't work. You jiggle it for a minute and then assess your options. What you choose to do next depends on what hypothesis you think is most probable: if you think you are having trouble positioning the key, you might ask a friend for help; if you think you picked up the wrong key, you will probably try a different one.

As intentional agents, we frequently plan and carry out goal-directed actions. Most of the time, these actions are successful. However, when we experience failure, we can experience not only the frustration of our intentions but also a problem of confounded evidence. Did we do something wrong or was something wrong in the world?

This problem of "me or the world" is perhaps the most common example of confounded causal variables that we encounter in everyday life. Of course, the variables "me" and "the world" can sometimes be more precisely defined. In the key example for instance, if you are the problem, you might have put the key in upside down, turned it in the wrong direction, or lack fine motor coordination. Alternatively, if you believe the problem lies in the world, the door might be jammed, or the lock might have been changed. However, these distinctions are subordinate to the primary problem of discovering whether you or the world is the culprit. When things go wrong, how do we identify the locus of failure?

As in any causally confounded situation, changing one variable at a time can disambiguate the evidence. Assuming that changing either variable is possible and equally costly,

a rational agent who wants to generate the effect should change the variable that seems most likely to be the source of the failure. If I think I'm the problem, I should hold the object constant and vary the agent (e.g., ask my friend to help); if I think the object poses the problem, I should hold myself constant and vary the object (e.g., try a new key).

There are many reasons to believe that recognizing, let alone solving, problems of confounding between the self and the world might require substantial expertise. Indeed, previous research suggests that both children and adults have difficulty recognizing when information is ambiguous (Penner & Klahr, 1996) and designing experiments that could generate informative evidence (Chen & Klahr, 1999; Koslowski, 1996; Kuhn, 1989). Such studies of formal scientific reasoning however, typically involve many hypotheses, including those that conflict with the learners' prior beliefs. In contexts where there are only two competing hypotheses and both are familiar and plausible, children seem to be sensitive to confounding at a much younger age (Gweon & Schulz, 2008; Kushnir & Gopnik, 2005; Schulz & Bonawitz, 2007; Sodian, Zaitchik, & Carey, 1991). Thus in simple cases, even very young children might be sensitive to competing hypotheses.

While a sensitivity to confounded variables might enable young children to recognize the "me vs. the world" problem, deconfounding the self and the world requires children to understand *how* to intervene on each variable. For example, imagine a simple confounded situation where a child tries a novel toy and fails to make it work; the child needs to understand that other people ('the agent' variable), and other toys of the same kind ('the world' variable), can both serve as useful sources of information. Here we briefly review some previous studies that suggest that even very young children might be capable of such an understanding.

A large body of literature on social referencing in infancy suggests that infants readily treat their caregivers as sources of information about the emotional valence of events (Sorce, Emde, Campos, & Klinnert, 1985; Walden & Ogan, 1988) and the referent of adults' attention (Baldwin, 1993; Carpenter, Nagell, Tomasello, Butterworth, & Moore, 1998). Moreover, infants use the information to regulate their own behavior. In particular, O'Neill (1996) showed that two-year-olds will request help from a knowledgeable (but not ignorant) parent in retrieving a hidden object, suggesting that toddlers not only look to parents for the information they might provide but also actively solicit such information.

Children's imitation of object-directed actions is also often interpreted as an indication that children perceive others as agents like themselves (the 'like me' hypothesis; Meltzoff & Brooks, 2001) and use adult actions for information about how to interact with an object (Gergely, Bekkering, & Kiraly, 2002; Gopnik & Meltzoff, 1994). Notably, children are more likely to imitate an adult's goal-directed action if they themselves have previously failed to generate a target outcome than if they have succeeded (Williamson, Meltzoff, & Markman, 2008) which suggests that young children can use adult actions as evidence about the cause of their own failures, and modify their own actions accordingly.

Such studies speak to children's understanding of other agents as potential sources of information about objects in the world. What about children's understanding that one object can be informative about other members of the object kind? Previous research has shown that preschoolers generalize non-obvious properties (like squeaking or magnetism) from one member of a kind to others (Gopnik & Sobel, 2000; Nazzi & Gopnik, 2000). Moreover, children maintain this expectation even when one exemplar fails to function as expected (Schulz, Standing, & Bonawitz, 2008). Indeed, 9-month-old infants can generalize a property of an object to other identical-looking object after a single exposure (Baldwin, Markman, & Melartin, 1993), and by 15 months infants can even integrate information about how the exemplars are sampled in their inferences about object properties (Gweon, Tenenbaum, & Schulz, 2010). These studies establish that children expect object properties to generalize across similar-looking objects, maintain that expectation even when they themselves fail to elicit the expected property, and, having experienced failure, can both solicit help from caregivers and act on other similar objects. This study however, is the first to investigate the possibility that infants might be sensitive to competing hypotheses for why their actions fail, and might rationally trade-off actions directed towards agents and actions directed towards objects. Here we ask whether 16-month-old infants implicitly recognize the ambiguity in a failed attempt to activate a toy. We predict that children should be more likely to ask for help when they themselves are the probable source of failure and more likely to test another toy when the probable cause of failure lies in the toy itself.

Experiment

In the current study, we introduce infants to three identical-looking toys, differing only in color (Green, Yellow, and Red). The experimenter shows the child that she can push a button on the Green toy and the toy will make music. In the Agent condition, the experimenter then hands the child the Green toy; in the Object condition, the experimenter hands the child the Yellow toy. All the children are allowed to try to activate their toy. However, because the Green toy is actually activated by a hidden switch and the Yellow toy is inert, the toys never activate for the infants.

The condition manipulation is designed to affect the relative probability of the two hypotheses for why the toy fails to activate. In the Agent condition, the hypothesis that the toy is broken is relatively improbable given that the toy had just worked moments before; the hypothesis that the child herself is doing something wrong should seem more probable. By contrast, in the Object condition, where the child's toy has never activated, the hypothesis that the toy doesn't work should seem more probable than the hypothesis that the child herself is doing something wrong (given that the button is conspicuous and easy to press). Thus, we created a situation in which infants might differentially weigh the two hypotheses about the cause of the failure. In both cases however, infants had identical sources of information that they could use to resolve the ambiguity. All children were seated next to their parents. By turning and asking their parent for help with the toy they had, they could test the 'agent' variable. All children could also reach for the Red toy, which sat on the end of a piece of felt cloth. By pointing to the Red toy or pulling the piece of felt cloth they could try to retrieve a toy of the same kind and test 'the object' variable. (We placed the Red toy at a distance to ensure that all infants would initially attend to the toy they were given.) Because previous research indicates that infants reliably understand the intentional structure of action in a cloth-pulling sequence by the age of 12 months (e.g., Sommerville & Woodward, 2005), we recruited infants slightly older than this age and verified in a warm-up period that they can pull the cloth to retrieve a toy.

We hypothesized that the infants' behavior would be sensitive to the relative probability of the competing hypotheses. Therefore, we predicted that infants in the Agent condition should be more likely to appeal to their parents; infants in the Object condition should be more likely to reach for the other toy.

Methods

Participants Thirty infants (mean: 16 months, 10 days; range: 14 – 20 months; 47% girls) were recruited from a local children's museum; infants were randomly assigned to an Agent condition or an Object condition ($n = 15/\text{condition}$). Six infants were replaced due to parental interference or experimental error. Two additional infants were replaced because they did not pull the cloth to retrieve a toy during the warm-up procedure. (See Procedure.) Finally, two infants (one in each condition) were excluded from analyses because they never showed any of the target behaviors. (See Results.)

Materials One commercially available toy (a plastic fish) was used during the warm-up period. Three similar-looking novel toys were built by attaching a wooden stick (10 cm in length) to a round plastic container (4 inches in diameter). The toys resembled small hand drums with handles. A square-shaped button (2 x 2 x 1 cm) was attached to the top of the container. This button was inert. Each object was covered with green, red, or yellow electrical tape and felt

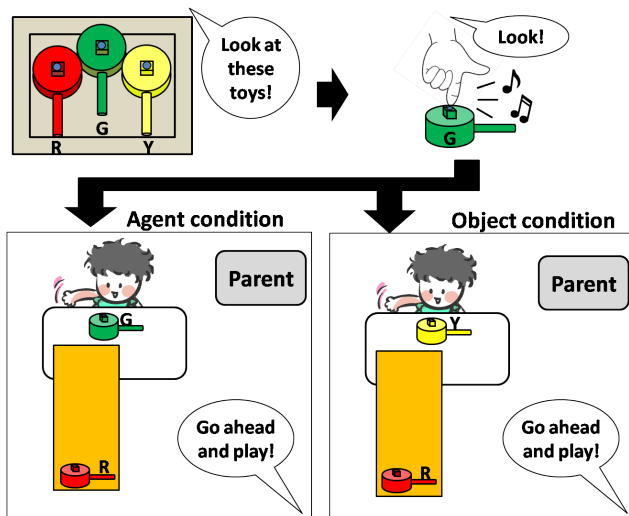

Figure 1: Schematic drawing of the experimental setup and procedure. R (Red), G (Green), Y (Yellow) refer to the color of the toys.

cloth. The Green toy had a small battery-powered circuit that was operated by a hidden switch at the bottom of the container: when the toy was laid flat on a hard surface and the fake button was pressed down, the real switch depressed and the toy played a musical tune (creating the appearance that pushing the fake button activated the toy). Children sat in a highchair. The tray on the high chair was covered with white felt, creating a surface that was too soft to activate the real switch at the bottom of the Green toy. The Green toy never worked on this tray when the fake button was pressed. The Red and Yellow toys did not have a musical mechanism inside, but contained play-dough so that all three toys were matched in approximate weight.

Procedure All children were tested individually in a quiet room inside the museum. The children sat in the highchair and the parents sat next to them on a chair. (See Figure 1 for experimental setup and stimuli.) Parents were instructed not to interact with the toys and only to smile and nod if the child addressed them. They were given a brochure about the study and asked to read it during the experimental procedure. Once the child was positioned in the highchair, the experimenter put a piece of orange felt cloth (approx. 20 x 75 cm) on the table and placed the warm-up toy on one end of the cloth. She pulled the cloth towards herself and retrieved the toy. Then she encouraged the infant to pull the cloth. Infants who did not pull the cloth and retrieve the toy after two demonstrations were excluded from analysis and replaced.

The experimenter removed the warm-up toy and introduced the child to a basket containing the Green, Red, and Yellow toys. She took the Green toy out, put it on the table, and pressed the button on top of the toy to play the music. She demonstrated this three times. Then she showed the child the basket containing the other two toys. She took out the Red toy and placed it on one end of the felt cloth. The toy was approximately 70 centimeters away from the

child and was not within direct reach of the child's hands. She placed the other end of the felt cloth on the child's tray within easy reach of the child. Then, the experimenter handed the child either the Green toy (Agent condition) or the Yellow toy (Object condition) and said, "Here you go, you can go ahead and play!" She took the basket with the remaining toy (the Yellow toy in the Agent condition: the Green toy in the Object condition) out of the child's line of sight. The child's behavior was videotaped for 90 seconds (24 children) or until the child fussed-out (6 children); all but one of the infants who stopped playing before 90 seconds played for at least 60 seconds. The remaining infant was in the Object condition and played for 35 seconds. There was no difference between conditions in children's mean length of free play (Agent Condition: mean 89 seconds; Object Condition: mean 84 seconds, $p = ns$).

Results

For our preliminary analyses, we looked at whether all the children imitated the experimenter's action on the toy and whether they were equally persistent in the Agent condition (where they were given the same toy on which the action had been modeled) and the Object condition (where they had to make an inductive generalization from the Green toy to the Yellow toy). Given previous research suggesting that even 9-month-olds readily make such generalizations (Baldwin et al., 1993), we did not expect any difference in their button-pushing behavior. Indeed, all but one infant immediately (within two seconds) pressed the inert button on the toy in front of them. There was no difference in the frequency of children's button-pushing attempts in the two conditions (Agent Condition: mean 3.0 times; Object Condition: mean 3.2 times, $p = ns$).

We also used two different measures to look at whether parents differentially cued the infants to ask for help in the two conditions. Two coders, blind to hypotheses and conditions, coded from videotape; the monitor was partially covered with a cardboard occluder so that only the parent was visible. One coder was asked to make Yes/No judgments about whether the parent ever encouraged the child to ask for help. A second coder rated parents' attempts to initiate communication on a scale from 1 (no attempts to communicate) to 7 (repeated attempts to communicate). There was no difference between conditions on either measure (% of Yes judgments = 7% in both conditions; mean rating: 1.71 (Agent) vs. 1.79 (Object), $p = ns$).

The primary measure of interest was whether children's first response to failure was directed towards their parents or to the other toy. To determine this, we coded three target behaviors: Ask, Point, and Pull. The criteria for coding a behavior as Ask was that the child turned to the parent¹ and

¹ The infants could also have asked the experimenter for help. However, the experimenter stood behind the high chair during the free play period and acted busy (i.e., by writing something on a clipboard). Therefore, although there were a few cases where the infants looked as if they wanted the experimenter's attention, we did not include these attempts as one of our target behaviors.

Figure 2: Experimental results. 2a. % infants Asking *first* or Pointing/Pulling *first* in each condition. 2b. % infants *ever* Asking or Pointing/Pulling in each condition (infants can perform more than one behavior, so the combined percentage within a condition can exceed 100). 2c and 2d. Same as 2a and 2b, respectively, but showing Point and Pull separately.

tried to give her the inoperative toy or grabbed the parent's hand and tried to bring it towards the inoperative toy (the Green toy in the Agent condition; the Yellow toy in the Object condition). We coded Point as a finger point to the Red toy or a direct reach for the Red toy. We coded Pull as pulling on the cloth and successfully retrieving the Red Toy. We predicted that children's first response to failure would be to Ask for help in the Agent condition but to Point or Pull in the Object condition. Additionally we coded whether infants ever showed the three target behaviors during free play, the latency to their first target behavior, and what they did with the Red toy if they retrieved it. The data for three target actions were originally coded by the experimenter, but also coded by an observer blind to hypotheses and conditions. The inter-coder reliability was high (Cohen's kappa = 92.6); using the data from the blind-coder did not change the results. All but two infants (one in each condition) performed at least one of the three target behaviors during the course of their free play; these two children were eliminated from subsequent analyses.

As predicted, children were significantly more likely to Ask First than Point or Pull first in the Agent condition than the Object condition ($\chi^2(1, N = 28) = 7.04, p < 0.01$). In the Agent condition, 10 infants (71%) Asked first and 4 infants (29%) Pointed or Pulled first; in the Object condition, 3 infants Asked first (21%); 11 infants (79%) Pointed or Pulled first. Within conditions, children were marginally more likely to Ask first than Point/Pull in the Agent condition ($p < 0.10$ by binomial test) and more likely to Point/Pull first than Ask in the Object condition ($p < 0.05$ by binomial test). See Figure 2a.

We also looked at how many infants in each condition exhibited each of the target behaviors at least once during

Figure 3: Data excluding Point behavior. 3a. % infants who Asked or Pulled *first* in each condition. 3b: % infants who *ever* Asked or Pulled during free play in each condition.

the course of their free play. Children were more likely to Ask for help over the course of their free play in the Agent condition than the Object condition ($\chi^2(1, N = 28) = 5.6, p < 0.05$, see Figure 2b.). Twelve infants (86%) in the Object condition Asked at some point; only 6 infants (43%) did so in the Object condition. Similarly, there was a trend for children to be more likely to Point to or Pull the red object in the Object condition than the Agent condition: 11 infants (79%) Pointed/Pulled at some point in the Agent condition whereas all 14 infants (100%) did so in the Object condition ($\chi^2(1, N = 28) = 3.36, p = .07$). See Figures 2c and 2d for the first target action and any instance of the target actions broken down by each of the three target behaviors.

There was no difference between conditions in the mean latency to the first target action (Agent condition, mean: 19.3 s; Object condition, mean: 25.4 s, $p = ns$). This suggests that the children in the two conditions were approximately matched in their motivation to act. There was also no difference in latency between the agent-directed and object-directed actions (Ask: 20.5 s; Point/Pull: 26.6 s, $p = ns$). This suggests that the agent-directed and object-directed actions were equivalently easy for the children to perform.

Although there was no overall latency difference, the Pulling action occurred (non-significantly) later than the Ask or Point actions (because most children in both conditions pointed before they pulled). Prima facie, Point is a less complex action than either Ask or Pull. Point required only a finger movement whereas Ask required the child to try to hand the object to the parent or to try to place the parent's hand on the object and Pull required a means/end sequence. We believe the collapsed Point/Pull measure is the correct measure of children's interest in the distal object as there is little doubt from the videotapes that infants coded as Pointing were unambiguously asking for the Red toy. However, to match for the overall complexity of the action sequence, we looked at whether infants were more likely to Ask or Pull first if the Point measure is excluded. Under this analysis, and excluding infants whose only target behavior was pointing (one child in the Agent condition; three children in the Object condition) infants were more likely to Ask than Pull in the Agent condition compared to the Object condition ($\chi^2(1, N = 24) = 11.7, p < 0.001$; see Figure 3a). Within conditions, infants in the Agent condition were more likely to Ask than Pull (12 Ask first, 1 Pull first; $p < 0.01$ by binomial test); infants in the Object condition were equally

likely to Ask and Pull (4 Ask first, 7 Pull first $p = ns$, by binomial test). Looking at any instance of Asking or Pulling over the course of free play, infants in the two conditions again tended to show different patterns of behavior ($\chi^2(1, N = 24) = 3.03, p = .08$; Agent condition: 12 Ask overall, 5 Pull overall; Object condition: 6 Ask overall, 9 Pull overall; See Figure 3b).

Finally, of those infants who pulled the cloth and successfully retrieved the Red toy (5 infants in the Agent condition; 9 agents in the Object condition), all but one immediately (within 2 seconds) pressed the button on the Red toy, suggesting that infants did indeed retrieve the toy in order to see whether they could make the toy go.

Discussion

These results suggest that when an object fails to function as expected, 16-month-old infants entertain competing hypotheses about the cause of the failure and act on the most probable hypothesis. Not only did almost every child (28 out of 30) actively try to elicit information from the available sources (another agent or another object), they selectively accessed different sources of information given different evidence about the likely cause for the failure. When the hypothesis that the agent caused the failure was more probable than the hypothesis that the toy was broken (because infants were given a toy that worked for the experimenter), the majority of infants asked their parents for help. In this condition, varying the 'agent' variable is the most effective strategy: if you're doing something wrong, doing the same thing with a different object will not solve the problem. By contrast, when the hypothesis that their toy was broken was more probable than the hypothesis that they were doing something wrong (because infants were given a similar but non-identical toy), the majority of infants reached for a new object. In this condition, trying another exemplar is the most effective strategy: if a toy is broken, asking someone else to act on the broken toy will not solve the problem. These results suggest that infants rationally trade-off help-seeking and object-exploration behaviors depending on the relative probability of the two hypotheses.

Are there alternative ways of accounting for the results? One possibility is that infants' differential behavior across conditions might reflect different affective responses to differentially frustrating situations rather than active requests for information. The manipulation was set up so that infants in the Agent condition would have a stronger expectation that their toy should work than infants in the Object condition. Arguably, infants in the Agent condition might have been more frustrated by their failure, and more likely to turn to their parents than infants in the Object condition. Conversely, infants in the Object condition arguably had a more "boring" toy than infants in the Agent condition (because they had never seen their toy activated). They thus may have been more motivated to discard it and reach for a new toy than infants in the Agent condition.

Further research is needed to definitively rule out these accounts but we believe that the current data renders both

explanations unlikely. First, differential frustration or boredom might be indicated by a difference in children's overall playtime between conditions but children played just as long in the Agent condition as the Object condition. Second, infants in the Agent condition who asked their parents for help did not show any signs of upset and did not look for comfort. They handed their parents the toy or tried to place their parents' hands on the toy but they did not cling to their parents or fuss out. Similarly, there was no indication that infants in the Object condition were more bored by the toy than infants in the Agent condition. Infants in the Object condition were just as likely to push the button on the toy as infants in the Agent condition, and they pushed the button just as persistently. Moreover, infants in the Object condition who retrieved the red toy immediately tried the button on the red toy. These behaviors suggest that infants in the Object condition expected that the toys would work and were strongly motivated to try to activate them. Thus the alternative accounts are inconsistent with how infants used the two different means: rather than reflecting frustration or boredom, infants' behavior is consistent with an attempt to generate an effective intervention. As noted however, conclusively distinguishing these possibilities requires further research. If for instance, an irrelevant distracter toy (rather than the Red toy) is placed at the end of the cloth, there should be no differences between the two conditions. We are currently running this control.

We note that the current study falls short of looking at whether children *learn* from the source of information they choose. That is, we cannot distinguish between the possibility that infants are taking the most rational steps to try to generate an outcome and the possibility that infants are (additionally) using the disambiguating evidence to determine the cause of the initial failure. In the current study, we deliberately asked the parents not to touch the toy, and the Red toy on the cloth was always inert. In future studies, we aim to look at whether learning occurs by studying infants' responses to different information that other people or other toys might provide. Imagine for instance, that if children retrieve the Red toy, it works for half the children and is inert for the other half. This evidence should give the children different information about the Yellow toy: if the Red toy works, the yellow toy is probably broken; if the Red toy does not work, it is now more probable that the child herself is the source of the failure. Thus if the Red toy is removed and the Yellow toy is returned to the children, they should be more likely to discard it if the Red toy worked, and more likely to ask for help if the Red toy failed. This would suggest that the infants' interventions not only serve the purpose of helping them make things happen but also help children disambiguate evidence to support causal learning. This research is also currently underway.

The study proposed above might also help clarify whether infants actually entertain the two competing hypotheses simultaneously, or whether only one of the two is considered in a given context. In the current study, some children who pulled the cloth and confirmed that the Red

toy did not work subsequently turned to their caregivers and asked for help. This suggests the possibility that children might indeed consider both hypotheses and act on the one favored by the evidence. Whether infants' choices of actions change dynamically given evidence that favors different hypotheses is an exciting topic for future research.

The current results however, already reveal impressive abilities in 16-month-old infants. There is abundant evidence that young children both ask adults for help (Dunham, Dunham, & O'Keefe, 2000; O'Neill, 1996) and explore objects in the world (Bonawitz, Shafto, Gweon, Spelke, & Schulz, submitted; Gweon & Schulz, 2008; Piaget, 1930; Gweon, Tenenbaum, & Schulz, 2010). This study goes beyond previous work in suggesting that infants' actively trade-off these two alternatives. Infants not only consider competing hypotheses about the failure of goal-directed actions, but also choose different means to resolve the ambiguity depending on which hypothesis is more probable. In the face of failure to achieve a goal, 16-month-old infants do not simply look to their parents nor do they simply move on to a new toy. Instead, they are able to infer the likely cause for their failure, and flexibly and rationally adjust their behavior. In solving the problem of assigning causal responsibility to themselves or the world, infants might lay the earliest foundations for scientific inquiry.

Developmental differences in learning the forms of causal relationships

Abstract

Children learn causal relationships quickly, and make far-reaching causal inferences on the basis of what they see. In order to be such efficient learners, they must bring abstract knowledge to bear on their problems. This paper addresses children's ability to acquire that knowledge. We present evidence that children can learn about the abstract properties of causal relationships using only a handful of events, and – consistent with a hierarchical Bayesian model of causal inference – children can be more sensitive to evidence than adults.

Introduction

Recent work suggests that children are skilled at inferring specific causal relationships from patterns of data (Gopnik et al., 2004; Sobel, Tenenbaum, & Gopnik, 2004). For example, they can infer which blocks will activate a machine based on the contingencies between the blocks and the machine's activation. But an additional question is whether children can infer more abstract causal principles from patterns in data, and use those principles to shape their subsequent predictions. For example, can a child infer that a particular type of machine activates reliably, or requires only a single cause to activate? Will those abstract discoveries bias the child's interpretations of new data?

Developmental data suggest that children do have broad inductive biases. For example, in language learning the shape bias and the mutual exclusivity principle influence more specific inferences about word meaning (Smith, Jones, Landau, Gershkoff-Stowe, & Samuelson, 2002; Markman & Wachtel, 1988). However there is debate about whether these biases are the result of innate constraints or are themselves the product of learning (Elman et al., 1996; Leslie, 1994). Recent formal work on hierarchical Bayesian models suggests that, at least in principle, the shape bias may itself be learned as a result of normative inferences from patterns of data (Kemp, Perfors, & Tenenbaum, 2007). Similar high-level biases apply to causal learning, and we know that children can learn about causal types (Schulz, Goodman, Tenenbaum, & Jenkins, 2008), and the plausibility of cross-domain relationships (Schulz, Bonawitz, & Griffiths, 2007). In this paper, we explore whether children can learn abstract principles about the forms of causal relationships themselves.

The hierarchical Bayesian approach suggests that the nature of inductive biases may change as evidence accumulates. Absent evidence, a learner without strong built-in biases should assign similar probabilities to a wide range of hypotheses. As data accumulate, the abstract hypotheses consistent with those data become more probable, and the learner

discounts any hypotheses that fit the current data but are less compatible with past experience. If this is correct, then we might expect to see different patterns of inductive bias in adults and children. In particular, children might rely less on past experience and more on present evidence than adults. This is a possibility that has not previously been explored in the causal learning literature, and one that we examine through head-to-head (or prior-to-prior) comparison of children and adults in a causal learning task that requires making an abstract generalization about the nature of causal relationships.

We test the high-level generalizations made by children and adults by contrasting two abstract “overhypotheses” (Goodman, 1955; Kemp et al., 2007) about how a causal system works. One is a noisy-OR model, in which each object has a certain independent probability of bringing about an effect. This model is pervasive in the literature on adult causal inference (e.g., Cheng, 1997; Griffiths & Tenenbaum, 2005). The other is an AND model in which individual causes are unable to produce an effect, but multiple causes in conjunction can produce an effect. We provided children and adults with evidence for either an AND or OR relationship and then examined how this evidence biased their judgment of a novel, ambiguous pattern of evidence. Would seeing several instances of a machine activated by a conjunction of causes lead them to assume that this would be the case for a new set of blocks? By comparing how children and adults respond to data that support these different overhypotheses, we can examine first whether children are capable of forming appropriate abstract generalizations, and second whether they are more willing to make these generalizations than adults.

The plan of the paper is as follows. First, we consider how an ideal Bayesian learner can gather evidence for overhypotheses relevant to causal induction. We then discuss the specific overhypotheses about the functional form of causal relationships that we contrast in this paper, together with a method that can be used to diagnose whether learners infer these overhypotheses from data. We go on to use this method to compare the abstract generalizations of children and adults in a causal learning task, finding support for the hypothesis that children are more willing to adopt a novel overhypothesis than adults. We close by discussing the implications of these results.

Causal overhypotheses

Children can identify causes using only a handful of observations (Gopnik et al., 2004), but the extent to which they learn

about the abstract properties of causal relationships remains largely unexplored. From a Bayesian standpoint, learning about causal structure requires having *a priori* beliefs – or priors – about what items are plausible causes, and expectations about how a given causal structure leads to different observable events. These expectations can be expressed formally using a *likelihood* function, which specifies the probability of observing a particular set of events based on the underlying causal structure.

Most work on probabilistic models of causal learning has assumed a specific kind of likelihood function. This likelihood function is based on causes and effects interacting in a “noisy-OR” manner, each having an independent opportunity to produce the effect (Cheng, 1997; Griffiths & Tenenbaum, 2005; Glymour, 1998). More precisely, a noisy-OR relationship implies that the probability that an effect E occurs given the presence of a set of causes C_1, \dots, C_N is

$$P(E|C_1, \dots, C_N) = 1 - \prod_{i=1}^N (1 - w_i) \quad (1)$$

where w_i is the probability that C_i generates the effect in the absence of other causes.

Despite the popularity of the noisy-OR in models of causal learning, other kinds of causal relationships are clearly possible. For instance, a noisy-OR model cannot describe an AND relationship, where an effect only occurs when multiple causes are present. This might be the case in an electrical circuit where multiple switches are wired in series, and a light only turns on when all of the switches are flipped. It is important, then, for models of causal inference to accommodate flexible beliefs about the forms relationships can take. Formalizing inferences about the form of a relationship is straightforward, using an expanded likelihood function, $P(E|C_1, \dots, C_N, F)$, where F captures information about the form of the causal relationship. For example, F could indicate that the relationship has a noisy-OR form, but another value of F might indicate that a causal relationship has an AND form.

Learning the form of a causal relationship and generalizing that discovery when reasoning about other causal relationships requires inference at multiple levels of abstraction. This kind of inference, in which lessons from one context can be carried forward for future learning, is easily captured by using a hierarchical Bayesian model (Tenenbaum, Griffiths, & Kemp, 2006; Kemp et al., 2007). A learner’s abstract beliefs, or overhypotheses, determine the probabilities of more-concrete hypotheses, each encoding specific causal structures and the form a relationship takes. These hypotheses, in turn, determine the likelihood of different patterns of events.

Formally, we can imagine an inference involving variables at three levels: the observed data D , hypotheses about the causal structure underlying those data H , and overhypotheses (or a “theory”, as in Griffiths & Tenenbaum, 2009) T representing generalizations relevant to evaluating those hypotheses (see Figure 1). Bayes’ rule then specifies how the events

Figure 1: The structure of a hierarchical Bayesian model.

a learner sees (D) should change the learner’s beliefs, both about the casual system at hand (H), and about the higher-level properties of that kind of system (T). Formally, we have

$$p(T|D) = \frac{p(D|T)p(T)}{p(D)} \quad (2)$$

where $p(T)$ is the prior probability of the overhypothesis T , $p(T|D)$ is the posterior probability, and $p(D)$ is obtained by summing the numerator over all overhypotheses T . The probability of the data given an overhypothesis is obtained by summing over all hypotheses consistent with that overhypothesis,

$$p(D|T) = \int p(D|H)p(H|T) dH, \quad (3)$$

and can be interpreted as an average of the probability of the observed data under those hypotheses weighted by the extent to which each hypothesis is consistent with the overhypothesis.

Intuitively, this hierarchical Bayesian approach provides a way to explain how learners can form and use abstract generalizations about causal systems. For example, if a child sees events that are likely under an AND relationship, such as a machine activating only when pairs of causal objects are placed on it, then the probability of an overhypothesis predicting future AND relationships increases. This is because the best hypotheses for explaining the observed events are those that are most likely under this overhypothesis, so Equation 3 yields a high value. Incorporating this value into Equation 2, the posterior probability for that overhypothesis will increase.

As the evidence supporting a particular overhypothesis increases, it will be easier to learn about the structure and form of causal systems that are consistent with that overhypothesis. This comes with a cost: if a causal system has strange or rare abstract properties, such as an unlikely functional form, much more evidence will be necessary to learn about it. The implication is that adults, who have seen a great deal of evidence, should find it very easy to learn about the structure and form of causal relationships that have typical properties. Conversely, children, with their limited experience, should be more sensitive to evidence when learning about relationships

that have unusual properties. In the following section, we discuss an experimental design for testing this idea.

The functional form of causal relationships

If children update their abstract beliefs about causal systems in a manner consistent with Bayesian inference, then the events they see should influence their judgments about different sets of events and prospective causes. To test this hypothesis, we used an experiment with two phases, each with a distinct set of objects. In the first phase, children saw a set of events designed to be likely under one of two abstract overhypotheses about the forms of causal relationships. In the second phase, they saw events where different beliefs about the form of the causal relationship should lead them to make different judgments about which objects are causes.

The specific evidence we provided to participants was very similar to that given to adults in Lucas and Griffiths (2009), where the task was to identify the blickets within a set of objects, knowing only that blickets have “blicketosity”. Prospective blickets could be placed on a “blicketosity meter”, causing it to either activate by lighting up and playing music or do nothing. People might entertain a variety of expectations about the relationship between the blickets and the machine, determining how they interpret different events. For example, if they think that two blickets are necessary to activate the machine, seeing a single object fail to activate it provides no information. At the same time, their expectations about the form of the relationship between blickets and the blicketosity meters can be shaped by the events they observe. For instance, seeing two objects fail to activate the machine separately but succeed together suggests that two blickets are necessary for activation.

We used events from two conditions from Experiment 2 of Lucas and Griffiths (2009). Since this experiment is closely related to the approach we take here, we will recapitulate the method and results. In the *AND*¹ condition of the experiment, participants saw a training block of events where objects labeled A, B, and C were placed sequentially on the machine, which failed to activate in all cases. Next, all pairs of objects were placed on the machine sequentially, with only A and B together causing activation. See Figure 2 for a summary of the events in the training and test blocks. Participants were then asked to rate the probability that A, B, and C were blickets on a 0-10 scale, with 0 indicating the object was definitely not a blicket, a 10 indicating it definitely was, and 5 indicating it was as likely to be a blicket as not.

After making these judgments, participants saw three new objects, D, E, and F, which they had never seen before, and a series of test events intended to be ambiguous, leading to different judgments about which of D, E, and F were blickets, depending on participants’ expectations about the form

of the relationship. If people expect that a single blicket suffices to activate the machine, they should believe then F is likely to be a blicket, while D and E are not. If, in contrast, people exploit the information provided by the training block so they conclude that two blickets are necessary to activate the machine, then they should think that objects D and F are blickets, and be uncertain about object E.

In the *OR* condition, participants saw a different set of events in the training block, which were chosen to indicate that an *OR* relationship applied (see Figure 2). Then they saw the same test events that the participants in the *AND* condition saw. Based on the training evidence, participants in this condition were predicted to say that only object F was a blicket.

As predicted, people in the *AND* condition assigned significantly higher probabilities to object D being a blicket, giving a mean score of 3.08 (SD=3.32), versus 0.23 (SD=0.99) in the *OR* condition. The mean rating was less than 5 in the *AND* condition, consistent with the idea that adults believe that disjunctive relationships are more probable, and could interpret the *AND* condition events in several ways, including as evidence for a noisy relationship in which the machine happened to fail to activate when a single, normally sufficient blicket was placed on it.

In summary, Lucas and Griffiths (2009) showed that people’s inferences about causal structure are driven by their beliefs about the probable forms of causal relationships, which are in turn influenced by events they have seen in the past. The specific pattern of judgments is consistent with the predictions of a hierarchical Bayesian model given priors reflecting a strong bias in favor of disjunctive (*OR*) and deterministic relationships. Such priors are also consistent with adults’ performance in other experiments (Lu, Yuille, Liljeholm, Cheng, & Holyoak, 2006). This prior could be chiefly due to adults’ experiences revealing that *OR* relationships are more common, or an innate bias. By comparing the judgments of 4-year-old children to those of adults, we aim to answer that question and better understand the origins of the abstract knowledge that drives efficient causal inference.

Causal overhypotheses in children and adults

We used the experimental design from Lucas and Griffiths (2009) to explore two questions about the use of causal overhypotheses by children and adults. The first question was whether children, like adults, can use events to update their knowledge about the likely forms of causal relationships, and apply that knowledge to learn the causal structure behind new and ambiguous sets of events. The second question was whether children are more or less sensitive to evidence supporting such high-level generalizations, as opposed to their prior beliefs.

If children are more likely than adults to call objects D and E blickets in the *AND* condition, we can conclude that much of the bias we see in adults is due to learning during and after childhood, including, for instance, experience with machines to which *OR* relationships apply. If children’s judgments are

¹Lucas and Griffiths labeled their conditions *conjunctive* and *disjunctive* rather than *AND* and *OR*, to highlight a hypothesis space that included a wide range of functional forms, including *AND* and *OR* as special cases. We use *AND* and *OR* here for the sake of simplicity.

Figure 2: Evidence presented to participants in the two training phases, as well as the subsequent test phase which all participants saw. Events are given as a set of prospective causes and the presence or absence of an effect. The bright-paneled machines represent events in which the effect occurs and the dark-paneled machines represent events in which the effect does not occur.

indistinguishable from adults', we have evidence that learning about the forms of causal relationships occurs early, or plays a minor role in driving our expectations. Finally, if there is no effect of training evidence on test-block judgments, we should question the applicability of the model used by Lucas and Griffiths (2009) to causal inference in children.

We can generate more detailed predictions by speculating about the priors that children bring to the problem of identifying blickets. It seems unlikely that children are constrained to a small set of discrete overhypotheses – it is more natural to suppose that they consider a space of possibilities that includes both OR and AND relationships as special cases. Following Lucas and Griffiths (2009), we use a sigmoid family of likelihood functions, where the probability of the machine's activation given that n blickets are present is

$$P(\text{effect} | N_{\text{blickets}} = n) = \frac{1}{1 + \exp\{-g(n - b)\}}. \quad (4)$$

The overhypotheses determine the probability of different values of the gain g and the bias b . The gain specifies how many blickets are necessary to activate the machine, and the bias reflects how noisy the relationship is. Lucas and Griffiths found that exponential priors predicting a high mean gain (3.34) and a low mean bias (0.23) – or reliable OR relationship – lead to model predictions that closely match adults' judgments. If children are happier believing that a relationship could be conjunctive or noisy, the priors that best capture their inferences should lead to *a priori* gains and biases closer to 1. This space of likelihood functions is intended to cover a range of relationships that are appropriate to the cover story and participants' prior knowledge, and we do not claim it includes all relationships that people could conceivably learn, such as those in which blickets prevent the machine from activating.

Participants

Children Thirty-two children were recruited from university-affiliated preschools, divided evenly between the *AND* and *OR* conditions. Children in the *AND* and *OR* conditions had mean ages of 4.46 (SD=0.27) and 4.61 (SD=0.31) years, respectively.

Adults UC Berkeley undergraduates received course credit for participating during lectures of an introductory psychology course. There were 88 participants in the *AND* condition and 55 in the *OR* condition. Five participants in the *AND* condition were excluded for declining to answer one or more questions.

Methods

Children Each child sat at a table facing the experimenter, who brought out three objects, each painted a different color, as well as a green box with a translucent panel on top, describing the box as "my blicketness machine".

At the beginning of the experiment, children were prompted to help the experimenter name the objects using their colors, e.g., "red". They were then told that the goal of the game was to figure out which of the objects were blickets, that blickets have blicketness inside them, and blickets cannot be distinguished from non-blickets by their appearance. No other information was provided about the relationship between blickets and the activation of the machine.

The children then observed a set of training events in which the experimenter placed objects alone or in pairs on the machine, which activated in some cases by lighting up and playing music. These events corresponded to either the *OR* condition or *AND* condition training given in Figure 2. After the children saw these events, they were asked whether each object was a blicket or not. Next, the experimenter brought out three objects that the children had not seen before. After the children named the new objects, the experimenter demonstrated the test events listed in Figure 2 and asked whether

Figure 3: Proportions of objects that were judged to be blinkets for children (top row) and adults (bottom row) for the *AND* (left column) and *OR* (right column) conditions. Error bars represent standard error of the mean.

each of these new objects was a blinket or not. In a departure from Lucas and Griffiths’s design, the experiment was repeated a second time for each child, using the same patterns of evidence, but with a distinct set of objects that varied by shape and had a uniform gray color. The identities of the individual objects were counterbalanced, as was whether the children saw the different-shaped or different-colored objects first.

Adults The adults were tested in groups, and saw demonstrations that were almost identical to what the children saw in the corresponding conditions. Unlike the children, the adults were not asked to name the objects, and they recorded their judgments on sheets of paper rather than responding verbally.

Results

Children The critical prediction was that children would be more likely to judge object *D* to be a blinket in the *AND* condition than in the *OR* condition, indicating that they were (1) learning about the form of the relationship between blinkets and the machine’s activation, and (2) transferring that abstract knowledge to make better inferences about novel objects and otherwise ambiguous events.

Children were more likely to judge object *D* to be a blinket in the *AND* condition than in the *OR* condition ($p < 0.005$, two-tailed permutation test). There was also a change in the predicted direction for object *E*, albeit non-significant.

Adults Adults were also more likely to judge object *D* to be a blinket in the *AND* condition than in the *OR* condition

($p < 0.005$, two-tailed permutation test), consistent with the results in Lucas and Griffiths (2009). See Figure 3, bottom row, for a summary of their judgments for the test objects.

Differences In the *AND* condition, the adults judged object *D* to be a blinket less frequently than children ($p < 0.005$, Fisher’s exact test). See Figure 3 for a summary of ratings in the three conditions. Children’s ratings were also higher for object *E* ($p < 0.001$, two-sided permutation test), which is consistent with their being quicker to learn that an *AND* relationship applies: under an *AND* relationship, the event where *E* fails to activate the machine is uninformative, so judgments of *E* being a blinket should reflect the base rate of blinkets occurring. The high frequency of other objects being blinkets under an *AND* relationship (4 of 5), plus a belief that blinkets are not rare, should lead a learner to expect that a novel object is somewhat likely to be a blinket.

Model fits We converted children’s judgments about blinkets to probabilities in order to examine them using the previously-mentioned hierarchical Bayesian model and sigmoid space of hypotheses. We treated is-a-blinket judgments as assertions that objects were definitely blinkets, and not-a-blinket judgments as assertions that objects were definitely not blinkets. Lucas and Griffiths (2009) found that priors favoring disjunctive, deterministic relationships – predicting a mean gain of 3.34 and a mean bias of 0.23 – fit adults’ judgments closely, with a mean squared error of 0.29 per judgment on a zero to ten scale. We found that similar priors best

captured adults' judgments in our experiment, giving a mean squared error of 0.80 with a mean gain of 5.30 and bias of 0.11.

These same priors were wildly inconsistent with children's inferences, giving a mean squared error of 6.12. In contrast, priors giving a mean *a priori* gain and bias of 1 – favoring neither AND nor OR relationships – were much more accurate, with a mean squared error of 0.58. The priors that best fit the children's judgments gave a mean gain and bias of 1.45 and 0.85, respectively, with mean squared error of 0.15.

Discussion

Our experiment was designed to explore two questions: whether children could make high-level generalizations about the form of causal relationships, and whether they were more willing to do so than adults. Our results show that children are capable of making such inferences, and that their judgments were more strongly influenced by the available evidence than adults, whose inferences reflected a bias toward OR relationships. Our results thus support the view that when learning about cause and effect, children are flexible learners whose inexperience may sometimes let them learn better from sparse evidence, especially in novel situations. These results are also consistent with treating the acquisition and application of causal knowledge as a matter of hierarchical Bayesian inference, where a learner has beliefs expressed at multiple levels of abstraction, with abstract theories driving specific hypotheses which, in turn, enable prediction and categorization.

Before closing, we will address two alternative explanations for our results. The first is that children are more likely than adults to judge any object to be a blicket. This is less consistent with the data than our interpretation, given that adults were more likely than children to call object *F* a blicket in the OR condition, and nearly as likely in the AND condition (75 percent of the objects versus 81 percent). A second alternative is that the children were confused by the training data in the AND condition, and responded to the novel objects by guessing randomly. This explanation can be ruled out by noting that children judged objects *D* and *F* to be blickets more often than chance would predict ($t(15) = 3.529$, $p < 0.005$).

The results of our experiment have implications for understanding causal learning, and for understanding cognitive development more generally. In terms of causal learning, these results suggest that the fundamental biases that lie beneath causal inference are more subtle and abstract than *a priori* preferences for specific kinds of causal relationships. We believe that trying to understand these biases is fertile ground for future research. For cognitive development, the idea that children are more flexible in their commitments about the way that causal systems tend to work seems like not just a necessary consequence of a hierarchical Bayesian approach, but an important insight for understanding how it is that children see the world differently from adults. The plasticity of beliefs that this implies helps to explain the bold exploration

and breathtaking innovation that characterizes children's interactions with the world.

Children's Imitation of Action Sequences is Influenced by Statistical Evidence and Inferred Causal Structure

Abstract

Children are ubiquitous imitators, but how do they decide which actions to imitate? One possibility is that children might learn which actions are necessary to reproduce by observing the contingencies between action sequences and outcomes across repeated observations. We define a Bayesian model that predicts that children will decide whether to imitate part or all of a sequence based on the pattern of statistical evidence. To test this prediction, we conducted an experiment in which preschool children watched an experimenter repeatedly perform sequences of varying actions followed by an outcome. Children's imitation of sequences that produced the outcome increased, in some cases resulting in production of shorter sequences of actions that the children had never seen performed in isolation. This behavior is consistent with our model's predictions, and suggests that children attend to statistical evidence in deciding which actions to imitate, rather than obligately imitating successful actions.

Keywords: Cognitive development; Imitation; Statistical learning; Causal inference; Bayesian inference

Introduction

Learning the causal relationships between everyday sequences of actions and their outcomes is a daunting task. How do you transform a package of bread, a jar of peanut butter and a jar of jelly into a peanut butter and jelly sandwich? Do you cut the bread in half before or after you put together the sandwich? Can you put the peanut butter on first, or does it always have to be jelly first? In order to achieve desired outcomes – from everyday goals such as eating a tasty sandwich to distinctive human abilities such as making and using tools – children need to solve a challenging causal learning problem: observing that the intentional actions of others lead to outcomes, inferring the causal relations between those actions and outcomes, and then using that knowledge to plan their own actions.

To learn from observation in this way, children cannot simply mimic everything they see. Instead, they must segment actions into meaningful sequences, and determine which actions are relevant to outcomes and why. Recent studies of imitation in children have produced varying answers to the question of whether children are capable of solving this problem. While children sometimes selectively reproduce the most obviously causally effective actions (Williamson, Meltzoff, & Markman, 2008; Schulz, Hooppell, & Jenkins, 2008), at other times they will “overimitate”, reproducing apparently unnecessary parts of a causal sequence (Whiten, Custance, Gomez, Teixidor, & Bard, 1996; Lyons, Young, & Keil, 2007), or copying an actor's precise means, when a more efficient action for accomplishing the same goal is available (Meltzoff, 1995). Sometimes children may produce both kinds of behavior in the same study. In the “rational imitation” studies by Gergely, Bekkering, and Kiraly (2002),

children saw an experimenter activate a machine with hands free or hands confined. Children both produced exact imitations of the actor (touching their head to a machine to make it go) and produced more obviously causally effective actions (touching the machine with a hand), though the proportion of such actions differed in the different intentional contexts.

We suggest that these different results reflect the multiple sources of information that contribute to a rational statistical inference about causally effective actions. Children need to balance their prior knowledge about causal relations, the new evidence that is presented to them by the adult, and their knowledge of the adult's intentions. Moreover, in the case of imitation there is often no single “right answer” to the question of what to imitate. After all, a longer “overimitation” sequence might actually be necessary to bring about an effect, though that might seem unlikely at first. The imitation problem can be expressed as a problem of Bayesian inference, with Bayes' rule indicating how children might combine these factors to formulate different causal hypotheses and produce different action sequences based on those hypotheses. It is difficult to test this idea however, without knowing the strength of various causal hypotheses for the children. Since previous studies involved general folk physical and psychological knowledge (such as removing a visibly ineffectual bolt to open a puzzle box) it is difficult to know how strong those hypotheses would be. By giving children statistical information supporting different hypotheses we can normatively determine how probable different hypotheses should be, and then see whether children's imitation reflects those probabilities.

It is also independently interesting to explore the role of statistical information in imitation. Recent studies show that children are surprisingly sophisticated in their use of statistical information such as conditional probabilities in a range of domains, from phonology (Saffran, Aslin, & Newport, 1996), to visual perception (Fiser & Aslin, 2002; Kirkham, Slemmer, & Johnson, 2002), to word meaning (Xu & Tenenbaum, 2007). Such information plays a particularly important role in both action processing (Zacks et al., 2001; Baldwin, Andersson, Saffran, & Meyer, 2008; Buchsbaum, Griffiths, Gopnik, & Baldwin, 2009) and causal inference (Gopnik et al., 2004; Gopnik & Schulz, 2007), and allows adults to identify causal subsequences within continuous streams of action (Buchsbaum et al., 2009). Varying the probabilities of events within action sequences may thus provide a way to vary the statistical evidence those sequences provide in favor of different causal hypotheses.

Statistical inference might be particularly important to

Observed Action Sequence	Potential Causal Sequences
ABC+	ABC, BC, C
DBC+	DBC, BC, C
Total Potential Causes	ABC, DBC, BC, C

Table 1: Example demonstrations, and the associated set of potential causal sequences. Letters represent unique observed actions, a + indicates a causal outcome.

imitation because it could allow children to not only determine the causal relationship between action sequences and outcomes, but to identify irrelevant actions within causally effective sequences. Imagine that I am making a peanut butter sandwich, and that between opening the jar, and spreading the peanut butter, I get peanut butter on my hands, so I wipe them on a paper towel. If this is the first time you’ve seen me make a sandwich, you might mistakenly think that hand-wiping is a necessary step. However, after watching me make a sandwich a couple of times, you might notice that while opening the jar always predicts spreading the peanut butter, it doesn’t always predict hand-wiping, and could infer that this step is extraneous. In most previous work on children’s imitation of casual sequences, children observed only a single demonstration of how to generate the outcome (e.g. Whiten et al., 1996; Lyons et al., 2007).

In this paper, we look at whether children use statistical evidence from repeated demonstrations to infer the correct causal actions within a longer sequence and imitate them. We present a Bayesian analysis of causal inference from repeated action sequence demonstrations, followed by an experiment investigating children’s imitative behavior and causal inferences. We showed preschool children different sequences of three actions followed by an effect, using our Bayesian model to guide our manipulation of the probabilistic evidence, such that the statistical relations between actions and outcomes differed across conditions in ways that supported different causal hypotheses. We then examine which sequences the children produced themselves, and compare children’s performance to our model’s predictions. We conclude by discussing our results in the context of broader work on imitation, and causal and intentional inference.

Bayesian Ideal Observer Model

In many real world situations, the causal structure of a demonstrated sequence of actions is not fully observable. In particular, which actions are causally necessary and which are superfluous may be unclear. One way children may overcome this difficulty is through repeated observations. By watching someone make a sandwich or turn on a lightbulb on multiple occasions, children can pick up on which actions consistently predict the desired outcome, and which do not.

While it is intuitively plausible that children can use the statistical evidence in repeated demonstrations to infer causal structure, we would like to verify that normative inferences from repeated observations of action sequences and their outcomes vary in a systematic way with different patterns of data. One way to derive what the normative distribution over

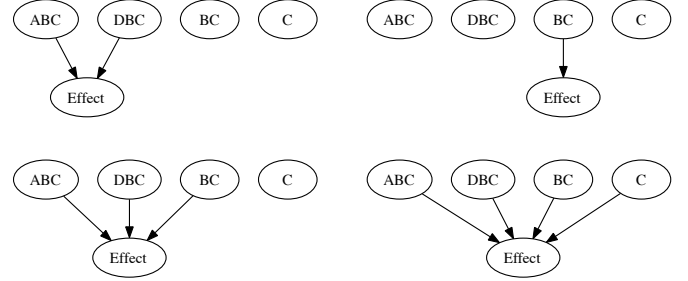

Figure 1: A subset of the hypothesis space. Each box represents a hypothesis about which action sequences are causal.

causes should be is through a Bayesian model (Gopnik et al., 2004; Griffiths & Tenenbaum, 2005). The Bayesian formalism provides a natural way to represent the roles of children’s prior assumptions and the observed data in forming their beliefs about which action sequences are likely to be causal.

Model Details

Given observations of several sequences of actions, we assume that children consider all sequences and terminal subsequences as potentially causal. These include both sequences that generate the outcome and those that do not. For instance, if the sequence “squeeze toy, knock on toy, pull toy’s handle” is observed, then squeeze, followed by knock, followed by pull handle would be one possible causal sequence, and knock followed by pull handle would be another. Given all of the observed sequences, we can enumerate the potential causes (see Table 1 for an example set of demonstrations and potential causes). As in previous work on children’s causal inference, we use a Deterministic-OR model (c.f. Cheng, 1997; Pearl, 1996), in which any of the correct sequences will always bring about the effect. To capture the intuition that there may be more than one sequence of actions that can bring about an effect, we consider all of the potential causes (such as in Table 1), as well as all disjunctions of these causes. The base causes, together with the disjunctions form the space of potential hypotheses, H (see Figure 1).

The learner wants to infer the set of causes, h , given the observed data, d , where the data are composed of an observed sequence of actions, a , and an outcome, e . Bayes’ theorem provides a way to formalize this inference. Bayes’ theorem relates a learner’s beliefs before observing the data, their prior $p(h)$, to their beliefs after having observed the data, their posterior $p(h|d)$,

$$p(h|d) \propto p(d|h)p(h), \quad (1)$$

where $p(d|h)$ is the probability of observing the data given the hypothesis is true. For Deterministic-OR causal models, this value is 1 if the sequence is consistent with the hypothesis, and zero otherwise. For example, given the hypothesis that squeeze is the cause, a consistent observation would be, knock then squeeze followed by music, and an inconsistent observation would be squeeze followed by no music. When multiple sequences of actions and effects are observed, we assume that these sequences are independent.

A key element in this inference is the learner’s prior expectations, $p(h)$. Children could have a variety of different beliefs about the kinds of sequences that bring about effects. For instance, they could believe that longer sequences, that include more of the demonstrated actions, are more likely to bring about effects. Or, they could believe that there tends to be only one correct sequence, as opposed to many possible sequences, that cause an effect. We capture these intuitions with a prior that depends on two parameters, β and p , which correspond to the learner’s expectations about the length of causal sequences and number of ways to generate an effect.

We formalize the prior as a generative model. Hypotheses are constructed by randomly choosing causal sequences, a . Each sequence has a probability p_a of being included in each hypothesis and a probability $(1 - p_a)$ of not being included,

$$p(h) \propto \prod_{a \in h} p_a \prod_{a \notin h} (1 - p_a) \quad (2)$$

where the probability of including causal sequence a is

$$p_a = \frac{1}{1 + \frac{1-p}{p} \exp(-\beta(|a| - 2))}, \quad (3)$$

and $|a|$ is the number of actions in the sequence a . Values of β that are greater than 0 represent a belief that longer sequences are more likely to be causes. Values of p less than 0.5 represent a belief that effects tend to have fewer causes. Together, Equations 1, 2 and 3 provide a model of inferring hypotheses about causes from observed sequences and their effects.

In our experiments, rather than probing children’s beliefs directly, we allow children to play with the toy. Therefore, to complete the model, we must specify how children choose action sequences, a , based on their observations, d . Intuitively, we expect that if we know the set of causes of the effect, h , we will randomly choose one of these actions. If we were unsure about which of several possible causes was the right one, then we may choose any of the possible contenders, but biased toward whichever one we thought was most likely. We capture these intuitions formally by choosing an action given the observed data, $p(a|d)$, based on a sum over possible hypotheses,

$$p(a|d) \propto \sum_{h \in H} p(a|h)p(h|d), \quad (4)$$

where $p(a|h)$ is one if a is a cause under h , and zero otherwise, and $p(h|d)$ is specified in Equation 1.

A Simple Modeling Example

We can now verify that the model makes distinct inferences from repeated demonstrations. In the first example, the demonstrated action sequences are ABC+, DBC+ as in Table 1. That is, a sequence of three actions A, B and C is followed by an effect. Subsequently, a different sequence of three actions, D, B, and C is followed by the same effect. In the second example, the observed sequences are ABC+, DBC. Here, the second three-action sequence is not followed by the effect.

Observed Sequences	ABC	DBC	BC	C
ABC+, DBC+	0.23	0.23	0.27	0.27
ABC+, DBC	1.0	0.0	0.0	0.0

Table 2: Example model results, $p = 0.5$ and $\beta = 0$.

Observed Sequences	ABC	DBC	BC	C
ABC+, DBC+	0.26	0.26	0.35	0.13
ABC+, DBC	1.0	0.0	0.0	0.0

Table 3: Example model results, $p = 0.1$ and $\beta = 1.0$.

Using values of $p = 0.5$ and $\beta = 0$ results in a prior that assigns equal probability to all possible causal hypotheses – a uniform prior. With this uniform prior, we can now find the probability of choosing to perform each action sequence to bring about the effect given the observed data, $p(a|d)$, as described in Equation 4. Our model infers that, in the first case, all the sequences are possible causes, with BC and C being somewhat more likely, and equally probable. Notice that the model infers that the subsequences BC and C are the most likely causes, even though neither was observed on its own. The second case is quite different. Here the model sees that DBC and its subsequences BC and C did not lead to the effect in the second demonstration, and infers that ABC is the only possible cause among the candidate sequences (see Table 2).

We now use values of $p = 0.1$ and $\beta = 1.0$ leading the model to favor simpler hypotheses containing fewer causes, and causes that use more of the observed demonstration.¹ This prior does not change results in the second case, where ABC is still the only possible cause. However, in the first case, the model now infers that the subsequence BC is the most likely individual cause, since it is the longest observed sequence to consistently predict the effect (see Table 3).

Model Predictions for Children’s Inferences

Our rational model makes differential predictions based on repeated statistical evidence, and is able to infer subsequences as causal without seeing them performed in isolation. We can now use the model to help us construct demonstration sequences that normatively predict selective imitation in some cases, and “overimitation” in others. If children are also making rational inferences from variations in the action sequences they observe, then their choice of which actions to imitate in order to bring about an effect should similarly vary with the evidence. We test our prediction that children rationally incorporate statistical evidence into their decisions to imitate only part of an action sequence versus the complete sequence in the following section.

Experiment

Method

Participants Participants were 81 children ($M = 54$ months, $Range = 41 - 70$ months, 46% female) recruited from local preschools and a science museum. An additional

¹These parameter values qualitatively fit children’s imitative behavior, as we discuss later in the paper.

“ABC” Condition	“BC” Condition	“C” Condition
ABC+	ABC+	ABC+
DEC	ADC	ADC+
ABC+	DBC+	DBC+
EDC	AEC	AEC+
ABC+	EBC+	EBC+

Table 4: The demonstration sequences for “ABC” , “BC” and “C” conditions. Each child observed the experimenter performing all 5 action sequences in their condition.

18 children were excluded from the study because of demonstration error (4), equipment failure (3), lack of English (1), unavailable birth date (1), did not try toy (6), extreme distraction (2), never performed trial termination action (1).

Stimuli There were two novel toys: a blue ball with rubbery protuberances, and a stuffed toy with rings and tabs attached to it. Six possible actions could be demonstrated on each toy. Children were assigned to one of three experimental conditions. In each condition, they saw a different pattern of evidence involving five sequences of action and their outcomes. Each individual action sequence was always three actions long. In the “ABC” pattern, the same sequence of three actions (e.g. A=Knock, B=Stretch, C=Roll) is followed by a musical effect three times, while in the “BC” pattern a sequence composed of a different first action, followed by the same two-action subsequence (e.g. A=Squish, B=Pull, C=Shake and D=Flip, B=Pull, C=Shake) is followed by the effect three times (see Table 4). In both patterns, two additional sequences that end in C and do not contain BC fail to produce the effect. Finally, in the “C” pattern the sequences of actions were identical to those in the “BC” pattern, but the outcome was always positive. The number of times each individual action is demonstrated in each sequence position is identical in all three patterns. As we show later in the paper, our Bayesian ideal observer model confirms that the statistical evidence in each pattern supports different causal inferences.

Procedure The experimenter showed the child one of the toys, and said: “This is my new toy. I know it plays music, but I haven’t played with it yet, so I don’t know how to make it go. I thought we could try some things to see if we can figure out what makes it play music.” The experimenter emphasized her lack of knowledge, so that the children would not assume she knew whether or not any of her actions were necessary. She then demonstrated one of the three patterns of evidence, repeating each three-action sequence (and its outcome) twice. The experimenter named the actions (e.g. “What if I try rolling it, and then shaking it, and then knocking on it?”), acted pleasantly surprised when the toy played music (“Yay! It played music!”), or disappointed when it did not (“Oh. It didn’t go”), and pointed out the outcome (“Did you hear that song?” or “I don’t hear anything. Do you hear anything?”). After she demonstrated all five of the 3-action sequences, she gave the child the toy and said “Now it’s your turn! why don’t you try and make it play music”. Throughout the experiment the music was actually triggered

Condition	Triplet	Double	Single	Other
“ABC”	20	1	2	4
“BC”	10	7	0	10
“C”	8	0	8	11

Table 5: Number of children producing each sequence type

by remote activation. To keep the activation criteria uniform across conditions, the toy always played music the first time a child produced the final C action, regardless of the actions preceding it, terminating the trial. Only this first sequence of actions was used in our analysis.

Children were videotaped, and their actions from the time they were handed the toy to trial termination were coded by the first author, and 80% of the data was recoded by a blind coder. Coders initially coded each individual action as one of the six demonstrated actions, or as “novel”. These sequences were then transferred into an “ABC” type representation, and subsequently coded as one of four sequence types: Triplet, Double, Single or Other (defined below). Inter-coder reliability was very high, with 91% agreement on the “ABC” type representations, and 100% agreement on sequence types.

Results and Discussion

Overall results are shown in Table 5. Children produced significantly different types of sequences across the three conditions, $p < 0.001$ (two-sided Fisher’s exact test). We will discuss results for the “ABC” and “BC” conditions first, and then return to the “C” condition.

Effect of Statistical Evidence on Imitation In their imitation, children could either exactly reproduce one of the three-action sequences that had caused the toy to activate (that is, ABC in the “ABC” condition or ABC, DBC or EBC in the “BC” condition), or they could just produce BC in isolation. We refer to these successful three-action sequences as “triplets”, and to the BC subsequence as a “double”.

Both a triplet and a double reflect potentially correct hypotheses about what caused the toy to activate in both conditions. It could be that BC by itself causes the toy to activate in the “ABC” condition and the A is superfluous, or it could be that three actions are necessary in the “BC” condition, but the first action can vary. In both conditions BC is followed by the effect three times.

If children automatically encode the adult’s successful actions as causally necessary, then they should exclusively imitate triplets in both conditions. However, if children are also using more complex statistical information, they should conclude that the BC sequence by itself is more likely to be causal in the “BC” condition than in the “ABC” condition, and that the triplet sequence is more likely to be causal in the “ABC” condition than in the “BC” condition. This is in fact what we found – the number of children producing triplets and doubles varied by condition, $p < 0.01$ (two-sided Fisher’s exact test), and differed significantly between the “ABC” and “BC” conditions $p < 0.05$ (two-sided Fisher’s exact test).

Effect of Differing Causal Outcomes on Imitation The pattern of evidence in the “BC” condition is more complex than in the “ABC” condition. This may have confused children, leading them to produce a variety of random actions, including BC. The “C” condition controls for this possibility. In this condition the sequences of actions were identical to those in the “BC” condition, but the outcome was always positive. As we show later, our Bayesian ideal observer model confirms that this provided statistical evidence for the hypothesis that C alone was sufficient to produce the effect.

In all three conditions, imitation of just the final C action in isolation was coded as a “single”. As in the “ABC” and “BC” conditions, only the subsequence BC was coded as a double in the in the “C” condition. Also consistent with the “ABC” and “BC” conditions, in the “C” condition all five demonstrated successful sequences (ABC, ADC, DBC, AEC and EBC) were coded as triplets.

The “C” condition is as complex as the “BC” condition. However in the “C” condition the final action C produced by itself reflects a likely causal hypothesis. If children selectively imitate subsequences based on the data, then children in the “C” condition should produce C more frequently than children in the “BC” condition, and children in the “BC” condition should produce BC more frequently than children in the “C” condition. Our results support this hypothesis. Children in the “BC” and “C” conditions differed significantly in the overall types of sequences they produced, $p < 0.001$ (two-sided Fisher’s exact test), and the number of children producing doubles and singles in the two conditions also varied significantly, $p < 0.001$, (two-sided Fisher’s exact test).

Performance of “Other” Actions Across all three conditions, children did not just obligately imitate one of the successful sequences or subsequences they observed – they also produced new combinations of actions. Overall, the types of “other” sequences produced did not qualitatively differ across conditions, and appear to be a mix of exploratory behavior and genuine errors. There was a trend towards children in the “BC” and “C” conditions performing more of these “Other” sequences than children in the “ABC” condition $p = 0.10$, (two-sided Fisher’s exact test). This difference becomes statistically significant when two children who imitated unsuccessful triplets are excluded from the analysis, $p < 0.05$, (two-sided Fisher’s exact test). This result is compatible with findings that children tend to increase their exploratory behavior when the correct causal structure is more ambiguous (Schulz & Bonawitz, 2007; Schulz et al., 2008). Finally, four children performed completely novel actions they had never seen demonstrated. All of these children were in the “BC” or “C” conditions, consistent with these conditions eliciting more exploratory actions.

Model Results

Supporting our experimental results, our model makes distinct predictions in each of the three experimental conditions, showing that the data lead to differential causal inferences.

Parameter values of $p = 0.1$ and $\beta = 1.0$ were chosen because they produced a qualitatively good match to children’s performances, as shown in Figure 2. The relatively high value for β suggests that children prefer longer (complete) causal sequences, perhaps representing a pre-existing belief that adults usually don’t perform extraneous actions. The relatively low value for p suggests that children employ a causal Occam’s razor, assuming that simpler hypotheses, which require fewer causes to explain the data, are more likely. Overall, these results suggest that children’s imitative choices conform closely to normative predictions.

Finally, while children performed similarly to our model’s predictions, there were some differences in performance as well. Children produced more triplets than our model predicted, especially in the “ABC” condition. One reason for this discrepancy may be that children are able to use information about the knowledge state and intentional stance of the demonstrator that our current model cannot take into account. Models that can incorporate intentional and pedagogical information, in addition to statistical evidence are an important area of future work (Goodman, Baker, & Tenenbaum, 2009; Bonawitz et al., 2009). We are currently developing such a model, and exploring the role of pedagogical cues in children’s imitation (Buchsbaum, Gopnik, Griffiths, & Shafto, submitted).

General Discussion

In this paper, we examined whether children are sensitive to statistical evidence in choosing the actions they imitate. We demonstrated that children can use statistical evidence to decide whether to imitate a complete action sequence, or to selectively imitate only a subsequence. In particular, children in the “ABC” condition imitated the complete sequence ABC more often than children in the “BC” condition, while children in the “BC” condition imitated the subsequence BC more often than children in the “ABC” condition. Children’s performance in the “C” condition demonstrated that the differential imitation in the “ABC” and “BC” conditions could not be explained as a result of task complexity.

The design of this experiment also eliminated other simple explanations for these results. There were the same absolute number of BC demonstrations followed by effects in all three conditions, but children only produced doubles in the second condition. Similarly, the absolute number of positive triplet demonstrations was the same in the “ABC” condition and the “BC” condition, and was smaller than in the “C” condition, but children produced more triplets in the first condition than in the other two conditions. Finally, the actual sequence of actions was the same in the “BC” and “C” conditions but children behaved differently in the two cases. Children appeared to selectively imitate by considering the conditional probability of the various events and outcomes, and formulating a set of causal hypotheses based on that data. They then produced responses that matched the probability distribution of the hypotheses, at least qualitatively.

It is also worth noting the information-processing com-

Figure 2: Left: Predictions of our Bayesian model. Right: Children's actual performance in Experiments 1 and 2.

plexity of this task. Children saw thirty similar actions and ten outcomes in each condition, and yet they appeared to track and use this information in deciding which actions to produce. This is consistent with other studies in which children and adults show surprising if implicit capacities to track statistical regularities.

These results extend earlier findings that show children take causal and intentional information into account appropriately in their imitation. They show that children also take into account statistical information about the conditional probability of events and do so in an at least roughly normative way. The studies also suggest a rational mechanism for the phenomenon of "overimitation." In particular, the "triplet" responses could be thought of as a kind of overimitation, reproducing parts of a causal sequence that are not actually demonstrably necessary for the effect. These results suggest that this behavior varies depending on the statistics of the data and the probability of various hypotheses concerning them.

Other factors may also influence the child's judgment of various causal hypotheses. For example, knowing that the adult is knowledgeable about the causal system, and is taking a "pedagogical stance" towards the evidence, may lead the child to different causal conclusions (Bonawitz et al., 2009). We are currently investigating the effect of pedagogical cues on imitation of causal action sequences (Buchsbaum et al., submitted). Similarly, seeing a repeated sequence of actions with no obvious physical causal outcome may lead children to suspect that the actions are intended to have a social or psychological rather than physical effect. Both these processes might lead to greater "overimitation" which would nonetheless be rational.

In general however, this study shows that children are sensitive to statistical information in determining which sequences of actions to imitate. Along with other studies, they support the idea that Bayesian procedures of statistical learning, procedures that allow the construction of causal models from statistical patterns, may play a significant role in many important kinds of early learning.

Acknowledgments. We thank Pat Shafto and Cari Kaufman for discussions on the model design, and Kimmy Yung, Mia Krstic, and Elon Ullman for help with data collection and coding. Thinking with the Body

David Kirsh (kirsh@ucsd.edu)
Dept of Cognitive Science
University of California, San Diego

Abstract

To explore the question of physical thinking – using the body as an instrument of cognition – we collected extensive video and interview data on the creative process of a noted choreographer and his company as they made a new dance. A striking case of physical thinking is found in the phenomenon of marking. Marking refers to dancing a phrase in a less than complete manner. Dancers mark to save energy. But they also mark to explore the tempo of a phrase, or its movement sequence, or the intention behind it. Because of its representational nature, marking can serve as a vehicle for thought. Importantly, this vehicle is less complex than the version of the same phrase danced ‘full-out’. After providing evidence for distinguishing different types of marking, three ways of understanding marking as a form of thought are considered: marking as a gestural language for encoding aspects of a target movement, marking as a method of priming neural systems involved in the target movement, and marking as a method for improving the precision of mentally projecting aspects of the target.

Keywords: Marking; multimodality; thinking, embodied cognition, ethnography.

1. Introduction

This paper explores how dancers and choreographers use their bodies to think about dance phrases. My specific focus is a technique called ‘marking’. Marking refers to dancing a phrase in a less than complete manner. See fig. 1 for an example of hand marking, a form that is far smaller than the more typical method of marking that involves modeling a phrase with the whole body. Marking is part of the practice of dance, pervasive in all phases of creation, practice, rehearsal, and reflection. Virtually all English speaking dancers know the term, though few, if any, scholarly articles exist that describe the process or give instructions on how to do it.¹

When dancers mark a phrase, they use their body’s movement and form as a *representational vehicle*. They do not recreate the full dance phrase they normally perform; instead, they create a simplified or abstracted version – a model. Dancers mark to save energy, to avoid strenuous movement such as jumps, and sometimes to review or explore specific aspects of a phrase, such as tempo, movement sequence, or underlying intention, without the mental complexity involved in creating the phrase ‘full-out’.

Marking is not the only way dancers ‘mentally’ explore phrases. Many *imagine* themselves performing a phrase. Some of the professional dancers we studied reported visualizing their phrase in bed before going to

sleep, others reporting mentally reviewing their phrases while traveling on the tube on their way home. Our evidence suggests that marking, however, gives more insight than mental rehearsal: by physically executing a synoptic version of the whole phrase – by creating a simplified version externally – dancers are able to understand the shape, dynamics, emotion, and spatial elements of a phrase better than through imagination alone. They use marking as an anchor and vehicle for thought. It is this idea – that a body in motion can serve as an anchor and vehicle of thought – that is explored in this paper.

It is a highly general claim. It has been said that gesture can facilitate thought, [Golden Meadow 05]; that physically simulating a process can help a thinker understand a process [Collins et al 91], and that mental rehearsal is improved by overt physical movement. [Coffman 90] Why? What extra can physical action or physical structure offer to imagination? The answer, I suggest, is that creating an external structure connected to a thought – whether that external structure be a gesture, dance form, or linguistic structure – is part of an interactive strategy of bootstrapping thought by providing an anchor for mental projection. [Hutchins, 05, Kirsh 09, 10]. Marking a phrase provides the scaffold to mentally project more detailed structure than could otherwise be held in mind. It is part of an interactive strategy for augmenting cognition. By marking, dancers harness their bodies to drive thought deeper than through mental simulation and unaided thinking alone.

Hand Marking

Fig 1a

Fig 1b

In Fig 1a an Irish river dancer is caught in mid move. In 1b, the same move is marked using just the hands. River dancing is a type of step dancing where the arms are kept still. Typically, river dancers mark steps and positions using one hand for the movement and the other for the floor. Most marking involves modeling phrases with the whole body, and not just the hands.

¹ Search by professional librarians of dance in the UK and US has yet to turn up scholarly articles on the practice of marking.

2. Methodology

To explore the role of physical activity in dance cognition we were fortunate to study the creation of a new dance piece by the noted choreographer Wayne McGregor, the resident choreographer of the Royal Ballet in London. WM created the dance we studied with his own company, Random Dance, a group of ten extremely talented dancers. An eleventh dancer from a different company in Europe joined the group for the first period of dance creation.

The dance company's process of creation occurred in two phases: a three week episode at the University of California, San Diego (UCSD) in the winter of 2009; and a second period in London, in the late summer of 2009, just preceding the official premiere at Sadler's Wells Theater.

Method: During each phase, written notes were taken in real-time. During the UCSD phase, fifteen students took notes; during the London phase, a single experienced ethnographer took notes. Both phases, UCSD & London, were exhaustively videotaped using five high definition video cameras placed on the walls, and, whenever possible, two standard video cameras were placed on the ceiling. The whole rehearsing process, 11AM to 5PM, five to six days a week was captured. Video footage exceeds 110 hours (times 5-6 cameras) and captures all scheduled interactions between choreographer and dancers during the dance making process.

Cognitive ethnography requires acquiring a detailed knowledge of a community of practice, and then using that knowledge to illuminate specific episodes of activity. [Williams 06]. To acquire knowledge of the community of practice we interviewed the choreographer as well as the dancers repeatedly. We also reviewed all notebooks, and used our interviews as an opportunity to discuss specific moments of creative activity. The choreographer was interviewed for between forty and sixty minutes on digital video each morning and night. The dancers were interviewed at the end of each rehearsal. Our aim with the dancers was to have them reflect on specific elements of the rehearsal that day, and wherever possible, to show us through movement the dancerly decisions they made. Four dancers were selected and interviewed for thirty minutes each day. About 70 hours of interviews, in total, were videotaped.

To code the video we used ELAN, a free software system developed by the Max Planck Institute for Psycholinguistics, designed originally for studying gesture and small-scale interactions. Systematic audiovisual analysis depends on having a well-defined vocabulary of coding – a classification of activity and phenomena. After a few days of ad hoc coding a formal vocabulary was established by the whole team (20 people) to characterize ongoing activity. After the UCSD phase of capture, we reviewed the video data and selected special phenomena, such as marking for more detailed coding. In the London phase, we interviewed dancers explicitly about marking to probe them on their own views about marking. These interviews were undertaken in addition to the normal 30

minute ones we conducted. In several such sessions, we had the dancers come before the camera and dance *in full* a phrase they knew well; we then asked them to show us several ways they might *mark* that same phrase, and to describe the reasons they would mark one way versus another. We also interviewed them in a less structured manner, often returning to the question: “When do you mark, and how?” which led to multiple follow up questions and nuances of speech, as well as spontaneous performances from the dancers. The videotaped answers, with the corresponding gestures and markings, were transcribed and analyzed in detail with ELAN. On this basis, we created a hierarchical taxonomy of marking, yielding the three parent groups reported below. Inter-coder reliability in distinguishing these parent marking types exceeded .9, on a sample of 25 video snippets of marking among our most experienced coders (n=3).

3. The Gross Function and Structure of Marking

At the highest level, three *functions* of marking can be distinguished.

1. *Marking-for-self*: dancers use their body to encode an aspect of a phrase for themselves. This may be for reinforcing memory, reflecting on sequence, or for scrutiny of spatial relations, among other reasons.
2. *Marking-for-others*, dancers use their bodies to encode an aspect of a phrase that others can focus attention on. For example, before a new performance, choreographer, choreographic assistant, and lighting manager review all phrases on stage for space.
3. *Joint-marking*: two or more dancers run through a phrase as a tightly coupled team, verifying timing and grips jointly for each other.

Small vs. Large Marking

Fig 2a

Fig 2b

Fig 2c.

Figs 2a, 2b, 2c show the contrast between small and large marking. In 2a, a male dancer is remembering a step, using his hand to small mark it. In 2b, a female dancer is showing how she marks a pirouette. She uses a formal gesture for a pirouette that she learned as a ballet dancer. Her marking is small and conventional. In 2c, a second female dancer marks a phrase using movements that are of comparable size to those in the full phrase. She is clearly modeling the phrase.

There are also a few things to note, at the highest level, about the *structure* of marking.

Variability of size: Marking comes in a continuum of sizes, from very small to full size (but less energetically). In ‘small marking’, the amount of movement is minimal; the marking movements tend to be in the upper body (hands and head mainly), and the objective is to review the steps, the relationship between simultaneous movements (arm and leg together), and occasionally to attend to timing. See figs 2a and 2b. In extreme cases, such as Irish river dancing (fig 1), marking may be done exclusively with two fingers marking foot rhythm, position, and movement. When marking is very small, it is a form of gesture. In larger marking, especially when the function is to show the floor space required by a movement, or to show off the structure of a phrase to someone else, the movements may be full size but with less intent, emotion, or energy than the real movement (fig 2c). They are imperfect models of the complete phrase, but lacking certain attributes, such as intensity, motion dynamics, or fine detail.

Substitutability: A movement in one body part can represent the movement in another. Hand movements and head tilts regularly stand for the motion of different body parts: a hand movement may represent a leg movement, a head turn may represent a torso turn or a whole body turn; if the legs perform in parallel, one leg may stand in for two. This too is shown in figs 2a and 2b. See figs 3a, b for a standing version and fig 1 for finger version.

Idiosyncratic vs. Conventional Marking

3a.

3b.

Fig 3. In 3a a dancer marks a leg movement with his hands in his own idiosyncratic manner that is a hybrid of conventional ballet marking and personal style. In 3b A dancer from a strong ballet tradition offers a conventional small marking with her hands.

Conventional: In classical ballet and other formalized dance forms, dancers are taught to use specific gestures as ways of marking certain moves. These are a conventionalized form of small markings. For instance, as seen in fig 2b, the female dancer marks for the interviewer with her hand to show that, at a certain point in the phrase, a pirouette is required. In fig 3b she shows us a gesture for a *pas de bourrée*. These small gestures refer to a complex sequence

of full moves well known by ballet dancers. We observed that dancers who do not rely on a ballet vocabulary still mark in a way that is reminiscent of ballet marking; but each dancer has personal idiosyncrasies that violate convention. In fig 3a, for instance, a dancer with deep training in both modern and ballet represents a leg movement with his arms, a hybrid marking that is part conventional and part personal gesture.

Aspectival: Marking typically represents an aspect of the full phrase, with some forms of marking focusing solely on tempo, others focusing on sequence, still others focusing on spatial position. For instance, when dancers mark for space they will keep the scale of the full phrase, but other aspects will be ignored or only partially represented, such as the dynamics of the phrase. At other times, just the movement of the upper body or the torso orientation may be marked and the movement of a leg or arm is left completely unmarked. Evidently, when dancers mark they are attending to only certain aspects of the phrase.

4. Analysis

Is it plausible to see marking as a vehicle of thought? There are a few promising ways to approach this question. Perhaps the most obvious line is that marking is a type of gestural semiotic system, possibly like a linguistic code. If gesture can function as a vehicle of thought, as some have argued, then why not marking?

It is useful to classify gestures according to where they lie on ‘Kendon’s Continuum’ (McNeill 92). At one extreme, there are “gestures of the kind that Kendon has called ‘quotable’ ... gestures that must be configured according to pre-established standards of form in order for them to function as signs, such as the OK sign among North Americans” (McNeill & Duncan 2000). These are compositional and behave in many respects like words or phrases in a language. At the other extreme are ‘gesticulations’. These are idiosyncratic, created on the fly, and motivated by imagery rather than convention.

In dance, marking in the classical tradition of ballet is convention-driven and quotable. Despite individual differences in marking style, dancers still conform to general norms. Although marking conventions vary from ballet company to company, it does not take long for a professional dancer to pick up the idiosyncrasies of a company. This suggests there are rules determining the structure of ballet marking, and that local differences in marking style should be viewed as akin to differences in accent or handwriting. They need to be learned but are not different in principle than dialects of a common language.

In contemporary dance, the *reference* of marking – the phrases full-out, or aspects of those phrases – are not easily segmented. Movements in contemporary dance are freer, often novel. There are also far fewer conventions governing how dancers should mark. But not none. In the group we studied, for instance, there were quite strict rules about how to mark for the choreographer or his assistant. The spatial

dimensions of the phrase were to be preserved, though energy, and pace could be lessened.

The implication is that marking might well lie nearer the language side on Kendon's continuum than the gesticulation side. This needn't be a surprise. If there are written notation systems for encoding dance, such as Laban notation, then as long as marking is as expressive as these notation systems, anything that can be encoded on paper can be encoded through marking. The one requirement is that there be semantic rules for interpreting the paper notation and semantic rules for interpreting marking.

It is here, however, that the analogy with language fails. Marking is a reliable language only when a) dancers are *marking for others* – the other forms of marking lack adequate semantic rules; and, b) only when the point of marking is to display space, position, and structural form, all aspects of the full-out phrase that the choreographer or his assistant can directly see in the marking itself. If the point of marking were to call attention to movement sequence or to motor preparation, external observers would often be unable to infer the movements being sequenced or prepared for.

This is perhaps the key point. If someone states, "there is a circle with radius 30 meters", a competent interpreter need not have seen such a circle beforehand to know what the sentence means. It is enough to know the meaning of the terms 'circle', 'radius', '30 meters' to generate an interpretation. That is what semantic rules are for. By contrast, in marking, because there is so much idiosyncrasy in marking when dancers are marking for themselves, or when marking an aspect of a phrase that is not visibly similar to the full-out phrase (space), observers cannot 'see' the full-out move 'in' a marked version unless they already know what the full-out looks like. This explains why dancers rarely, if ever, mark a phrase they do not already know, and why choreographers never request dancers to show them novel phrases by marking – they insist on a full-out. Evidently, both parties need a clear idea of the target in advance of the marking. They have to have seen the full-out phrase to be able to 'project' it from its marking.

I believe this proves that much if not the majority of marking is not language like. It relies on prior acquaintance with the target, and then matching the mark to its target. That process more closely resembles a pattern completion process than a generative process of constructing the target. Languages are essentially generative, the point of marking is to avoid generating the whole target.

But if marking does not behave as a language this raises a paradox: if a dancer, or an observer, needs a clear idea of the full-out phrase in order to correctly interpret its marked version, why bother with the marking? How can marking ever be more powerful than inner visualization or imagination alone? What more can the physical manifestation of a movement add to the target already 'mentally grasped' through imagination?

One answer is that physical movement is helpful when one wants to measure the distance covered in a phrase. External distance is not guaranteed to be accurate in a

mental representation. [Ledermen 87]. And there may be other physical dimensions available in the physical execution of a phrase that are only implicit in its mental representation (for instance, the physical tension in leaping off the floor or lifting another person).

But, beyond making physical attributes measurable, [see Kirsh 10], what extra *cognitive benefits* can physical marking provide that surpass mental rehearsal?

Here are two possibilities. They offer a different take on how marking might serve as a vehicle of thought.

1. Marking is a way of *anchoring projection* to a target. By providing a marked version of a target, a dancer can project a better representation of the target than imagination unaided. Marking, therefore, is a causally important way of augmenting thought. It is a component of a *distributed vehicle of thought*, consisting of an inner part and an outer part, which enables clearer thoughts. (cf. Hutchins 05)
2. Marking is a way of *priming* the neural system of a dancer, thereby enhancing imagination (or projection) by activating cortical elements that would be involved in the full-out movement. Marking is a way of enhancing the vividness and detail of imagination.

Marking as a method of anchoring projection. In the phenomenology of perception, a distinction can be drawn between perception, projection, and imagination. See fig 4.

- When we *perceive* an object, our experience is that we are seeing an object that is really there; we feel it is what causes our perception.
- When we *project* onto an object, we experience ourselves intentionally augmenting the object; we feel we partially cause our experience.
- When we *imagine* an object, we feel as if we are the sole cause of our imagined experience.

Fig 4. The difference between perception, projection, and imagination is represented here by three conditions of a tic-tac-toe game. Perception: subjects *see* moves. Projection: subjects see only the tic-tac-toe grid, and mentally *augment* it with moves. Imagination: subjects see a blank page and all aspects of the game are imagined – no external stimuli to scaffold or structure imagination.

The application to marking is shown in Fig 5. If the full-out phrase is represented by the complete triangle in 5a, marked versions are represented by 5b – 5e. The marked versions are either fractions or distortions of fractions of the full. But they support projection to full-out, if one has been exposed to the full-out already.

This form of projection is not a standard completion process. In completion, the target is a superset of the fragment. For example, *tang_ _ _* is a *stem* that supports completions like *tangent*. The fragment *ta_g_ _ s* supports the completions *targets* or *tangles*. In both cases, the target completes the fragment. In projection, the structure that augments the fragment need not complete it because it may produce a new structure that has none of the subset structure. For instance, in 5c, the completion is larger in all dimensions except corner angle. In 5d and 5e, even the angles are not preserved. Projection is not completion.

Kirsh [09] showed that it is easier to conceptualize a target, or recover more memory of a target's structure, if there is something outside that one can 'lean on' for support. It is easier to project than to imagine if there is something helpful outside to support the projection. Recall is better for projected imagery than imagined imagery [ibid].

Marking as Projection

Fig 5. The idea of marking as a sequence of illustrations of decreasing verisimilitude to the full phrase. 5a: a complete path at full scale. 5b: same path, full scale, shown by vertices and directions. 5c: smaller path, the interpreter must now know the scaling function. 5d: a stylized version of 5a. 5e, a smaller version of 5d, interpreter must project both shape, angles, and know the scaling function.

The relevance to marking is that when dancers mark, they may be creating a physical scaffold that facilitates projection. This would explain what 'extra' a dancer gets by physically marking a phrase rather than mentally rehearsing it. They get an external structure they can extrapolate from. This enables them to generate a conception of the final target that is more vivid, complete, and requiring less mental effort, than when they mentally rehearse without the support of overt movement. Moreover, dancers are able to choose how much extra memory support they want, just by marking more completely. When their mental image of the target is already clear, their marking may be minimal. When they have a weak mental image of the target, they may mark it more extensively, thereby increasing the vividness and control over their conception of the target.

Marking as a method of priming. A second benefit of marking may be that it involves more brain activity than mental rehearsal alone. It may facilitate muscle memory of details or deeper processing of movement goals.

The importance of muscle memory in dance is part of standard teaching. Muscle memory refers to the system of motor procedures – motor schemata – that have been stabilized through practice and are activated during performance. [Krakauer 06] Initial movements prime later movements. Priming also facilitates projection. Priming refers to an increased sensitivity to a stimulus due to prior exposure to a related stimulus. For instance, subjects who recently hear, see, think, and especially perform a particular movement will recognize aspects of that movement, sooner than those who have not. (Koch et al 04) The extent of priming is also a function of the depth of processing involved in the earlier exposure. [Challis, 92, Smith et al 83]. A person who thinks hard about a dance phrase – its energy, sequence, rhythm or spatial extent – will prime more choreographic relatives of the phrase, and prime them more deeply, than someone who merely sees the phrase briefly. Since motor preparation, spatial planning, and proprioceptive monitoring are involved in marking, it is likely that even more areas of cortex are involved in marking than in mental rehearsal alone. This suggests that during marking, there will be more opportunities for deeper processing – more chance to see deeper relations among movement components – than during mental rehearsal. Marking should prime the phrase more deeply, making it easier to remember it in the future.

If marking helps a dancer to envision the target phrase better, it helps to explain why marking is beneficial. Given the importance of internal processes, however, marking is best understood as the external part of an internal-external process. It is best seen as the external part of a distributed vehicle of thought.

5. Conclusion

I have argued that marking is a form of physical thinking. A dancer creates a partial version of a phrase, attends to it while creating it, and because of processes like priming and projection, the dancer is able to understand something deeper about the phrase's structure than through imagination alone. When dancers mark, they are closely coupled with the dance product they are externalizing. *They rely on that product to think with.* Their performance of the marked phrase is part of their ongoing process of grasping the phrase. In some ways, their relation to marked material is reminiscent of what E. M. Forster (27) said about language: "How can I know what I'm thinking until I see what I say". For Forster, the external vehicle of a thought – its linguistic formulation – was a real time achievement of putting the thought into words. It made the thought more precise in virtue of the constraints of language. There was no point asking whether the articulated content was the same as some internal version already encoded in an internal language intrinsically understood, as suggested by Fodor (75) and others. For Forster, as well as for Wittgenstein (51), the articulation is part of the thinking process.

My suggestion, here, is that for a dancer, Forster's rhetorical question can be rephrased as: "How can I know

what my phrase really is until I see what I do?" A dancer's thought of his or her phrase is partly shaped by what is marked. Dancers do think about their phrases without dancing them or marking them. But, by *marking-for-self* dancers *think better* about their full-out phrase. Physical movement replaces mental computation. Instead of imagining transformations, they execute them externally. Marking is part of a distributed vehicle of thought with internal and external parts closely coupled.

The More the Merrier? Examining Three Interaction Hypotheses

Abstract

While high interactivity is one of the key characteristics of one-on-one human tutoring, a great deal of controversy surrounds the issue of whether interactivity is indeed the key feature of tutorial dialogue that impacts students' learning. In this paper we investigate three interaction hypotheses: a widely-believed monotonic interactivity hypothesis, a better supported interaction plateau hypothesis, and our tactical interaction hypothesis. The monotonic interaction hypothesis predicts that increasing interactivity causes an increase in learning; the plateau hypothesis states that increasing interactivity yields increasing learning until it hits a plateau, and further increases in interactivity do not cause noticeable increases in learning. Finally, the tactical interaction hypothesis predicts that interactivity only increases learning when interactions are guided by effective tutorial tactics. In this paper, we examine each hypothesis in the context of an empirical study, the results of which support the tactical interaction hypothesis.

Keywords: machine learning; reinforcement learning; pedagogical strategy; Intelligent Tutoring Systems.

Introduction

One-on-one tutoring is a highly effective educational intervention. Tutored students often perform significantly better than students in classroom settings (Bloom, 1984). Computer learning environments that mimic aspects of human tutors have also been highly successful. Intelligent Tutoring Systems (ITSs) have been shown to be highly effective at improving students' learning in real classroom settings (Koedinger et al., 1997; VanLehn, 2006). A key characteristic of one-on-one tutoring, with both human and computer tutors, is high interactivity.

A common assumption, often referred to as the *monotonic interaction hypothesis* (VanLehn, Graesser, et al., 2007) is that greater interactivity leads to greater learning.

However, several studies have failed to confirm this hypothesis. Experiments with human tutors found no significant differences in learning gains when content was carefully controlled and interactivity was directly manipulated (M. T. H. Chi et al., 2001, 2008; Rose et al., 2001). Experiments that compared human tutors and several Natural Language dialogue-based computer tutors also found no significant differences in learning as interactivity varied across students (Evens & Michael, 2006; VanLehn, Graesser, et al., 2007; Reif & Scott, 1999; Katz et al., 2003; Fossati et al.,

2008). In a meta-analysis of the tutoring literature, VanLehn found little support for the monotonic interactivity hypothesis and instead proposed the interaction plateau: the hypothesis that increased interactivity increases learning up to a point (roughly, the level of interactivity afforded by conventional step-based ITSs); beyond that threshold, however it does not yield any noticeable increases in learning (VanLehn, submitted).

On the other hand, for any form of tutoring the tutor's behaviors can be viewed as a sequential decision processes wherein, at each discrete step, the tutor is responsible for selecting the next action to take. Each of these tutorial decisions affects successive actions. Some existing theories of learning suggest that when making tutorial decisions, a tutor should adapt its actions to the students' needs based upon their current knowledge level, affective state, and other salient features (Vygotsky, 1971; Collins et al., 1989; Koedinger & Aleven, 2007). Most studies cited above made use of human tutors for their highly-interactive condition, simply assuming that expert tutors will take optimal actions. However, Chi et al. and others have argued that human tutors may not always make optimal tutorial decisions (M. T. H. Chi et al., 2001, 2008). Given that tutoring is a rather complex procedure and tutors have to make many decisions fairly rapidly, even expert human tutors may not take the full advantage of the tutorial alternatives.

Therefore, in this paper we propose a third hypothesis: the *tactical interaction hypothesis*. It states that interactivity only increases learning when interactions are guided by effective tutorial tactics. By "tutorial tactics" we refer to the policies used for selecting the tutorial action taken at each step when there are multiple actions available. In other words, we hypothesize that the tutors' success will not be governed by *how often* they give interactive prompts or ask the students questions but *how well*.

To investigate the three hypotheses, we focused on two tutorial actions: *elicit* and *tell*. During the course of one-on-one tutoring, tutors often face a simple question, should they *elicit* the next step information from the student, or should they *tell* the student the next step directly? There are many theories, but no widespread consensus on how or when an *elicit* or a *tell*

(a) Elicit Version	(b) Tell Version
1. T: So let's start with determining the value of v_1 . 2. T: Which principle will help you calculate the rock's instantaneous magnitude of velocity at T1? {ELICIT} 3. S: definition of kinetic energy 4. T: Please write the equation for how the definition of kinetic energy applies to this problem at T1 {ELICIT} 5. S: $ke_1 = 0.5 * m * v_1^2$ 6. T: From $KE_1 = 0.5 * m * v_1^2$, ...	1. T: So let's start with determining the value of v_1 . 2. T: To calculate the rock's instantaneous magnitude of velocity at T1, we will apply the definition of kinetic energy again. {TELL} 3. T: Let me just write the equation for you: $KE_1 = 0.5 * m * v_1^2$. {TELL} 4. T: From $KE_1 = 0.5 * m * v_1^2$, ...

Figure 1: Elicit vs. Tell

should be taken (Vygotsky, 1971; Aleven et al., 2004; Collins et al., 1989). Generally speaking, eliciting more information from the student will result in a more interactive tutorial dialogue. Figure 1 compared a pair of dialogues extracted from logs in this study. Both dialogues begin and end with the same tutor turn (lines 1 and 6 in (a) and 1 and 4 in (b)). In dialogue (a) the tutor chooses to elicit twice (lines 2-3 and 4-5 respectively). Dialogue (b), by contrast, *covers the same domain content* with two tell actions (lines 2 and 3). As a consequence, dialogue (a) is more interactive than (b).

In this paper, we quantify the *interactivity* of a dialogue via the Interactivity ratio (I-ratio) which we define as the number of elicitation decisions divided by the total number of elicit or tell decisions in a given dialogue. The higher this value, the more interactive the tutorial dialogue.

$$I - \text{ratio} = \frac{N_{Elicit}}{N_{Elicit} + N_{Tell}} \quad (1)$$

Unlike the monotonic and plateau hypotheses, validation of the tactical interaction hypothesis requires effective tutorial tactics. In most computer learning environments the pedagogical tutorial tactics are hard-coded rules designed to implement preexisting cognitive and/or pedagogical theories. Typically, these theories are considerably more general than the specific interaction decisions that designers must make. This makes it difficult to tell if a specific policy is consistent with the theory. Moreover, it is often difficult to empirically evaluate these tactics because the tutor's overall effectiveness depends upon many factors, such as the usability of the system, how easily the dialogues are understood, and so on. Ideally, several versions of a system are created, each employing different tutorial tactics. Data is then collected with human subjects interacting with these different versions of the system and the results are compared. Due to the high cost of experiments, however, only a handful of policies are typically explored. Yet, many other reasonable policies are possible.

In recent years, work on the design of dialogue systems has involved several data-driven methodologies. Among these, Reinforcement Learning (RL) has been widely applied (Singh

et al., 2002). In this work, rather than implementing pedagogical policies drawn from human experts or theories, we applied and evaluated RL to derive pedagogical tutorial tactics using pre-existing interactivity data.

General Approach

For this study, we induced two sets of tutorial tactics: the Normalized Gain (NormGain) tactics, derived with the goal of making tutorial decisions that contribute to students' learning, and the Inverse Normalized Gain (InvNormGain) tactics, induced with the goal of making less beneficial, or possibly useless, decisions. The two sets were then compared with human students on Cordillera (VanLehn, Jordan, & Litman, 2007), a Natural Language Tutoring System teaching students introductory college physics. Using Cordillera in lieu of human tutors allowed us to rigorously control the content and vary only the interactivity. In order to avoid artifacts due to imperfect natural language understanding, Cordillera incorporated a human wizard whose sole task was to rapidly match students' actual utterance to one of the expected student utterances displayed in a menu. The wizard made no tutorial decisions.

In the learning literature, it is commonly assumed that relevant knowledge in domains such as math and science is structured as a set of independent but co-occurring Knowledge Components (KCs) and that KC's are learned independently. A KC is "a generalization of everyday terms like concept, principle, fact, or skill, and cognitive science terms like schema, production rule, misconception, or facet" (VanLehn, Jordan, & Litman, 2007). For the purposes of tutoring, these are the atomic units of knowledge. It is assumed that a tutorial dialogue focusing on a single KC will not affect the student's understanding of any other KC. This is an idealization, but it has served developers well for many decades, and is a fundamental assumption of many cognitive models (Anderson, 1983; Newell, 1994). When dealing with a specific KC, the expectation is that the tutor's best policy for teaching that KC (e.g., when to Elicit vs. when to Tell) would be based upon the student's mastery of the KC in question, its intrinsic

difficulty, and other relevant, but not necessarily known, factors specific to that KC. In other words, an optimal policy for one KC might not be optimal for another. In this study, we focused on eight KCs. We induced eight policies and conducted eight tests of the three hypotheses, one per KC.

Later results indicated that on average the percentage of elicit prompts students received during the tutoring is more than 70% for both groups in this study, thus based on the standard set in (VanLehn, submitted) the tutorial dialogues reported here are well beyond the threshold of the level of interactivity afforded by conventional step-based ITs. Therefore, we expect that on each KC:

1. If the monotonic hypothesis is correct, the group that learned more would have a higher I-ratio.
2. If the interaction plateau hypothesis is correct, both NormGain and InvNormGain students would learn equally well regardless of interactivity difference.
3. If the tactical interaction hypothesis is correct and our RL-based tutorial tactics are indeed effective, NormGain students would learn more than InvNormGain peers regardless of interactivity difference.

First we will briefly describe how we apply machine learning to induce tutorial dialogue tactics. Then we will describe our study and its results.

Applying RL to Induce Tutorial Tactics

Much of the previous research on the use of RL to improve dialogue systems has typically used Markov Decision Problems (MDPs) (Sutton & Barto, 1998) to model dialogue data (Singh et al., 1999). An MDP formally corresponds to a 4-tuple (S, A, T, R) , in which: $S = \{S_1, \dots, S_n\}$ is a state space; $A = \{A_1, \dots, A_m\}$ is an action space represented by a set of action variables; $T : S \times A \times S \rightarrow [0, 1]$ is a set of transition probabilities $P(S_j|S_i, A_k)$, which is the probability that the model would transition from state S_i to state S_j after the agent takes action A_k ; $R : S \times A \times S \rightarrow R$ assigns rewards to state transitions. Finally, $\pi : S \rightarrow A$ is defined as a policy, which determines which action the agent should take in each state in order to maximize the expected reward.

The central idea behind our approach is to transform the problem of inducing effective pedagogical tactics into computing an optimal policy for choosing actions in an MDP. Inducing pedagogical tactics can be represented using an MDP: the states S are vector representations composed of relevant student-tutor interaction characteristics; $A = \{Elicit, Tell\}$ in this study, and the reward function R is calculated from the system's success measures and we used learning gains. Once the (S, A, R) has been defined, the transition probabilities T are estimated from the training corpus, which is the collection of dialogues, as: $T = \{p(S_j|S_i, A_k)\}_{i,j=1,\dots,n}^{k=1,\dots,m}$. More specifically, $p(S_j|S_i, A_k)$ is calculated by taking the number of times that the dialogue is in state S_i , the tutor took action A_k , and the dialogue was next in state S_j divided by the number of times

the dialogue was in S_i and the tutor took A_k . Once a complete MDP is constructed, a dynamic programming approach can be used to learn the optimal control policy π^* and here we used the toolkit developed by Tetreault and Litman (Tetreault & Litman, 2008).

In this study, the reward functions for inducing both the NormGain and the InvNormGain sets were based on Normalized Learning Gain (NLG) defined as: $NLG = \frac{posttest - pretest}{1 - pretest}$ because it measures a student's gain *irrespective of his/her incoming competence*. Here *posttest* and *pretest* refer to the students' test scores before and after the training respectively; and 1 is the maximum score. More specifically, the NormGain tutorial tactics induced by using the student's $NLG \times 100$ as the final reward while the InvNormGain ones was induced by using the student's $(1 - NLG) \times 100$ as the final reward. Apart from the reward functions, the two sets were induced using the same general procedure.

In order to learn a policy for each KC, we annotated our tutoring dialogues and action decisions based on which KCs a tutor action or tutor-student pair of turns covered ($\kappa \geq 0.77$ for each of the eight KCs). Additionally, we have mapped students' pre- and post-test scores to the relevant KCs for each test item. The rest of this section presents a few critical details of the process, but many others must be omitted to save space. Overall, the RL approach in this study differed from that of the previous study (M. Chi et al., 2009) in many aspects. First, we have three training corpora in this study: the Exploratory corpus collected in 2007, the Dich-Gain corpus collected in 2008, and a Combined training corpus. Second, in order to examine a range of possible tactics we included 50 features based upon six categories of features considered by previous research (Moore et al., 2004; Forbes-Riley et al., 2007) to be relevant. Additionally, we also used a different method of searching the power set of the 50 features. Finally we directly used the $NLG \times 100$ for inducing NormGain policies and $(1 - NLG) \times 100$ for inducing InvNormGain ones instead of dichotomizing the NLGs when inducing policies previously.

Figure 2 shows an example of a learned NormGain policy on one KC, "Definition of Kinetic Energy". The policy involves three features:

[StepDifficulty:] encodes a step's difficulty level. Its value is estimated from the students' log files based on the percentage of correct answers given on the step.

[TutorConceptsToWords:] which represents the ratio of the physics concepts to words in the tutor's dialogue. This feature also reflects how often the tutor has mentioned physics concepts overall.

[TutorAvgWordsSession:] The average number of words in the tutor's turn in this session. This feature reflects how verbose the tutor is in the current session.

MDP generally requires discrete features and thus all the continuous features need to be discretized. The top half of Figure 2 lists how each of the three features was discretized. For example, For StepDifficulty, if its value is above 0.38, it

[Feature:]			
StepDifficulty:	$[0, 0.38) \rightarrow 0;$	$[0.38, 1] \rightarrow 1$	
TutorConceptsToWords:	$[0, 0.074) \rightarrow 0;$	$[0.074, 1] \rightarrow 1$	
TutorAvgWordsSession:	$[0, 22.58) \rightarrow 0;$	$[22.58, \infty) \rightarrow 1$	
[Policy:]			
Elicit:	0:0:0 0:0:1 1:0:1 1:1:0 1:1:1		
Tell:	0:1:0		
Else:	0:1:1 1:0:0		

Figure 2: A NormGain Policy on KC_{20} For ET Decisions

is 1 (difficult) otherwise, it is 0 (easy). The lower half of Figure 2 shows there are 8 rules learned: in 5 situations the tutor should elicit, in one situation it should tell; in the remaining 2 cases either will do. For example, when all three features are zero (which means when the step is easy, the tutor ratio of physics concepts to words so far is low, and the tutor is not very wordy in the current session), then the tutor should elicit as 0:0:0 is listed next to the [elicit]. As you can see, three features already provide relatively complex tutorial tactics and the induced policies were not like most of the tutorial tactics derived from analyzing human tutorial dialogues.

The resulting NormGain and InvNormGain policies were then implemented back into Cordillera yielding two new versions of the system, named NormGain-Cordillera and InvNormGain-Cordillera respectively. The induced tutorial tactics were evaluated on real human subjects to see whether the NormGain students would out-perform the InvNormGain peers.

Methods

Participants

Data were collected over a period of two months during the summer of 2009. Participants were 64 college students who received payment for their participation. They were required to have a basic understanding of high-school algebra. However, they could not have taken any college-level physics courses. Students were randomly assigned to the two conditions. Each took from one to two weeks to complete the study over multiple sessions. In total, 57 students completed the study (29 in the NormGain condition and 28 in the InvNormGain condition).

Domain & Procedure

The tutoring addressed work-energy problem solving from a first-year college physics course. The eight primary KCs were: the weight law (KC_1), definition of work (KC_{14}), Definition of Kinetic Energy (KC_{20}), Gravitational Potential Energy (KC_{21}), Spring Potential Energy (KC_{22}), Total Mechanical Energy (KC_{24}), Conservation of Total Mechanical Energy (KC_{27}), and Change of Total Mechanical Energy (KC_{28}).

All participants in the study followed the same procedures and used the same training and testing materials as were used when collecting the training corpora. More specifically, the participants all: completed 1) a background survey; 2) read a text covering the target domain knowledge; 3) took a pretest;

4) solved the same seven training problems in the same order on Cordillera; and 5) finally took a posttest. The pretest and posttest were identical. Except for following the policies (NormGain vs. InvNormGain), the remaining components of Cordillera, including the GUI interface, the same training problems, and the tutorial scripts, were identical for all students.

Grading

The tests contained 33 test items covering 168 KC occurrences. Each occurrence was graded by a single experienced grader who was not aware of the study condition from which it arose. These were then summed and normalized to the range of [0,1]. Other grading rubrics were also tried. They presented the same pattern of results as the ones presented next.

Results

No significant difference was found between the two conditions in terms of the total training time spent on Cordillera: $t(55) = 0.27, p = .79$. The NormGain group spent ($M = 259.98$ mins, $SD = 59.22$) and the InvNormGain group spent ($M = 264.57$ mins, $SD = 67.60$). For each student, Cordillera had made on average 260 decisions on whether to Elicit or to tell during the training and on a KC by KC basis, the number of such decisions varies from 4 on KC_1 to 72 on KC_{20} .

Learning Performance

First, we investigated whether students learned by training on Cordillera. A one-way ANOVA was used to test for learning performance differences between the pre- and posttests. Both groups made reliable learning gains from pre-test to post-test: $F(1,56) = 31.34, p = .000$ for the NormGain condition and $F(1,54) = 6.62, p = .013$ for the InvNormGain condition respectively. On a KC by KC basis, the NormGain conditions learned reliably on all the eight primary KCs while the InvNormGain learned reliably on five primary KCs save for KC_{14} , KC_{22} , and KC_{28} .

Next, we compared the learning performance between the two conditions. Random assignment appears to have balanced the incoming student competence across conditions. There were no statistically significant differences between the two conditions on the mathSAT scores nor in the pre-test scores: $t(55) = 0.71, p = .48$. On a KC by KC basis, no significant difference was found between the two conditions across all eight primary KCs except that on KC_{27} , the NormGain group score marginally higher than the InvNormGain group: $t(55) = 1.74, p = 0.088$ (see Table 1). In order to account for varying pretest scores, the adjusted Post-test scores were compared between the two conditions by running an ANCOVA using the corresponding pre-test score as the covariate.

The NormGain condition out-performed the InvNormGain on the overall adjusted posttest scores: $F(1,54) =$

Table 1: Between-Group Comparison on Pre-Test and Adjusted Post-Test Scores Across Primary KCs

KC	TestScore	NormGain	InvNormGain	Stat	d
KC_1	Pretest	0.42 (0.15)	0.39 (0.22)	$t(55) = 0.66, p = 0.51$	0.16
	Adjusted Posttest	0.64 (0.12)	0.54 (0.12)	$F(1, 54) = \mathbf{9.80}, p = \mathbf{0.0028}$	0.85
KC_{14}	Pretest	0.43 (0.23)	0.44 (0.25)	$t(55) = -0.17, p = 0.86$	-0.04
	Adjusted Posttest	0.65 (0.17)	0.53 (0.17)	$F(1, 54) = \mathbf{6.47}, p = \mathbf{0.014}$	0.72
KC_{20}	Pretest	0.38 (0.17)	0.37 (0.22)	$t(55) = 0.31, p = 0.76$	0.05
	Adjusted Posttest	0.67 (0.11)	0.58 (0.11)	$F(1, 54) = \mathbf{10.30}, p = \mathbf{0.002}$	0.83
KC_{21}	Pretest	0.45 (0.20)	0.43 (0.24)	$t(55) = 0.35, p = 0.72$	0.09
	Adjusted Posttest	0.75 (0.13)	0.65 (0.13)	$F(1, 54) = \mathbf{7.62}, p = \mathbf{0.008}$	0.78
KC_{22}	Pretest	0.42 (0.25)	0.39 (0.26)	$t(55) = 0.41, p = 0.68$	0.12
	Adjusted Posttest	0.63 (0.17)	0.51 (0.17)	$F(1, 54) = \mathbf{7.77}, p = \mathbf{0.007}$	0.72
KC_{24}	Pretest	0.46 (0.15)	0.41 (0.23)	$t(55) = 0.89, p = 0.38$	0.26
	Adjusted Posttest	0.64 (0.11)	0.58 (0.11)	$F(1, 54) = \mathbf{4.22}, p = \mathbf{0.045}$	0.56
KC_{27}	Pretest	0.53 (0.21)	0.42 (0.24)	$t(55) = 1.74, p = 0.088$	0.5
	Adjusted Posttest	0.74 (0.18)	0.63 (0.18)	$F(1, 54) = \mathbf{5.88}, p = \mathbf{0.019}$	0.62
KC_{28}	Pretest	0.37 (0.20)	0.36 (0.26)	$t(55) = 0.13, p = 0.90$	0.04
	Adjusted Posttest	0.53 (0.17)	0.47 (0.17)	$F(1, 54) = 1.61, p = 0.21$	0.36

10.689, $p = .002$, $d^1 = 0.86$. On a KC by KC basis, Table 1 summarize the comparisons on the pre-test and adjusted posttest scores between the two conditions. The third and fourth columns in Table 1 list the means and SDs σ of the NormGain and InvNormGain groups' pretest or adjusted posttest scores on the corresponding KC. The fifth column lists the corresponding statistical comparison and the sixth column lists the Cohen's d of the comparison. Table 1 shows that the NormGain condition out-performed the InvNormGain across all primary KCs (in bold) except for KC_{28} , on which no significant difference was found between the two groups.

I-ratios

We next investigated the interactive characteristics of the derived tutorial tactics by comparing the tutorial dialogues' I-ratios between the two groups. Surprisingly, there were no significant differences between the two groups on the overall I-ratio: $t(55) = -0.395$, $p = 0.694$. More specifically, we have $M = 0.758$, $SD = 0.073$ (maximum is 1) for the NormGain group and $M = 0.763$, $SD = 0.018$ for the InvNormGain group respectively.

However, once the results were examined on a KC by KC basis there were significant differences between the two groups on each of the eight primary KCs. Figure 3 shows that the NormGain condition was more likely to get elicits than the InvNormGain condition on KC_{14} , KC_{20} , KC_{21} , and KC_{22} ; and the InvNormGain condition was more likely to get elicits than the NormGain condition on KC_1 , KC_{24} , KC_{27} , and KC_{28} .

Figure 3: Compare I-ratio Across KCs

Examining The Three Interaction Hypothesis

The monotonic interactivity hypothesis states that more interactivity should lead to increased learning. Because the NormGain group learned more than the InvNormGroup across all eight KCs except KC_{28} , which was a null result, the NormGain group should also have a larger I-ratio on all seven KCs. From Figure 3, it was shown that this was *not* the case for KC_1 , KC_{24} and KC_{27} . Thus, our data are not consistent with the monotonic interactivity hypothesis.

The interaction plateau hypothesis states that increasing interactivity yields increasing learning until it hits a plateau, and further increases in interactivity do not cause noticeable increases in learning. The main difference between this hypothesis and monotonic interactivity hypothesis is once beyond a certain level of interactivity whether increasing interaction would impact students' learning gain or not. In order to test this hypothesis, we mainly focused on the six KCs (all but KC_{14} and KC_{28}). This is because on these six KCs both NormGain and InvNormGain groups' I-ratios were more than 48% (see Figure 3) which is well beyond the threshold of the level of interactivity afforded by conventional step-based ITSs based on the definition set in (VanLehn, submitted). If

¹Cohen's d , which is defined as the mean learning gain of the experimental group minus the mean learning gain of the control group, divided by the groups' pooled standard deviation.

the interaction plateau hypothesis is true, then the NormGain group should learn just as much as the InvNormGain group on each of the six KCs. Table 1 however shows that the NormGain group learned more than the InvNormGain group across all six KCs. Thus, the interaction plateau hypothesis is not consistent with our data.

Finally, the tactical interaction hypothesis states that interactivity does not increase learning unless they are governed by effective tutorial tactics. If this is true and all our derived RL-based policies were indeed effective, the NormGain group would learn more than the InvNormGain group across all KCs. This hypothesis was supported by seven of the KCs, and on KC₂₈ there was only an unreliable trend in the expected direction. Thus, of all three hypotheses, the tactical interaction hypothesis receives the most support from our data.

Discussion

Overall, our results inform the ongoing discussion of Socratic vs. didactic tutoring by suggesting that a tutor's success is not governed by *how often* they prompt or ask the students questions but *how well*. In particular, the reason human tutors so often failed to be more effective than simple, unoptimized dialogue-based tutors in those previous studies may be that effective policies for tutorial interaction are complex and not easily derived from the tutors' experience. This in turn suggests that an optimized dialogue-based tutoring system, such as NormGain-Cordillera, would be potentially even more effective than expert human tutors. Although controlling for content is difficult when human tutors are involved, testing this speculative hypothesis would certainly be interesting.

Finally, this study suggests that instead of using an overall tutorial tactics for all KCs, inducing KC-based tutorial tactics seems is necessary in that the induced tutorial tactics seems generated different tutorial decisions for different KCs in this study. Additionally, our results demonstrate that RL may be fruitfully applied to derive adaptive pedagogical tutorial tactics from student-computer interactivity data. However, this technique is not yet well understood. It is not completely clear to us, for instance, why our first attempt at inducing policies was suboptimal. In future work, we plan to explore the use of richer POMDP models, and do additional empirical evaluation of the RL approach.

Abstract

This paper extends our previous work (Kim, Weitz, Heffernan & Krach, 2009) which compared a “classic” worked examples (WE) condition with a tutored problem solving (TPS) condition. By classic we mean the WE condition does not include tutoring, a self-explanation component, or fading. The aim of the current study was to compare the WE and TPS conditions with a mixed condition, which presents students with WE-TPS pairs. More specifically, for conceptual problems a pure WE condition was compared with a WE-TPS condition and for procedural problems a pure TPS condition was compared with a WE-TPS condition. While overall learning occurred in all conditions no significant differences were found between conditions. Further, our findings echo the results of earlier studies, that students who receive worked examples learn more efficiently – that is, they need significantly less time to complete the same learning material. This is an important finding for educators because building classic worked examples is considerably easier than building tutoring.

Keywords: tutored problem solving; worked examples

Introduction

Research on worked examples (e.g., Sweller & Cooper, 1985; Ward & Sweller, 1990) has demonstrated that when students were presented with example-problem pairs rather than problems only, they could attain higher learning outcomes because their working memory capacity was not overloaded. Worked examples reduce problem solving demands by providing worked-out solutions. Therefore, more of the learners’ limited processing capacity (i.e., working memory capacity) can be devoted to understanding the domain principles and their application to the problem at hand (Renkl & Atkinson, 2007).

In recent years, a considerable number of studies have explored the conditions under which examples aid in acquiring cognitive skills (for a review, see Atkinson,

Derry, Renkl, & Wortham, 2000; Renkl, 2005, 2009). While the impressive body of research on worked examples to date has been quite successful, it also has two important shortcomings. Firstly, the studies are mostly conducted in a laboratory setting without being extended to the more challenging authentic classroom setting and secondly, the studies have almost exclusively compared learning by studying examples to untutored problem solving.

One very successful tutored problem-solving approach is the use of Cognitive Tutors (Koedinger, Anderson, Hadley, & Mark, 1997; Koedinger & Aleven, 2007). These computer-based tutors provide individualized support for learning by doing (i.e., solving problems) by selecting appropriate problems to be solved, by providing feedback and problem-solving hints, and by on-line assessment of the student’s learning progress. Because such a tutored environment offers a significant amount of guidance it is a much more challenging control condition than traditional problem solving against which to measure the possible beneficial effects of worked examples. Additionally, research on Cognitive Tutors aims to be examined in the authentic classroom setting (*in vivo* experimentation) which creates a much richer and challenging testing environment compared to a laboratory setting.

Several recent studies have embedded worked examples in a variety of Cognitive Tutors and investigated whether the examples still had beneficial effects over the tougher tutored control condition (e.g., Salden, Aleven, Schwonke, & Renkl, in press; Schwonke et al., 2009). More specifically, these studies proved that replacing some problems with worked examples further enhances student learning by reducing instructional time to the same outcome and/or increasing student outcomes than tutored problem solving.

Of particular interest for the current paper are the studies by McLaren, Lim, and Koedinger (2008) which compared

worked examples with pure TPS (tutored problem-solving) within a Stoichiometry Cognitive Tutor. The results across three studies showed that the students who received worked examples did not learn more than the students who received pure TPS. This reinforces the prior claim that TPS poses a new challenge for the research on worked examples in being a much harder control condition. However, an important consistent finding in the McLaren et al. studies is that the students who received worked examples did learn more efficiently, using 21% less time to complete the same problem set. If these results were to scale across a 20-week course, students could save 4 weeks of time – yet learn just as much.

Another educational system that provides tutored problem solving in classroom settings is the Assistment system (e.g., Razzaq & Heffernan, 2009). Additionally, a further similarity between the Cognitive Tutors and Assistment is their focus on *in vivo* experimentation which allows for an examination of student learning in its most authentic environment. In a previous *in vivo* study Kim, Weitz, Heffernan and Krach (2009) explored the benefits and limitations of worked examples by comparing a “pure worked-example” (pure WE) condition with a pure TPS condition on conceptual and procedural learning. “Pure” means that students in the TPS condition received only TPS remediation while students in the WE condition received solely WE remediation. Note that in contrast to the Cognitive Tutor studies cited above, neither condition included a self-explanation component. The results showed that for conceptual problems students learned more in the pure WE condition and for procedural problems students learned more in the pure TPS condition. In agreement with the findings by McLaren et al. (2008), pure WE was more efficient – that is, it took students less time to do pure WE than TPS.

The current paper addresses a study which extends this research by comparing the best pure condition from the previous study with mixed approaches. That is, for conceptual problems we compare learning resulting in a pure WE condition to one that mixes WE and TPS. For procedural problems we compare a pure TPS approach to a condition that mixes WE and TPS. With these conditions we examine whether the findings of the previous study will still hold. More specifically, if pure WE is better than WE-TPS for conceptual problems and pure TPS is better than WE-TPS for procedural problems it could provide further evidence that examples are always better for conceptual learning and tutored problem solving is always better for procedural learning.

Overall, the outcomes of this study will suggest important guidelines for designing intelligent tutors and provide meaningful insights into the students’ learning process. In practical terms, building worked examples is significantly less time consuming than building tutoring; if worked examples are as good as or better than traditional intelligent tutoring – and more efficient – this is valuable information.

The Experiment

Our study involved college students taking an introductory statistics course. Statistics is a good domain for this research as it includes both procedural and conceptual components.

Student Characteristics

Participating students were enrolled in an introductory statistics course at Worcester Polytechnic Institute (WPI), a private university specializing in engineering and the sciences. Eighty-four students, mostly first-year engineering students, participated in the experiment, which was conducted as one of the course’s regular lab session.

Design

The tutorial and test problems were typical of problems given in introductory statistics courses. The subject matter concerned one-sample confidence intervals of the mean and was taught on days preceding the experiment. There were no assignments or tests on these topics due before the experiment. At the start of the experiment, students were randomly assigned to one of four groups with equal probability; the resulting student numbers are outlined in Table 1. Note that the mild non-uniformity in numbers is caused by randomness.

Table1: Initial Student Allocation to Groups

Group	Procedural Problem Tutorials	Conceptual Problem Tutorials	No. Students
1	WE-TPS	WE-WE (pure WE)	29
2	WE-TPS	WE-TPS	21
3	TPS-TPS (pure TPS)	WE-WE (pure WE)	17
4	TPS-TPS (pure TPS)	WE-TPS	17

This design allows the comparison of WE-TPS with pure TPS on procedural problems by comparing the performance of students in groups 1 and 2 with that of students in groups 3 and 4. Likewise pure WE may be compared with WE-TPS for conceptual problems by comparing the performance of students in groups 1 and 3 with that of students in groups 2 and 4.

An example of a procedural problem is one that asks the student to calculate a confidence interval. A conceptual problem might ask about the impact on the width of a confidence interval if the sample size is doubled. Procedural problems align with the NSF-Funded ARTIST project guidelines (<https://app.gen.umn.edu/artist/glossary.html>) for “statistical literacy,” and conceptual problems with “statistical reasoning” and “statistical thinking” (delMas, 2002).

Of the eighty-four students that participated we excluded ten students who spent less than 5 minutes in the post-test

from our analysis due to time and motivation issues. Further, we eliminated eleven students from the conceptual part of the analysis as they did not complete the conceptual problems in the tutorial. Note that the conceptual problems were towards the end of the tutorial. The final number of students used in each condition of the analysis is provided in Table 2. In both instances where we eliminated students from the analysis, roughly the same numbers were removed from each group.

Table 2: No. Students in Each Group

Group	Procedural Problem Tutorials	No. Students	Conceptual Problem Tutorials	No. Students
1	WE-TPS	25	WE-WE (pure WE)	21
2	WE-TPS	19	WE-TPS	18
3	TPS-TPS (pure TPS)	13	WE-WE (pure WE)	10
4	TPS-TPS (pure TPS)	15	WE-TPS	12
Total		72		61

The ASSISTment System

Our experiment was conducted via the ASSISTment intelligent tutoring system (<http://assistment.org>). It is similar to the CTAT system (Koedinger Aleven, Heffernan, McLaren, & Hockenberry, 2004), used in some of the previously mentioned studies (McLaren, et al., 2008), in that the system provides the student with tutoring on the individual steps of a problem, generally breaking a problem down into 3-4 steps. For each step, a student is asked to provide an answer, and receives feedback on their answer until they get it correct. Our system differs from the CTAT structure in several ways including that there is only one solution path and the intermediate solution goals are highlighted. A further difference is that our system does not contain a self-explanation component.

The tutorials were comprised of three pairs of problems.¹ Each pair was comprised of two isomorphic problems. The first two pairs were procedural problems and the last problem pair was conceptual in nature.

TPS-TPS (Pure TPS) Condition

For this study the ASSISTment system was modified to force students to work through the TPS for the first problem of each pair. This “forced TPS” approach ensures that each student experiences tutoring. After completion of the first problem of the pair, the student is presented with an isomorphic problem and is asked by the system to provide the answer. If the student gets this second problem correct, the student is done with the problem. If the student gets the

answer incorrect or indicates that s/he needs help solving the problem, the system provides TPS support.

In terms of tutoring, the system gives immediate corrective feedback for each attempt at solving a problem. The student can choose to answer the problem or ask the system to break it into steps. However, if the student answers incorrectly the system automatically breaks the problem into steps. For each step, the student will receive immediate feedback and has the possibility to request hints.

WE-WE (Pure Worked Example) Condition

Firstly, it should be noted that “classic” worked examples are used which do not contain tutoring, a self-explanation component, or fading.

The student is presented with the same first problem as in the TPS condition, and a worked solution including the necessary steps to take in that problem. After studying the worked example, the student is then presented with an isomorphic problem, the exact same second problem as in the TPS condition, which the student is expected to solve. The student has access to the first WE while trying to solve the second. If the student gets this second problem correct, the student is done with the problem. If the student gets the answer incorrect or indicates that s/he needs help solving the problem, the system provides the worked solution for the problem for review by the student.

WE-TPS (Mixed) Condition

The student is presented with the first problem and a worked solution to that problem, similar to the WE-WE condition. After studying the worked example, the student is then presented with the second problem. If the student gets this isomorphic problem correct, the student is done with the problem. If the student gets the answer incorrect or indicates that s/he needs help solving the problem, the system provides TPS support. See Table 3 for an overview of the problem pairs for each experimental condition.

Table 3: A Comparison of Intelligent Tutoring and Worked Examples

	Pure TPS (TPS-TPS)	Pure WE (WE-WE)	Mixed (WE-TPS)
First Problem	Student studies with forced TPS	Student studies WE	Student studies WE
Second Problem	Student is given opportunity to solve the problem. If student answer is incorrect, the problem is marked incorrect and,		
	TPS is provided	WE is provided	TPS is provided

The students were allowed to work though both tutorials at their own pace. One week before the experiment students were given a ten minute tutorial on how to use the ASSISTment software for which they were allowed to work through at their own pace. They created an account for

¹ All of our materials are available at <http://teacherwiki.assistment.org/wiki/index.php/CogSci2010> so other researchers can inspect them.

themselves, and enrolled in their professor's class. They got a few minutes of practice with the system during which they did one worked example and one tutored problem solving.

The experiment consisted of three parts: pre-test, tutorial, and post-test. The pre-test and post-test were identical, and were comprised of four procedural problems and three conceptual problems.

The students were given 20 minutes to go through the pre-test without any feedback, 40 minutes for their tutorials, and 20 minutes for the post test (see Table 4). In order to control time, students were not supposed to be allowed to move to the next part of the experiment until a designated time passed. However, in practice we actually had some students not following the directions when asked to move to the next part of the experiment.

Table 4: Outline of Experiment

One Sample Confidence Interval for the Mean
Several Days Prior to Lab Session
<ul style="list-style-type: none"> Lecture on the topic
During Lab Session
1. Pre-Test (20 min; students' initial knowledge)
<ul style="list-style-type: none"> 20 minutes Four procedural and three conceptual.
2. Condition (Tutorials)
<ul style="list-style-type: none"> 40 minutes 3 pairs of Problems: 2 procedural, one conceptual (3 parts)
3. Post-Test (20 min; students' knowledge after trial)
<ul style="list-style-type: none"> Same problems as Pre-Test

Results

Learning by Problem

Table 5 provides the percentage of students across all conditions getting each problem correct on the pre- and post-tests. Student learning is clearly evident for all items ($z = 3.78, p < .001, d = 1.36$).

Following the approach in item response theory (Embretson & Reise, 2002), throughout the remainder of this section, we summarize student performance on a problem or on a category of problems by the adjusted percent correct, that is, the percent correct adjusted by problem difficulty. We then define learning for problems as the difference in adjusted percent correct between post-test problems and the corresponding pre-test problems.

Qualitatively speaking, this means that students who correctly answer harder items will get more credit than students who correctly answer easier items.

We determined these adjusted values using a generalized linear mixed effects model, also referred to as a generalized linear multilevel model (Bates & Sarkar, 2007; Rabe-Hesketh, Skrondal, & Pickles, 2005).

Table 5: Learning by Problem

Problem	Percent Students Correct	
	Pre-Test	Post-Test
Procedural		
1	5.6%	58.3%
2	16.7%	73.6%
3	15.3%	43.1%
4	30.6%	54.2%
Conceptual		
1	11.5%	27.9%
2	73.8%	91.8%
3	37.7%	52.5%

Learning by Condition

Table 6 below summarizes the learning results by type of tutorial. So, for example, for procedural problems, students in the WE-TPS improved their performance by 40.1% (54.9% - 14.8%).

Table 6: The Adjusted Percent Correct

		Percent Correct
Procedural Problems	Pre-Test	14.8%
	WE-TPS	54.9%
	TPS-TPS	63.3%
Conceptual problems	Pre-Test	37.8%
	WE-TPS	61.2%
	WE-WE	61.7%

For procedural problems, students in the pure TPS condition outperformed students in the WE-TPS condition. However, this difference (63.3% vs. 54.9%) is not significant ($p = 0.23$). Likewise, for conceptual problems, the results indicate a small benefit for the pure WE condition over the WE-TPS condition (61.7% vs. 61.2%); these results are clearly not statistically significant ($p = 0.95$).

Learning Time

As noted earlier, previous research has consistently indicated that doing worked examples requires significantly less time for students than tutored problem solving.

Table 7: Times for Students to do the Tutorial Problems

		n	Mean	SD
Procedural Problems	WE-TPS	44	18.03	7.79
	TPS-TPS	28	26.00	10.63
Conceptual Problems	WE-TPS	30	6.70	2.53
	WE-WE	31	6.60	3.17

Table 7 provides the mean and standard deviation of student times in each group for both types of problems in the tutorial. Focusing on the procedural problems, we see the same pattern here with students in the WE-TPS condition taking less time than those in the pure TPS

condition. These results are statistically significant ($t = 3.42$, $p < .01$, $d = 0.86$).

As the conceptual problems were placed after the procedural problems in the tutorial (condition), the above-reported conceptual times may have been artificially constrained. We observed that procedural times and conceptual times are negatively correlated – an indication that individuals who spent a lot of time on the procedural problems ran out of time on the conceptual problems. Note (again) that we excluded students who did not finish the conceptual part of the tutorial from our post-test results.

Discussion

This paper extends our previous work (Kim et al., 2009) comparing pure WE with pure TPS approaches where the results showed that pure WE was more effective for conceptual problems, while pure TPS was more effective for procedural problems. Furthermore, pure WE was more efficient in that students took less time to work through the WE condition than the TPS condition. The aim of the current study was to compare these pure WE and TPS conditions with a mixed condition, which presents students with WE-TPS pairs. More specifically, for conceptual problems a pure WE condition was compared with a WE-TPS condition and for procedural problems a pure TPS condition was compared with a WE-TPS condition.

While overall learning occurred in all conditions and the pure methods come out ahead in terms of student learning, the results are not statistically significant. More specifically, there were small non-significant differences favoring the pure WE condition for conceptual problems and the pure TPS condition for procedural problems. Furthermore, the efficiency effect of the previous study was replicated meaning that students needed less time to complete the WE tutorial than the TPS tutorial. These results are similar to the findings of McLaren et al. (2008) who also did not find significant differences in student learning but who also found that students who received worked examples did learn more efficiently, using 21% less time to complete the same problem set.

It should be noted that McLaren et al. (2008) and other studies use worked examples in combination with tutoring, a self-explanation component, and/or fading. In contrast to those studies, the worked examples used in our experiments are “classic” worked examples which do not include these extra elements. While these elements can undoubtedly improve learning our studies shows that the use of classic worked examples in tutored problem solving can still result in similar outcomes without any detrimental effect on student learning. As such, the replication of the time efficiency effect makes a strong case for the use of classic worked examples in tutored problem solving.

A possible explanation for the lack of significant main differences could be offered by Rittle-Johnson, Siegler, and Alibali (2001) who stated that effects of worked examples on procedural tasks might be more indirect and need more time to materialize. In fact, other studies (e.g., Anthony,

2008; Salden, et al., 2009) that compared TPS and WE also did not find significant differences on the post-test but they did find positive effects favoring the WE conditions on a delayed post-test.

A further explanation might be found in the time limit that we imposed on the students. We had to exclude eleven students from our data analysis because they did not have enough time to complete the conceptual problems in the tutorial. Had we given them more time then we might have been able to observe possible conceptual learning differences.

For future studies we would like to explore other factors which could deepen the insights on the beneficial effects of worked examples in TPS. One possible factor is students’ prior knowledge which can have a mediating influence on their learning progress if students with differing prior knowledge levels work through the same training material. In line with the expertise reversal effect (Kalyuga, 2007), students who have a high knowledge level could even experience detrimental effects of worked examples. In future studies we could use the pre-test scores to check if such differences in prior knowledge exist and use this information to determine what experimental condition a student ought to be in.

Furthermore, in accordance with Schwonke et al. (2009) we could try to add thinking aloud to differentiate learning effects. In their first study Schwonke et al. also did not find student learning differences but they used thinking aloud protocols in their second study which subsequently showed a higher learning gain in terms of conceptual knowledge for the example-enriched TPS condition. It is plausible that students who were thinking aloud about the worked examples engaged in deeper processing of conceptual knowledge than the students in the control TPS condition without examples. Consequently, being able to talk aloud about the worked examples might have led to the observed higher learning gain.

Finally, adding a delayed post-test to our future studies might also enable us to differentiate differences between TPS and WE-TPS conditions. Rittle-Johnson et al.’s statement that the effects on procedural tasks might need time to materialize has been proven to be accurate in other studies compared tutored problem solving and worked examples (e.g., Anthony, 2008; Salden, et al., 2009). More specifically, if worked examples support students in engaging with the conceptual knowledge more deeply but only over longer period of time then this has significant implications for developing computer-based learning programs which use worked examples.

In conclusion, our results extend the previous findings of TPS and WE-TPS comparisons. The tutored problem solving environment poses a more challenging control condition than traditional problem solving conditions. Yet across two studies and in line with the McLaren et al. (2008) studies we consistently found that students needed less time to complete the training phase when being presented with worked examples without any loss of student learning on

the post-test. These results are even more impressive as our experiments used classic worked examples, which do not offer tutoring or a self-explanation component, as those used by McLaren et al. (2008).

This is an important finding for educators because building classic worked examples is considerably easier than building tutoring and in fact is easier than building worked examples with more features. Future studies are needed to further investigate under what circumstances classic worked examples can make computer-based instructional materials more efficient.

Acknowledgments

This work was funded in part by the National Science Foundation CAREER Award the US Department of Education (R305K030140) but the opinions are solely those of the authors. Furthermore, the authors would like to express their gratitude to Professor Joseph D. Petrucci for his invaluable help in running the study.

Abstract

Integrating worked examples with problem solving yields more effective and efficient learning, as does intelligent tutoring support for problem solving. This study examines the impact of integrating worked examples and intelligent tutor support for algebra modeling problems. Students in three conditions alternately studied worked examples (either static graphics, interactive graphics or static tables) and solved Algebra Cognitive Tutor problems. A control group solved all the problems with the Cognitive Tutor. Students in the four groups developed equivalent problem-solving skills, but students learned more efficiently in the interleaved worked example conditions, requiring 26% less time to complete the problem set. There were no differences among the four groups in two measures of robust learning – a retention test and a transfer test. But students in the static table condition could more accurately describe what algebraic model components represent in problem situations than could students in the other three conditions.

Keywords: Education; Problem solving; Learning; Classroom Study; Intelligent Tutors; Worked Examples.

Introduction

Extensive research has documented the beneficial impact on learning of interleaving worked examples with problem solving (Kalyuga, et al 2001; Pashler, et al, 2007; Sweller & Cooper, 1985; von Gog, Paas, & Van Merriënboer, 2004). Novices learn more quickly and deeply from a sequence of problems if they are asked to alternate between explaining worked-out examples of problem solutions and solving problems than if they are asked to solve all the problems in the sequence.

Typically in this research problem solving is supported by whole-answer feedback. After students complete a problem solution, whether successfully or not, they are given an example of a correct solution. This comparison condition is relatively weak, since step-by-step assistance in problem solving has been shown to be both more effective (improved learning outcomes) and more efficient (less learning time to achieve the same learning outcome) than whole answer feedback. For instance, Corbett & Anderson (2001) compared step-by-step feedback and whole-answer feedback in the Lisp Programming Cognitive Tutor and found that students in the former condition finished a fixed set of problems in one-third the time required by those in the latter condition, and made 40% fewer errors on posttests.

As a result, the question arises whether interleaving worked examples with problem solving scaffolded by intelligent tutoring systems might also yield improved learning outcomes and/or improved learning efficiency. McLaren, Lim and Koedinger (2008) examined this question in an intelligent tutor for chemistry problem solving and found that interleaving worked examples with problem solving yielded the same learning outcome as the baseline problem-solving condition, but in less time, thereby increasing learning efficiency.

Several studies have examined the impact of incorporating “faded” worked examples into Geometry Cognitive Tutor (GCT) modules in which students solve geometry problems and justify each step with a problem-solving principle (Aleven & Koedinger, 2002). In example fading (Renkl & Atkinson, 2003) the first problem is presented as a complete worked example, and in successive

problems students complete progressively more steps themselves until students are finally solving complete problems. When faded worked examples were incorporated into GCT, learning was more efficient (students spent less time to reach the same level of skill) and some evidence was obtained that the worked-example condition yielded deeper understanding (Salden, et al, 2008; Schwonke, et al, 2009).

The present study examines the impact of interleaved worked examples in a Cognitive Tutor (CT) module for Algebra problem solving. The study has two purposes. First, the study examines the impact of interleaving worked examples on students' learning time, their problem-solving skill and their depth of understanding. Second, the study evaluates three alternative types of worked examples: (1) Static Graphics in which problem components are represented graphically; (2) Interactive Graphics in which students participate in constructing the graphical problem representation; and (3) Static Tables in which problem components are represented symbolically in a table, analogous to the problem-solving interface.

This study compares four learning conditions; three conditions in which each type of worked example is interleaved with Cognitive Tutor problem solving and a fourth, Cognitive Tutor problem-solving baseline condition.

The following sections describe the problem solving domain, the Cognitive Tutor problem-solving environment and the three types of worked examples.

The Domain: Algebraic Modeling

In this study students are asked to solve "mixture problems," for example:

You have an American Express credit card with a balance of \$715 at an 11% interest rate and a Visa credit card with a 15% interest rate. If you pay a total of \$165 in annual interest, what is the balance on your Visa card?

The problem-solving goal is to construct a symbolic model of the situation that can be used to solve the problem, e.g.:

$$(.11 \times \$715) + (.15 \times V) = \$165$$

The problem-solving curriculum consists of four problem types: Two types of "arithmetic problems," in which the unknown value is naturally represented as an isolated variable on one side of the equation, and two types of "algebra problems" in which the unknown quantity is more naturally represented as a variable that is embedded in one or in two expressions in the equation. See Figure 1 for an example of each type.

Cognitive Tutor Problem Solving

Figure 2 displays the interface for the Cognitive Tutor at the end of a problem. Each problem describes a mixture scenario and provides a scaffold to scaffold the relationship between the scenario components and the mathematical representations of the components. Students enter a number, variable or operation into each cell. After completing the

[Arithmetic Type 1] You have a MasterCard with a balance of \$532 at a 21% interest rate. You also have a Visa credit card with a balance of \$841 at a 16% interest rate. How much money are you paying in total interest?

$$(.21 \times \$532) + (.16 \times \$841) = T$$

[Arithmetic Type 2] Shelly owed \$475 in total interest on her MasterCard and Visa accounts. Her MasterCard charges 19% interest and her Visa Card charges 22% interest. She paid the interest on her Visa Card debt of \$1100. How much interest does she still owe on her MasterCard?

$$\$475 - (.22 \times \$1100) = M$$

[Algebra Type 1] You have an American Express credit card with a balance of \$715 at an 11% interest rate and a Visa credit card with a 15% interest rate. If you pay a total of \$165 in annual interest, what is the balance on your Visa card?

$$(.11 \times \$715) + (.15 \times V) = \$165$$

[Algebra Type 2] You have a total balance of \$1405 on two different credit cards— an American Express credit card with a 12% interest rate and a Discover credit card with a 24% interest rate. If you owe a total of \$224 in annual interest, what is your balance on the Discover card?

$$(.24 \times D) + (.12 \times [\$1405 - D]) = \$224$$

Figure 1: An example problem situation and symbolic model for each of the four problem types.

table, the student enters an equation to model the situation in the text cell at the bottom of the screen. The activities were created with the Cognitive Tutors Authoring Tools (CTAT) environment (Aleven, et al, in 2009). As in all cognitive tutors, students received accuracy feedback on each step, could request advice on any step, and were required to complete a correct solution to each problem.

You have an American Express credit card with a balance of \$715 at an 11% interest rate and a Visa credit card with a 15% interest rate. If you pay a total of \$165 in annual interest, what is the balance on your Visa card?

Unknown = Variable =

	Balance	Interest Rate	Interest Owed
American Express	715	11%	0.11*715
Visa	B	15%	0.15B
Total	---		165

Equation:

Figure 2: The Cognitive Tutor interface at the completion of a problem.

Worked Examples

Three types of worked examples were developed, in the Animation Tutor environment (Reed, 2005), each consisting

of multiple successive screens. In each case the first screen presented a problem statement alone. Successive screens developed an analysis of the problem’s component structure in graphical or tabular form.

(1) *Static Graphics (SG)*. Figure 3 shows the final screen of a static graphics worked example. The first screen displayed just the problem statement at the top. Students successively press the Continue arrow to see (1) the first stack of money which represents an account balance and interest owed, (2) the second stack of money which represents the second account balance and interest owed, and (3) both the third stack, which represents the total interest, and the symbolic model at the bottom of the screen.

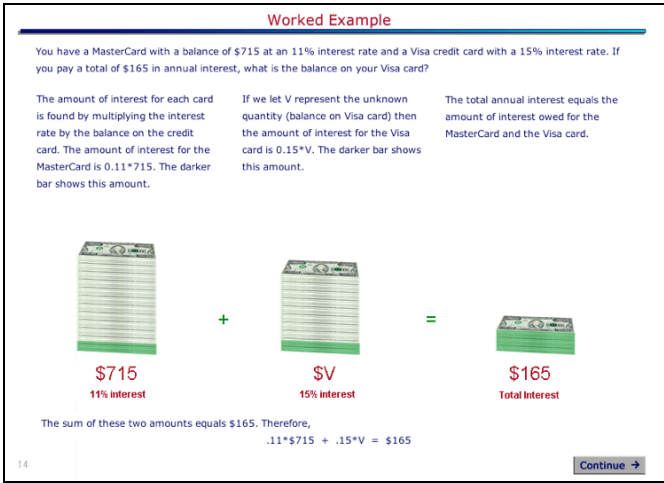

Figure 3: A static graphics worked example at the completion of the example.

(2) *Interactive Graphics (IG)*. Interactive graphics worked examples are the same as the SG worked examples, except that students construct the total interest stack. Students click on the interest component at the bottom of each of the other two stacks and drag that component over to the total interest stack to add up the total interest. Interactive worked examples were developed for all the algebra problems and introduced with a single arithmetic problem. Students in the IG condition viewed static graphic examples for the other arithmetic problems.

(3) *Static Table (ST)*. Figure 4 displays the final screen of a static table worked example. As with the graphics examples, the first screen displays the problem statement alone. Students successively click the Continue arrow to see (1) the column labels and first row of the table, which represents an account balance and interest owed, (2) the second row of the table which represents the second account balance and interest owed, and (3) the symbolic model of the situation beneath the table.

Design Principles. The three types of worked examples all follow two principles of multimedia design (Sweller, 2003; Mayer 2001; Moreno & Mayer, 2007). The first is the proximity principle that different media be closely integrated in space. Verbal explanations are therefore placed immediately above, and the equation immediately below,

either the bars or the table in the worked examples. The second principle, minimize cognitive load, is achieved by presenting the solution in successive segments.

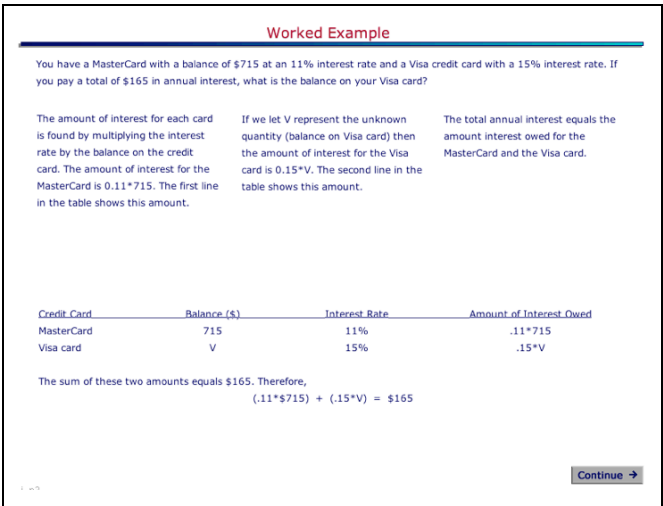

Figure 4: A static table worked example at the completion of the example.

Predictions

Time and Learning efficiency. Time-on-task in learning is expected to be less in the worked example conditions than in the problem-solving condition. Students typically study worked examples in less time than they can generate problem solutions, even with intelligent tutoring support (McLaren, et al, 2008; Salden, et al, 2008; Schwonke, et al, 2009). However, interleaved worked examples are only more efficient if students in those conditions acquire as good, or better, problem-solving skills as students in the problem solving condition.

Robust Learning. There are several reasons to expect that students may acquire a deeper understanding of problem solving in the interleaved worked example conditions. Cognitive Load theory (Sweller, 2003) suggests that worked examples can eliminate the cognitive load associated with generating problem solutions, and free up capacity that students can devote to understanding the solutions. In this study, all the worked-example conditions describe the mapping between the mathematical representations and the problem situations, so students may acquire a better understanding of the underlying semantics, an understanding that should support better retention and transfer to novel problem situations. In addition, the two graphics conditions may promote better retention than the other two conditions, since they encourage visual thinking (Reed, 2010), thereby creating multiple memory codes, both graphical and symbolic (Mayer, 2001; Paivio, 1986). Finally, interactive graphics may foster still better retention than static graphics, since interactively constructing key quantities in the graphics representation, (Moreno & Meyer, 2007), creates a third, motor code (Engelkamp, 1998; Glenberg, et al, 2004; Reed, 2006, 2008).

Robust Learning Measures

A problem-solving pretest and posttest were employed to measure gains in students' algebra problem-solving skills. In addition, three "robust learning" tests were employed to measure students' depth of understanding.

(1) *Retention*. A retention test examined students' arithmetic and algebra problem solving skills after a one-week interval.

(2) *Transfer*. A transfer test described "mixture" situations with novel quantitative structures and asked students to generate mathematical models of the situations, which also had novel structures.

(3) *Model Description*. The Cognitive Tutor Model Analysis Tool (Corbett, et al, 2000, 2007; Corbett, Wagner & Raspat, 2003) was employed to ask students to explain the structure of arithmetic and algebraic models. As displayed in Figure 5, each problem presents a problem description and a mathematical model of the situation. Students select entries from menus to describe what each hierarchical component of the symbolic model represents in the problem situation. As in all Cognitive Tutors, students receive feedback on each problem step, can request advice on each step, and are required to complete a correct solution to the problem.

This mathematical expression	represents:
432	The balance you owe on your American Express Card
0.14	The interest rate on your American Express Card
$0.14 * 432$	The interest you owe on your American Express Card
D	The balance you owe on your Discover card
0.17	The interest rate on your Discover card
0.17D	
$0.14 * 432 + 0.17D$

Method

Participants

128 students enrolled in Cognitive Tutor Algebra courses in three Pittsburgh-area high schools participated in the study.

Design

The study was completed over the course of three computer sessions in the students' Algebra Cognitive Tutor courses. In the first two sessions, students completed 16 mixture problems, eight problems per day. The students in each of the three courses were randomly assigned to one of four learning conditions. Students in the three worked example conditions studied example solutions for the odd numbered

problems and solved the even numbered problems with the Cognitive Tutor each day. Students in the fourth condition solved all the problems each day with the Cognitive Tutor.

Learning Materials

Four types of mixture problems were developed, two "arithmetic" types and two "algebraic" types, as displayed in Figure 1. Four problems of each type were developed, for a total of 16 problems. Two problems of each type involved interest payments on two credit cards, as displayed in the figures. The other two were mining problems, about extracting metals from two ores of different quality. The four problems of each kind were presented in succession, with the two equivalent interest problems first, followed by the two equivalent ore problems.

Test Materials

Four test measures of student learning were developed.

Day-2 Problem-Solving Test. Paper-and-pencil tests were developed consisting of two problems, equivalent to the two types of algebra problems students solved with the online tutor that day. Each problem presented a mixture problem situation and students were asked to generate an equation to model the situation. Two test forms were developed and within each condition, each form served as the pretest for half the students, who then switched to the other form for the posttest, so that the pretests and posttests were matched across the full set of students, but for each student the pretest and posttest were different.

Day-3 Retention Test. This test consisted of four problems, equivalent to the four types of problems students had solved with the online tutor. Again, each problem presented a mixture problem situation and students were asked to generate an equation to model the situation.

Day-3 Transfer Test. The Day-3 transfer test consisted of an arithmetic problem and an algebra problem in which students were asked to generate symbolic models of situations with novel structures.

Day-3 Model Component Descriptions. Four Model Analysis problems were developed. Each problem corresponded to one of the four problem types students had solved on the prior two days of the study. Each problem presented a mixture scenario and presented a symbolic model of the scenario. Students were asked to describe what each hierarchical component of the equation represents in the real-world situation, by selecting entries from menus.

Procedure

In the first session, the online problem solving and worked example activities were introduced, then students worked through the eight arithmetic mixture problems. In the second session, students completed a two-problem paper pretest, worked through eight algebraic problems, then completed a two-problem paper posttest. In the third session, which followed a week later, students completed the four-problem paper retention test, followed by the two-problem paper transfer test and finally the four Model Analysis problems.

Results and Discussion

Four students were excluded from the analyses because they missed the second session and seven others were excluded for talking to others as they worked on the problems.

Day-2 Pretest-Posttest Learning Gains

As displayed in Table 1, there were substantial pretest-posttest learning gains in all four learning conditions, averaging 26 percentage points. In an analysis of variance, this main effect of test type was significant $F(1,105) = 52.14$, $p < .001$. There was no significant difference of learning condition $F(3,105) < 1$, and no significant interaction of test type and learning condition $F(3,105) < 1$.

Table 1: Learning Time per problem for Day 1 and Day 2 (minutes) and Day-2 pretest and posttest accuracy (percent correct).

Learning Conditions	Day 1 Time	Day 2 Time	Pretest %correct	Posttest % correct
CT	2.30	2.15	7	37
IG	1.52	1.68	7	28
SG	1.68	1.52	4	34
ST	1.75	1.72	8	28
Mean	1.81	1.77	6	32

Learning Efficiency

Table 1 displays average learning time per problem for the first two sessions. Elapsed time was not measured for the first worked example in each session (since the environment did not directly record time), so the first pair of equivalent problems in each session is excluded from this analysis for all four groups. In addition, 13 students were excluded from the Day-1 analysis and 16 students from the Day-2 analysis because of missing data. While there were no differences in skill acquisition outcomes among the four conditions, students in the three interleaved worked example conditions spent less time in learning, and so learned more efficiently.

Students in the three worked example conditions averaged 28% less time per problem on Day 1 than students in the problem solving condition (1.65 vs 2.30) and 24% less time per problem on Day 2 (1.64 vs. 2.15). The main effect of condition is significant for Day 1, $F(3,100) = 6.88$, $p < .001$ and for Day 2, $F(3,97) = 6.33$, $p < .001$. Bonferroni comparisons revealed that the CT group differed from each one of the three worked example groups both on Day 1 and on Day 2, $p < .02$ in each case. The three worked example groups did not differ from each other.

These average times mask a highly significant Group x Problem interaction on Day 1, $F(3,100) = 93.12$, $p < .001$, and on Day 2, $F(3,97) = 90.19$, $p < .001$. On Day 1 the three worked example (WE) groups averaged 0.78 min. on the worked examples, while the CT group averaged 2.98 min. solving the corresponding problems. The WE groups averaged 2.53 min. on solving the subsequent equivalent problems, while the CT group averaged 1.63 min. on those problems. On Day 2, the WE groups averaged 0.62 min. on

the worked examples and the CT group averaged 2.82 min. solving those problems. The WE group averaged 2.67 min. solving the subsequent problems and the CT group averaged 1.50 min. on those problems.

Robust Learning

Of the 117 students included in the study, 102 completed the day 3 robust learning activities. Table 2 displays results of the three robust learning measures included in the study: (1) retention of problem-solving skill; (2) transfer of problem-solving skill; and (3) explanations of symbolic model components.

Retention Test. Table 2 displays students' test accuracy on the one-week retention test of problem-solving skill. Retention test accuracy did not vary significantly across the four learning conditions, $F(3,90) < 1$.

Transfer Test. As can be seen in Table 2, students in the four learning conditions averaged 17% correct on the transfer test of problem-solving skill. The main effect of learning condition was not significant $F(3,90) < 1$.

Model Component Descriptions. The model analysis task required students to describe what a total of 31 hierarchical equation components represented in the four real-world problem situations. Table 2 displays the average percentage of these 31 descriptions on which students' first menu selection was correct. There was no significant difference among the groups in an ANOVA, $F(3,97) < 1$. But the ST group performed consistently best in describing the model components, achieving the highest accuracy for 18 of the 31 components (vs. 5 for the IG and SG groups and 3 for the CT group). This difference is significant in a Friedman two-way ANOVA of rank ordering, $\chi^2(3) = 20.00$, $p < .001$.

Table 2: Day-3 Robust learning measures: Retention, transfer and model analysis accuracy (percent correct).

Learning Conditions	Retention %correct	Transfer % correct	Model Analysis % correct
CT	32	15	52
IG	29	18	52
SG	29	21	53
ST	26	13	58
Mean	29	17	54

Conclusion

The main results confirm earlier conclusions in chemistry and geometry that incorporating worked examples into intelligent tutor-supported problem solving can improve learning efficiency. While students developed similar problem-solving skills across the four conditions, students spent 26% less time completing the sixteen problems in the three interleaved worked-example conditions than in the problem-solving comparison condition.

However, there is relatively thin evidence that incorporating worked examples yielded a deeper understanding of problems solving, as expected by Cognitive Load theory. Students in the static table worked example condition demonstrated a better understanding of the referential semantics that link the mathematical representations and real-world problem situations than students in the problem solving condition. However, this deeper knowledge did not support greater problem solving accuracy, retention or transfer. Students in the two graphics worked example conditions also did not show more robust learning than students in the problem solving condition.

Learning during Intelligent Tutoring: When Do Integrated Visual-Verbal Representations Improve Student Outcomes?

Abstract

Research has shown that integration of visual and verbal information sources during learning promotes successful student outcomes. However, it is unclear whether it is better to provide students with integrated visual-verbal representations, or to require them to build such integrated representations themselves. In a classroom study, three conditions were used to explore the impact of integrated visual-verbal representations that emphasized rule-diagram mappings in geometry. Students viewed highlighted rule-diagram mappings during learning, generated these mappings themselves, or saw only numerical information embedded in diagrams (control). Students' problem-solving knowledge was measured at posttest and delayed posttest. Overall, students who generated rule-diagram mappings during intelligent tutoring demonstrated better long-term understanding of geometry principles, but effects were only visible at delayed posttest. Results show that integrated visual-verbal representations best support deep learning when they help the learner make connections between features of a visual representation and relevant domain information, and student interactions can be an effective method to scaffold these connections.

Keywords: Intelligent tutoring; Diagrams; Problem solving; Long-term retention; Visual representations

Introduction

Research in multimedia learning has demonstrated that adding visual representations to text materials frequently improves students' learning outcomes (e.g., Carney & Levin, 2002). Studies of cognitive processing with multimedia materials have demonstrated that visual materials support learning by increasing students' generation of effective self-explanations during study (Ainsworth & Loizou, 2003; Butcher, 2006).

However, not all visual representations are equally effective in supporting learning. Diagrams have been shown to be more effective when verbal materials (such as textual labels for diagrams) are integrated directly into the visual representation (e.g., Hegarty & Just, 1993) before they are presented to students. Other research has shown that student-driven integration of visual and verbal materials supports learning with complex materials and may promote goal-oriented behaviors during subsequent, self-directed learning (Bodemer, Ploetzner, Bruchmüller, & Hacker, 2005). Together, these research results suggest clear benefits

of integrated visual-verbal representations for learners. However, they also raise the question of whether learners should be provided with integrated visual representations or if it is better to require learners to generate the integrated representations themselves.

The question of whether or not to provide students with integrated visual-verbal representations highlights the *assistance dilemma* (Koedinger & Aleven, 2007). The assistance dilemma refers to the difficulty of deciding when interactive learning environments should provide vs. withhold information in order to support optimal student learning. The assistance dilemma reflects a technology-based application of the long-standing instructional concept of *desirable difficulty* (e.g., Bjork, 1994). Desirable difficulty refers to the finding that increasing the difficulty of a learning activity can improve long-term knowledge outcomes, even though performance during training may suffer. Desirable difficulty argues against a common assumption that optimal learning is facilitated when instructional materials are designed to ease student comprehension and increase successful performance. Thus, a key question for intelligent tutoring systems using visual representations is: when should intelligent tutoring systems provide integrated visual-verbal support vs. withhold this support in order to optimize student learning outcomes?

Connecting Diagrams to Domain Knowledge

The assistance dilemma and the concept of desirable difficulty raise the important question of when to provide vs. withhold integrated visual-verbal representations for optimal learning. However, a central question is what type of integrated representation is most beneficial to learners.

Much of the research on integrated visual representations has made use of visuals that physically embed additional information into a visual representation. Multimedia presentations have been shown to support deeper understanding of instructional materials when they provide students with diagrams into which textual labels and definitions have been embedded (e.g., Hegarty & Just, 1993). In geometry, research has shown that students learn more when they are provided with representations in which numerical measures have been integrated into diagrams (Tarmizi & Sweller, 1988) or when they are provided with color-coded highlighting that links text references (e.g., a

reference to angle ABC) with relevant diagram elements (Kalyuga, Chandler, & Sweller, 1999). Overall, research shows clear benefits for integrated visual-verbal representations during learning. However, integrated visual-verbal representations may not, in and of themselves, prompt learners to make connections to key domain ideas.

Evidence suggests that individuals with deep domain understanding tend to exhibit strong connections between domain concepts and visual representations. For example, experts in geometry use key diagram configurations to cue relevant geometry knowledge (i.e., theorems and principles) during problem solving (Koedinger & Anderson, 1990). During mathematical problem-solving, mathematicians repeatedly analyze connections between generated visual representations, changing goals, and the emerging problem situation (Stylianou, 2002).

Unlike experts, novices do not demonstrate close connections between visual representations and domain knowledge during problem solving. In geometry, novices tend to process diagrams in isolated ways, focusing on visual features without considering their relationship to deeper, conceptual aspects of problems (Lovett & Anderson, 1994). Ainsworth (2006) argues that a central cognitive task in learning with multiple representations is developing an understanding of the relationship between a visual representation and relevant domain information.

One way to support novice learning in geometry, then, may be to scaffold student interactions with visual representations in a way that improves their understanding of the relationship between visual features of geometry problems (i.e., geometry diagrams) and the geometry principles/rules used in problem solving. In geometry, problem solving requires that learners connect meaningful diagram configurations to relevant geometry principles. For example, in Figures 2 and 3, angle ABC is an *interior angle*, *same side* to angle BCD. Learners should recognize that the diagram contains two parallel lines (AB, DC) intersected by a transversal (BC). Angles ABC and BCD are on the interior of the parallel lines, and on the same side of the transversal. Thus, they are *interior angles, same side* and can be solved using this rule. In this study, we used highlighted diagram features to demonstrate the mapping between diagrams and relevant geometry principles in the domain (see Figures 2 and 3); hereafter, these are referred to as diagram-domain representations.

Integrated Diagrams in Intelligent Tutoring

In previous research (Butcher & Aleven, 2007, 2008), we explored the use of interactive visual diagrams as a method to support the development of integrated visual-verbal knowledge during intelligent tutoring in geometry. The research vehicle for this work was the Geometry Cognitive Tutor, an intelligent tutoring system (ITS) grounded in cognitive theory that provides multiple forms of support for student learning by doing: tracking students' knowledge development using a model of student competency, selecting problems for students to complete that match

identified learning needs, structuring problem-solving steps for students, giving feedback on all student actions, and providing hints upon student request or when the student makes repeated errors. Details about Cognitive Tutor features are available elsewhere (e.g., Anderson, Corbett, Koedinger, & Pelletier, 1995).

Butcher and Aleven (2007, 2008) varied the site of student interaction during geometry problem solving in an intelligent tutoring system: students used either an *interactive diagram* or a *solutions table* version of the intelligent tutoring system (see Figure 1). Students using the interactive diagram tutor clicked directly on diagram elements to enter answers and receive feedback, thus creating an integrated representation in which numerical answers were embedded in the visual representation. Students in the control condition used the solutions table to enter their answers and receive feedback. Although the solutions table kept a running record of students' answers, numerical values were not integrated directly into the diagram. Results showed that students who interacted with the diagrams to develop an integrated representation learned geometry principles more deeply (as evidenced by transfer task performance: Butcher & Aleven, 2007) and retained their problem-solving skills for longer periods of time (Butcher & Aleven, 2008).

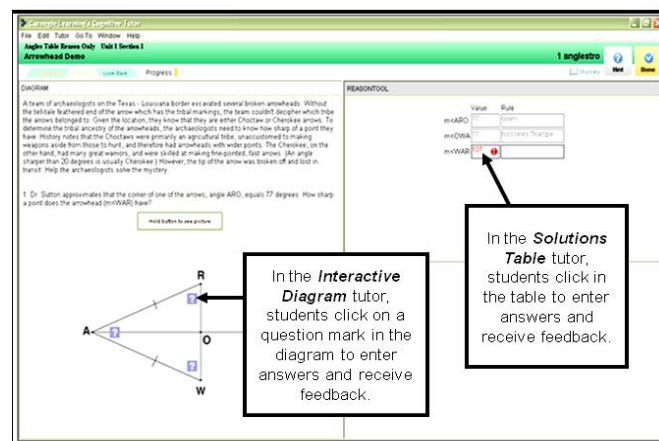

Figure 1: Condition-based differences in interactions with an intelligent tutor (Butcher & Aleven, 2007, 2008).

Despite the success of these diagram interactions in an already-successful intelligent tutoring system, there was still ample room for student improvement at assessment. It is possible that diagram interaction helped students focus on relevant visual elements during problem solving, but the integrated representations that students developed did not make it clear how diagram elements mapped onto domain information.

Student Generation of Integrated Representations

Simply providing students with visual representations that connect diagrams features to domain information may not be optimal for learning. Research has shown that requiring

students to actively integrate visual and verbal information (i.e., using a drag-and-drop interface to produce a labeled diagram) improves learning outcomes and increases the quality of students' self-directed learning behaviors (Bodemer et al., 2005). However, it is unclear whether interactions that emphasize diagram-domain mappings during problem-solving practice can improve learning more than interactions that build integrated visual-verbal representations (cf., Butcher & Aleven, 2007, 2008).

The purpose of this study was to explore the potential benefits of providing students with integrated representations that emphasized the mapping between diagram elements and domain information during intelligent tutoring vs. requiring students to generate these integrated representations. Both conditions were compared to a control condition in which students interacted with diagrams to embed numerical information into the diagrams (i.e., student interactions created an integrated, visual-verbal representation that did not emphasize domain connections).

Method

Participants

Eighty-three students from five 10th grade geometry classrooms at a vocational school in rural Pennsylvania participated in the study as part of their normal classroom curriculum, which included practice with the Geometry Cognitive Tutor once a week (one 75 min session per week).

Grade-matched triplets of students were identified within each class, using students' first semester geometry grades as a measure of prior knowledge. From every grade-matched triplet, one student was randomly assigned to each of the three experimental conditions described below.

Materials

Student-Highlighting Condition The purpose of the student highlighting condition was to require student interactions with the intelligent tutor that generated integrated diagram-domain representations during problem-solving practice in the Cognitive Tutor. In this condition, if a student entered an incorrect answer or reason during practice, s/he was locked out of the numerical answer field until s/he identified the correct geometry principle needed to solve the problem-solving step. Once the correct principle was identified, students highlighted the diagram features relevant to that principle (see Figure 2). These highlights created an integrated diagram-domain representation of the problem situation. As seen in Figure 2, highlighting was scaffolded by a list of diagram features that appeared after students entered a correct geometry principle for a problem-solving step. Students were required to highlight each diagrammatic feature in the list (e.g., for *Interior Angles, Same Side*, students were prompted to highlight the parallel lines, the transversal, and the two relevant angles).

Students highlighted a diagrammatic feature by clicking directly on it; students could deselect a highlighted feature by clicking on it again. Students received immediate

feedback on each highlighted feature in the diagram. Incorrect highlights turned red on the diagram and in the accompanying answer area. Correct highlights were kept on the screen until the problem-solving step was completed.

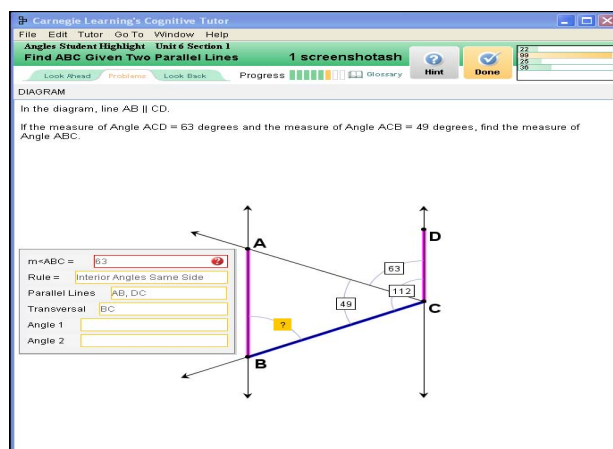

Figure 2: In-progress student highlighting of diagram for *interior angles, same side* rule. Parallel lines and transversal have been highlighted so far.

Tutor-Highlighting Condition This condition utilized the same representations as the student-highlighting condition, but in this case the tutor *provided* students with the highlighted diagram-domain representation. Following a problem-solving error and student identification of a relevant geometry principle, the tutor automatically highlighted the diagram. The screen shot in Figure 3 shows the result of the tutor highlighting; it is important to note that the final representations in the student- and tutor-highlighting conditions were equivalent, differing only in whether the student or tutor generated the representation.

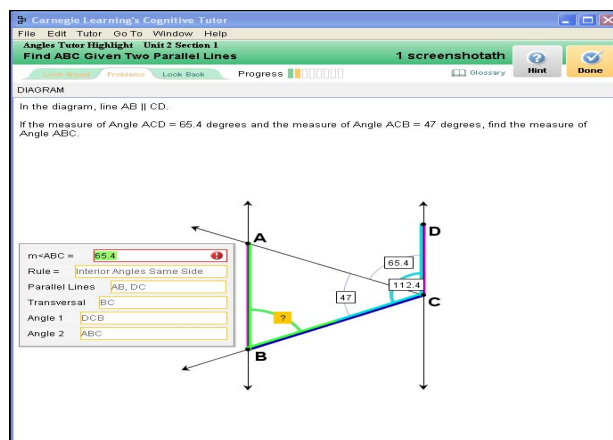

Figure 3: Tutor-highlighted diagram following student error

No Highlighting (Control) The control condition was the successful interactive-diagram version of the Geometry Cognitive Tutor from Butcher and Aleven (2007). This condition did not involve any highlighting of visual diagram features by either students or the intelligent tutoring system.

However, students entered answers directly into the geometry diagram; this created an integrated visual-verbal representation in which numerical values were embedded in the visual diagram.

Assessments *Problem-Solving Pre- and Posttest* The problem-solving pre- and posttest consisted of 16 total items. For each to-be-solved item, students needed to provide a numerical answer (e.g., 65°) and the geometry principle that was used to derive the numerical answer (e.g., Vertical Angles). The problem-solving posttest was the same as the pretest, but problems appeared in a different order. One point was given for each correctly-solved angle and correctly-identified principle. Due to a technical error and student absences, data was collected from 68 participants at pretest and from 70 students at posttest.

Delayed Posttest The delayed posttest was given on the computer, four weeks following the posttest. The delayed posttest followed the same format as the pre- and posttest, but with less complex problems. Students received one point per correctly-solved angle and correctly-identified geometry principle, for a maximum of 8 points on each dependent measure. Due to high numbers of student absences in the week that the delayed posttest was given (near the end of the school year), 41 students completed the delayed posttest.

Procedure

Participants were given up to 30 minutes to complete the pretest during their geometry class. Pretests were delivered via computer; students were instructed to try their best to complete the problems, and to take a guess if they were not sure of an answer. After completing the pretest, students worked with their assigned tutor version for four weeks during a 75-minute, weekly computer lab. This computer lab was a normal part of the students' geometry classes, and all students had used non-experimental versions of the Geometry Cognitive Tutor during previous sessions in the computer lab. The Geometry Cognitive Tutor used in each condition did not differ in problem content, the number of required problems, or the knowledge models used by the Cognitive Tutor.

One week after completing the study, students were given up to 45 minutes to complete the posttest during their geometry computer lab. A delayed posttest was administered one month following the posttest. Participants had up to 30 minutes to complete the delayed posttest.

Results and Discussion

Training Performance

In the Geometry Cognitive Tutor, learners provide a numerical answer and a geometry principle (aka "rule") that justifies the numerical answer for each problem-solving step. Log data from student practice with the Geometry Cognitive Tutor were analyzed to assess performance on the

first answer and geometry rule attempted by a learner for each problem step during practice. Data were calculated only for problem steps that were not given in the problem statement. That is, data were analyzed only for problem steps in which students needed to apply a geometry principle in order to calculate a correct answer. Student progress in the Geometry Cognitive Tutor was self-paced and, in general, was slower than anticipated by either the experimenters or the students' classroom teachers. Because the intelligent tutoring system requires mastery learning before students can continue to the next instructional unit, not all students completed the three instructional units in the experimental version of Geometry Cognitive Tutor. In total, 72 students produced tutor log data in unit 1 (control: $n = 23$, tutor-highlighting: $n = 25$, student-highlighting: $n = 24$). Forty-five students reached unit 2 (control: $n = 14$, tutor-highlighting: $n = 16$, student-highlighting: $n = 15$), but only 27 students reached unit 3 (control: $n = 10$, tutor-highlighting: $n = 8$, student-highlighting: $n = 9$).

Due to the drop in student numbers at each instructional unit, three multivariate analyses of covariance (MANCOVAs) were used to assess student performance in each unit of the tutor. Dependent variables were the percent correct of students' initial attempts at numerical answers and geometry rules for each not-given problem-solving step. Students' pretest scores on numerical answers and geometry rules were used as covariates to control for prior knowledge. As seen in Figure 4, unit 1 data demonstrated no significant differences in practice performance on numerical answers or geometry rules ($F_s < 1$).

Figure 4: M (and SE) percent correct for answers and geometry rules in unit 1 during intelligent tutor practice

Unit 2 also failed to show any significant condition differences in problem-solving performance on answers or geometry rules ($F_s < 1$). For the few students who reached unit 3, students who interacted with the tutor to generate integrated diagram-domain representations had a slight, though non-significant, advantage on numerical answers ($F_{(2, 22)} = 2.7, p < .09$). However, as seen in Figure 5, there were no differences in students' accuracy in using geometry rules to justify their problem-solving steps during practice.

Figure 5: *M* (and *SE*) percent correct for answers and geometry rules in unit 3 during intelligent tutor practice

Problem-Solving Performance

Overall, 33 students completed all three assessments (control: $n = 13$, tutor-highlighting: $n = 11$, student-highlighting: $n = 10$). Data were analyzed using a repeated-measures MANOVA, where test time (pretest, posttest, delayed posttest) was the repeated factor.

For numerical answers, results showed no test time by condition interactions (Linear: $F < 1$; Quadratic: $F_{(2, 31)} = 1.48$, $p > .24$). However, as seen in Table 1, students' performance on geometry principles showed a significant test time by condition interaction (Linear: $F_{(2, 31)} = 4.97$, $p = .01$, $\eta_p^2 = .24$; Quadratic: $F_{(2, 31)} = 3.28$, $p = .05$, $\eta_p^2 = .18$). Students in the student-highlighting condition were best able to justify their problem-solving steps with geometry rules at delayed posttest; however, no differences were seen at the short-term posttest. Figures 6 and 7 show the pattern of means on the posttest and delayed posttest, respectively, adjusted for pretest performance.

Table 1: *M* (and *SD*) percent correct on geometry rules

	Pretest	Posttest	Delayed Posttest
Control	18.2 (16.7)	25.5 (14.3)	19.4 (18.0)
Tutor-Highlighting	11.1 (10.6)	23.2 (21.2)	17.7 (11.4)
Student-Highlighting	12.4 (7.2)	16.3 (13.6)	31.7 (14.2)

As seen in Figure 6, there were no significant condition differences at posttest. If anything, the pattern of results at posttest was consistent with a disadvantage for students who highlighted diagrams during practice. Although this may seem inconsistent with the overall pattern of performance in unit 3 during intelligent tutoring practice (see Figure 5), one should remember that not all students taking the posttest reached unit 3 in the intelligent tutor.

Figure 6: *M* (and *SE*), adjusted for pretest performance, on posttest numerical answers and geometry rules.

One month later, at delayed posttest, the data paint a different picture. Although there were no differences in students' accuracy in providing numerical answers at delayed posttest, students who generated integrated diagram-domain representations during practice were better able to justify their problem-solving steps with relevant geometry rules. It is important to note that this advantage was found even though control students made use of integrated diagrams with embedded numerical answers. Moreover, the advantage cannot be attributed to additional information in the diagram-domain representations, as students who were provided with these representations by the tutor did not outperform the control group in correctly using geometry rules (see Figure 7).

Figure 7: *M* (and *SE*), adjusted for pretest performance, on delayed posttest numerical answers and geometry rules.

To confirm results obtained from the small group of students with full assessment data, two additional analyses were conducted. First, a MANCOVA was used to assess performance changes for all 68 students with pre- and posttest data (control: $n = 23$, tutor-highlighting: $n = 24$, student-highlighting: $n = 21$). Dependent variables were

performance on numerical answers and geometry rules at posttest; covariates were students' performance on answers and rules at pretest. Results were consistent with the small sample, showing no condition differences for either numerical answers or geometry rules ($F_s < 1$). A second, similar MANCOVA was conducted for all 41 students with pre- and delayed posttest data (control: $n = 14$, tutor-highlighting: $n = 13$, student-highlighting: $n = 14$). Results again were consistent with the small sample, showing a significant advantage of the student-highlighting condition for geometry rules ($F_{(2, 36)} = 4.04, p = .03, \eta_p^2 = .18$), but not numerical answers ($F_{(2, 36)} = 1.38, p > .26$).

General Discussion

Overall, results show that *providing* integrated visual-verbal materials to students during intelligent tutoring does not improve students' learning outcomes. However, findings show that using *interactions to build* integrated diagram-domain representations can support long-term understanding. Students who generated integrated representations that emphasized diagram-domain mappings during problem-solving practice showed no performance advantages in using geometry principles at practice or posttest, but were best able to apply these principles one month following instruction.

Results are consistent with the idea that student interactions can support deep learning with visual information. However, results also argue that integrated visual-verbal representations best support deep learning when they help the learner make connections between features of the visual representation and relevant domain information. The current study shows that student interactions can be an effective method to scaffold these connections. Findings also demonstrate the importance of measuring long-term knowledge gains, as student performance during practice and short-term assessments may not provide an accurate picture of deep understanding.

Abstract

We present Explanatory Reasoning for Inductive Confidence (ERIC), a computational model of explanation generation and evaluation. ERIC combines analogical hypothesis generation and justification with normative probabilistic theory over statement confidences. It successfully captures a broad range of empirical phenomena, and represents a promising approach toward the application of explanatory knowledge in new situations.

Keywords: induction; analogy; probabilistic reasoning

Introduction

We are constantly making guesses. When we come across something new, we know about it in part from its relations to other things and we attribute to the novel the properties of the familiar. For instance, when Apple announced the iPad, technology reporters alternately compared it to tablet PCs, which are similar in size and function, and the iPhone, which is similar in appearance and operating system. In each case, the game was to predict the features of the new object on the basis of the old ones.

Property inductions of this kind—extending known properties of one category to other categories—have been heavily studied in experimental psychology (see Heit, 2000, for a review). Such inductions seem to take advantage of taxonomic knowledge about category structures as well as specific knowledge about particular categories (Shafto, Kemp, Bonawitz, Coley, & Tenenbaum, 2008).

One intuition, pursued here, is that people make inductions by adapting explanations for known properties to novel categories. People are habitual generators of explanations: Scientists explain natural phenomena; engineers explain why structures will or will not support various loads; mathematicians explain why a formal property does or does not hold of a particular situation or object; and everyone routinely explains much more mundane things such as why the doorbell rang, why we smell gas in the kitchen and why a child has a fever. Explanations serve many cognitive functions, but perhaps none is more important than their ability to support inductive inferences: A person who can explain a novel observation can have much greater confidence in their inferences about the circumstances under which that observation is likely to be repeated than a person who cannot explain it—which is why, for example, your auto

mechanic is better than you are at knowing whether that strange noise your car is making is likely to be dangerous.

In order to apply explanations of past experiences to novel situations, a cognitive architecture must solve several problems. First, it must be able to generate and retain explanations in the first place. Second, it must have a way to generate novel hypotheses about a current situation from its beliefs about past circumstances. Finally, it must be able to distinguish when a novel explanation is plausible in the current situation, and when it is not.

Bayesian models, and particularly hierarchical Bayesian models, are adept at the last of these goals. For example, the model of Kemp and Tenenbaum (2009) carves known situations into disjoint domains, and applies to novel situations the domain assumptions that appear most appropriate. However, human reasoners also adapt explanation patterns across multiple, dissimilar domains (Medin, Coley, Storms, & Hayes, 2003). Although such cross-domain reasoning is the *sine qua non* of analogical approaches to reasoning (Falkenhainer, Forbus, & Gentner, 1989; Hummel & Holyoak, 1997), models of analogy generally provide no basis for generating probabilistic estimates of confidence in their inferences.

In this paper, we present the model ERIC, Explanatory Reasoning for Inductive Confidence (see also Landy & Hummel, 2009). ERIC uses a combination of analogical and probabilistic reasoning to (a) generate explanations for newly learned facts, (b) evaluate the plausibility of those explanations in light of its existing knowledge, (c) use those explanations to update its confidence in its existing knowledge and (d) make judgments about the plausibility of new inferences. The resulting model accounts for a large body of empirical findings from the literature on inductive confidence (e.g., Heit, 2000; Shafto et al., 2008).

A central tenet of the model is that the mind uses analogy to adapt old explanations to new situations and then uses those new explanations both to determine its confidence in the new observation and to update its confidence in its existing knowledge—both existing basic facts and existing explanations. The knowledge updated includes both the source analogs (i.e., the old explanations used to generate the new ones) and the analogies themselves (i.e., the mappings from the old [source] explanations to the new [target] explanations). As a result, if an analogy results in a good explanation, then the model becomes more convinced both that the source was true and that the analogy was good.

A second central tenet is that the mind generates these explanations permissively and habitually: Presented with any new “fact” or observation, the mind will generate as many potential explanations of that fact as possible and assign a likelihood or confidence value to each; in turn, these values are used to update its confidence in the very facts that participated in the explanations themselves.

Some models of induction (e.g., Kemp & Tennenbaum, 2009) explicitly carve knowledge into separate domains, and assume that categorically different processes apply to situations attributed to those domains (e.g., reasoning in one way about ontological knowledge and in a different way about geographical knowledge). A third tenet of the model is that knowledge, including knowledge about generating processes, is applied to relevant situations regardless of domain. That is, the processes underlying explanation and confidence estimation are the same across and within all areas of knowledge: Any differences between, say, ontological knowledge and other knowledge domains (e.g., geographical location, diet or behavioral traits) emerge as a natural consequence of the relationship between individual sets of facts, and not through an explicit and absolute categorization into domain.

Finally, in line with other integrative general knowledge models, the goal of ERIC is not to be entirely formally consistent (Wang, 2009). For instance, it will not necessarily be the case that $a \sim a$ is guaranteed to be false.

Property Induction

We report a collection of simulations using ERIC to perform a property induction task (Osherson, Smith, Wilkie, López, & Shafir, 1990; Rips, 1975). In this task, a subject (or ERIC) is given a *premise*, which is assumed to be true (e.g., “robins get disease d ”), based upon which they are asked to estimate the likelihood of a *conclusion* (e.g., “birds get d ”). The dependent measure of interest is the estimated likelihood of the conclusion as a function of the relation between the major term in the premise (here, “robins”) and that in the conclusion (“birds”), and of the relation between these categories and the property induced (“disease d ”).

ERIC

Overview

ERIC is based on the following assumptions about the nature of the property induction task:

1. A person enters the laboratory with knowledge (facts, explanations, theories) believed in with varying degrees of confidence.
2. Faced with the premise, the subject tries to explain it by building a fairly large set of potential explanations by analogy to known cases.
3. Each explanation is assigned an inductive confidence that combines confidence in the knowledge involved in the explanation and confidence in the generating analogies.

4. These explanations are added (provisionally) to knowledge, and the confidence of existing statements is updated using Bayesian inference.
5. Faced with a conclusion, the subject repeats process of explanation and confidence updating.
6. Confidence in the conclusion is high to the degree that the explanations are strong.

As input, ERIC takes an explanandum—either a premise or a conclusion. As output, it generates potential explanations, each with an assigned confidence, and an estimate of the confidence in the explanandum itself. Applied to property induction, the mechanism operates in two stages: First, ERIC explains the premise(s) and any knowledge gleaned from those explanations is added to the knowledge base. Next, it explains the conclusion using that augmented knowledge. The result of these processes is an estimate of the likelihood that the conclusion is true.

Knowledge Representation

All of ERIC’s knowledge is represented in standard propositional notation, augmented to capture the logical and causal relations that link propositions into explanations. Atoms are of the form $f(a)$, $g(a, b, c)$, and so on. Connectives \wedge , \vee , and \sim are used in their usual sense to mean *and*, *or*, and *not*.

Two less universal connectives provide a language for representing explanations and analogical mappings. The connective \Rightarrow denotes an explanatory or causal relationship. For example, $q \Rightarrow r$ should be read as “ q (if true) would tend to explain (cause) r .” In contrast to some prior models (e.g., Falkenhainer et al., 1989; Hummel & Holyoak, 1997), causal connections are treated as special types, and not as generic two-place predicates (see also Hummel & Landy, 2009). Syntactically, they are equivalent in ERIC to a material conditional.

The second novel connective is the *mapping relation*, $q \simeq r$, which asserts that q and r map to each other in some analogy, and provides ERIC’s initial estimate that q and r might map to each other in some future analogy. Mapping connections have learned confidences.

Confidence Each statement, q , is assigned a *confidence* value between 0 and 1, which is intended to work much like an intuitive probability that the statement is true. Indeed, we will refer to the confidence as “the probability of q ,” or $p(q)$.

Statements in the initial knowledge set have a preset initial confidence. Regular property statements and cause relations (e.g., $q \Rightarrow r$) that do not appear in the initial knowledge have a confidence set to arbitrary low values (0.1 and 0.001).

Explanations An explanation is a recursive binary modal structure, with the pattern $E(\text{explanation}; \text{explanandum})$, where the explanandum is a statement, and the explanation is a set of statements. They have the form of a modus ponens: Some set of (possibly recursively justified) causes

and an explanatory connective statement justify the effects. For instance, the explanation:

$$E_1(p, q, E_2(r, r \Rightarrow q; q), p \wedge q \Rightarrow s; s).$$

asserts that “ p, q (where q is explained by r), and $[p$ and q cause $s]$ jointly cause s .”

An explanation differs from a causal connective in several ways. First, a causal connective is purely dispositional, while an explanation asserts that *in fact*, the explanation explains the explanandum. An explanation thus encodes a derivation pattern, rather than a potential relationship. Further, an explanation carries its own internal semantics; it denotes a possible state of affairs.

Knowledge base ERIC’s knowledge consists of three major classes of statements: simple property statements, such as *eats(Robin, Worm)*; simple explanations, such as generic taxonomic explanations of the form $isa(A, B) \wedge x(B) \Rightarrow x(A)$; and taxonomic assertions, of the form $isa(Robin, Bird)$. It is worth noting here that taxonomic assertions are simply property statements, and not a special part of the model mechanism.

Justification

ERIC revises its beliefs (e.g., explanations) using two kinds of justification: analogical and explanatory. For either, the effect of a justification, j , on an explanandum, i , is to update the probability of i according to a probabilistic-OR rule:

$$p(s) \leftarrow p(j) + (1 - p(j))p(s) \quad (1)$$

Intuitively, (1) can be read as meaning that if the justification, j , is correct, then the assertion, s , it justifies must be correct, but if it is not, then s might still be correct with (base rate) probability $p(s)$.

The initial confidence of an explanation is simply the probability that all the statements in the explanation are true:

$$p(j) = \prod_{e \in E} e \quad (2)$$

Analogical Justification Intuitively, an analogy, $r \sqsupset q$, justifies q to the extent that the source analog (r) is true, and the mapping is reliable. Thus,

$$p(j) = p(r)p(r \sqsupset q) \quad (3)$$

The target of an analogical justification is always a causal statement. These are updated by applying the justification to the cause statement via equation (1), just as with explanatory justification.

Explanation Generation

When a new explanandum, q , is presented to ERIC, two steps are recursively applied to generate new explanations of q . First, each fact in the current knowledge base that

shares any literals with q is postulated as a possible explanation for q . For example if $q = g(a)$ and if $f(a)$ is known, then one explanation postulated will be $f(a) \Rightarrow g(a)$. Confidence in this shallow explanation will initially be set to a very low value. Second, existing explanations (including those inside explanations) are expanded and justified by analogy to other explanations in knowledge.

Any potentially useful analogical mapping, e.g., $(a \Rightarrow b) \sqsupset (c \Rightarrow d)$, is computed by mapping the elements of a, b onto those of c, d using Holyoak and Thagard’s (1989) ACME mapping algorithm. ACME’s mapping strengths range between 0 and 1, and so translate conveniently into confidences. ACME combines structural isomorphism and semantic relationships. In ERIC, these semantic relationships are computed directly from the knowledge base (see Projectable Literals, below).

The best match produced by ACME is used as the basis for an analogy. This approach has two effects. First, the explanatory relation is justified by the analogical statement, using (3). Second, statements appearing in the analog but not in the current explanation are imported.

These two processes are applied to each explanation in the current set a fixed number of times (three in the current simulations). Each explanation in the final set justifies the conclusion; the result is the confidence in the conclusion.

Projectable Literals Analogical similarity integrates structural overlap and semantic relationships (Taylor & Hummel, 2009). That is, structural relations being equal, ERIC prefers analogies about identical or similar terms to comparisons among distantly related items.

The semantic similarity—more accurately, *projectability* (Simmons & Estes, 2008; Sloutsky, Kaminski, & Heckler, 2005)—of a onto b , p_{ab} , can come from either of two sources. If two terms have been related by past explanatory analogies, then the projectability is stored in the form of a mapping statement. The projectability of two previously unrelated terms is calculated from ERIC’s knowledge:

$$p_{ab} = e^{-d_{ab}} \quad (4)$$

where

$$d_{ab} = \alpha s_a + \beta s_b - \gamma s_{ab} - \delta m_{ab}$$

α, β, γ and δ are free parameters (15/40, 2/40, 1/40, and 17/40, respectively). Here s_a is the summed confidence in sentences in which a appears; s_b and s_{ab} are defined analogously. Intuitively, a is projectable onto b to the extent that they appear in similar relational roles in LTM (γs_{ab}) or to the extent that b is a kind of a (δm_{ab}) and to the extent that a does not appear in roles in which b does not and vice-versa ($\alpha s_a + \beta s_b$). If a mapping connection exists between a and b then ERIC uses the mapping strength as p_{ab} : ERIC learns that facts about a generally apply to b .

The differential applicability of known explanations to novel situations constructs a kind of soft domain separation. Although any knowledge can be applied to a new situation in principle, close knowledge will be applied with far more

confidence. As a result, cross domain analogies have most effect in the absence of other good explanations. This differential applicability of old explanation replaces the construction of explicit domains of explanations (Kemp & Tenenbaum, 2009) used in other approaches, and in general may implement generic symbolic rules (Gentner & Medina, 1998; Sun, 2006).

Knowledge Revision

In property induction, a certain number of premises (collectively π) are followed by a conclusion statement, c . In calculating confidence in a conclusion, ERIC first generates explanations of the premises. It uses these to update its knowledge base. If π consists of multiple premises, then each individual premise is explained; the full set of explanations is the set of all possible combinations of explanations for individual premises.

Learning a new premise means adding it to the knowledge base with confidence=1. Learning a new fact should inform the learner to the degree that the fact was surprising; it should increase confidence in things that would explain that fact. Both intuitions can be captured by Bayes law, if we are careful about where our terms come from.

$$p(e|\pi) = \frac{p(\pi|e)p(e)}{p(\pi)} \quad (5)$$

The prior probability, $p(\pi)$, is the confidence in π resulting from the explanation process. Intuitively, $p(\pi|e)$ is the confidence we would have in π if some particular fact e were known with certainty. This value can be found by repeating the process of justifying π , setting the confidence of e to 1 for each fact that appears in explanations for π , including analogy sources, and assertions of analogical validity. It should be clear that the use of this law is not normative here, since the values are not strictly probabilities. However, the law forms one good way to incorporate evidence into belief systems. ERIC postulates that people use something like this kind of inference.

Figure 1: The strengths of induction of a property from one category to a related category. In general, ERIC makes stronger inductions from more closely related categories.

In property induction, ERIC uses the knowledge base that results from explaining the premise to explain the conclusion. Since each explanation justifies the conclusion, confidence in the conclusion results from the application of (1) once for each explanation.

In principle, the resulting confidence values could be matched directly to human probability estimates. In practice, current limitations of the model (especially its extremely impoverished “knowledge”) make such point-by-point comparison uninformative, so our evaluation of the model will focus on the relative rankings of sets of explanations.

Simulations and Results

ERIC predicts that inductions, and even patterns of inductions, will be strongly dependent on knowledge, and particularly on contextually relevant knowledge. For this reason, conclusions about the predictions of ERIC must be made relative to some particular set of knowledge.

Taxonomic Simulations

Taxonomic relationships have received much attention in the literature on category inductions; we decided to explore two knowledge bases built largely around taxonomic knowledge. In the first, a taxonomic structure of “animals” was constructed with *isa* statements, including two mammals, six birds, and two reptiles. Animals were, in turn, defined by membership to the superordinate “living things.” One general taxonomic explanation was included, over elements that did not appear in any other statements. The pattern of this explanation was: $isa(x,y) \wedge f(y) = f(x)$.

The second knowledge base included all of these taxonomic facts, but also included a fairly arbitrary set of about 200 facts, including property statements and casual explanations, both taxonomic and not taxonomic. This knowledge base tests the generality of the conclusions across a noisier knowledge base.¹

Since inductions from a category to its subset are explanations, like all explanations, they are not certain. Furthermore, close ancestors generally provide more support than more distant ancestors. Figure 1 compares ERIC’s inductions from immediate superordinates of a category (“parents”), and from the superordinates’ superordinates (“grandparents” see Figure 1). Thus, a premise “birds have x” provides more support to the conclusion “robins have x” than does “animals have x”. This pattern matches the empirically discovered category inclusion fallacy (Heit, 2000; Sloman, 1998). Figure 1 shows that this same pattern appears with the richer knowledge base, as well.

Within taxonomic categories at the same level (e.g., the species level), taxonomic proximity again can vary. Figure 2 shows the results of simulations varying the taxonomic proximity, and also the number of premises in the induction

¹ The full contents of all knowledge bases described here can be found online at <http://www.richmond.edu/~dlandy/cogsci10/>.

Figure 2: The strengths of induction of a property from zero, one or two categories to others at the same level.

(that is, the number of species of which the property was asserted). In the absence of knowledge, ERIC generally predicts that inductions tend to be stronger between categories that are closely related (see Figure 2). More premises tend to make inductions stronger; moreover, ERIC shows a general diversity effect: when multiple premises come from unrelated categories, that tends to increase inductions more than when they have a common superordinate. This is true in general because two close premises will tend to be best explained by explanations in terms of their common superordinate, while diverse premises are likely to be explained in terms of distant superordinates. This pattern is complicated, however, by an interaction between the diversity of the premises and their similarity to the conclusion. If one premise category is close to the conclusion category, a single premise category already generalizes fairly strongly, because most explanations for the premise are highly mappable into the conclusion; adding a second close premise improves the induction very slightly or not at all. However, if the second premise is from a very different category (making the premises more diverse), then ERIC's explanations are likely to be less finely tuned to the conclusion category, and confidence decreases slightly. This pattern again matches empirical literature (Osherson et al., 1990; Sloman, 1993).

Typicality

To explore how ERIC uses typicality information, we augmented the taxonomic knowledge base with two kinds of information. Both involved four members of a common animal family ("birds"), with four features. The *typical* member had the same four features. The *typical plus* member had the same four features plus an additional two not shared by other members. The *typical minus* had only two of the features, and no additional features. The final *atypical* member had two shared features, and two unique

features. A second knowledge base had the same exemplars and features, plus explanations for each feature.

ERIC computed confidence in the induction of a blank property from each premise bird to the conclusion bird. Figure 3 displays the results. Generally, as with people (Heit, 2000), increased typicality led to higher inductive confidence. One interesting exception to this pattern was that in the features only case, inductions were slightly stronger from the premise category with relatively few features than from the premise category with many typical categories. This is because this "unknown" category was exceptionally projectable, due to having very few features. When more explanations were available, the relatively high number of good potential explanations for the typical category dominated, leading to strong inductions.

Causal Knowledge

Because ERIC extends its knowledge based on the overall analogical quality, the predicate attributed to a premise and conclusion category can also strongly impact induction, if facts involving that premise or a related one are part of prior knowledge. A predicate similar to those that appear as part of good, projectable explanations about similar categories sets will generally form strong inductions; projectable predicates known to apply to very different creatures, or those about which little is known, tend to project less well.

We illustrated this property by creating knowledge corresponding to the taxonomic and predatory structures explored by Shafto et al (2008). For a set of seven animals, predation and taxonomic facts were encoded in memory. Two generic explanations involved a "disease" spread by predation, and an "organ" shared by animals sharing a taxonomic category. Inductions were generated for each creature regarding a different "disease" and "bone."

As illustrated in Figure 4, inductions on the bone graded taxonomically. Premises involving species with the same parent (distance 0) generalized more strongly than more distantly related species. Diseases also showed a taxonomic structure, but less strongly than bones did. Furthermore, the disease was strongly affected by ecological relationships, generating an asymmetry such that predators were judged more likely to get diseases carried by their prey than were prey whose predator was known to catch the disease.

Figure 3: ERIC's predictions of induction strength, varying the typicality of the premise category.

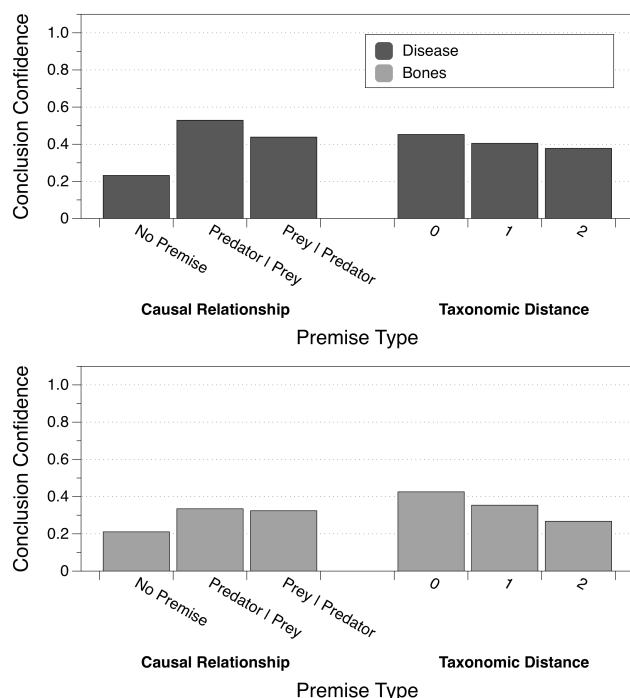

Figure 4: Dependency of inductive strength on both property and category relationships.

The latter still formed a strong induction in the disease case, because a prey carrying a disease made a good explanation for why a predator would have it; this explanation was thus well-supported during the premise explanation phase of ERIC's reasoning process. These patterns are quite similar to human judgments (Shafto et al., 2008), and demonstrate ERIC's ability to adjust the application of "rules" to different areas of knowledge.

Both properties showed taxonomic degradation. This is because both kinds of knowledge are in the system, and so both affect, to some degree, the same judgments. The model predicts that people will also blend different theories and domains of knowledge when making inductions.

Conclusions

ERIC combines deductive probabilistic inference with inductive analogical inference to generate and evaluate the likelihood of explanations, the propositions they comprise and the observations they explain. The resulting model, still in an early stage of development, successfully predicts and explains a wide range of phenomena in the property induction literature. Much work remains to be done (e.g., representing probabilities more realistically, allowing explanations to decrease as well as increase confidence, and making the generation of analogical explanations psychologically plausible rather than computationally exhaustive, among many others), but at this point ERIC seems a promising way to overcome the limitations of purely analogical, and purely Bayesian approaches to explanation generation and evaluation.

Explanations make inconsistencies harder to detect

Abstract

What role do explanations play in reasoning about inconsistencies? We postulate that when people create explanations, they use them to resolve conflicting information. This hypothesis predicts that inconsistencies should be harder to detect once individuals have in mind an explanation of the inconsistency. We report four experiments that tested this prediction. Experiments 1a and 1b corroborated the effect when participants made inferences from inconsistent assertions. Experiment 2 compared the effect of explanations of inconsistencies with those of a similarly demanding task. Experiment 3 ruled out a potential confound.

Keywords: inconsistency, explanations, belief revision, reasoning, principle of resolution

Introduction

The word ‘why’ is used to elicit explanations for the mysteries of daily life. Why is my car making that noise? Why didn’t the Redskins win last Sunday? Why isn’t my experiment working? Indeed, a central feature of human rationality is the ability to construct explanations of observed behaviors and phenomena (Harman, 1965). Recent research has explored the function and developmental trajectory of explanatory reasoning (Keil, 2006; Wellman, Hickling, & Schult, 1997). There is consensus among researchers that explanations are related to causal inference (Johnson-Laird, Girotto, & Legrenzi, 2004; Sloman, 2005; Walsh & Johnson-Laird, 2009), and that explanations impact reasoning, categorization, and learning (Lombrozo, 2006). Less is known about the contexts under which explanations are generated, i.e., it is unclear when and how individuals decide to produce explanations.

How do you reveal what a person understands about some subject matter? One way is to ask the person to explain it, because explanations require individuals to communicate their knowledge and beliefs about the phenomenon in question. Explanations can also occur in other tasks that draw upon general knowledge. For instance, explanations are useful when you are learning new information (Amsterlaw & Wellman, 2006; Chi, De Leeuw, Chiu, & Lavancher, 1994; Crowley & Siegler, 1999; Rittle-Johnson, 2006), and they help to predict future behaviors (Anderson & Ross, 1980; Einhorn & Hogarth, 1986; Lombrozo & Carey, 2006; Ross, Lepper, Strack, & Steinmetz, 1977). Individuals spontaneously produce explanations when they try to form categories (Shafto & Coley, 2003) and when

they judge how well concepts cohere with one another (Murphy & Medin, 1985; Palatano, Chin-Parker, & Ross, 2006). We propose that an additional function of explanatory reasoning is to resolve inconsistencies.

Explanations resolve inconsistencies

Consider the following:

If people are tired then they go to sleep.

A person was tired, but he did not go to sleep.

The two assertions are inconsistent, i.e., they cannot both be true. Given such an inconsistency, it is felicitous to ask: “why not?” But the same question is infelicitous when the assertions are obviously consistent with one another:

If people are tired then they go to sleep.

A person was not tired, and he did not go to sleep.

It seems strange to elicit an explanation for consistent assertions, and reasoners are likely to balk at such a request. Thus, an inconsistency calls for people to search for explanations, while an explanation is less appropriate when expectations are met.

We hypothesize that individuals resolve a set of inconsistent causal assertions by using an explanation to interpret each assertion, a view we call the *principle of resolution*. The principle assumes that when an inconsistency is detected among a set of assertions, reasoners construct explanations to restore consistency to the set (Johnson-Laird et al., 2004). They then interpret the assertions based on the consequences of the explanations. Consider the inconsistency above. One explanation for the person not going to sleep is that he was under some deadline, and so pursued his work despite his fatigue. The explanation provides an exception to the generalization that if people are tired they go to sleep. However, instead of abandoning it, reasoners are likely to construe it as an idealization that holds by default: it is true in many cases, but tolerates exceptions. The assertion may be interpreted as something akin to the generic assertion, i.e., ‘people who are tired go to sleep’ (Khemlani, Leslie, Glucksberg, & Rubio-Fernandez, 2007; Leslie, 2008). The principle of resolution thus allows individuals to use explanations to resolve inconsistencies by weakening the initial interpretation to that of an idealization rather than a universal truth.

One potential side effect of the principle is that when reasoners have an explanation of an inconsistency in mind, they may overlook the inconsistency on subsequent assessments of the assertions. If they interpret the conditional as an idealization, their new interpretation may

prevent them from detecting the conflict between the two assertions. Indeed, they may even forget that the reason for constructing the explanation in the first place was to resolve an inconsistency. To test this prediction, participants in four experiments were asked to detect an inconsistency after they had carried out various tasks.

Experiments 1a and 1b

Experiments 1a and 1b examined whether reasoners spontaneously construct explanations when faced with inconsistent scenarios, and whether those explanations made it more difficult to detect inconsistencies. They were presented with problems such as:

If a person is bitten by a viper then the person dies.

Someone was bitten by a viper, but did not die.

The participants in Experiment 1a evaluated the consistency of two assertions, either before or after they stated what follows from the assertions. The participants in Experiment 1b evaluated the consistency of the assertions before or after they responded to the question, “why not?” When individuals make an inference from inconsistent assertions, they should tend to infer explanations. The principle of resolution posits that when people create explanations, they interpret the assertions in the light of their explanation. It predicts an interaction: when individuals create an explanation first, they should be less accurate subsequently at detecting inconsistencies in comparison with those who have not created an explanation.

Method

Participants. 36 participants were recruited for Experiment 1a, and 40 participants were recruited for Experiment 1b. They volunteered through an online platform hosted through Amazon.com, and they completed the study for monetary compensation. None of the participants had received any training in logic.

Design and Procedure. On each trial, participants were given a set of consistent or inconsistent assertions (see Appendix A). Half of the problems presented a generalization (1) that was inconsistent with a categorical assertion (2), e.g.,

1. *If someone is very kind then he or she is liked by others.*

2. *Someone was very kind but was not liked by others.*

For the remaining problems, the inconsistency was eliminated by dropping the first clause in the categorical assertion (4), e.g.,

3. *If someone is very kind then he or she is liked by others.*

4. *Someone was not liked by others.*

Participants received an equal number of consistent and inconsistent problems, and carried out two tasks in succession for each problem, a consistency task and a task designed to elicit explanations. For the consistency task,

participants had to answer the question, “Can both of these statements be true at the same time?” They responded by pressing one of two buttons marked “Yes” or “No”. In Experiment 1a, participants also performed an inferential task, i.e., they answered the question, “What, if anything, follows from the statements above?” In Experiment 1b, they performed a more orthodox explanation task, i.e., they answered the question, “Why not?” They typed their responses into a text box provided on the screen. They were unable to see their response to the first task when they carried out the second task. In Experiment 1a, 20 participants performed the inferential task before the consistency task, and 16 participants performed the two tasks in the opposite order. In Experiment 1b, 20 participants performed the explanation task before the consistency task, and 20 performed the two tasks in the opposite order. All of the problems were similar to the two examples above, and participants received each set of contents only once. Each participant received the problems in a different random order.

Results and Discussion

Table 1 reports the proportions of trials on which participants correctly evaluated the assertions as consistent or inconsistent in Experiment 1a. Overall, participants were more accurate on consistent problems than inconsistent problems (77% vs. 50%, Wilcoxon test, $z = 3.27$, $p < .005$, Cliff’s $d = .42$), and the group that carried out the consistency task first was marginally more accurate than the group that initially made an inference about the assertions (70% vs. 58%, Mann-Whitney test, $z = 1.66$, $p = .10$, Cliff’s $d = .32$). These main effects were a consequence of the low rate of accuracy on inconsistent problems observed for the group that carried out the inferential task first. Their responses corroborated the principle of resolution, and the predicted interaction was significant: the group that initially carried out the inferential task was less accurate at detecting inconsistencies than consistencies, while the group that initially carried out the consistency task was just as accurate at detecting either type of problem (Mann-Whitney test, $z = 3.03$, $p < .005$, Cliff’s $d = .59$). Accuracy in the evaluation of consistency in Experiment 1a therefore depended on whether or not participants initially made an inference about the assertions. The effect is likely to reflect the use of inferences that explain the inconsistency.

Table 1: The percentages of correct evaluations of consistency in Experiment 1a depending on whether participants carried out the evaluation or the inferential task first.

	Inconsistent problems	Consistent problems
Group that carried out the consistency task first	73	68
Group that carried out the inferential task first	33	84

Table 2 reports the proportions of correct responses in Experiment 1b. Participants were far more accurate at detecting consistencies than inconsistencies (89% vs. 45%, Wilcoxon test, $z = 4.00$, $p < .0001$, Cliff's $d = .69$). The group that initially evaluated the consistency of the assertions was more accurate than the group that initially provided an explanation (79% vs. 56%, Mann-Whitney test, $z = 3.07$, $p < .005$, Cliff's $d = .66$). And the predicted interaction was significant: the difference between accuracies on inconsistent vs. consistent problems was greater for the group that carried out the explanatory task first (Mann-Whitney test, $z = 2.02$, $p < .025$, Cliff's $d = .48$). As in Experiment 1a, participants in Experiment 1b were less accurate at detecting inconsistencies when they initially provided an explanation.

These results support the principle of resolution, which predicted that explanations would make it more difficult to detect inconsistencies. However, it is possible that the difficulty to detect inconsistencies could have occurred because the explanation and inferential tasks were inherently more difficult. In other words, there may not have been anything unique about the explanation task, and the same effects could have been observed had reasoners performed any task that increased processing load. The evidence for such an account is mixed: in Experiment 1a, participants who initially made an inference were more accurate at detecting consistencies than participants who initially carried out the consistency task (84% vs. 68%).

Table 2: The percentages of correct evaluations of consistency in Experiment 1b depending on whether participants carried out the evaluation or the explanation task first.

	Inconsistent problems	Consistent problems
Group that carried out the consistency task first	64	93
Group that carried out the explanation task first	27	86

Hence, a difference in processing load cannot readily explain this pattern of results. It should have decreased performance on both sorts of problem, but in fact the participants did better on the consistent problems. In contrast, a difference in processing load could explain the results of Experiment 1b, because in this case the participants who answered the question 'why not?' first, went on to evaluate the consistency of both sorts of problem worse than those participants who began with this evaluation task. Experiment 2 therefore sought to determine whether any demanding task could dull reasoners' sensitivity to inconsistencies, or whether explanations are unique in decreasing accuracy.

Experiment 2

To test whether explanations uniquely contribute to low rates of accuracy when individuals have to detect inconsistencies, the participants in this experiment evaluated the consistency of a set of assertions after carrying out one of two tasks: one group provided an explanation of the assertions and the other group decided whether some clauses of the assertions were more surprising than others. The surprisingness task was chosen because it required reasoners to take into account all the assertions, but it did not require them to construct explanations of inconsistencies. Those participants who performed the surprisingness task received trials such as the following one:

If the aperture on a camera is narrowed, then less light falls on the film

The aperture on this camera was narrowed but less light did not fall on the film

In light of these statements, which of the following is more surprising?

- 1. It's more surprising that the aperture on this camera was narrowed.*
- 2. It's more surprising that less light did not fall on the film.*

They received the same instructions for consistent trials, and responded by choosing between one of two alternative responses. Once their responses were registered, they carried out the consistency task. The other group of participants typed out their response to the question "Why not?" before completing the consistency task.

Method

Participants. 40 participants from the same online platform as in the previous studies and completed the experiment for monetary compensation.

Design and Procedure. Participants received an equal number of consistent and inconsistent problems, and received the same set of problems used in the previous study. Half the participants carried out the explanation task before the consistency task and the other half carried out the surprisingness task before the consistency task. They were unable to see their responses to the initial task when they carried out the consistency task. Participants received each set of contents only once, and each participant received the problems in a different randomized order.

Results and Discussion

Table 3 reports the proportions of correct responses in Experiment 2. The results again corroborated the principle of resolution. Participants were less accurate for inconsistent than consistent problems when they carried out the explanation task than when they carried out the surprisingness task (Mann-Whitney test, $z = 1.64$, $p = .05$, Cliff's $d = .30$). No decrease in accuracy was observed for consistent problems between the two groups (86% vs. 84%,

Mann-Whitney test, $z = .63$, $p = .53$). The results rule out the possibility that the effects reflected differences in processing load.

Table 3: The percentages of correct evaluations of consistency in Experiment 2 depending on whether participants carried out the surprisingness task first or the explanation task first.

	Inconsistent problems	Consistent problems
Group that carried out the surprisingness task first	75	86
Group that carried out the explanation task first	47	84

The experiment replicated the previous effect: participants who created explanations often went on to evaluate an inconsistent set of assertions as consistent, but the surprisingness task had no such effect. The study ruled out the possibility that any demanding mental task would yield the same results, because participants who rated how surprising the assertions were did not go on to err in their evaluation of the inconsistent problems. And both groups went on to evaluate consistent problems with no reliable difference in accuracy between them.

In Experiment 2, reasoners either carried out the surprisingness task or else the explanation task before judging the consistency of the assertions. That is, no participant was exposed to the two different task orders. Experiment 3 sought to extend the results to a context in which each participant carried out both tasks.

Experiment 3

Experiment 3 tested whether explanations impair evaluations of consistency more than judgments of surprisingness. On each trial, participants either provided an explanation, a judgment of surprisingness, or neither, before they evaluated the consistency of the assertions.

Method

Participants. 25 participants from the same online platform as in the previous studies completed the experiment for monetary compensation. None had received any training in logic.

Design and Procedure. Participants served as their own controls, and received an equal number of consistent and inconsistent problems. The materials consisted of those used in the previous studies. For a third of the trials, participants carried out only the consistency task; on another third, they carried out the surprisingness task before the consistency task; and on the remaining trials they carried out the explanation task before the consistency task. The three

conditions were intermingled, and each participant received the problems in a different randomized order. Participants received each set of contents only once, and the contents were rotated over the three conditions so that each content occurred equally often in each condition in the experiment as a whole.

Results and Discussion

Table 4 provides the proportions of correct responses in Experiment 3. Participants were more accurate on consistent problems than inconsistent problems (71% vs. 52%, Wilcoxon test, $z = 2.38$, $p < .01$, Cliff's $d = .26$), and accuracy varied by the three types of trials (Friedman analysis of variance, $\chi^2 = 6.20$, $p < .05$). These main effects can be attributed to the drop in accuracy on inconsistent problems when participants had provided explanations.

The study yielded the predicted interaction between the type of trial and the consistency of the problem, i.e., participants were less accurate on inconsistent problems when they had carried out the explanation task than when they had carried out the surprisingness task or no prior task, whereas their accuracies for consistent problems were comparable to one another across the different tasks (Page's $L = 304.5$, $z = 2.55$, $p < .001$).

Table 4: The percentages of correct evaluations of consistency in Experiment 3 depending on whether participants carried out only the consistency task, the surprisingness task first, or the explanation task first.

	Inconsistent problems	Consistent problems
Consistency task only	60	70
Surprisingness task, then consistency task	56	76
Explanation task, then consistency task	40	68

As in the previous studies, Experiment 3 showed that explanations increased the likelihood that participants evaluated inconsistent assertions as consistent. The effect cannot be explained as a function of task demand, because participants did no better after they carried out the surprisingness task than after they had carried out no prior task. The study also extended the findings to a study in which the participants carried out all the different sorts of task. We conclude that the effect of explanations on consistency ratings is robust.

General Discussion

Across four experiments, participants erroneously evaluated inconsistent assertions as consistent after they had created an explanation for the inconsistency. Experiment 1a found that people produced the effect when they were asked to make inferences from the assertions, and Experiment 1b

extended the effect by directly eliciting explanations. Experiment 2 reproduced the effect by comparing those who formulated explanations with those who performed an unrelated task. Experiment 3 extended the effect to a context in which participants carried out the tasks in different orders. If participants had focused only on the assertions they were asked to read, the creation of an explanation should have had no effect on the evaluation of consistency in any of our experiments. Instead, the participants failed to detect inconsistencies as a result of creating explanations. When individuals resolve an inconsistency by explaining it, they are likely to establish a consistent interpretation of the facts of the matter and the original assertions. They have reasoned from inconsistency to consistency (see Johnson-Laird et al., 2004), and this newfound consistency makes it harder to detect the original inconsistency of the assertions.

Two gaps in the present account remain. First, the quality of the explanations that the participants created appeared to vary, but further research is needed to interrelate this quality, say, to the latency of a correct evaluation of the inconsistent assertions. Second, the precise mechanism underlying the phenomenon has yet to be pinned down. When individuals explain an apparent inconsistency among a set of assertions, their explanation may sometimes rule out one of the assertions as false, and it may sometimes yield an idealized interpretation of a conditional generalization. For example, is the conditional assertion:

If a person is bitten by a viper then the person dies.

true or false? Given the further premise, say, that Viv was bitten by a viper, many people are likely to make the inference that Viv died. Yet, in answer to the preceding question, they might respond, “there are exceptions”. In other words, the conditional expresses a truth that holds by default, i.e., a counterexample does not overturn it. In contrast, individuals are likely to judge that the conditional assertion:

If a person's brain is deprived of oxygen for 1 hour then the person dies.

is true unequivocally. And they might not be prepared to believe a description of an apparent counterexample.

The results of our experiments corroborate the principle of resolution, which states that when individuals detect an inconsistency, they formulate explanations to restore consistency. They subsequently can interpret the inconsistent assertions according to the consequences of their explanations. As a result they may treat conditional assertions as tolerating exceptions, which they can explain by invoking disabling conditions (Cummins, 1995). For example, consider the following problem:

If a person pulls the trigger then the pistol fires.

Someone pulled the trigger but the pistol did not fire.

If, like many of our participants, you explain the inconsistency by believing that there were no bullets in the pistol's chamber, then you have qualified the first assertion. It is true only when bullets are in the pistol's chamber, i.e., an enabling condition is satisfied. When bullets are not in

the pistol's chamber, the conditional no longer holds (Johnson-Laird et al., 2004).

The present studies demonstrate the power and purpose of explanatory reasoning. Reasoners can draw inferences or answer the question ‘why not?’ without realizing that the set of assertions they reason about is inconsistent. The explanations they construct make it less likely that they will subsequently detect the inconsistency, because a plausible explanation serves to resolve the inconsistency. In some situations, this behavior is sensible and practical, because it allows individuals to revise their beliefs. In other situations, however, the behavior may account for striking lapses in reasoning. When a plausible explanation is available, regardless of whether it is true, reasoners may overlook glaring inconsistencies and behave in accordance with the explanation.

The present studies demonstrate the power and purpose of explanatory reasoning. Reasoners can draw inferences or answer the question ‘why not?’ without realizing that the set of assertions they reason about is inconsistent. The explanations they construct make it less likely that they will subsequently detect the inconsistency, because a plausible explanation serves to resolve the inconsistency. In some situations, this behavior is sensible and practical, because it allows individuals to revise their beliefs. In other situations, however, the behavior may account for striking lapses in reasoning. When a plausible explanation is available, regardless of whether it is true, reasoners may overlook glaring inconsistencies and behave in accordance with the explanation.

In sum, individuals who construct explanations of inconsistent assertions have difficulty evaluating those assertions as inconsistent. They do so erroneously, as the assertions remain in conflict with one another regardless of whether an explanation is available.

Appendix A

The assertions used in the experiments (generalizations were paired with consistent or inconsistent categorical assertions).

Domain	Generalization	Consistent Categorical	Inconsistent Categorical
Biology/physiology	If a person is bitten by a viper then they die	Someone did not die	Someone was bitten by a viper but did not die
Biology/physiology	If a person does regular aerobic exercises then that person strengthens his or her heart	Someone did not strengthen his heart	Someone did regular aerobic exercises but did not strengthen his or her heart
Mechanical	If a car's engine is tuned in the special way then its fuel consumption goes down	This car's fuel consumption did not go down	This car's engine was tuned in the special way but its fuel consumption did not go down
Mechanical	If graphite rods are inserted into a nuclear reactor, then its activity slows down	The nuclear reactor's activity did not slow down	Graphite rods were inserted into this nuclear reactor but its activity did not slow down
Mechanical	If the aperture on a camera is narrowed, then less light falls on the film	Less light did not fall on the film	The aperture on this camera was narrowed but less light did not fall on the film
Mechanical	If a person pulls the trigger then the pistol fires	The pistol did not fire	Someone pulled the trigger but the pistol did not fire
Natural	If a substance such as butter is heated then it melts	This piece of butter did not melt	This piece of butter was heated but it did not melt
Natural	If these two substances come into contact with one another then there is an explosion	There was no explosion	These two substances came into contact with one another but there was no explosion
Psychological	If someone is very kind then he or she is liked by others	Someone was not liked by others	Someone was very kind but was not liked by others
Psychological	If a person receives a heavy blow to the head then that person forgets some preceding events	Pat did not forget any preceding events	Pat received a heavy blow to the head but did not forget any preceding events
Social/economical	If people make too much noise at a party then the neighbors complain	The neighbors did not complain	People made too much noise at a party but the neighbors did not complain
Social/economical	If the banks cut interest rates then the economy increases	The economy did not increase	The banks cut interest rates but the economy did not increase

Why does explaining help learning? Insight from an explanation impairment effect

Joseph Jay Williams (joseph_williams@berkeley.edu)

Abstract

Engaging in explanation, even to oneself, can enhance learning. What underlies this effect? Williams & Lombrozo (in press) propose that explanation exerts *subsumptive constraints* on processing, driving learners to discover underlying patterns. A category-learning experiment demonstrates that explanation can enhance or impair learning depending on whether these constraints match the structure of the material being learned. Explaining can help learning when reliable patterns are present, but actually *impairs* learning when patterns are misleading. This *explanation impairment effect* is predicted by the subsumptive constraints account, but challenges alternative hypotheses according to which explaining helps learning by increasing task engagement through motivation, attention, or processing time. The findings have both theoretical and practical implications for learning and education.

Keywords: explanation; self-explanation; learning; constraints; impairment; category learning

Most teachers and tutors have had the experience of explaining a concept to another person and achieving greater understanding as a result. How does engaging in explanation generate this beneficial effect? This question's importance is underscored by the ubiquity of the phenomenon, and by converging evidence from cognitive science, education, and cognitive development confirming that explanation plays a significant role in learning.

Explanations have been implicated in theories of how conceptual knowledge is represented and how categories are learned (Carey, 1985; Gopnik & Meltzoff, 1997; Murphy & Medin, 1985). Education researchers have demonstrated that explaining has a potent effect on students' learning and fosters deep understanding that allows generalization to novel contexts (Chi et al, 1989; Chi et al, 1994). Research in cognitive development reveals even more profound effects (Wellman & Liu, 2006; Wellman, in press). Prompting children to explain can accelerate conceptual change, such as developing an understanding of number conservation (Siegler, 2002) and false belief (Amsterlaw & Wellman, 2006).

Many extant accounts of explanation's effects have emphasized the metacognitive benefits of explanation, such as prompting learners to identify and fill gaps in their knowledge (Chi et al, 1994; Chi, 2000). Explanations may also focus learners on uncovering the causes that underlie observed outcomes (Wellman & Liu, 2006), or may enhance learning by increasing task engagement in the form of

additional motivation, attention, or processing time (for discussion see Siegler, 2002).

Williams and Lombrozo (in press) propose and find empirical support for the *subsumptive constraints* account, according to which explaining exerts constraints on processing that drive people to interpret what they are learning in terms of underlying patterns and regularities. The account is motivated in part by "subsumption" and "unification" theories of explanation from philosophy (Friedman, 1974; Kitcher, 1981), which propose that good explanations show how what is being explained is an instance of a unifying pattern: explanations cite generalizations that *subsume* what is being explained. If the explanations learners generate must satisfy this constraint, explaining will drive learners to reason and construct beliefs in the service of identifying patterns. When useful regularities exist, the subsumptive constraints account predicts positive effects of explanation through the discovery of generalizations. However, this account also predicts that seeking explanations can *impair* learning if there is a mismatch between the subsumptive constraints and the material being learned—for example, in situations in which patterns are nonexistent or misleading.

This paper tests the prediction that such an *explanation impairment effect* exists. Investigating the conditions under which explanation *hurts* learning can inform theories which aim to specify the mechanisms by which explanation *helps* learning, analogous to the study of visual illusions in perception. The conditions under which human perception or cognition succeeds can be less informative than those under which it breaks down and produces errors because the latter serve as a window onto the cognitive machinery underlying perception, in the case of visual illusions, or cognition, in the case of explanation and learning.

In fact, examining explanation's detrimental effects can discriminate the subsumptive constraints account from current theories, which to date have not predicted explanation impairment effects. In particular, a *task engagement* account advocates that engaging in explanation leads learners to be more engaged with the learning task, through increased motivation, attention, or time, which should benefit learning in virtually all contexts. The task engagement account provides an intuitive explanation for the beneficial effects of explaining, positing mechanisms that extend to contexts beyond explanation.

Some studies argue that explanation has effects that go beyond task engagement, showing that its effects surpass

control conditions that promote motivation, attention and processing time (e.g. Amsterlaw & Wellman, 2006; Chi et al, 1994; Williams & Lombrozo, in press). However, these studies cannot rule out the possibility that explaining simply engages these mechanisms to a greater degree than the control tasks, highlighting the difficulty of discriminating between competing accounts solely on the basis of explanation's beneficial effects.

Identifying explanation impairment effects is also of clear practical importance, as educators must know when prompted or spontaneous explanation will be detrimental (see also Kuhn & Katz, 2009). Moreover, a deeper understanding of the process by which explaining helps learning can inform educational interventions. If explaining simply boosts students' engagement with the task of learning or increases metacognitive awareness, then it can be expected to produce an 'all-purpose' benefit for learning. But if it helps through more specific mechanisms, such as constraining learners to find underlying principles, then it will be more helpful in some contexts than in others. Its effect may depend on the content being learned, learners' prior knowledge, and other factors.

As in previous work (Williams & Lombrozo, in press), to investigate explanation our study utilizes category learning, which has been studied extensively and lends itself to carefully controlled artificial materials, permitting rigorous tests of competing accounts. Moreover, previous research supports the idea that explanation can and does play a role in category learning. When learners possess prior knowledge that explains why category features co-occur, they discover patterns underlying category membership and learn to classify items more quickly (Bott & Heit, 2000; Kaplan & Murphy, 2000; Murphy & Allopenna, 1994; Rehder & Ross, 2001; Wattenmaker, Dewey, Murphy, & Medin, 1986). There is also evidence that explanations influence the relative importance of features in learning novel categories (Lombrozo, 2009), and that explaining category membership can influence which features are used in categorization (Chin-Parker et al, 2006). Understanding how explaining influences category learning can thus shed light on the acquisition and representation of conceptual knowledge.

Experiment

Our category learning experiment tested the prediction that explanation can help or hinder learning, depending on the relationship between the material being explained and the subsumptive constraints imposed by explanation. Participants learned about two artificial categories of vehicles by classifying unlabeled items and then receiving feedback on their classification. After feedback and while studying the labeled item, participants in the *explain* condition were prompted to provide an explanation (out loud) for the item's category membership. In contrast, participants in the *classify* condition were free to use any study strategy and simply prompted to share what they were

thinking out loud.

The category structures supported at least two bases for categorization, which are illustrated in Table 1 (materials adapted from Kaplan & Murphy, 2000). First, each of the 5 items in each category had a unique color feature. Remembering the 10 idiosyncratic color features always permitted accurate classification of all 10 items. Second, each item contained a feature that was associated with the unifying thematic pattern of jungle vehicles (e.g., drives in jungles, lightly insulated) or arctic vehicles (e.g., drives on glaciers, heavily insulated). In the *reliable pattern* condition, the theme could also be used to perfectly classify 10 out of 10 items based on the presence of an arctic or jungle vehicle feature. However, in the *misleading pattern* condition, the theme led to accurate classification for only 8 out of 10 items, and incorrect classification for the remaining 2 items. The experiment therefore used a 2 (study condition: *explain* vs. *classify*) x 2 (pattern type: *reliable* vs. *misleading*) design.

Dax	Kez
Theme Feature (1)	
Made in Norway	Made in Africa
Has Treads	Has Wheels
Heavily Insulated	Lightly Insulated
Used in Mountain Climbing	Used on Safaris
Drives on Glaciers	Drives in Jungles
Idiosyncratic Color Feature (1)	
Blue	Cyan
Silver	Magenta
Purple	Olive
Red	Maroon
Yellow	Lime
Irrelevant Features (3)	
Two doors/four doors	
Manual transmission/Automatic transmission	
Vinyl seats/Cloth seats	

Table 1. Features associated with each category. Each category item contained one theme feature, one idiosyncratic color feature, and three irrelevant features that were not diagnostic of category membership.

The subsumptive constraints account predicts that engaging in explanation should drive participants to discover and utilize the theme whether it is reliable or misleading, as the theme is more subsuming than the idiosyncratic color features. However, use of the theme should help learning when it is reliable but perpetuate classification errors when it is misleading, thereby *impairing* learning. In contrast, if explanation helps learning by boosting task engagement through increased motivation, attention, or processing time, it should produce a benefit regardless of pattern type.

Method

Participants There were 240 participants (60 in each of four conditions) from the UC Berkeley community who participated for monetary reimbursement or course credit.

Materials Each category was represented by five items, for a total of ten items. Each item was described by a list of five features (see Table 1): one *idiosyncratic color* feature (e.g. blue), one *theme*-related feature from either the arctic vehicle theme (e.g. heavily insulated) or the jungle vehicle theme (e.g. lightly insulated), and three *irrelevant* features that (a) occurred equally often in each category and so were not diagnostic and (b) were unrelated to the arctic/jungle themes (e.g. two doors). The pairing of theme and idiosyncratic color features was randomly chosen in each block of 10 items. The idiosyncratic color features were perfectly predictive of category membership (10 out of 10 items). The theme-related features were perfectly predictive (10 out of 10) in the *reliable* pattern condition, but predictive for only 8 out of 10 items in the *misleading* pattern condition. In each block, a different pair of theme features was randomly chosen to be misleading.

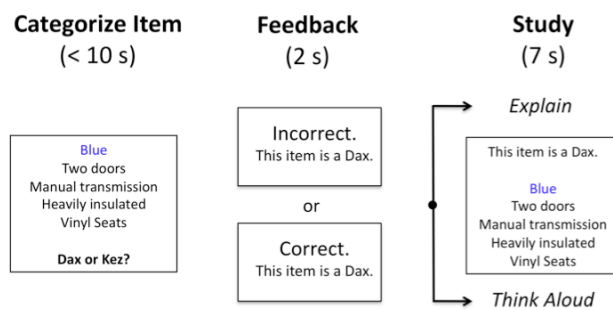

Figure 1: Structure of a single learning trial: item presentation and classification, feedback, and study.

Procedure The *reliable* and *misleading* conditions were run sequentially: data were first collected for 120 participants in the *misleading* pattern condition, then for 120 in the *reliable* condition. The *explain* and *classify* conditions were randomly interleaved, with participants randomly assigned to one or the other study condition. The experiment consisted of learning, test, and explicit report phases.

Learning phase. The structure of a learning trial is shown in Figure 1. On each learning trial an item description was presented as a list of five features, and participants had up to 10 seconds to categorize it as a “Dax” or a “Kez.” The idiosyncratic color feature was always displayed on the first line in the color it named (e.g. the feature “red” was shown in red). All other features were presented below it in a random order, and shown in black. Feedback was provided after categorization, and the item was shown with the correct category label for 7 seconds. During this study period, participants in the *explain* condition were prompted (for example) to “Explain why this might be a Dax,” and those in the *classify* condition were prompted with: “This item is a Dax. (Remember to say out loud whatever you are

thinking.)” In both conditions participants spoke out loud to a voice recorder.

A random ordering of all 10 items constituted a block. Participants completed the experiment when they reached the learning criterion of correctly categorizing all 10 items in a single block, or the maximum of 15 blocks.

Classification test. Each of the 10 *idiosyncratic* and 10 *theme* features was individually presented onscreen and participants categorized it as belonging to a Dax or Kez, rated confidence in their decision (from 1 to 10), and how typical the feature was of its chosen category (1 to 7).¹ Idiosyncratic and theme features were presented in separate, randomly ordered blocks.

Ten *conflict* items were then presented in which an idiosyncratic feature was pitted against a theme feature. Features were paired so that using the idiosyncratic color features to categorize would generate an opposite response to using the theme features.²

Explicit report. At the end of the experiment participants were asked what differences might exist between categories and about their strategy for categorization; responses were typed onscreen.

Results

Learning measures, discovered differences between categories, and accuracy in the classification test are shown in Table 2. Significant differences between the *explain* and *classify* conditions are bolded.

	Reliable Pattern		Misleading Pattern	
Measures	Explain	Classify	Explain	Classify
Learning				
Perc. Reaching Criterion	93%	88%	48%	75%
Mean No. Blocks	6.9	7.9	11.5	10.2
Discovered differences between categories (from explicit reports)				
Theme Features	62%	43%	28%	10%
Color Features	37%	57%	45%	70%
Classification test accuracy				
Theme Features	0.83	0.74	0.70	0.60
Color Features	0.78	0.83	0.81	0.89
Conflict Items	0.40	0.55	0.63	0.83

Table 2. Measures of learning, discovered differences between categories, and classification test accuracy, as a function of *study condition* and *pattern type*. Significant differences between study conditions are bolded.

¹ These measures mirrored the results on classification accuracy and are not discussed further.

² After the classification test in the *reliable* condition, eight *transfer theme* features that were related to the arctic/jungle themes but had not been studied in the learning phase were presented for individual categorization and in *transfer conflict* items. Performance on these items was similar to those with studied theme features and are not discussed further.

Measures of learning. The mean number of blocks to reach the learning criterion is shown in Table 2, and frequency histograms in Figure 2, as a function of *study condition* and *pattern type*. A 2 (study condition: *explain* vs. *classify*) x 2 (pattern type: *reliable* vs. *misleading*) ANOVA on the number of blocks to learn revealed a significant interaction: the effects of explanation differed depending on whether the pattern was reliable or misleading, $F(1, 236) = 6.33, p < 0.05$.³

Figure 1: Mean number of blocks to reach the learning criterion of correctly categorizing all 10 items in a block, as a function of *study condition* and *pattern type*. Maximum number of blocks is 15.

Figure 2: Frequency histogram of the number of blocks to reach learning criterion, as a function of *study condition* and *pattern type*. Bin size is three blocks.

The main effect of *pattern type* was also significant, $F(1, 236) = 44.49, p < 0.05$, suggesting that the *misleading* pattern slowed learning, although this interpretation should be qualified because participants were not randomly assigned to these two conditions. When the thematic pattern was reliable, there was a non-significant trend for the *explain* group to learn faster than the *classify* group, $t(118) = 1.43, p = 0.16$.⁴ When it was misleading, the *explain* group took *longer* to learn, $t(118) = 2.11, p < 0.05$. In fact, the number of participants who learned how to classify (reached the learning criterion of correctly categorizing one

³ To address concerns about non-normality, we sorted the number of blocks to learning into five bins of three blocks (as in the histogram in Figure 1) and performed an ordinal regression with *study condition* and *pattern type* as factors. This analysis also found a significant interaction.

⁴ To address concerns about non-normality, all *t*-tests reported in this paper were checked with non-parametric Mann-Whitney U tests, which generated the same conclusions.

block of 10 items) was lower in the *explain* condition than the *classify* condition, $\chi^2(1) = 5.4, p < 0.05$. As predicted by the subsumptive constraints account, explanation's effects interacted with the structure of what was being learned, and actually *impaired* learning when a misleading pattern was present.

Discovered differences between categories. To test whether explaining exerted its effects through discovery of the theme, participants' explicit reports about the differences between categories and their categorization strategy were coded for mention of the theme-related and color features (see Fig. 3).⁵ Participants in the *explain* condition more often reported theme features as a difference between categories than those in the *classify* condition, whether the pattern was reliable, $\chi^2(1) = 4.04, p < 0.05$, or misleading, $\chi^2(1) = 9.79, p < 0.05$. Participants in the *classify* condition more often reported color features (*reliable* pattern: $\chi^2(1) = 4.82, p < 0.05$; *misleading* pattern: $\chi^2(1) = 4.48, p < 0.05$). Explaining increased learning of theme-related category differences and decreased learning of theme-unrelated (color) features.

Figure 3: Proportion of participants whose explicit reports revealed discovery that theme and color features differed across categories, as a function of *study condition* and *pattern type*.

Classification test results. Accuracy in classifying theme and color features presented in Figure 4 shows that the *explain* and *classify* groups' different knowledge of theme versus color features also manifested itself in categorization performance. A 2 (study condition: *explain* vs. *classify*) x 2 (feature type: *theme* vs. *color*) repeated measures ANOVA on accuracy revealed a significant interaction for both the *reliable*, $F(1, 118) = 3.96, p < 0.05$, and *misleading*, $F(1, 118) = 9.85, p < 0.05$, conditions. Participants who explained learned which category the theme features were associated with better than those who classified, with the reverse pattern for color features.

The *conflict* items pitted an idiosyncratic color feature against a theme feature in a categorization decision, and the proportion of items categorized in accordance with the color features was defined as the *conflict score*. This measure was

⁵ Agreement between two independent coders was 84% and reported results are for the first coder.

larger for the *classify* condition than the *explain* condition, whether the pattern was reliable, $t(118) = 2.00$, $p < 0.05$, or misleading, $t(118) = 3.42$, $p < 0.05$.

Discussion

While most past research has documented explanation's positive effects, we found an explanation impairment effect: when a misleading pattern was present, explaining category membership impaired learning to categorize. Although counterintuitive, this impairment confirms a prediction of the subsumptive constraints account (Williams & Lombrozo, in press), according to which explaining exerts constraints that drive learners to interpret what they are learning in terms of underlying patterns.

The experiment provides evidence for an interaction between the subsumptive constraints exerted by explanation and the structure of the category. When compared to merely thinking aloud during study, explaining category membership further drove participants to rely on a unifying thematic pattern in categorization rather than use idiosyncratic features, even though both conditions engaged in the demanding task of classification learning with feedback. This produced (nonsignificant) positive consequences for learning when the thematic pattern was reliable, and (significant) negative consequences when it was misleading. Our explanation impairment effect provides evidence against a task engagement account of why explaining helps learning: if explaining merely increases motivation, attention, or processing time, it should not have impaired learning when the pattern was misleading.

A critical reader might have the intuition that the results of this experiment are unsurprising: prompting participants to explain tells them to find a pattern, which helps or harms learning depending on its existence. However, no previous account of explanation and learning has explicitly proposed that explaining constrains people to find patterns or predicted an impairment, instead focusing on metacognitive monitoring, identifying gaps in knowledge, or motivation and attention. A prompt to explain could have made participants attend more to their errors, justify individual categorizations by appeal to the salient and objective color features, or increased motivation to find a reliable basis for categorization. The subsumptive constraints account motivates our specific design and accounts for *why* people

feel compelled to seek underlying patterns in response to explanation prompts.

Another criticism could be that this impairment effect is an artifact of an artificial lab task involving a “misleading” theme. However, our goal was precisely to characterize the conditions under which explanation's subsumptive constraints are detrimental. The finding that eliciting explanations impairs learning in any context is novel and consequential for current theories. Moreover, real-world cases involving misleading regularities and suspicious coincidences abound (Griffiths & Tenenbaum, 2007) and provide a promising direction for examining this effect outside the lab. It should be noted that *deeper processing* was not considered under the umbrella of task engagement. We do not see deeper processing as a specific competing account (like motivation) because we interpret the subsumptive constraints account as a specific proposal about the *nature* of the deeper processing explanation evokes.

Evidence for the subsumptive constraints account over the task engagement account has potential implications for education. If explaining does not merely produce an ‘all-purpose’ enhancement but exerts particular constraints on learning, more research is needed to understand the contexts in which self-explanation interventions are most effective and when they may be detrimental. First, one important question is how the explanation impairment effect varies with the quality of the explanatory pattern, that is, how misleading it is. In our misleading condition, the themes were misleading but only *partially* so: Classifying on the basis of theme features alone could result in moderately good accuracy (80%). The size of the learning impairment may have increased if the themes were even more misleading, but it is equally plausible that it would have *decreased* because subjects might choose to discard use of an explanatory pattern that is yielding poor performance (Murphy & Kaplan, 2000). The extent to which explaining may encourage learners to persevere on a very low quality explanatory pattern remains to be determined.

Second, it is also important to assess the benefits of explanation *relative* to alternative learning activities, such as elaboration, direct instruction, or analogical comparison, and to examine how their complementary strengths and limitations can be combined. Williams and Lombrozo (in press) found that explaining drove discovery of underlying patterns but resulted in *worse* memory for details than describing. This is problematic because elaborating information in memory and receiving direct instruction may be more valuable at an early stage of learning. The subsumptive constraints account suggests that explaining will not necessarily be useful throughout a study episode (as would be predicted if it promoted task engagement), but will have its strongest effects when learners have already acquired factual background knowledge and need to discover and understand principles that underlie these facts. Successful demonstrations of the self-explanation effect may involve precisely such cases.

Other interesting directions for future research include the role of explanation in generating beliefs about both correct and misconceived underlying principles, in the effects of anomalies in belief revision (Chi, 2000), and in the deployment of prior knowledge (Chi et al, 1994; Williams & Lombrozo, in press). Such research will also be practically important for avoiding classroom manifestations of explanation impairment effects. For example, Kuhn and Katz (2009) suggested that requests for explanations on one task led children to later justify their knowledge of causal relationships by explaining how the relationships could exist, rather than citing observed evidence.

This is the first experiment to examine category learning through classification and feedback with (and without) additional prompts to explain. The learning differences generated by explaining suggest that category learning may involve processes beyond those that reduce immediate classification error. Bott et al. (2007) report that people learned about a thematic pattern underlying category membership (the same used in this experiment) in the *absence* of classification errors – a surprising violation of the classic *blocking effect* – while in the current experiment explaining drove learning about this pattern *despite* classification errors. A deeper understanding of these and other learning phenomena may be gained by considering the contribution of both classification error *and* the construction of knowledge that satisfies the constraints of explanation, whether it is prompted or spontaneous. For example, participants' spontaneous explanations may shed light on how prior knowledge is deployed, and when category learning is driven by explicit rule use versus bottom-up exemplar-based processing that reduces classification error.

The current research emphasizes the importance of subsumptive constraints in explanation's effects on learning, and demonstrates the value of explanation impairment effects for identifying the mechanisms by which explaining enhances learning. We are beginning to explore the relationship between prior knowledge and explanation (Williams & Lombrozo, in press (b)) and expect further investigation, in category learning and other learning contexts, to reveal a complex interaction between the constraints imposed by explanation, prior knowledge, and the structure of what is being explained.

Explanation Constrains Learning, and Prior Knowledge Constrains Explanation

Joseph Jay Williams (joseph_williams@berkeley.edu)

Tania Lombrozo (lombrozo@berkeley.edu)

Department of Psychology, University of California, Berkeley

Abstract

A great deal of research has demonstrated that learning is influenced by the learner's prior background knowledge (e.g. Murphy, 2002; Keil, 1990), but little is known about the processes by which prior knowledge is deployed. We explore the role of explanation in deploying prior knowledge by examining the joint effects of eliciting explanations and providing prior knowledge in a task where each should aid learning. Three hypotheses are considered: that explanation and prior knowledge have independent and additive effects on learning, that their joint effects on learning are subadditive, and that their effects are superadditive. A category learning experiment finds evidence for a superadditive effect: explaining drives the discovery of regularities, while prior knowledge constrains which regularities learners discover. This is consistent with an account of explanation's effects on learning proposed in Williams & Lombrozo (in press).

Keywords: explanation; self-explanation; learning; prior knowledge; constraints; generalization; category learning

What processes underlie the critical capacity to acquire information and generalize to future situations? The topic of learning is one with a long history in cognitive science and development, and with important practical applications to education. While much research in cognitive science has focused on mechanisms that are independent of the specific knowledge people possess about a domain, studies have repeatedly and reliably demonstrated that prior background knowledge has profound effects on learning. This work suggests that characterizing how prior knowledge influences learning is a key issue for theories of learning.

Effects of prior knowledge have been particularly well characterized in the context of category learning. Prior knowledge that relates the features of a category allows learners to discover an underlying thematic pattern and learn the category more quickly (e.g., Murphy & Allopenna, 1994), and prior knowledge can also influence the construction of features in a way that supports classification (Wisniewski & Medin, 1994). Most broadly, prior knowledge has been seen as helpful because it exerts constraints on the process of knowledge acquisition (Keil, 1990), such as reducing the set of hypotheses learners entertain (Tenenbaum, Griffiths & Kemp, 2006). Most proposed mechanisms for category learning – such as encoding of exemplars, prototype formation, and other associative learning mechanisms – do not capture effects of prior knowledge (see Murphy, 2002), although more recent computational models attempt to incorporate such effects (e.g., Rehder & Murphy, 2003; Tenenbaum et al, 2006).

One possibility is that generating *explanations* plays a role in the effects of prior knowledge on learning. In this paper we consider the relationship between eliciting

explanations and effects of prior knowledge. Engaging in explanation during study has been shown to promote learning and generalization in a range of knowledge-rich domains, for both adults (e.g. Chi, et al, 1994) and young children (for a review see Wellman & Liu, 2006). The process of “self-explaining” may be effective in part because explaining integrates new information with prior knowledge (Chi et al, 1994).

Previous work on eliciting explanations has considered the role of prior knowledge in mediating learning gains, but with mixed results. Some studies find that eliciting explanations has the greatest benefit for learners with low levels of prior domain-knowledge (e.g., Renkl et al., 1998), and that self-explanation training may be more useful for learners with low domain knowledge (McNamara, 2004). Other studies have not found a relationship between pre-test performance and the magnitude of post-test gains (e.g. Chi & VanLehn, 1991; Chi et al., 1994; Rittle-Johnson, 2006), although there is suggestive evidence that learners with more background produce higher-quality self-explanations (Renkl, 1997; Best, Ozuru, & McNamara, 2004).

Williams and Lombrozo (in press) propose a *subsumptive constraints* account of the role of explanation in learning that suggests how explanation and prior knowledge might interact to guide learning. The subsumptive constraints account is inspired by theories of explanation in philosophy which propose that explanations show how what is being explained is an instance of (subsumed by) a general pattern. If the explanations learners generate must satisfy this constraint, then attempting to explain should drive learners to discover regularities and underlying principles that are present in the material being explained. In support of this proposal, Williams and Lombrozo (in press) found that participants who explained items' category membership were more likely to discover a subtle regularity underlying category membership than participants who described category items, thought aloud, or engaged in free study.

The subsumptive constraints account suggests two ways in which explanation and prior knowledge could interact. First, explanations could determine *which prior knowledge* is deployed. According to the subsumptive constraints account, learners should invoke beliefs that demonstrate how what is being explained can be subsumed under general patterns. Second, the account suggests that prior knowledge could provide a source of constraint on *which subsuming generalizations* are considered explanatory. Consider the task of learning about the categories “psychology lecturer” and “psychology student” from the limited observation of a single lecture. The underlying bases for the categories could be that a psychology student is seated while a psychology

lecturer is standing, but this generalization seems like an implausible basis – and a poor explanation – for category membership. Distinguishing law-like generalizations from accidental generalizations is notoriously difficult (for discussion in philosophy see Carroll, 2008; and in psychology, Kalish, 2002), but prior knowledge may provide one source of constraint on which patterns are seen as explanatory, therefore determining which patterns participants are more likely to discover and employ in seeking explanations.

To investigate the relationship between explanation and prior knowledge, we restrict our focus to cases where explanation and prior knowledge would be expected to help learning, and consider whether their joint effects on learning are independent and additive, subadditive (less than the sum of their independent effects), or superadditive (greater than the sum of their independent effects).¹

The proposed experiment uses a category-learning task in which there are patterns underlying category membership, and an explanation manipulation (explain vs. free study) is crossed with a prior knowledge manipulation (knowledge relevant to an underlying pattern is provided vs. no additional knowledge). The experiment aims to discriminate three alternative hypotheses about the joint effects of explanation and prior knowledge on learning.

One possibility is that explanation and prior knowledge have independent and additive effects. This hypothesis is a sensible default in the absence of evidence that eliciting explanations and prior knowledge interact, and no specific accounts have been proposed as to how prior knowledge might be deployed through explaining. Independent effects of explanations and prior knowledge would be likely if explaining helps learning through mechanisms that do not interact with those by which prior knowledge plays a role. For example, explaining might increase attention and motivation, while prior knowledge might independently constrain the hypotheses under consideration.

A second possibility is that prior knowledge and explanation have subadditive benefits. This could occur if the effects of explanation and prior knowledge are achieved through common mechanisms. For example, prompts to explain and the provision of prior knowledge may both guide learners to seek meaningful regularities in category structure. Explaining when prior knowledge is already available may therefore have little benefit above simply possessing prior knowledge.

¹ Whether explanation and prior knowledge help or hurt learning depends on the nature of what is being learned. Prior beliefs about a domain may be incorrect, or explaining may drive learners to unreliable patterns (Williams & Lombrozo, in press; Williams, Lombrozo, & Rehder, in press). In this paper we do not aim to investigate interactions of explanation and prior knowledge in settings where either will individually impair learning. In many real-world cases and educational contexts, both explaining and prior knowledge would be expected to benefit learning – for example, if there are regularities to discover and prior knowledge is correct – and this is the kind of setting we explore.

A final possibility is a superadditive effect of explanation and prior knowledge, such that explanation and prior knowledge interact in a way that produces a learning benefit that exceeds either of their independent effects. This could occur if explanations deploy prior knowledge that might otherwise be inert, or if prior knowledge influences the generation of explanations in a way that fosters more effective learning. The subsumptive constraints account suggests one way this might work: attempting to generate explanations (e.g. for category membership) could invoke prior beliefs in order to supply candidate subsuming patterns, and prior beliefs could simultaneously constrain which candidate subsuming regularities are deemed explanatory.

Experiment

There are many ways that prior knowledge could impact learning, and accordingly a multitude of ways in which prior knowledge could be manipulated. In this experiment, we provide category labels intended to activate prior knowledge relevant to which features might underlie membership.

We used eight category items, shown in Figure 1. There were two rules that could be used to categorize: an *antenna rule* (shorter left vs shorter right antenna) and a *foot rule* (pointy vs flat feet). The *prior knowledge* variable was operationalized by providing uninformative category labels that were neutral with respect to the two rules (*low* prior knowledge condition: items labeled as Glorp and Drent robots) versus labels that could be related to the foot rule (*high* prior knowledge condition: labeled as Outdoor and Indoor robots). The motivation for these rules was that participants' knowledge might account for Outdoor robots having pointy feet and Indoor robots having flat feet, but not for why Outdoor or Indoor robots would have shorter left or right antennae.²

While all participants were informed that they would later be tested on their ability to categorize robots, those in the *explain* condition were prompted to explain the category membership of the Glorp and Drent (or Indoor & Outdoor) robots, while those in the *free study* condition were allowed to study the robots without specific prompts, yielding a *task* variable with two levels (explain vs. free study).

The two (*Task*: Explain vs. Free Study) x two (*Prior knowledge*: Low vs. High) design therefore allowed for a test of whether the joint effect of explanation and prior knowledge on learning a basis for categorization is independent and additive, subadditive, or superadditive.

² Participants could have drawn on prior knowledge to explain why antenna length was related to being Outdoor/Indoor, or have had beliefs that conflicted with, for example, Outdoor robots having pointy feet, but the significant difference between conditions suggests this was not true for the majority of participants.

Participants

Two hundred and forty (60 in each condition) UC Berkeley students participated for course credit or monetary reimbursement (161 in the lab, 79 online).

Materials

The task involved *study items*, *test items*, and *transfer items*.

Study items. There were two categories of alien robots; the image participants saw in the *high prior knowledge* condition is displayed in Figure 1. The category labels were chosen based on whether the condition was *low* or *high* prior knowledge: the robots were labeled as *Glorps* and *Drents* in the low prior knowledge condition, and as *Indoor* and *Outdoor* robots in the high prior knowledge condition.

Each robot was composed of six elements: left color (blue, green, red, yellow), right color (brown, cyan, grey, pink), body shape (square, circular), left antenna length (short, long), right antenna length (short, long), and foot shape (eight different geometric shapes). Color and body shape were uncorrelated with category membership: every right and left color occurred exactly once per category, and each category had two robots with square bodies and two with circular bodies. All four Outdoor (Glorp) robots had a shorter left antenna and all four Indoor (Drent) robots had a shorter right antenna. Although each robot had a unique geometric shape for feet, there was a subtle regularity across categories: all four Outdoor (Glorp) robots had pointy feet while all four Indoor (Drent) robots had flat feet. For simplicity, from this point on we refer to the robots in each category by their high prior knowledge label (*Outdoor/Indoor* robots).

Figure 1: Study items.

This category structure supported at least three distinct bases for categorization. First, participants might not draw any generalizations about category membership, and instead categorize new items on the basis of their similarity to individual study items, where similarity is measured by tallying the number of shared features across items. We call this *item similarity*. Alternatively, participants could notice the antenna feature (Outdoor robots had shorter left antennae, Indoor robots shorter right antennae) and use it as a categorization rule: this is termed the *antenna rule*. Finally, participants could discover that although each robot had a unique geometric shape for feet, there was a subtle

regularity termed the *foot rule*: Outdoor robots had pointy feet and Indoor robots had flat feet.

Test probe items. Three types of test item were constructed by taking novel combinations of the features used for the study items. Each type yielded a categorization judgment (of Outdoor/Indoor) that was diagnostic of one basis for categorization (item similarity, antenna rule, foot rule), by pitting that basis for categorization against the other two. For example, categorizing a yellow/gray robot with a shorter right antenna and pointy feet as an Indoor robot would suggest a participant relied on the antenna rule. We call these item similarity probes (three items), antenna rule probes (three items), and foot rule probes (four items). There was one extra item for which all three bases gave the same response.

Transfer Items. These four items used completely novel foot shapes to distinguish participants who genuinely drew an abstract generalization concerning “pointy” versus “flat” feet from those who simply recognized the importance of particular foot shapes. For each item, the foot rule was pitted against item similarity and the antenna rule.

Procedure

The task involved a study phase, a categorization phase, and additional measures designed to probe what participants had learned about the categories.

Study phase. Participants were instructed that they would be looking at two types of robots on the planet Zarn: Outdoor (Glorp) and Indoor (Drent) robots, with labels chosen based on being in the *high* or *low* prior knowledge condition. They were also informed that they would later be tested on their ability to remember the robots they had seen, and their ability to decide whether robots were Outdoor (Glorp) or Indoor (Drent) robots.

After advancing the instruction screen they saw a color image displaying the eight study items in a scrambled order, with each robot numbered 1 through 8 and category membership clearly indicated for each robot (the actual image for the high prior knowledge condition is shown in Figure 1). In both conditions participants were informed that they were seeing eight robots on ZARN and that the picture would be onscreen for two minutes. Participants in the *explain* condition were told “Explain why robots 1, 2, 3 & 4 might be Outdoor (Glorp) robots, and explain why robots 5, 6, 7 & 8 might be Indoor (Drent) robots.”³ Participants typed their explanations into a box onscreen. Those in the *free study* condition were told “Robots 1, 2, 3 & 4 are Outdoor robots, and robots 5, 6, 7 & 8 are Indoor robots.” The image was onscreen for exactly two minutes and then the screen automatically advanced.

Categorization phase. The eleven test items were presented in random order, followed by the four transfer items in random order, with participants categorizing each robot as Outdoor (Glorp) or Indoor (Drent).

³ In all quoted prompts, the alternative labels (Glorp/Drent instead of Outdoor/Indoor) are displayed in parentheses, but only one set of labels was actually displayed.

Probability of pattern. To assess participants' belief about the presence of a defining feature or rule, they were asked: "What do you think the chances are that there is one single feature that underlies whether a robot is Outdoor (Glorp) or Indoor (Drent) - a single feature that could be used to classify ALL robots?"

Category differences. Participants were explicitly asked "Were there any noticeable differences between Outdoor (Glorp) and Indoor (Drent) robots? If you think there were, please be SPECIFIC about what you thought the differences were."

*Ranking of question informativeness.*⁴

Features used for categorization. Participants were asked which features they used in categorizing robots. There was a separate line to enter features of Outdoor (Glorp) robots and features of Indoor (Drent) robots.⁵

Antenna Informativeness. Participants were asked if they could tell whether a robot was Outdoor (Glorp) or Indoor (Drent) by looking at its antenna, and if they could, to state what the difference was.

*Antenna classification.*⁴

Explanation self-report. All participants were asked if they were trying to explain the category membership of robots while the image of all 8 robots was onscreen.

Previous exposure. Participants were asked if they had seen the robots before, or already done an experiment using the materials.⁶

Foot informativeness. Participants were asked if they could tell what category a robot belonged to by looking at its feet, and if they could, to state what the difference was.

Results

In the interests of space, we do not report all dependent measures, especially as many support the same conclusions.

Each of the three kinds of test probe items pitted one basis for categorization against the other two, so participants' patterns of categorization over the full set was used to determine whether their basis for categorization was most consistent with 'item similarity', the 'antenna rule', or the 'foot rule', with ties coded as 'other'. The proportion of participants using each basis is shown in Table 1, as a function of condition. In addition to examining the basis participants' used, direct measures of *antenna rule discovery* and *foot rule discovery* were also coded from participants' responses to questions about whether they could classify robots based only on antenna or feet. These generally mirrored the findings on rule use. Figure 2 shows the proportion of participants who discovered the foot and

antenna rules and Figure 3 shows the proportion that discovered a rule (antenna or foot), as a function of condition.

A log-linear analysis on *task* (explain vs. free study), *prior knowledge* (low vs. high), and *foot rule use* (used vs. did not use foot rule, as computed from inferred basis) revealed a significant three-way interaction, $\chi^2(1) = 7.27, p < 0.01$, while that for *foot rule discovery* was marginal, $\chi^2(1) = 3.16, p = 0.08$. Explanation and prior knowledge had a joint, superadditive effect on use of the foot rule. This interaction was driven by privileged use of the foot rule by participants who explained *and* had high prior knowledge (the explain-high PK condition): the combination of explaining and relevant prior knowledge exceeded the effects of each factor on its own. In fact, in the absence of explaining (i.e., the free study conditions) prior knowledge did not have an effect on foot rule use, $\chi^2(1) = 0.06, p = 0.81$.

	Foot Rule	Antenna Rule	Item Similarity	Other
Explain- Low PK	0.32	0.60	0.05	0.03
Explain- High PK	0.67	0.25	0.06	0.02
Free Study- Low PK	0.35	0.22	0.38	0.05
Free Study- High PK	0.35	0.20	0.40	0.05

Table 1: Proportion of participants using each basis for categorization, by condition.

Figure 2: Proportion of participants who discovered the foot and antenna rules, by condition.

Figure 3: Proportion of participants who discovered a rule (antenna or foot), by condition.

There was also a three-way interaction between task, prior knowledge and both *antenna rule use*, $\chi^2(1) = 5.48, p < 0.05$, and *antenna rule discovery*, $\chi^2(1) = 5.40, p < 0.05$, driven by the explain-low PK condition. Overall, use of a

⁴ This question asked participants to rank how informative different questions would be about membership, but is redundant with other reported measures and so omitted to save space.

⁵ Some participants' categorization responses were reverse coded, if their explicit reports about the differences between categories or features used to categorize revealed they had reversed category labels, such as stating that outdoor robots had flat feet when in fact the opposite was true.

⁶ Those who indicated previous participation were excluded.

rule (either antenna or foot) was higher for explainers (interaction between task and whether a rule was used, $\chi^2(1) = 42.76, p < 0.001$, while reliance on *item similarity* was higher in the free study condition (interaction of task and item similarity use, $\chi^2(1) = 41.90, p < 0.001$). Interestingly, overall rule discovery was actually higher in the explain-low PK than explain-high PK condition, $\chi^2(1) = 4.09, p < 0.05$.

Discussion

In the context of category learning, we found that explanation and prior knowledge interacted, producing an effect on the discovery of a regularity related to prior knowledge that surpassed the independent effects of explanation or prior knowledge alone. This finding challenges the possibility that explaining and prior knowledge influence learning independently. Since a subadditive effect was not found, it also provides evidence against the hypothesis that explanation and prior knowledge draw on the same mechanisms or resources in promoting learning. The best explanation for the current findings is that explanation and prior knowledge influence learning by neither independent nor identical means, but have an interactive relationship.

This relationship can be understood in terms of the subsumptive constraints account of explanation and learning (Williams & Lombrozo, in press). If explaining exerts the constraint that learners generate explanations that show how what is being explained is subsumed by a general pattern, prior knowledge can provide constraints on which patterns support reasonable explanations. In the current experiment, explaining why items were Outdoor and Indoor robots drew on prior knowledge that constrained learners to explain membership in terms of the foot rule rather than a rule concerning antenna length. Not all subsuming patterns are equally explanatory; patterns must also make sense in light of prior knowledge.

An alternative account could instead implicate attentional mechanisms: Explaining promotes attention to items while prior knowledge exerts constraints on which item features are the focus of this attention, leading to an interactive effect on discovery of the foot rule. However, prior knowledge did not focus attention on the foot rule in the free study conditions. Moreover, Williams et al (in press) provide evidence that explaining can actually *impair* learning, suggesting that its effects go beyond increasing attention to exerting subsumptive constraints. If explaining influences attention, the evidence suggests it is not a generalized attentional boost to encode item details or monitor more information, but through constraints to attend to underlying patterns, which we would endorse as consistent with the subsumptive constraints account.

While we report a superadditive effect of explanation and prior knowledge, there are likely contexts in which different kinds of interactions would obtain. For example, it is known that the learning benefits of explanations (Williams et al, in press) and of prior knowledge (Wattenmaker et al, 1986)

depend on the relationship between the constraints imposed by explanation or prior knowledge and the structure of the material being learned. If explanation exerts inappropriate constraints or prior knowledge is incorrect, their joint effects will be markedly different. Also, in cases where explanation automatically recruits prior knowledge or prior knowledge produces spontaneous explanation, their joint effect may appear to be independent or subadditive. The goal in the current work was to take a first and necessarily circumscribed step towards the ambitious goal of understanding the interactions between explanation and prior knowledge in learning.

Despite these limitations, the findings have implications for education and suggest interesting directions for applied research. Providing evidence that explaining invokes and is influenced by prior knowledge helps to explain why it has such powerful effects on learning. Explaining drives the discovery of regularities *and* guides learners to interpret what they are learning in terms of what they already know: an activity students may not engage in spontaneously even if they possess relevant prior knowledge.

If explaining promotes consistency with prior knowledge, its benefits may depend on having acquired correct and useful prior knowledge. Learning strategies that focus on acquiring background knowledge may be a necessary precursor to activities that involve explanation, and failures of explanation may suggest the need to develop background knowledge. The dangers inherent in incorrect prior knowledge are also brought into clear relief: effects of explaining may be reduced by incorrect or inappropriate prior knowledge, and may even be harmful. Examining the relationship between explanation and prior knowledge might therefore be one way to understand robust misconceptions and difficulties with conceptual change.

The current findings speak to the possibility that explanation is a mechanism by which prior knowledge is brought to bear in learning. In this experimental context, simply providing prior knowledge was insufficient to support learning: the high and low prior knowledge free study conditions did not differ in rule discovery. It may be that when learners explain and must satisfy subsumptive constraints, prior knowledge is accessed and deployed to inform which patterns are subsuming, so that explaining is a mechanism by which prior knowledge influences learning. Further research could explore what kinds of prior knowledge explaining might deploy, such as logical or causal inferences versus information stored in memory. Another issue concerns the amount of prior knowledge necessary for these interactive effects. The current experiments compared just two levels of prior knowledge, although prior knowledge spans a much broader continuum.

If explaining deploys prior knowledge in learning, it may be that spontaneously explaining category membership plays a role in knowledge effects on category learning. This possibility is bolstered by demonstrations that explaining increases use of features that are unified by prior knowledge into thematic patterns (Chin-Parker et al, 2006; Williams et

al, in press). Moreover, Wisniewski & Medin (1994) reported that activating prior knowledge through meaningful category labels drove the construction of novel and abstract features. The effects they report may in fact be best understood in terms of an interaction between prior knowledge and explanations for category membership, which the subsumptive constraints account can help explain.

Explanation's effects on category learning warrant an examination of the relationship between explanation-based learning and existing models of category learning. While the subsumptive constraints account aligns naturally with rule-based models (e.g. Nosofsky et al, 1994), the reported interaction shows how both our account and rule-based models need to be extended to account for effects of prior knowledge on *which* rules count as good bases for category membership. More broadly, while representations such as exemplars play one role in learning about a category, the effect of explanation may be to construct more abstract representations that are consistent with general prior knowledge about a category, such as its origin or function.

The current work suggests a number of future directions. Do different types of prior knowledge differentially support learning, such as prior knowledge about causal mechanisms vs. functions? When does prior knowledge help because it supplies candidate patterns that can subsume observations, versus help because it informs which patterns are subsuming? Given that subsumption and consistency with prior knowledge both constrain learning, how do they trade off? These and further questions await future research.

Acknowledgments

We thank Ania Jarosewicz and Preeti Talwai for collecting data and providing other assistance and feedback on this project. This work was partially supported by the McDonnell Foundation Collaborative Initiative on Causal Learning, and JJW was supported by an NSERC post-graduate scholarship.

Symposium summary

A broad range of findings across the cognitive sciences has emerged revealing surprising flexibility and dynamic flux in a large range of cognitive domains. These include exciting new discoveries of neuroplasticity well into adulthood, discoveries of great cognitive variability as a function of the statistical properties of one's environment (from patterns in natural languages, to those in embodied experience), and discoveries of the surprisingly dynamic microstructure of cognition. Do such findings demonstrate that many fundamental aspects of cognition are indeed quite flexible? Or does finding that some aspect of cognition is flexible mean that it is therefore not fundamental? Or is flux the only truly fundamental thing about cognition in the first place? The talks in this symposium will speak to these questions from a variety of perspectives (incorporating ideas from development, neuroscience, computational insights, and cross-cultural approaches), and help us clarify our thinking about what such findings mean.

Variability and Specificity in Human Neuroplasticity: Flux is Fundamental!

Helen Neville and Christina Karns
Brain Development Lab, University of Oregon

The brain is in a state of constant change. In fact, one might argue that the reason some systems have such short critical periods is the constant pressure from competing systems in a rapidly changing brain. Different brain systems and related functions display markedly different degrees or 'profiles' of neuroplasticity in human development. Some systems are strongly determined and are not altered even when experience has been very different. Others are highly modifiable by experience and dependent on experience but

only during particular time periods. There are several different such sensitive periods, even within a domain of processing. A third 'plasticity profile' is demonstrated by those neural systems that remain capable of change by experience throughout life. Neuroplasticity is a double-edged sword that permits both enhanceability and vulnerability. These findings contribute to a basic understanding of the nature, mechanisms and constraints of human brain plasticity, a fundamental player in all aspect of cognition. In addition, they can contribute information of practical significance in the design and implementation of educational programs.

Flexibility does not imply flux

Arthur B. Markman
University of Texas

Cognitive Science often focuses on the core aspects of cognitive processing that are common across individuals. Indeed, we often treat adaptability to context and variability across individuals as statistical error. Periodically, however, this variability comes into focus. This focus on variability is typically accompanied by calls for a fundamentally different way of characterizing cognitive processing such as dynamical systems, situated cognition, or embodied cognition. That is, there is an implicit assumption that the fluidity of cognitive processing is somehow incompatible with many of the core explanatory constructs in the field. I argue that variability and flexibility in cognitive processing is crucial for us to understand, but that they are explicable without having to give up most of the traditional representational and processing assumptions of cognitive science. I illustrate this point with examples from analogical reasoning, decision making, and motivation.

Surfing the Standing Wave of Cognition

Michael J. Spivey
University of California at Merced

Many of the most noticeable properties of cognition appear to be stable structures, concepts and categories in the mind that seem to function like static representations of things out in the world. This appearance of stability stands out in sharp relief at the time scale of several seconds, during momentary introspection or in a paper-and-pencil experiment. At finer and coarser time scales, there are dramatic patterns of change in those same cognitive structures, during neural processing and real-time responses and during long-term task performance and learning. This endemic property of flux that both underlies and overlays our subjectively stable mental entities has become the poster child for a theoretical framework in cognitive science calling itself the dynamical systems account of cognition (e.g., Chemero, 2009; Elman et al., 1996; Kelso, 1996; Port & Van Gelder, 1996; Spivey, 2007; Thelen & Smith, 1994; Ward, 2002). In this framework, the mental entities that appear as stable structures in cognition are much like standing waves which, if not examined at multiple time scales, cannot be properly understood. Essentially, even those things that appear stable in cognition are actually seen to be in flux when carefully analyzed. Therefore, if being in flux somehow prevents a property from being fundamental, then nothing in cognition is fundamental.

Solid as a rock, smart as a rock?

Lera Boroditsky
Stanford University

The human ability to flexibly adapt to a wide and unpredictable range of circumstances is the very trademark of human intelligence. When we study flexibility and diversity in human thought, we are approaching what may in fact be the human essence, those qualities that distinguish us from all other creatures. In this talk I will highlight a number of discoveries of radical diversity in human cognition, as a function of cultural and linguistic context. I will highlight four categories of differences that constitute different aspects of being “fundamental”: differences that are deep, differences that are pervasive, differences that are big, and differences that are important. These findings demonstrate that many aspects of cognition that were previously thought to be static or pre-determined, are indeed quite flexible, the product of cultural invention and transmission. Studies of cross-cultural variation demonstrate that people can construct a variety of radically different perspectives on the same physical reality. I will argue that it is this flexibility that allows us to construct ever more complex and sophisticated conceptual tools, and adapt so successfully in cultural as opposed to in evolutionary time. When it comes to higher-level cognition, being solid as a rock may only be desirable if one wants to be as smart as one.
