Prepositions in natural languages often appear to be governed by arbitrary conventionalized idiomatic uses (e.g., Vandeloise, 1991). For example, native English speakers tend to take it for granted that one uses the preposition “on” to refer to the date on which one was born but one uses “in” to refer to the month in which one was born. These are of course conventional idiomatic uses that didn’t have to be that way, and are “partly a matter of collocational habit” (Lindstromberg, 1998, p. 76). How are these idiomatic prepositional uses processed in the mind? On one account, locative prepositions such “in” and “on” lose their original

literal semantic content of containment and support respectively, to take on grammatical characteristics, a process often described as grammaticalization (Hopper & Traugott, 1993). Thus, conventionalization over time would lead to semantic bleaching, such that the same prepositions – and the expressions they are embedded in – would be processed differently, whether they are used literally or idiomatically. Some evidence for a processing difference between literal (spatial) and idiomatic (temporal) uses of prepositions comes from a preliminary neuropsychological study. Kemmerer (2005) reports that brain-damaged subjects with left perisylvian lesions failed a test of knowledge of the temporal meanings of prepositions, but passed a test that assessed knowledge of the corresponding spatial meanings of the same prepositions, suggesting that the spatial and temporal meanings of prepositions are represented and processed independently of each other in the brains of adult speakers.

In the present study we considered an alternative hypothesis, namely that idiomatic prepositional uses in one’s native language are not entirely arbitrary, as they may activate image-schematic perceptual simulations during language processing (Gibbs, 2006; Richardson, Spivey, Barsalou, & McRae, 2003; Zwaan, 2004). Spatial prepositions have been studied for artificial intelligence and automated translation (e.g., Andre et al., 1987; Retz-Schmidt, 1988), as well as for their complex mappings to various gradations in spatial relations (e.g., Bowerman & Choi, 2003; Coventry & Garrod, 2004) and image-schematic mental representations (Brugman & Lakoff, 1988). In particular, previous research has demonstrated our tendency to use spatial metaphors to help us understand time (e.g., Boroditsky, 2000). A wide variety of laboratory experiments have clearly demonstrated a role for embodied sensorimotor properties (or “perceptual simulations”) in language processing (e.g., Barsalou, 1999; Bergen, Matlock, Lindsay, & Narayanan, 2007; Glenberg & Kaschak, 2002; Richardson et al., 2003). There is in fact a long history to embodied sensorimotor accounts of language that predates the recent spate of laboratory experiments. The field of cognitive linguistics has provided a number of spatial

descriptions of linguistic meanings in the form of “image schemas” (Gibbs & Colston, 1995; Lakoff, 1987; Langacker, 1987; Talmy, 1983). In particular, image schemas (two-dimensional layouts of idealized trajectors and landmarks) have proven especially illustrative for understanding the varied meanings of spatial prepositions (Brugman & Lakoff, 1988; Talmy, 1983; Tyler & Evans, 2003). Indeed, image schemas may be the quintessential generic form of the perceptual simulations that underlie the understanding of prepositions like over, on, and in.

Therefore, it may not be surprising to find that more specific properties of spatial relationships (such as the containment properties of “in”, or the support properties of “on”) become articulated in our perceptual simulations of the spatial metaphors we use for understanding time. Thus, although they are idiosyncratic, idiomatic uses of prepositions in English such as “I will see you on Thursday” may not be entirely arbitrary. Rather, they may involve perceptual simulations and/or image schemas based on the preposition being used (e.g., Brugman & Lakoff, 1988). We set out to test this hypothesis in Experiment 1.

Studying the processing of idiomatic prepositions in adult native speakers bears not only theoretical import, but also practical implications for learning a second language. Prepositional uses are recognized as notoriously difficult for English L2 learners to acquire, especially when their native language has no equivalent prepositions (e.g., in Korean, I May was born), or it possesses one single general preposition that collapses the meaning of two (e.g., in Japanese, *ni* subsumes both in and on), or it uses different prepositions (e.g., in Italian, I am going in Italy). Textbooks and materials for English second language (L2) learners emphasize the arbitrary nature of non-literal prepositional uses and have little to offer except the instruction to memorize either rules or examples. In Experiment 2, we hypothesized that Japanese L2 learners of English struggle with prepositional uses particularly because they cannot rely on the congruent perceptual simulations underlying such uses. In the Discussion section, we argue that an embodied account of sentence processing can potentially change instructional practices in second language education. We propose that if image-schematic mental representations are part and parcel of sentence processing, then language teaching curricula should benefit from taking advantage of that additional source of information in training second-language learners.

To summarize, the main goal of Experiments 1 and 2 was to investigate the influence of language on the activation of image schematic perceptual simulations. Perceptual simulation was operationally defined as the process of selecting a visually presented object, a calendar, congruent with a conventionally accepted response to a target question (date or month of birth). There were two experimental conditions (Date and Month), both of which incorporated four calendar diagrams designed to invoke perceptual simulations of support (Figure 1, item 1) or containment (Figure 1, item 2) or neutral filler items (Figure 1, items 3

and 4). Participants were first asked to think about the date or month of their birthday, then select one of the four calendars (in the experimental conditions). Japanese learners of English were additionally asked to respond to a sentence completion task eliciting the prepositions in or on. The following research questions were intended to explore the issues outlined above:

1. Do native speakers of English select calendar images whose perceptual simulation (container vs. support) is congruent with the unmentioned preposition (on or in) that is associated with the prompted question (date of birth or month of birth, respectively)?

2. Do Japanese speakers of English as a foreign language select calendar images whose perceptual simulation (containment vs. support) is congruent with the unmentioned preposition that is associated with the prompted question?

3. For the Japanese participants, does the presence or absence of an image influence the accuracy of responses in the sentence completion task?

4. Do those Japanese speakers who do select the congruent image respond with the correct English preposition?

5. In the case of Japanese participants, do higher proficiency speakers select the congruent primes more often than lower proficiency speakers?

Figure 1. Calendar diagrams used in the date prompting condition, with the support image at the top-left.

Figure 2. Calendar diagrams used in the month prompting condition, with the containment image at the top-left.

Experiment 1

Different languages use their spatial prepositions to carve up the various possible spatial relationships in a variety of ways. For example, where English uses “in” for containment spatial relationships, and “on” for support spatial relationships, Spanish and Japanese use a single preposition (“en” and “ni” respectively) for both containment and support (for discussion, see Coventry & Garrod, 2004). Moreover, where English collapses tightly-fitting containment and loosely-fitting containment into a single “in” category, Korean uses the prepositions “kkita” for the former (plus tight-fit support) and “nehta” for the latter (Bowerman & Choi, 2003; Choi & Bowerman, 1991; Mandler, 1992). Interestingly, English-learning infants can actually learn the tight-fit containment-or-support spatial category (referred to as “kkita” in Korean) when they are given a spoken novel word with which to label the image (Casasola, Bhagwat, & Burke, 2009). Thus, children’s categorization of spatial relationships is influenced by the spatial prepositions they grow up with. Might even adults’ real-time perceptual simulations of the language they read and hear be influenced by the preposition they use to describe an event (even if that preposition does not call for a literal meaning, but a purely idiomatic one)?

Method

Participants Fifty-one native English-speaking students were recruited at the University of Hawai‘i at Mānoa.

Materials Since almost every spatial preposition in every language has a quite varied range of uses (e.g., Bowerman & Choi, 2003; Brugman & Lakoff, 1988; Haspelmath, 1997; Lindstromberg, 1998), the experiment focused on a particular idiomatic use of a spatial preposition, and examined the perceptual simulations that native speakers may be generating when they understand that particular idiom. Two sets of four calendar diagrams were designed to each include a single image that would invoke a perceptual simulation of support or containment. For instance, in the top-left corner of Figure 1, the diagram corresponds to the expression, born on [date] because it displays a spatial affordance of support, and the diagram in the top-left corner of Figure 2 corresponds to the expression, born in [month] because it displays a spatial affordance of containment. The circle and triangle diagrams are filler items intended to distract participants from figuring out the experimental manipulation and also to mitigate the potential influence of cultural bias due to the prototypicality of the flat calendar. The arrangement of the support and containment calendar diagrams was counterbalanced from left to right to avoid location preferences.

Procedure Randomly assigned participants were first prompted (without mentioning the prepositions “in” or “on”) to think about the date or month of their birthday. Then one of two questions, “Which one of these calendars would you use to indicate the date [or, month] of your

birth?” accompanied the calendar images depicted in Figure 1 or Figure 2 depending on the experimental condition. The calendar images were printed on a US letter sheet of paper. Participant choices were recorded by the experimenter.

Results

Congruence of perceptual simulations To address the above research questions in Experiments 1 and 2, Pearson’s Chi-squared test with Yates’ continuity correction was used to determine whether observed differences were statistically significant. An alpha level of .05 was set for each test we conducted. Experiment 1 was devised to answer the first research question, regarding the congruence of perceptual simulations in native speakers. The English native speakers in this study tended to select calendar images whose perceptual simulation was congruent with the preposition associated with the prompted question: 98% selected the support calendar when prompted with the date question, and 41% selected the container calendar when prompted with the month question. There was a significant relationship ($\chi^2 = 23.73$, $df = 1$, $p < .001$) between the date or month question prompt (eliciting in or on) and the type of calendar chosen (containment or support). Thus, it appears that spatial schemas can be activated in one’s native language when thinking about time even for idiomatic prepositional usages.

Experiment 2

A key topic of research in the area of spatial language is the cross-linguistic variation of how a given language’s spatial prepositions partition and categorize various spatial relationships (Bowerman & Choi, 2003) – which brings us to the crux of the question addressed in Experiment 2. When second language (L2) learners make errors with spatial prepositions, what is the character of the perceptual simulations they generate (see also Coventry & Guijarro-Fuentes, 2008; Tyler & Evans, 2003)?

Method

Participants Eighty-two native Japanese-speaking undergraduate students enrolled in an English program at a private university in Tokyo, with a mean age of 20.5 years ($SD = 5.4$), voluntarily participated. On average, they had studied English for 8.8 years ($SD = 2.6$), and had spent a mean of 0.9 years abroad in English-speaking countries ($SD = 2.1$). When asked to rate their ability to use English on a scale of one to 10, their average rating was 4.5 ($SD = 1.6$).

Materials The same materials as Experiment 1 were used. Materials were remotely delivered via the Internet using a survey software (www.surveymonkey.com).

Procedure Participants were randomly assigned to an experimental condition or a control condition. In the experimental condition, participants were prompted with the statement that read “Think about the date [or, month] of your birthday” and then asked to select a calendar picture as

in Experiment 1. In the control condition, participants were prompted with the same statement but did not view the calendar pictures. Next all participants in both conditions were asked either, “What is the date of your birthday?” or “What is the month of your birthday?” and subsequently typed their answer in a blank field preceded by the stem, “I was born ...”. Following this, they completed a 10-item cloze test (Brown, 1998) and filled out a questionnaire in Japanese, in part based on the Language Experience and Proficiency Questionnaire (Marian et al., 2007). All participants’ responses (calendar choice, sentence completion, cloze items chosen, and responses to the questionnaire, were recorded by the survey software, and later downloaded for analysis by the experimenter.

Results

Congruence of perceptual simulations in L2 learners Our second question in this research project aimed to address the issue of congruence between prepositional use and elicited schemas with Japanese-speaking EFL learners. Here, in stark contrast to the findings in Experiment 1 with native English speakers, the results indicated no relation between the date or month question and calendar choice: 85% selected the support calendar when prompted with the date question, and 30% selected the container calendar when prompted with the month question ($\chi^2 = 0.92$, $df = 1$, $p = .34$). As might be expected, second language learners of English in this study did not show a tendency to select calendar images congruent with the time question posed to them. To directly compare native and non-native speakers, we collapsed the data from Experiment 1 and 2, and fitted a generalized log-linear model with three variables (Native Language, Prompt Question, Calendar Diagram). This saturated statistical model yielded a significant three-way interaction. To properly assess this significance, we followed a model simplification method (Crawley, 2005), by deleting the three-way interaction from the model, and checking whether a simpler model would lose explanatory power. Indeed the models differed ($p = 0.025$), so we retained the more complex model with the three-way interaction. The analyses confirmed that only the native English speakers show a tendency to select calendar diagrams consistent with the prompt question posed to them.

Calendar images and accuracy in L2 learners Our third research question asked whether the presence or absence of an image would influence English non-native speakers’ accuracy of responses by way of a visual priming. Answers to the question, “What is the date of your birthday?” or “What is the month of your birthday?” were coded as either correct or incorrect for the experimental and control groups, depending on whether participants produced on or in. For the date question, neutral responses in which participants optionally deleted the preposition (e.g., *I was born Ø December 11th*) were excluded from the analysis ($n = 12$). To begin with, there was no apparent difference in the ability of participants assigned to the date and month to use

prepositions correctly to answer the above question: 55% of participants in the date condition and 50% in the month condition used the correct preposition ($\chi^2 = 0.33$, $df = 1$, $p = .57$). Also, no significant interaction was found between the experimental and control group in terms of accuracy of response ($\chi^2 = 0.16$, $df = 1$, $p = .69$). Therefore, the presence or absence of the calendar images appeared not to influence accuracy of production. This is reasonable, given that participants were presented with a choice of four different calendars, and thus it is not apparent which of the four should have independently primed the a correct answer. These results appear to rule out an account in terms of conceptual priming, that is that conceptual representations based on a visual context prime other conceptual representations and preposition choices in production.

The possibility of an influence of calendar choice on accuracy was more closely examined through research question four, which probed whether participants who selected the congruent image provided an accurate response to the target question. Only 40% of them did ($\chi^2 = 1.2$, $df = 1$, $p = .27$), suggesting that for these participants, there is no relationship between image choice and accurate production.

Image choice and proficiency in L2 learners Finally, the fifth research question examined the likelihood of a relationship between image choice and proficiency level. After standard test item analysis techniques were applied to the cloze test, two items with low discrimination indices were excluded. Internal reliability was found to be .61 for the remaining eight items. We ran a logistic regression analysis, using a generalized linear model, with cloze test scores predicting congruency of calendar choice. Although the results were not significant under a two-tailed test ($t = .56$), there was a positive trend (slope coefficient = 0.08688) toward higher proficiency participants selecting images corresponding with the prepositional uses implied by the prompt question. This trend was confirmed using a chi-square analysis. A median cut-off point for high versus low proficiency was established and the relationship between choosing an image congruent with the prompt question and proficiency level (cloze test) was tested. Although these results were not significant ($\chi^2 = 2.13$, $df = 1$, $p = .14$), of those participants who did select the congruent image, a greater number were in the high proficiency group (19) than in the low proficiency group (11).

General Discussion

The present study looked at the susceptibility of individuals to forming spatial image schematic perceptual simulations when thinking about non-spatial metaphorical expressions. Although prompted to consider time, native speakers activated schemas for spatial prepositions, as shown by their selection of calendar images congruent with either containment or support. On the contrary, Japanese-speaking learners of English as a foreign language tended not to associate the spatial and temporal meanings of prepositions in this manner.

At present a number of questions remain unanswered about the role of perceptual simulations in second language learning. We suggest a few avenues for research that we are currently investigating, and that would shed light on whether it is possible to use image-schemas to assist L2 learning. First, further research should address to what extent L2 proficiency matters in activating perceptual simulations. The Japanese group we tested was comprised of low-to-intermediate level of English learners, who had mainly received formal schooling in Japan and little or no genuine immersion. It is possible that a comparison between this group and a more proficient group of L2 speakers will reveal a significant difference in the learners' susceptibility to perceptual simulations.

Follow-up studies will test for the reverse direction of the effect obtained in Experiment 1. That is, can priming a particular perceptual simulation influence the type of phrase that a speaker chooses to produce? Previous work has shown that participants' use of *in* and *on* is influenced by a variety of factors in the scene, including animacy of the Figure and the Ground, as well as the function and degree of concavity of the Ground, (Feist & Gentner, 1998; 2003). Future experiments could explore this use of *in* and *on* for idiomatic expressions that only metaphorically involve a spatial relation. For example, participants could be presented a single picture of either the box-like calendar (Fig. 2 top-left) with the month of their birthday included in its top portion or the flat calendar (Fig. 1 top-left) with the day of their birthday included in its top portion. They would then be instructed to report their date [or, month] of birth, and the measure is whether they use the preposition *in* or *on*. This type of manipulation would provide evidence regarding the bi-directionality of influences between perceptual simulations and language processing – showing not only that concepts can potentiate sensorimotor primitives (Mahon & Caramazza, 2008), but also that sensorimotor primitives can potentiate concepts. This is particularly relevant for L2 learning situations where the exposure to the statistical patterns of a specific idiom are less robust. Under such circumstances, the choices between seemingly-acceptable prepositions and perceptual simulations are more open-ended, and thus malleable by one another. Conversely, the extensive statistical exposure of English L1 speakers is expected to entrench their perceptual simulations, resulting in a more uni-directional influence. Evidence of perceptual malleability in L2 learners would then set the stage for other manipulations investigating the learnability of prepositions in L2. It is possible that perceptual experience guides learning and use. In fact, Celce-Murcia and Larsen-Freeman (1999) have claimed that “anchoring the meaning of prepositions in spatial relationships is the first step to helping students learn to deal with areas where the meaning is more abstract” (1999, p. 405). Activating the spatial meanings of these prepositions may give rise to simulations of containment and support that serve to anchor the temporal senses of *in* and *on*, respectively. New experiments can thus be devoted to an explicit investigation of a novel

visual-context-oriented method of learning prepositions in a second language. Experiments that follow from this line of research can make explicit comparisons and tests between alternative second language teaching methods (e.g., Brown, 2006; Cook, 1996; Long & Doughty, 2009; Nunan, 1999), as well as explore additional prepositions. While language educators have often made suggestions regarding the use of images and other cognitively appropriate stimuli in teaching English prepositions (e.g., Celce-Murcia & Larsen-Freeman, 1999), their suggestions often lack rigorous empirical grounding. In particular, it remains for studies to incorporate both the use of pedagogic tasks involving pictures and the insights available from experimental cognitive linguistics in a single series of laboratory studies.

The two experiments presented in this study are merely the first steps in this research project, but they suggest that assisting the learning of subtle idiomatic use of spatial prepositions by adding visual aids that correspond to the image schemas (or perceptual simulations) associated with those prepositions might be a viable solution to helping L2 learners use language in a more native-like manner. By encouraging learners to think about the perceptual simulations that match the prepositions being used, language teaching materials and methods can make some of the more subtle and seemingly-arbitrary properties of a second language become more accessible to learners. Finally, such image-schema-based training methods could also help assess the effectiveness of motor simulations in the treatment of language disorders. For example, Kemmerer (2005) reports that brain-damaged subjects with left perisylvian lesions failed a test of knowledge of the temporal meanings of prepositions, but passed a test that assessed knowledge of the corresponding spatial meanings of the same prepositions. Training regimes that activate particular motor simulations might help reestablish the spatio-temporal links of prepositional usages in brain-damaged patients.

In closing, the two experiments reported here suggest that L1 and L2 speakers pay differential attention to image properties when spatial language is employed to talk about time. The results seem to support a conclusion consistent with the idea that image schemas may underlie perceptual simulations recruited during language processing. These experiments add to evidence that shows how spatial language directs attention as a function of particular entities and the interaction between them (Coventry, et al., 2010), which points to an explanation grounded in both cognitive linguistic theory and embodied sensorimotor accounts. Findings from future research may offer insight into the role of language experience.

A Motion Aftereffect from Literal and Metaphorical Motion Language: Individual Differences

Alexia Toskos Dils (atoskos@stanford.edu)

Abstract

Do people spontaneously form visual mental images when understanding language, and if so how truly visual are these representations? We test whether processing linguistic descriptions of motion produces sufficiently vivid mental images to cause direction-selective motion adaptation in the visual system (i.e., cause a motion aftereffect illusion). We tested for motion aftereffects (MAEs) following explicit motion imagery, and after processing literal or metaphorical motion language. Intentionally imagining motion produces an aftereffect in the overall sample with some participants showing a greater aftereffect than others. We then find that participants who show the strongest imagined motion aftereffects also show aftereffects in the natural course of processing motion language (without instructions to imagine). Individuals who do not show strong motion aftereffects as a result of imagining motion also do not show them from processing motion language. However, the aftereffect from language gained strength as people were exposed to more and more of a motion story. For the last two story installments (out of 4), understanding motion language produced reliable MAEs across the entire sample. The results demonstrate that processing language can spontaneously create sufficiently vivid mental images to produce direction-selective adaptation in the visual system. The timecourse of adaptation suggests that individuals may differ in how efficiently they recruit visual mechanisms in the service of language understanding. Further, the results reveal an intriguing link between the vividness of mental imagery and the nature of the processes and representations involved in language understanding.

Keywords: embodiment, language comprehension, perception, motion aftereffect, individual differences

Introduction

A good story can draw you in, conjure up a rich visual world, give you goose-bumps, or even make you feel like you were really there. To what extent is hearing a story about something similar to really witnessing it? What is the nature of the representations that arise in the course of normal language processing? Do people spontaneously form visual mental images when understanding language, and if so how truly visual are these representations? In this paper we make use of the motion aftereffect illusion to test whether processing linguistic descriptions of motion produces sufficiently vivid mental images to cause direction-selective adaptation in the visual system (i.e., cause a motion aftereffect).

A number of findings suggest that people do spontaneously engage in imagery during language

comprehension and that processing language affects performance in subsequent perceptual tasks (e.g., Bergen, Lindsay, Matlock, & Narayanan, 2007; Meteyard, Bahrami, & Vigliocco, 2007; Richardson, Spivey, Barsalou, & McRae, 2003; Rinck & Bower, 2000; Rinck, Hähnel, Bower, & Glowalla, 1997; Spivey & Geng, 2001; Stanfield & Zwaan, 2001; Zwaan, Madden, Yaxley, & Aveyard, 2004; Zwaan, Stanfield, & Yaxley, 2002;).

What mechanism might underlie these interactions between linguistic processing and perception? The explanation frequently offered is that the representations generated during the course of language comprehension share processing resources with perception, recruiting some of the very same brain regions (Barsalou, 1999). As evidence for this possibility fMRI measures have revealed that classically ‘perceptual’ brain areas are recruited in service of language comprehension (e.g., Saygin, McCullough, Alac, & Emmorey, 2010). While these findings are consistent with the hypothesis, questions remain. The spatial resolution of current fMRI technology is coarse. A typical voxel (the smallest unit of measurement) may include 100,000 neurons. It is possible then that what appear in fMRI to be the same regions activated in linguistic and visual tasks are in fact neighboring (or closely interleaved) but distinct neural populations, potentially with quite different computational properties.

One powerful paradigm for determining whether neural populations involved in particular tasks indeed overlap is that of adaptation. In this paper, we make use of one such adaptation measure, the motion aftereffect (MAE). The MAE arises when direction-selective neurons in the human MT+ complex lower their firing rate as a function of adapting to motion in their preferred direction. The net difference in the firing rate of neurons selective for the direction of the adapting stimulus relative to those selective for the opposite direction of motion produces a motion illusion. For example, after adapting to upward motion, people are more likely to see a stationary stimulus or a field of randomly moving dots as moving downward, and vice versa (e.g., Blake & Hiris, 1993). To quantify the size of the aftereffect, one can parametrically vary the degree of motion coherence in the test display of moving dots (as in Blake & Hiris, 1993). The amount of coherence necessary to null the MAE (i.e. to make people equally likely to report the motion as upward or downward) provides a nice measure of the size of the aftereffect produced by the adapting stimulus.

Winawer, Huk, and Boroditsky (2008, 2010) adapted this technique to test for MAEs after participants either viewed still images implying motion (e.g., a runner in mid-leap), or simply imagined motion without any visual stimulus. Both implied and purely imagined motion produced reliable MAEs. These studies support fMRI findings suggesting the hMT+ complex is recruited in the service of mental imagery (Goebel, Khorram-Sefat, Muckli, Hacker, & Singer, 1998; Grossman & Blake, 2001), and further suggest that this activation is driven by direction-selective neurons.

Here we explore whether natural language comprehension can likewise produce MAEs. To the extent that people spontaneously engage in imagery in service of language comprehension, understanding motion language should yield MAEs (albeit likely weaker than those produced during explicit, effortful imagery). The present study was designed to test this prediction. Participants listened to stories describing motion in a particular direction and then judged the direction of a moving field of dots. The direction in which motion language affects subsequent motion perception speaks to the mechanisms underlying language comprehension. One possibility is that motion language adapts the same direction-selective mechanisms that subserve motion perception; this would cause people to see a real visual stimulus (e.g., dynamic dots) as moving in a direction *opposite* to that described in the adapting language. Another possibility is that understanding motion language recruits higher-level convergence areas that process visual motion, resulting in a bias to see dot motion in the *same* direction. Such a congruence effect is reported by Sadaghiani et al (2009) who showed that hearing the words ‘right’ and ‘left’ biased participants to see an apparent motion stimulus as moving in the same direction. fMRI data revealed that this audiovisual interaction was driven more by activity in the anterior intraparietal sulcus (IPS) than hMT+. A third possibility is of course that motion language does not recruit visual motion processing resources of any kind, resulting in no bias in dot motion perception.

Further, the direction and extent of transfer from language to perception may depend on an individual’s visual motion imagery ability. People differ from one another in mental imagery ability, and these differences correlate with individual differences in spatial tasks and object perception (Kozhevnikov, Kosslyn, & Shephard, 2005). In Winawer et al (2010), most but not all participants showed MAEs as a function of imagining motion, and the degree of adaptation differed across people. We reasoned that people who show stronger adaptation as a result of imagining, should be more likely to show adaptation as a result of understanding motion language. It would be reasonable to expect that individuals who do not show an MAE as a result of explicitly imagining motion should also not show one as a result of processing motion language. To test for this possibility, we tested each participant both in an explicit visual imagery condition (as in Winawer et al (2010)), and in conditions where linguistic motion was used as an

adapting stimulus. This allowed us to compare the effects of language for each participant with those of explicit imagery.

Finally, the present study is designed to test whether literal and metaphorical descriptions of motion recruit similar perceptual processes. To this end, we contrasted literal motion stories that described the motion of physical objects with metaphorical motion stories that used motion verbs to talk about changes in abstract entities (e.g. rising and falling stock prices).

Experiment

The experiment consisted of five parts: (1) a baseline task in which we measured participants’ motion direction sensitivity, (2) a familiarization task in which participants viewed the stimuli to be imagined later in the study (3) the main experimental task in which we tested for MAEs following imagining motion or listening to stories describing motion, (4) a memory task in which we measured participants’ recognition memory for the stories, and (5) an exit questionnaire in which we ascertained participants knowledge of the motion aftereffect and their explicit predictions about the direction of effects.

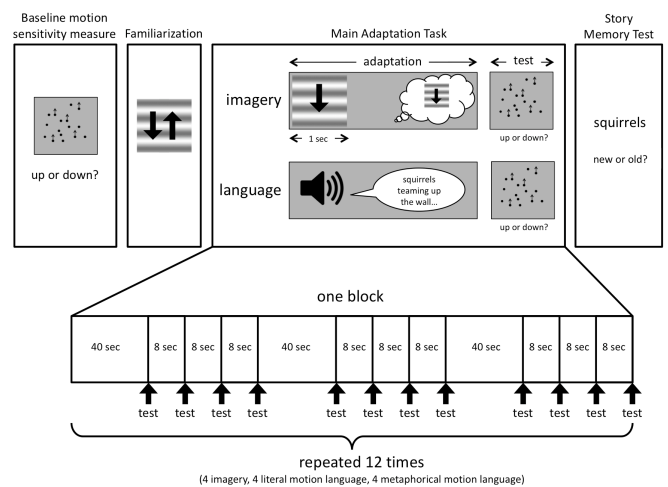

Figure 1: Schematic of experimental design highlighting the block and trial structure of the main adaptation task. In the imagery blocks, an upward or downward facing arrow superimposed on a static image of the grating indicated the direction in which to imagine the stripes moving. This cue faded slowly over the course of a second. Once the cue disappeared completely, a flickering fixation cross appeared at the center of the screen. Participants were instructed to fixate on the cross while imagining the stripes and to use the rate of the flicker to help them remember how fast the stripes should move. Participants were also instructed to use the fixation cross as a cue for when to start and stop imagining motion. In language blocks, participants listened to stories using headphones while fixating a dot centered on the monitor. Participants were told to listen carefully to the stories, as there would be a memory test. They were not instructed to imagine.

Methods

Participants Sixty Stanford students participated in exchange for payment.

Stimuli and Procedure

Main Experimental Task: The task design, procedure, and visual stimuli used were modeled on those used in Winawer et al (2010). On each trial participants judged the direction of dot motion after either listening to stories describing motion or engaging in explicit visual motion imagery. Trials were presented in 12 interleaved blocks. There were 6 block types, 3(motion type: imagined motion, literal motion, or metaphorical motion) by 2(motion direction: upward or downward).

Adaptation Stimuli: In the literal motion condition the stories used motion language to describe the movement of physical objects (e.g., squirrels, ping-pong balls). In the metaphorical motion condition, the stories used motion language to describe changes in abstract entities (e.g. stock prices, emotions). 12 literal and 12 metaphorical stories were used with an upward and a downward version for each, yielding a total of 48 stories. Individual participants heard 24 stories (either the upward or the downward version of each story, but not both). Example stories are in Table 1. In the imagery condition, participants were instructed to imagine upward and downward moving gratings (as in Winawer et al. (2010)). The trial structure for the language and imagery conditions is depicted in Figure 1.

Table 1: Sample stories heard by participants.

Literal Motion: Upward Story (Four installments)

1. You are running a psychology experiment in which you have trained hundreds of squirrels to race each other up a wall for a piece of food. Now you want to see what happens when they are all released at the foot of the wall at once. You watch through a small window in the next room as the cages are opened and the squirrels leap onto the wall in a frenzy. The little fur balls scurry up the wall in one relentless stream, despite obvious defeat in the race. Zip! The brown creatures surge up the wall with amazing agility. You see the same behavior in squirrel after squirrel – one swift jump onto the wall and an instantaneous burst upward. Zoom! The squirrels rush up the wall like a giant current. As if in a trance, the squirrels swiftly stream past your eyes in their race for the top of the wall.

2. Zoom! More and more squirrels jump onto the wall and scurry upwards. You watch them course up the wall in a blur.

3. The squirrels continue to sprint upwards in a flash. They spout onto the wall and surge directly toward the top.

4. Your eyes remain focused on the mob of squirrels teeming up the wall. You can no longer pick out individuals as they dash for the top.

Literal Motion: Downward Story (Four installments)

1. You are running a psychology experiment in which you have trained hundreds of squirrels to race each other down a wall for a piece of food. Now you want to see what happens when they are all released at the top of the wall at once. You watch through a small window in the next room as the cages are opened and the squirrels descend onto the wall in a frenzy. The little fur balls scurry down the wall in one relentless stream, despite obvious defeat in the race. Zip! The brown creatures surge down the wall with amazing agility. You see the same behavior in squirrel after squirrel – one swift drop onto the wall and an instantaneous burst downward. Zoom! The squirrels rush down the wall like a giant current. As if in a trance, the squirrels swiftly stream past your eyes in their race for the bottom of the wall.

2. Zoom! More and more squirrels drop onto the wall and scurry downwards. You watch them course down the wall in a blur.

3. The squirrels continue to sprint downwards in a flash. They pour onto the wall and surge directly toward the bottom.

4. Your eyes remain focused on the mob of squirrels teeming down the wall. You can no longer pick out individuals as they dash for the bottom.

Metaphorical Motion: Upward Story (Four installments)

1. You are standing in the middle of the trading floor at the New York stock exchange one busy morning. The room is buzzing with announcements of rising stock prices. First JP Morgan rockets dramatically. Accenture and Delaware blaze to new heights. Suddenly, Lincoln's stock surges, along with Time Warner. You hear animated reports of Toyota, Coca Cola, and The Gap going sky-high! You can hardly believe it, but Google's stock soars higher than ever. Walmart zips skyward, too. All morning, you marvel at the continually spiking stocks!

2. You hear that Ford and Exxon Mobile are really ramping up. Hewlett Packard is erupting too!

3. Next you hear that Nokia is boosting quickly. Likewise, Sprint, AT&T and Verizon are surging dramatically.

4. Stock prices heighten rapidly for Proctor and Gamble as well as Clorox. McDonalds' stock also jets to new heights!

Metaphorical Motion: Downward Story (Four installments)

1. You are standing in the middle of the trading floor at the New York stock exchange one busy morning. The room is buzzing with announcements of falling stock prices. First JP Morgan plummets dramatically. Accenture and Delaware tumble to new lows. Suddenly, Lincoln's stock plunges, along with Time Warner. You hear agitated reports of Toyota, Coca Cola, and The Gap hitting record lows! You can hardly believe it, but Google's stock sinks lower than ever. Walmart zips downward, too. All morning, you marvel at the continually diving stocks!

2. You hear that Ford and Exxon Mobil are really sinking down. Hewlett Packard is taking a nose-dive too!

3. Next you hear that Nokia is slumping quickly. Likewise, Sprint, AT&T and Verizon are tumbling dramatically.

4. Stock prices level rapidly for Proctor and Gamble as well as Clorox. McDonalds' stock also plunges to new lows!

Block structure: In the two language conditions, each block consisted of 3 stories with 4 installments each, for a total of 12 trials per block. Each story was broken up into one longer paragraph and three shorter 'top-up' installments so that multiple measurements could be collected for each story. The longer installments lasted on average 40.00 seconds, and the top-up installments 8.29 seconds. The imagery blocks mirrored this structure. Participants imagined motion for 40 seconds, and on the three subsequent 'top-up' trials, participants imagined motion for 8 seconds. This pattern was repeated 2 more times within the block to parallel the 3 stories used per block in the language conditions.

Adaptation Test: Following each story or imagery installment, participants judged the direction of motion coherence in a field of moving dots without feedback. The moving dot stimuli were presented as in Winawer et al. (2010). Each dot display had net motion coherence either up or down. For each subject, two coherence values were sampled: 12.5% and 25% of the coherence necessary for asymptotic performance (as assessed individually for participants in the baseline task). Coherence and direction of motion were fully crossed and balanced across trials and participants.

Exit questionnaire: At the end of the experiment we ascertained participants' familiarity with the motion aftereffect and also asked them to generate a prediction

about which way they thought the effect would go. Participants were asked: *Have you ever heard of the Motion Aftereffect or Waterfall Illusion?* and *After viewing upward motion, which way would you expect a static image to appear to move?*

Results

The distance between the null points of the logistic fits for upward and downward motion (normalized coherence values at which participants are equally likely to report upward and downward motion) was computed for both the imagined and linguistic motion conditions for each participant. Positive values reflect adaptation. Six participants whose results exceeded three standard deviations from the mean for all participants were excluded from subsequent analyses. The literal and metaphorical linguistic motion conditions did not significantly differ from one another ($t(53) = 0.219, p > .5$), and so were combined for analysis. Results are plotted in Figures 2-4.

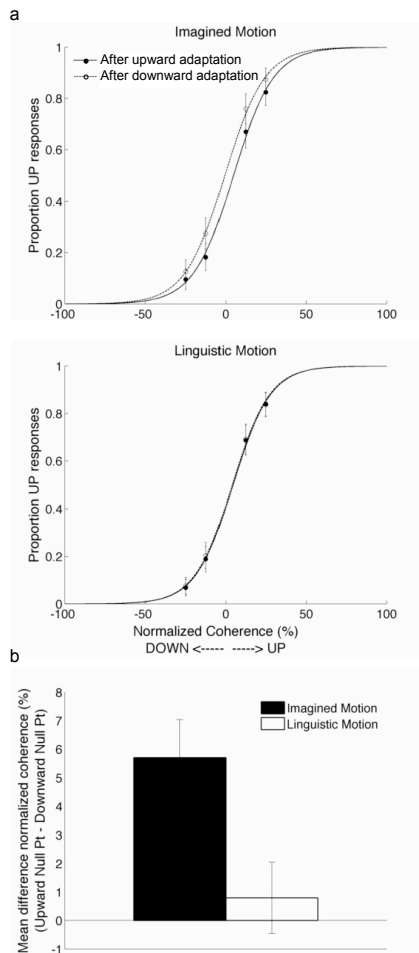

Figure 2: (a) Proportion of “UP” responses following imagined motion and linguistic motion across all participants. Error bars represent standard error. (b) Separation in motion response functions for imagined and linguistic motion across all participants. Positive values reflect adaptation. Error bars denote s.e.m.

In the overall sample, participants showed a reliable MAE after imagining motion ($M = 5.7\%$ normalized coherence, $SD = 9.8\%$) ($F(1,53) = 18.26, p < .001$) (replicating Winawer et al, 2010), but not after listening to motion stories ($M = 0.8\%$ normalized coherence, $SD = 9.2\%$) ($F(1,53) = 0.40, p > .5$). The two conditions differed reliably from one another ($F(1,53) = 10.81, p < .005$).

We reasoned that individuals who do not show MAEs as a result of explicitly imagining motion should also not show them as a result of processing motion language. However, participants who do show MAEs from motion imagery may show them from processing motion language as well. Indeed, there was a significant correlation between the effects of motion imagery and motion language ($r(52) = .34, p < .02$), such that stronger adaptation from imagining motion predicted stronger adaptation from understanding motion language (Figure 3).

Figure 3: Correlation across all participants between the separation in motion response functions for imagined and linguistic motion, $r(52) = .34, p < .02$.

To confirm that participants who showed adaptation to imagined motion also showed it in response to linguistic motion, we sorted participants based on the magnitude and sign of the effect of explicit motion imagery and divided them into three groups of equal size (Imagery $Mdns = 15.1\%, 3.8\%, -1.7\%$, and $SIQRs = 6.6\%, 1.6\%, 5.0\%$ normalized coherence) (Figure 4). We will refer to these as strong, weak, and no MAE groups respectively.

Indeed, the group that showed strong MAEs after explicitly imagining motion also showed reliable MAEs after listening to motion language (Language $Mdn = 5.6\%$, $SIQR = 4.7\%$) ($n = 18, p < .031$, sign-test, 2-tailed). There was no difference in the strength of this adaptation effect between the literal and metaphorical language conditions, $n = 18, p > .40$. The two groups that showed weak or no MAEs from imagery, did not show reliable MAEs from language: ($Mdn = -1.7\%$, $SIQR = 5.0\%$) ($n = 18, p > .05$), and ($Mdn = 0.8\%$, $SIQR = 5.1\%$) ($n = 18, p > .5$) for groups that showed weak or no MAEs respectively. The effects of

language in the strongest MAE group differed reliably from the other two groups, $\chi^2(1, N=54)=7.27, p<.01$.

Figure 4: Participants were sorted based on the size of the aftereffect in the imagery condition and divided into three equal-sized groups. The plot shows the median separation between motion response functions for each group. Error bars denote SIQR.

To examine the timecourse of the MAE from imagined and linguistic motion, we subtracted the proportion of “up” responses following upward motion from those following downward motion across adaptation installments (e.g., the 4 installments of a story, or the analogous 4 imagery installments). The mean difference by installment across all participants is plotted in Figure 5. In the explicit imagery trials, the MAE appears after the initial 40-second installment of imagining (as would the MAE from real visual motion), and participants remain adapted for subsequent installments (there is no linear effect of installment, $F(1,53) = 0.076, p > .5$). In the two language conditions, however, the MAE does not emerge until later installments (there is a reliable linear effect of installment, $F(1,53) = 6.59, p < .05$). After the 3rd and 4th story installment, there is a reliable motion aftereffect including all participants, $M=4.0\%, SD = 12.7\%; F(1,53) = 5.42, p < .05$. Motion language appears to produce a reliable MAE across the entire sample only after sufficient exposure to each story.

These findings raise the possibility that individual differences in the MAE from linguistic motion reflect differences in how efficiently people recruit visual direction-selective mechanisms rather than qualitative differences in which mechanisms are recruited. Indeed, the linear effect of story installment does not differ among those who show strong, weak, and no MAEs from motion imagery ($F(2,51)=.144, p>.5$), with everyone showing the same trend toward more adaptation as they get further into the story.

Testing for effects of explicit bias: Of the 54 participants included in the analysis, 43 completed an exit questionnaire about their knowledge and predictions about the motion

aftereffect (the remaining 11 omitted this portion of the study). Only three reported having heard of the motion aftereffect. Participants’ expectations about the direction in which adapting to visual motion in one direction might affect subsequent visual processing did not reliably bias ($F(1,39) = 0.37, p>.50$) or interact with ($F(1,39) = 0.33, p>.50$) the effects of imagined and linguistic motion. This finding confirms that the results obtained in this study are not a product of participants’ expectations or explicit biases regarding the direction of the effects.

Figure 5: Mean difference in proportion upward responses following upward and downward motion across the four motion installments. The data are plotted for the overall sample. Positive values reflect adaptation, and error bars denote s.e.m.

Discussion

We tested whether processing linguistic descriptions of motion produces sufficiently vivid mental images to cause direction-selective motion adaptation in the visual system (i.e., cause a motion aftereffect illusion). We predicted that the perceptual consequences of processing language should depend on an individual’s mental imagery ability. Imagery ability was operationalized as the extent to which explicit visual motion imagery produced an MAE in each participant. Put another way, imagery ability or vividness is the extent to which people recruit perceptual resources heavily enough to adapt them during explicit imagery.

We replicated previous work showing that intentionally imagining motion produces an aftereffect. We then found that participants who show the imagined motion aftereffect most strongly also show this aftereffect in the natural course of processing motion language (without instructions to imagine). The same effects held for both literal and metaphorical language. Individuals who did not show a motion aftereffect as a result of imagining motion also did not show an aftereffect from processing motion language overall. However, the aftereffect from language gained strength with the number of story installments. For the last two installments (out of 4), understanding motion language

produced reliable MAEs across the entire sample. This finding suggests the possibility that individuals may differ in how efficiently they recruit visual mechanisms in service of language comprehension. Future work will examine the effects of systematically varying exposure to motion language and the degree of story immersion on the MAE. Participants' knowledge of the MAE and their explicit predictions about the direction that the MAE should go did not predict their pattern of results. This helps us ensure that the patterns observed were not simply due to participants' explicit biases or expectations.

A further question concerns the effects from metaphorical motion language. Some researchers have found that literal and metaphorical language produce similar transfer effects to perceptuo-motor tasks (e.g., Boulenger, Hauk, & Pulvermüller, 2009; Glenberg & Kaschak, 2002; Richardson et al., 2003), while others have found no evidence for transfer from metaphorical language (Bergen et al., 2007). In our study, literal and metaphorical motion language produced the same effects. Our stimuli and methods differ from previous studies in many ways. One potentially important difference is that our stimuli were connected narratives that built over time, whereas the studies just cited used isolated sentences. Our results suggest that for language processing to produce effects on low-level visual processing, a greater amount of exposure to or immersion in a connected narrative may be necessary.

The results of the present study demonstrate that at least for a subset of the population, processing language spontaneously creates sufficiently vivid mental images to produce direction-selective adaptation in the visual system. Future work will examine the source and possible cognitive consequences of the individual differences we observed. Why might some people be better able to recruit or effectively modulate the activity of sensory neurons through top-down processes? Further, are there resulting systematic differences in the content and nature of representations people form in the service of understanding language?

Language-Driven Motor Simulation is Sensitive to Social Context

Abstract

People use their bodies differently in different social situations. In Korea, Japan, and Thailand, for example, there are culture-specific conventions for how to transfer small objects. People use one hand to transfer objects to people of equal or lower social status, but two hands with people of higher status. But does individual knowledge of these conventions for how to use one's body extend to other aspects of cognition? For instance, it is known that understanding action language involves internally simulating what it would be like to perform described actions. Do people mentally simulate actions appropriate to the social context described in a sentence? We report on a behavioral experiment, conducted with people born and raised in Korea, that investigated whether cultural practices affect the actions that people represent during language comprehension. We report evidence that motor simulations do indeed reflect social constraints on action.

Keywords: sentence processing; mental simulation; motor simulation; embodiment; social cognition; culture.

Introduction

What are the cognitive processes involved in understanding the meaning of a sentence that you hear or read? Behavioral and brain imaging evidence over the past several decades has revealed that – among other mechanisms – one process that is engaged routinely and mostly unconsciously is mental simulation (Barsalou, 1999). When you hear or read a sentence about an event, you use your visual system to simulate what the mentioned entities would look like: how they would move (Kaschak et al., 2005), what color (Connell, 2007), orientation (Stanfield & Zwaan, 2001, Zwaan et al., 2004) and shape (Zwaan et al., 2002) they would have, and so on. Similarly, when a sentence describes actions, you engage mental simulations of the described actions (Glenberg & Kaschak, 2002; Tettamanti et al., 2005; Buccino et al., 2005; Kaschak & Borreggine, 2008; Bub et al., 2008; Bergen & Wheeler, In press, Bergen et al., In press).

Key evidence that understanding motor language engages motor routines comes from the so-called “Action-sentence Compatibility Effect” (Glenberg & Kaschak, 2002): manual responses to make sentence sensibility judgments are facilitated when the motion of the physical response is compatible with the sentence's implied direction. For instance, *You handed the puppy to Katie* speeds manual

responses away from the body, while *Katie handed the puppy to you* speeds movements toward the body.

Research in this area has shown that implied features of a described scene – even when only implicit – show up in the comprehender's mental simulation. For example, people simulate handshapes specifically afforded by the objects mentioned. For instance, *Mary caught the marble* primes a grasping handshape, while *Mary caught the watermelon* primes an open palm handshape (Bergen & Wheeler, 2005). However, it is unknown at present whether language-driven motor simulation is sensitive to not only physical but also social constraints on action.

Part of acculturation is for people to learn culture-specific prescriptions for motor action (Mauss, 1934). For instance, in Korean culture, people learn to use both hands when giving an object to someone of higher social status, but only one hand with peers or social inferiors. This is obviously a learned behavior – many other cultures around the world do not share this particular convention. What's more, it's a cultural action convention that's specific to social context. In order to transfer an object appropriately to someone, you have to determine what your relative social status is, so as to engage an action using the right number of hands.

In the study described below, we ask whether socially-contingent prescriptions for motor action reach into other aspects of cognition as well, in particular, language comprehension. Does hearing about an action performed in a particular social situation elicit simulation of the prescribed physical behavior that conforms to the cultural constraint? More specifically, do Koreans who hear sentences about object transfer simulate using one hand or two hands, depending on the relative social status of the mentioned recipient? If they do, this would suggest that the motor simulations are flexibly tailored to the social situations comprehenders would encounter in the described situations. In addition, it would suggest that motor simulations have features specific to culture-specific constraints on action.

Method

The logic of the experiment was relatively simple. Participants listened to sentences in Korean about transferring small objects to recipients who were of either high status or low status. After the end of each sentence, they made a meaningfulness judgment about the sentence, which required them to press buttons either with two hands

or just with their right hand. We predicted that if the participants were automatically engaging motor representations of actions that used either one hand or two hands (appropriate to the social status of the mentioned recipient) then the status of the recipient and the number of hands they had to use to respond should show an interaction in their effect on measured response times.

Participants

Thirty-two native Korean speakers at the University of Hawai'i participated in this experiment and received \$5 in compensation. They all had been born and raised in Korea but moved to the U.S. for their higher education. All but 2 people had lived in Korea for at least 20 years. Their mean length of residency in Korea was 24 years (range: 13.5–35, std: 4.6), while the mean of their age was 27.8 (range: 20–45, std: 6.38). All had normal or corrected-to normal vision and hearing. All but one were right-handed.

Materials

We constructed twenty pairs of critical sentences in Korean, all of which are meaningful and describe transfer of a small object. The object in all these sentences is conventionally transferred to people of higher status using two hands and to people of equal or lower status using one hand. Examples of high status and low status sentences are in (1) and (2), below.

(1) [High Status]

Ne-nun cikum kyoswu-nim-kkey phyenci-lul tuli-koisse.
'You are now (humbly) giving a letter to (your) professor.'

(2) [Low Status]

Ne-nun cikum tongsayng-hanthey phyenci-lul cwu-koisse.
'You are now giving a letter to (your) younger sibling.'

The sentences in each pair (like (1) and (2)) differed in two ways. First, while High-status sentences mentioned people of conventionally high status as recipients (such as professors, doctors, lawyers, etc.), low status sentences had recipients who were of lower status or close peers, (like younger siblings, nieces, friends, etc.). Second, the sentences about transfer to people of high status were accompanied by grammatical/lexical markers called *honorifics*, which indicated that the status of the recipient is higher than the status of the subject (*you*). These markers are present on the recipient noun, the dative case marker, and the verb, and as confirmed in a norming study, this is the most natural and proper way to describe an object transfer to a social superior in Korean. (We'll discuss these honorific markers and their implications in more detail in the Discussion section below.) All critical sentences had *you* as the subject, were in the present tense, and used active dative sentence structure.

Beyond the critical stimuli, we created some additional materials. In order to disguise the intent of the experiment, we prepared twenty meaningful filler sentences that were

not about transfer of a small object. Because participants were performing a forced choice task, we needed forty non-sensible fillers to balance the twenty critical and twenty meaningful filler sentences. By including these, we ensured that each participant was expected to respond "Yes" half of the time overall. So that participants could not learn to use syntactic properties of the sentences to make judgments, half of the non-meaningful sentences were dative sentences, while the other half included sentences varying in structure and length – just like the meaningful sentences. Also, orthogonally, approximately half of all items mentioned high-status people in somewhere in the sentences, whereas the other half mentioned equal- or lower-status people.

Design, Procedure, and Predictions

Participants performed a sentence meaningfulness judgment task. They were seated in front of a computer with two keyboards aligned side-by-side in front of them (as in Figure 1 below). The keyboards were oriented such that the long axis of the keyboards projected out directly in front of the participant, at their midline. Participants first pressed the yellow keys with their two thumbs to begin auditory presentation of a sentence – these are at the bottom of the image in Figure 1, and were on the edge of the keyboard closest to the participant. Once they decided whether the sentence made sense or not, they released the yellow buttons to press either the "Yes" or "No" buttons on the keyboard to indicate their decision. The response buttons were positioned to require the participant to use either both hands (the green buttons) or only their right hand (the pink buttons) to press the buttons. Participants were instructed to press the pink buttons with two fingers of their right hand and the green buttons with the index fingers of their two hands. We measured the Reaching Time – the time from the yellow-button release until the "Yes" or "No" button press, because we were interested in seeing if simulation of the socially expected action would influence subsequent motion execution.

Figure 1. Configuration of keyboards to collect bimanual (green buttons) and unimanual (pink buttons) responses.

Participants pressed down the yellow buttons with the thumbs of their two hands to initiate presentation of a sentence, then pressed either the pink or green buttons to indicate their meaningfulness judgment.

We assigned participants to one of two starting conditions – they began with two-handed responses (the green buttons) meaning either “Meaningful” or “Non-meaningful” (and the pink buttons assigned complementarily). We switched the key assignments for each participant halfway through the experiment. Ten training trials preceded each half. Each participant heard the high-status recipient version of a randomly selected half of the critical sentences (e.g., (1)) and the low-status version of the other half (e.g., (2)). Each session lasted less than 20 minutes.

If native Korean speakers engage motor representations of two-handed actions when processing sentences about object transfer to people of high social status, and one-handed actions when processing sentences about transfer to people of equal or low status, then we should observe an interaction of Hand-Number by Sentence-Type.

But the direction of this interaction effect between language and action is a more difficult matter. Both match advantages (i.e., faster responses in the matching conditions) and mismatch advantages (i.e., slower responses in the matching conditions) have been reported in the literature. A close reading, however, leads us to expect a *mismatch* advantage; that is, two-handed responses will be faster when participants have just heard a sentence about transferring an object to someone of lower status, and conversely, one-hand responses should be faster when the preceding sentence describes transfer of an object to someone of higher status.

We are led to predict this mismatch advantage, rather than a perhaps more intuitive match advantage, for the following reason. Priming effects of action language on motor control are quite sensitive to timing. When there is a delay (more than 500 milliseconds) between the word that denotes the action and the action itself, language about actions facilitates motor actions that have broadly similar characteristics, such as the direction of motion (Glenberg & Kaschak, 2002; Kaschak & Borreggine, 2008; Bergen & Wheeler, In press) or handshape (Bergen & Wheeler, 2005; Bub et al., 2008). However, when the critical action word and the motor action are temporally aligned (within 500 ms), actions that are similar but not exactly the same will in fact be inhibited (Bergen, 2007; Bergen et al., In press, see also the review in Kaschak et al., 2005). That is, there is a *mismatch* advantage when an action verb (e.g., *throw*) immediately precedes activation of a motor routine for a similar but subtly different action (e.g., *push*), as compared with a less similar action (e.g., *kick*) (Bergen et al., In press).

Critically, Korean differs from English in terms of where in the sentence the main verb is placed. In English, the verb in canonically ordered sentences occurs after the subject and before the object. This means that in a sentence about someone acting on something (like *You handed Andy the pizza*), the verb appears relatively early in the sentence. In

Korean, however, the verb occurs at the end of the sentence (as exemplified in (3) below). As a result, when a participant is asked to perform an action immediately after the end of a Korean sentence, it falls within the 500ms window in which we observe mismatch-advantages for similar but non-identical actions. In this experiment, the described actions are indeed different in certain ways from the action of pressing keyboard buttons. Handing someone a business card or a letter, for instance, is different from pressing keyboard buttons in terms of its force, acceleration, palm orientation, handshape, and other motor details. Because participants are asked to process language about an action and then perform a similar but subtly different action very soon thereafter, we expect that Korean sentences should produce a mismatch advantage. This is unlike canonical English sentences, which, due to their verb occurring earlier in the sentence, would be expected to produce *match* advantages, as has been found in other studies investigating language-action interaction effects (e.g., Glenberg & Kaschak, 2002).

- (3) Ne-nun Andy-hanthey ku pizza-lul *kenneyesse*.
You-TOPAndy-DAT the pizza-ACC handed.
‘You handed Andy the pizza.’ (English translation)

Results

Among data from 32 participants and 20 critical items, results from two participants and one item were excluded due to low mean accuracy (more than 3 standard deviations below the participants’ and items’ overall means of 97% and 96%, respectively). The means for accurate responses from each of 30 participants and 19 items all fell within 3 standard deviations from the overall means for participants and items, respectively, and none were therefore eliminated as outliers.

The dependent measure was Reaching Time, the time it took participants from release of the yellow buttons until press of the pink or green buttons, indicating that the sentence was meaningful. We first eliminated all incorrect responses. Correct responses to critical items were then winsorized using 3 standard deviations from each participant’s mean as a cut-off and submitted to the subsequent inferential statistical tests. Mean reaction times in each condition are shown in Figure 2.

We performed two two-way repeated measures ANOVAs (one by participants and one by items) to look at effects of the two independent variables – Sentence-Type with Hand-Number. We found one significant main effect, that was unrelated to our hypothesis; bimanual responses were on average slower than unimanual responses, regardless of the Sentence-Type manipulation: $F_1(1,29)=20.21$, $p<.001$; $F_2(1,18)=27.18$, $p<.001$. More importantly, however, we also observed an interaction between Hand-Number and Sentence-Type that was significant both by participants $F_1(1,29)=7.60$, $p=0.01$, and by items, $F_2(1,18)=6.60$, $p=0.02$. This effect, as seen in Figure 2, seems to have been driven by slower two-handed responses in reaction to sentences

about object transfer to high status recipients than low status recipients, and one-handed responses that were slightly slower after sentences about transferring objects to low status recipients than high status recipients.

Figure 2: Response times as a product of high status and low status sentences, when manual responses were made with one hand or two hands, show a significant interaction between Hand-Number and Sentence-Type

Subsequent pairwise comparisons indicated that this interaction effect was driven mainly by the differences in bimanual responses. That is, the mean reaction time to respond with two hands was significantly slower when the manual action was preceded by high status sentences than low status sentences ($t_1(29)=2.05$, $p=.02$; $t_2(18)=2.11$, $p=.027$). However, looking at the one-handed responses revealed no significant effect of Sentence-Type on Reaching time.

Discussion

The results reported above indicate that Korean speakers' manual responses to indicate sentence meaningfulness were significantly influenced by the social context mentioned in the sentences they were processing. People were significantly slowed down in making bimanual actions after they heard sentences describing object transfer to someone of higher social status, as compared with sentences about people of equal or lower status. In contrast, unimanual responses were slower with the low status sentences than the high status sentences, although this numerical difference did not approach statistical significance.

This result is yet another piece of evidence in line with previous findings, showing that people engage their motor systems while processing language about interacting with objects and moving their bodies more generally. The study of how exactly we extract meaning from utterances is still in its infancy. And yet, the discovery that modality-specific systems are automatically engaged during the process suggests one part of the puzzle – it could be that motor (and perceptual) simulation plays a functional role in language understanding by allowing the comprehender to construct an experience that is in some ways like what it would be to experience a distal described scene. This simulation may do

more than merely create a subjective experience akin to what the comprehender would experience when confronted with the described scene; it might also facilitate inference or be used to generate predictions or interpolate implied but implicit elements of the scene.

However, the findings we've reported here is different from previous work. The current study's findings suggest that the motor activation comprehenders engage during language processing is tailored not only to the objects described but also to the culturally appropriate motor actions that one would perform in the described social context. This suggests that motor simulation isn't merely activated by specific words. Instead, it reflects a computation of socially appropriate action, which must take into account not merely low-level physical properties of a mentioned object, but social variables like age and position. On some accounts, people perform mental simulation to create representations of what it would be like if they were immersed in the described experience (Zwaan, 2004). The finding that people take social variables into account when constructing motor simulations is coherent with this account.

While the finding reported above highlights the importance of social knowledge in language comprehension, the difference we observed between the high and low status sentences could be due to either or both of two differences between them. As we discussed above, the sentences differed both in terms of the social character of mentioned recipients, as well as in the presence or absence of honorific markers. Honorifics—also known as indexical politeness forms—are grammatical and lexical markers in the Korean language that systematically encode the speaker's socio-culturally appropriate regard towards the addressee and/or the referent (Sohn, 1999). In our stimuli, the High Status sentences, as exemplified in the example (1), indicated that the status of the recipient was higher than that of the subject (*you*) by employing honorific markers in three places within the sentence, since that is how native Korean speakers would most naturally express this. The marker *-nim* 'sir/madam' on the recipient noun indicates deference to the high status referent. The marker *-kkey* '(honorable) to' is a case marker used for a high status recipient. The verb root *tuli-*, which is the humble form of the plain verb *cwu-* 'give', is used to indicate deference to the high status recipient. To any native Korean speaker, the presence of these honorific markers clearly indicates that the subject of the sentence (*you*) has a lower status than the mentioned recipient. When these honorifics are dropped, Korean speakers naturally understand that the status of the sentential subject is at least equal or even higher to the mentioned recipient. For instance, dropping honorifics is a common way for Korean students to make fun of their teachers behind their back.

Due to these two kinds of differences, when we compare effects of these two sentence types (1) and (2), we cannot tell if the status of the recipients or the presence/absence of honorifics is responsible for the differences in hand

responses. We believe it is critical to determine whether the social status of the recipients by itself produces the interaction effect, or whether the presence of honorifics is important as well.

To investigate this question, we are currently collecting data for a follow-up study. In that study, we closely matched the current experiment's design and materials, but included a third Sentence-Type condition, one with sentences using high status recipients but no honorific markers. If these sentences behave like the high status sentences in this first experiment, that will suggest that it is the status of the recipient, and not the presence of honorifics, that produces the effect we've observed. But if we find that these new sentences behave like low-status sentences, then this will lead us to conclude that honorifics present in a sentence are a critical factor affecting the motor routines people simulate. This in turn will tell us a little bit about how world knowledge and linguistic cues affect the motor simulations comprehenders construct.

In the Method section, we presented the reasoning why we expected a mismatch-advantage rather than a match-advantage. We found such an effect, and the next step is for us to investigate whether the proposed explanation is correct. We intend to do this through another study, currently under design, in which we change the structure of the critical Korean sentences, so that several words appear at the end of the sentence, after the transfer-action verb. When we thereby increase the interval between the action verb and the subsequent motor response, our explanation would predict that we should find a reversal in the direction of the effect: from a mismatch- to a match-advantage.

The final aspect of the findings reported here that may be of interest is the result of the follow-up pairwise t-tests reported in the Results section. The significant mismatch advantage we observed appears to have been driven more by the bimanual responses than the unimanual responses. We'd like to offer two possible explanations for this fact.

First, in situations of actual transfer, people use the right hand regardless of the status of the recipient; two-handed actions use both hands by definition, and one-handed actions conventionally use the right hand, as left hand transfer is regarded as disrespectful in Korean culture. As a result, both the high-status and low-status sentences should engage motor circuitry involved in the use of the right hand. And the two sentence types might thus interfere to the same extent with subsequent one-hand actions. By contrast, two-handed transfer actions are more similar to – and thus are more interfered with following – sentences about high-status actions, which also use two hands.

A second possible explanation for the larger effect in two-handed responses than one-handed responses is that it could result from differences in the degree to which the two actions are routinized. Perhaps reaching actions to press buttons with one hand are so common as to be routinized to the point where people perform them at floor (i.e., shortest possible reaction times). This would leave little room for effects of previously heard sentences on reaching behavior.

In contrast, using both hands is a more difficult task, particularly when participants are trying to maximize both speed and accuracy. It could be that greater difficulty in bimanual action provided room for the critical Sentence-Type factor to more differentially influence reaction times. Indeed, the significantly faster responses in the one-hand condition, as compared with the two-hand condition, are compatible with this floor account. We expect our follow-up studies will further illuminate the extent to which the ACE paradigm can tease apart the action execution resulting from a mental computation of the socially appropriate action, versus an action execution based on a routinized motor command.

Conclusion

Is language-driven motor simulation sensitive to not only physical but also social constraints on action? The current study suggests that it is. We've presented three new findings. First, the motor simulation that people engage during language comprehension includes the number of hands one would use to perform a described action. Second, cultural-specific rules for motor control enter into these mental simulations. For Korean people, it is customary to tailor the number of hands one uses to transfer objects to the relative social status of the self and the object recipient. This social knowledge about proper actions is engaged in the form of active motor representations of the number of hands appropriate in each social context, even when people merely hear language describing those events. Finally, the direction of action-sentence interactions is different in Korean and English – arguably due to differences in word order. These findings clearly indicate that language understanding is a constructive process that broadly engages heterogeneous cognitive systems – it uses our understanding of physical actions, and even the social conventions surrounding those actions.

These results raise a host of potentially productive follow-up questions. Do people engage socially constrained motor knowledge during other non-motor tasks, such as object perception or recall? Do people raised biculturally, such that they have two distinct systems of motor conventions, simulate different actions depending on the cultural context or the language of an utterance? And is a social constraint on action the type of thing that can be learned late in life – do people introduced to a culture and language as adults also simulate socially appropriate actions? Clearly, there is much more to know about how social constraints on action are learned and what other aspects of cognition they affect.

Acknowledgments

The authors are grateful to Chae Eun Kim for assisting the stimuli recording, Bodo Winter for helpful suggestions on this work, and to Korean students at the University of Hawai'i who participated in the experiment.

Abstract

How do we learn causal structures? All current approaches use scenarios in which trials are temporally independent; however, people often learn about scenarios unfolding over time. In such cases, people may assume that other variables don't change at the same instant as an intervention. In Experiment 1, participants were much more successful at learning causal structures when this assumption was upheld than violated. In Experiment 2, participants were less influenced by such temporal information when they believed the trials to be temporally independent, but still used the temporal strategy to some extent. People seem to be inclined to learn causal structures by connecting events over time.

Keywords: causal reasoning; causal structures; time

Introduction

How do our concepts of event units influence how we learn causal structures? Despite the surge of research on causal structure learning, there has been little attention to how learners "connect" streams of information over time.

Existing theories of how people learn causal structures have focused on cases with events considered to be *independent*. For example, suppose we are trying to learn the causal relationships between three economic variables: employment, GDP, and consumption. Existing psychological theories suggest that one looks at the relationships among the variables across *many separate countries* to determine the causal structure. We call this strategy the *independent events* strategy because the countries are assumed to be independent.

An alternative approach is to pick one country and follow the three variables over time. We could track whether GDP goes up when employment goes up, etc. We call this strategy the *dependent events* or *temporal* strategy because the state of each variable is dependent on its prior state.

Psychologically, the temporal strategy may be pervasive and perhaps a default. As temporal beings we often perform or witness sequences of actions on one entity. For example, a car mechanic or computer technician can repair different components until the problem is solved. A psychotherapist can attempt to change one person's beliefs, emotions, and behaviors systematically over time. A physician can intervene on heart rate, breathing, and blood pressure to stabilize a patient. In many real-world situations we do interact with causal systems repeatedly over time, and thus

the temporal strategy may be common if not a default for learning causal structures.

In formal statistics we have developed specialized procedures for independent cases (e.g., between-subjects) and dependent cases (e.g., repeated-measures, time-series). Analogously, do people use different learning strategies for the two scenarios? In the following sections we detail the different inferences people might make.

Interventions with Independent Trials

Consider first one prominent account of how people learn causal structures from interventions when trials are independent (e.g., Gopnik et al., 2004; Pearl, 2000; Steyvers et al., 2003). According to this model, when you intervene upon a variable such that you control its state, that variable is assumed to be independent from its other causes, but its effects are still dependent on that variable. Consider again the example of learning the causal relationships between employment (E), GDP (G), and consumption (C). Pretend that a priori it is possible that any of these factors could influence or be influenced by any of the other factors. To learn the causal structure, one could intervene on each of the three variables to determine which other variables are influenced by (dependent upon) the intervention.

Suppose that the true causal structure is a chain; E influences G , which influences C ; $E \rightarrow G \rightarrow C$. If we could institute jobs-creation programs in 10 countries, we would expect them to have high G and C . If, hypothetically, we instituted a mass lay-off of government employees, we would expect comparatively low G and low C . These opposite interventions demonstrate how G and C are dependent on E . If we somehow selectively *boosted* G for 10 new countries, they would have high C , but the same E as if we *decreased* G for 10 other countries; C is dependent on G but E is not. And if we gave 10 countries a boost in C , and another 10 countries a decrease in C , the two countries should have the same E and G ; neither is dependent upon C .

If instead the true causal structure is a common cause such that E influences both G and C , $G \leftarrow E \rightarrow C$, we would expect a different pattern of (in)dependence. If we increase or decrease G , the respective countries would have the same levels of E and C because they are independent of G .

This strategy can identify the precise causal structure because each causal structure has a different pattern of (in)dependence when the variables are intervened upon.

Importantly, however, this strategy requires that the observations be independent. This strategy does *not* look at whether one country's GDP *improves after* increasing employment compared to *before* (a within-subjects design). It only compares the outcome of countries with increased vs. decreased employment.

Repeated Interventions Over Time

In contrast to the case just described, there are many scenarios in which a person intervenes repeatedly on one entity, and states of variables are fairly stable over time (e.g., car mechanic, physician). Consider a case in which we repeatedly intervene to increase or decrease E , G , and C within the United States. Suppose that the true causal structure is $E \rightarrow G \rightarrow C$, and initially the country is in a recession and all three variables are low. If we start a job-creation program, we would expect G , and C to increase *compared to before the intervention*. Then, suppose that we decreased G . We would expect E to *stay high*, but C to decrease. Finally, suppose that we encouraged consumption. We would expect E and G to stay the same. In contrast, suppose that the true causal structure is $G \leftarrow E \rightarrow C$. Now, if we increase G , we would expect E and C to stay the same, but we would expect both to change if we intervened on E .

In sum, if we repeatedly intervene on one entity, we expect variables that are not influenced by the intervention to *remain constant*. If we intervene upon a variable X , and another variable Y changes *from the previous state*, it is a sign that X causes Y . If Y does not change when X is manipulated, it is a sign that X does not cause Y . These inferences are intuitive given the assumption that causes are generally stable and don't happen to change at the same moment that another cause is manipulated. This temporal assumption of "stability" is analogous to the atemporal assumption that interventions are independent of other causes (e.g., Pearl, 2000; see also Rottman & Ahn, 2009a).

Testing Whether People Use the Two Strategies

The temporal strategy is very different from the strategy appropriate for independent observations. Only in the temporal case are the changes in variables over time important for learning causal structure and thus the order of the trials is critical.

To determine whether people are sensitive to the temporal information, we created pairs of data that have the same sets of 24 intervention trials, but with different trial orders. For example, consider the chain data in Figure 1. There are three variables (X , Y , and Z) and two possible values (0, and 1). Bold represents an intervention. For example, on Trial 1 for the useful chain condition, X was intervened upon and set to 1. Y and Z consequently have the value 1.

According to the independent trials strategy, both orders suggest the chain $X \rightarrow Y \rightarrow Z$. When X is intervened and set to 1, Y and Z are also 1. When Y is set at 1, Z is 1, but X can be either at 0 or 1 because X is not dependent on Y . Finally, if Z is set to 1, X and Y could both be 0 or 1 because they are independent of Z .

However, according to the temporal strategy, the two orders lead to very different inferences because the useful condition upholds the stability assumption but the misleading condition violates it. The "useful" condition suggests the $X \rightarrow Y \rightarrow Z$ causal structure. Whenever X is changed, Y and Z also change (e.g. the transition from Trials 1 to 2). Whenever Y is changed, Z also changes, but X stays the same (e.g., Trials 2-3). When Z changes, X and Y stay the same (e.g., Trials 4-5). In contrast, misleading conditions were designed to suggest the presence of links that do not exist. For example, on Trial 2, Z is changed from 1 to 0, and X and Y also change to 0, suggesting that Z causes X and Y . Additionally, causal links are not consistent. On Trial 2, Z appears to cause X and Y to change to 0, but on Trial 3 it does not cause them to change back to 1. Finally, the existence of real links is obscured. For example, on Trial 5, X is changed from 0 to 1, but Y is already at 1, obscuring that X influences Y . In sum, the "misleading" condition suggests different links from the "useful" condition, and does not clearly identify one causal structure.

We used this order manipulation in two experiments. In Experiment 1, we tested whether people do in fact use the temporal strategy. In Experiment 2, we tested whether people appropriately switch between the two strategies based on the causal scenario.

Trial	Chain						Common Cause					
	useful			misleading			useful			misleading

Figure 1: Summary of Data for Two Causal Structures in Experiment 1.

Experiment 1

In Experiment 1, we created a scenario in which one causal setup is repeatedly intervened upon over time. Thus participants would likely think that the temporal information was relevant. We presented participants with data generated by five causal structures. For each causal structure, there was a useful and misleading set of data. If participants use the temporal strategy, they will learn the causal structures more accurately in the useful condition.

Methods

Twenty undergraduates completed the study for payment at \$10 per hour or partial course credit. Participants first read a cover story about three light bulbs. Participants were told that they would be instructed to turn on or off specific lights and should try to “learn how each light affects the others.”

Next, participants saw 10 scenarios created by crossing the Order of the Data (useful vs. misleading) \times Causal Structure (chain, $X \rightarrow Y \rightarrow Z$; common cause, $Y \leftarrow X \rightarrow Z$; common effect, $X \rightarrow Z \leftarrow Y$; one link, $X \rightarrow Y$, Z is unrelated; no links, X , Y , and Z , are unrelated). The 10 scenarios were ordered in a Latin square grouped by causal structure such that each scenario appeared first for some participants.

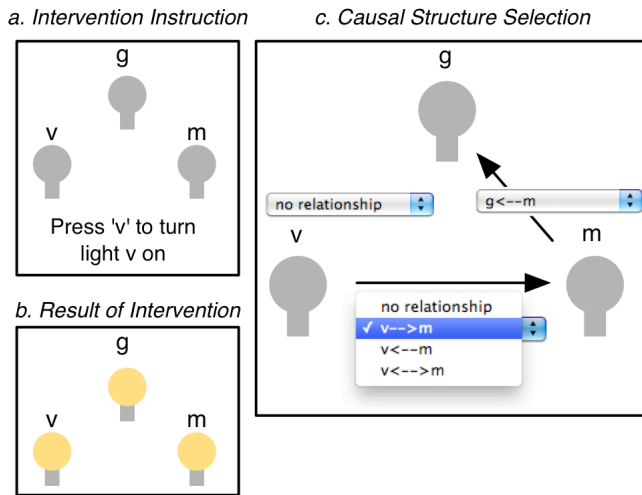

Figure 2. Example Screenshots from Experiment 1.

During each scenario, participants saw three light bulbs. Each bulb was named by a letter, and different letter triads were used across the 10 scenarios. Initially, all three bulbs were off. Then participants were instructed to intervene to turn on or off specific bulbs (e.g., Figure 2a). To intervene, participants pressed the key associated with the letter for the given bulb. After the intervention, participants observed the outcome of the intervention (which bulbs were on or off) for 2 seconds (e.g., Figure 2b). Then, while the bulbs were still visible, instructions appeared for the next intervention.

Each scenario had 24 interventions total, 8 per bulb; 4 on and 4 off. The data were determined in the following way. The causal relations were deterministic; when a bulb was intervened upon, all its effects (and all of their effects)

assumed the same value. Exogenous variables had a base-rate of .5. For the common effect structure, the effect was on if either of the causes was on.

For the “useful” conditions, the trials were ordered in a way that upheld the stability assumption explained in the introduction whereas the “misleading” conditions violated it. Figure 1 displays a summary of the data for the chain and common cause scenarios. The data for the other three causal structures can be obtained from the authors.

After each scenario, participants selected the causal structure that they believed to have generated the pattern of data for the given scenario (e.g., Figure 2c). Participants selected arrows indicating the direction of the causal relationships between the three light bulbs. For each pair of bulbs (e.g., X and Y), participants chose between “no relationship; neither light influences the other”, “ $X \rightarrow Y$; X influences Y ”, “ $X \leftarrow Y$; Y influences X ”, or “ $X \leftrightarrow Y$; X and Y both influence each other.” Participants did not receive feedback of the accuracy of their causal model. Finally, participants started the next scenario.

Results

Accuracy in causal structure inferences was assessed in the following way. For each pair of bulbs, X and Y , X can cause Y or not, and Y can cause X or not. Thus for each pair of bulbs, participants had the possibility of identifying zero, one, or two correct causal relations. Across the three bulbs in a given scenario, participants had the possibility of identifying zero to six correct causal relations.

For all of the five causal structures, participants identified more correct causal relations in the useful than misleading conditions $t(19) > 8.32$, $ps < .01$ (Figure 3), suggesting that they used the trial order for learning causal structures.

Figure 3: Mean Accuracy (Std. Errors) in Experiment 1.

There are two trends in participants’ mistakes. First, in the useful chain condition ($X \rightarrow Y \rightarrow Z$), participants had difficulty learning that Y was a mediator between X and Z . This requires noticing that when Y is manipulated, X has no

influence on Z. Eighteen out of the 20 participants thought that X also caused Z directly, probably because when X was turned on and off, Z also changed state. Similar findings have been interpreted to suggest that people sequentially learn individual causal links rather than simultaneously learn an entire causal structure (Fernbach & Sloman, 2009).

Second, in the misleading conditions, participants frequently correctly identified true causal links, but they also mistakenly thought that other links existed. They often thought that links were bidirectional, even though they were just unidirectional. In the one link and no link conditions, they also frequently inferred relationships between variables with no causal relations. These inferences resulted in participants often misidentifying the majority of the causal links; the accuracy in all misleading conditions was below chance responding of 3, all $ts(19) > 2.4$, $ps < .03$. However, these inferences make sense according to the temporal strategy; the misleading orders were designed so that variables that were not effects of a manipulated variable frequently change at the same time as the intervention, suggesting additional causal relationships.

In sum, the results strongly suggest that participants were sensitive to the order of the trials and were using the transitions between trials to infer causal relationships.

Experiment 2

In Experiment 1, it was rational for participants to use a temporal strategy to learn causal structures because participants observed entities change over time. The purpose of Experiment 2 was to determine how flexibly people apply the temporal vs. independent strategies given different scenarios. We created two scenarios intended to give maximal cues to participants that the trials were either independent (analogous to a between subject design) or dependent (analogous to a within-subjects design). Previous studies have successfully used such a manipulation (Rottman & Ahn, 2009b). We then tested whether participants would infer different causal structures in useful vs. misleading orders. If participants use the temporal strategy for the dependent case, they would be more accurate in the useful than misleading order, as in Experiment 1. Additionally, if they do not use temporal information in the independent scenario, they would not have different levels of accuracy for the two orders.

Methods

Sixteen students from the same population participated.

Participants first read a cover study story asking them to pretend that they are assistants in a biology lab studying hormones in amoebas. They would “produce” or “suppress” hormones by injecting chemicals into the amoebas and “learn how each hormone affects the others.” They were told that the “hormones work immediately... without any perceivable delay.”¹

¹ This statement about no delay was intended to rule out the possibility of second order causal relationships (e.g., if Hormone A

Next, participants saw eight scenarios. Each scenario presented three hormones. “+” and “-” signs denoted the results of the hormones, presence and absence respectively. The eight scenarios were created by crossing Number of Amoebas (one vs. many) \times Trial Order (useful vs. misleading) \times Causal Structure (common cause, $Y \leftarrow X \rightarrow Z$ vs. one link, $X \rightarrow Y$, Z is unrelated). The design was entirely within subjects. The 8 scenarios were ordered in a Latin square such that each scenario appeared first for some participants, and the scenarios were grouped by number of amoebas. The trial order and causal structure manipulations were the same as in Experiment 1, so the following paragraphs focus on the number of amoebas manipulation.

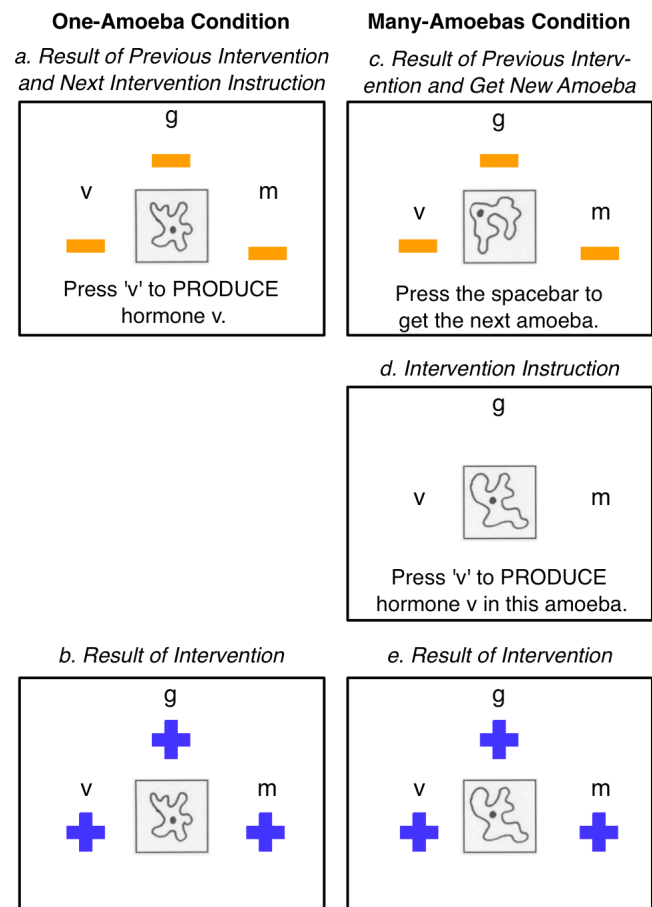

Figure 4: Example Screenshots from Experiment 2.

The one-amoeba condition, analogous to a within-subjects design, emphasized the dependent nature of the data. The one-amoeba procedures were similar to those in Experiment 1; participants repeatedly intervened on one amoeba. While the result of the previous intervention was displayed, participants were instructed to “PRODUCE” or “INHIBIT”

is produced and suppressed twice in a row, then Hormone B would be produced), which some participants reported in pretesting. In both the dependent and independent conditions, the interventions do work immediately after the intervention key is pressed.

a specific hormone (e.g., Press “y” to PRODUCE hormone y; e.g., Figure 4a). After the intervention, participants observed the result of the intervention for 2 seconds (e.g., Figure 4b). While the results were visible, instructions for the next intervention appeared. Additionally, a picture of one amoeba was present for the entire scenario to emphasize the repeated interventions on a single entity over time.

The many-amoebas condition, analogous to a between-subjects design, emphasized the independent nature of the data. Participants made 24 interventions on 24 different amoebas. After the results of a given intervention were displayed, participants were instructed to “Press the spacebar to get the next amoeba” (e.g., Figure 4c). When the spacebar was pressed, a picture of a new amoeba appeared. Simultaneously, the results of the intervention on the previous amoeba (“+” and “-” marks) disappeared (e.g., Figure 4d). We removed the previous results to make it perceptually difficult to track the changes of the hormones over time. Two seconds later, the prompt for the next intervention appeared (e.g., Press “y” to PRODUCE hormone y in this amoeba). When the intervention key was pressed, the hormone results appeared for the current amoeba (e.g., Figure 4e). All of these modifications were intended to signal that the hormones within one amoeba were independent of the hormones within other amoebas.

After each scenario, participants selected the causal structure that they believed to have generated the data.

Results

The dependent variable was the same as in Experiment 1 – the number of correctly identified causal relations per scenario (zero to six).

A 2 (one vs. many amoebas) \times 2 (trial order) \times 2 (causal structure) repeated-measures ANOVA was performed. There was a main effect of trial order; participants correctly identified more causal relationships in the temporally useful than misleading orders, $F(1,15)=45.28$, $p<.01$, $\eta_p^2=.75$ (Figure 5). However, the most critical result for this experiment is a significant interaction between number of amoebas and trial order, $F(1,15)=12.61$, $p<.01$, $\eta_p^2=.46$.² Though there was a large difference between the useful and misleading orders for the one-amoeba condition, there was a smaller difference between the many-amoebas conditions, suggesting that participants were less sensitive to the temporal order of trials in the many-amoebas condition. This finding makes sense if participants believed that the trials were independent in the many-amoebas condition.

However, even though participants used the temporal strategy less in the many-amoebas condition, they still used it to some extent; there was still a significant difference between the useful and misleading, many-amoebas conditions, $t(15)=3.59$, $p<.01$. Furthermore, participants did

not simply transfer the temporal strategy from the one-amoeba condition; they were more accurate in the useful than misleading many-amoebas conditions even before experiencing the one-amoeba scenarios, $t(7)=3.21$, $p=.02$.

Figure 5: Mean Accuracy (Std. Errors) in Experiment 2.

There are two other important patterns. First, participants did worse in the many-amoeba than one-amoeba, useful condition, $t(15)=2.57$, $p=.02$. This finding makes sense if participants were using the temporal strategy less in the many-amoebas condition. However, according to the independent trials strategies (e.g., Gopnik et al., 2004; Steyvers et al., 2003), participants should have been able to correctly identify the causal structures in the many-entity conditions. Second, participants were not even above chance in the many-amoebas, misleading condition, $t(15)<1$. Yet again, participants should have been able to identify the correct causal structures according to the independent trials strategy. The low accuracy in both many-amoebas conditions suggests that participants may have difficulty applying such statistical strategies.

In sum, participants are able to switch between the temporal vs. independent strategies to some extent based on knowledge of the learning scenario. However, even in the many-amoebas condition, participants used the temporal information to some extent, suggesting that it is a common strategy for learning causal structures.

General Discussion

In two experiments, we demonstrated that people learn causal structures very well when entities are repeatedly manipulated over time (i.e. within-subjects or repeated measures situations). In Experiment 1, participants were much more accurate at learning causal structures when the data were ordered to reflect causes that are stable over time (don’t happen to change at the moment another variable is intervened upon), a plausible real-world assumption. In Experiment 2, participants were less sensitive to the temporal order of trials when they were given reason to believe that the trials were independent (i.e. between-subjects situation).

² The only other finding was a marginally significant interaction between causal structure and trial order, $F(1,15)=4.03$, $p<=.06$, $\eta_p^2=.21$. The difference between the useful and misleading orders was slightly larger for the common cause than one link conditions.

Predominance of the Temporal Strategy

Why did participants in the many-amoebas condition in Experiment 2 still make use of the temporal information to some extent? There are two possible explanations. First, people may have still thought that the hormones within different amoebas were dependent upon one another. (For example, if all the amoebas were physically adjacent, perhaps hormones could mix across the amoebas.) Alternatively, people might have been able to learn that the trials were dependent from the data itself. In reality, in the many-amoebas, useful condition, the order was statistically dependent. For example, exogenous variables (e.g., X in $X \rightarrow Y \rightarrow Z$) only changed state when X was intervened upon. For long periods of time, X stayed the same (e.g., Trials 2-6 in Figure 1, Chain, Useful) even though its base rate is .5.

However, there is also a second possibility – the temporal strategy is likely simpler than the statistical strategies proposed for independent events (e.g., Gopnik et al., 2004; Steyvers et al., 2003). Thus, it is possible that people tend to use this strategy even in cases when the independent strategy is more appropriate. Perhaps the time-based strategy serves as a useful heuristic that is often accurate. In the real world, much of our causal reasoning involves manipulating and observing sequences of events unfolding over time (e.g., a car mechanic repairing different components until the problem is solved or a physician manipulating a patient's heart rate, breathing, and blood pressure to stabilize the patient). Given how frequently we engage in temporal reasoning, it may be hard to ignore temporal information such as the order of trials in these experiments even when we should for independent events.

Learning Causal Structure from Temporal Delay

Lagnado and Sloman (2004, 2006; see also Burns & McCormack, 2009; Meder et al., 2008; White, 2006) showed how people use temporal *delays* when learning causal structures. For example, if you intervene upon X , and then Y appears, and later Z appears, you would likely infer $X \rightarrow Y \rightarrow Z$. This strategy pertains to the time course of how a causal signal propagates through a network and the order in which the reasoner becomes aware of the states of the nodes. This strategy is entirely consistent with the current one, and they likely often work in parallel in the real world. However, they are distinct. In the current studies, both of the non-manipulated variables appear simultaneously for all causal structures. Additionally, in the previous studies (e.g., Lagnado & Sloman, 2006), the trials were independent and were often randomized.

Summary

Overall, people learn causal structures over time quite fluently and indeed seem biased to assume that this is the default mode of causal interpretation. Instead of treating trials as independent, which has been assumed by many approaches of causal structure learning, people weave together information across trials into larger event units.

The use of a temporal strategy can result in very quick and accurate causal structure learning when the trials are ordered in a temporally useful way. However, applying an incorrect causal strategy can result in substantially worse performance. For example, applying a more independent events strategy for events that were truly dependent and ordered in a useful fashion resulted in considerably worse performance than when participants applied the temporal strategy (Experiment 2). One intriguing possibility is that applying the temporal strategy when the events are truly independent could also likely result in reduced performance. Elaborating when and how people apply different learning strategies for diverse scenarios is an important future aim.

The Induction of Hidden Causes: Causal Mediation and Violations of Independent Causal Influence

Abstract

In order to explain the apparent violation of a causal assumption, people often posit hidden causes. The assumption of independent causal influence states that the power of a cause to produce or prevent an effect is independent of other causes. Some preventers violate independent causal influence; we conducted an experiment to test whether people posit a hidden mediating cause to explain these preventers. The results indicated that participants are more likely to posit a hidden mediator when the preventer violates independent causal influence.

Keywords: causal reasoning; causal inference; prevention; hidden causes; unobserved causes

Introduction

Although people often reason about simple cause and effect, they typically assume that such causal relationships are embedded in complex causal structures with hidden causes. So while people know that aspirin prevents headaches, they also believe that this relationship is mediated by some complex biological mechanism involving hidden causes. In many circumstances, the hidden causes are inconsequential. Knowing how aspirin prevents headaches is less important than knowing that it does so. Indeed, people often reason appropriately with only shallow causal knowledge (e.g., Keil, 2003). However, hidden causes may be important in other circumstances.

In particular, hidden causes may be important when the observed causes violate causal assumptions such as the Markov assumption in causal Bayesian network models (Pearl, 2000; Spirtes, Glymour, & Scheines, 1993/2000) or the assumptions for inferring causal power (Cheng, 1997; Novick & Cheng, 2004). Inferences about hidden causes have been demonstrated in a number of studies where some causal assumption is violated. Children appeal to hidden causes in order to explain probabilistic causation, and this may reflect an assumption that causation is deterministic (Schulz & Sommerville, 2006; see also Lu, Yuille, Liljeholm, Cheng, & Holyoak, 2008). Similarly, both adults (Gopnik, Glymour, Sobel, Schulz, Kushnir, & Danks, 2004; Hagmayer & Waldmann, 2007; Luhmann & Ahn, 2007) and infants (Saxe, Tenenbaum, & Carey, 2005) posit hidden causes when there is an unexplained effect, presumably reflecting the assumption that every effect has a cause (Kant, 1781/1965). Finally, people infer a hidden contextual cause when the causal power of the observed cause interacts

with its context (Liljeholm & Cheng, 2007; Rottman & Ahn, 2009).

In this paper, we focus on the assumption of *independent causal influence* (Cheng, 1997; Novick & Cheng, 2004). Independent causal influence requires that the power of one cause to produce or prevent the effect is constant: it does not change with context or with the occurrence or non-occurrence of other causes. According to independent causal influence, if aspirin prevents headaches caused by colds, then it will also prevent headaches caused by dehydration, stress, and so on. We investigate a specific violation of independent causal influence that arises in prevention.

Preventive scope is the range of circumstances across which a preventer works (Carroll & Cheng, 2009). A *broad preventer* stops the effect no matter what the cause, but a *narrow preventer* only stops the effect when the effect is produced by a certain *targeted cause*. Aspirin and nasal spray illustrate the difference between broad and narrow prevention. As a broad preventer, aspirin prevents headaches of all kinds (e.g., headaches caused by colds and headaches caused by stress). As a narrow preventer, sinus spray only prevents headaches caused by colds; it would not prevent a headache caused by stress.

Narrow prevention violates the assumption of independent causal influence because the power of the preventer depends on which cause is producing the effect *e*: a narrow preventer prevents *e* when it is brought about by the targeted cause *c*, but it does not prevent *e* otherwise. However, it is possible to reconcile narrow prevention and the assumption of independent causal influence by positing a certain type of hidden cause: a hidden *mediator*. Suppose that *c* produces *e* indirectly through a mediator and that the narrow preventer prevents the mediator rather than preventing *e* directly (see Figure 1). Once the mediator is included in the explanation, none of the causal relationships violate independent causal influence: *c* and the preventer independently influence the mediator, and the mediator and other causes independently influence *e*. As long as other causes of *e* produce *e* via mechanisms other than the mediator, the preventer will only stop *e* when it is being produced by *c*. Thus, narrow prevention would only appear to violate the assumption of independent causal influence because there is an unobserved mediator.

Figure 1: Mediation as an explanation of narrow prevention. Generative and preventive causation are denoted by arrows and modified arrows terminating in a circle, respectively.

Previous research (Carroll & Cheng, 2009) demonstrated that people distinguish between narrow and broad prevention, but the relationship between preventive scope and the inference of hidden mediation is less clear. Although participants in the previous research identified the mediation shown in Figure 1 as an explanation for narrow prevention, they only did so in a two-alternative forced-choice procedure. This shows that participants preferred the explanation in Figure 1 to the available alternative (an explanation where the preventer directly stopped the effect), but it is impossible to tell whether participants would have endorsed this explanation outside of this particular forced-choice question. Participants may have endorsed causal mediation as the better – but potentially unappealing – explanation of the two available choices. Furthermore, the experiment previewed the choices before showing the participants any data, and this may have biased participants towards interpreting the data with one of the provided explanations. Whether causal mediation is a favored explanation for narrow prevention more generally remains to be seen. Moreover, previous research did not clarify the relationship between preventive scope and the assumption of independent causal influence.

To assess whether the causal mediation explanation of narrow prevention is appealing more generally, we tested whether people endorse causal mediation after encountering a narrow preventer.

Method

Participants were asked to imagine themselves as researchers at a medical research company. They were directed to investigate how two fruit products from the rain forest – pane fruit and asmine juice – influence whether someone will have a headache. In all conditions, participants were shown some clinical trials where pane fruit caused headaches and asmine juice prevented headaches. We manipulated whether asmine juice was a narrow or broad preventer. After viewing the data, participants reported whether they expected asmine juice to prevent headaches under various circumstances. Finally, the

participants were given a series of statements and were asked to endorse or reject each statement. One of these statements presented the mediation explanation.

Participants

Forty undergraduates at the University of California, Los Angeles (UCLA) participated to obtain course credit in a psychology course. Participants were assigned to the narrow ($n = 20$) or broad ($n = 20$) prevention condition.

Materials

The data presented in the narrow and broad prevention conditions are shown in Table 1. The critical difference between the conditions can be seen by comparing the effect of asmine juice on headaches attributed to the background cause. In the broad prevention condition, drinking asmine juice reduced the number of headaches even when pane fruit was not consumed. This can be seen by comparing the number of headaches when people neither ate pane fruit nor drank asmine juice to the number of headaches when people drank asmine juice but did not eat pane fruit (see the top half of Table 1). In the narrow prevention condition, it did not do so.

Table 1: The frequency of headaches (the effect) as a function of pane fruit (cause), asmine juice (preventer), and prevention condition. F = pane fruit, J = asmine juice.

Observed Causes	Broad prevention	Narrow prevention
none	10 out of 50	10 out of 50
J	5 out of 50	10 out of 50
F	40 out of 50	40 out of 50
J, F	20 out of 50	20 out of 50

As shown in Figure 2, the data were presented in displays containing cartoon faces. Each cartoon face represented a person in the clinical trial, and the type of cartoon face (happy face or sad face) indicated whether the person had a headache.

Procedure

Participants were randomly assigned to the broad or narrow prevention conditions and then given the following cover story:

Imagine that you work for a drug company that develops headache medications. You have heard rumors about a certain area in a rainforest where many of the fruits influence whether someone has a headache (either by causing a headache or preventing it).

The drug company has asked you to investigate these claims.

You decided to run clinical trials to assess the influence of pane fruit and asmine juice. You recruited

volunteers and randomly divided them into groups. Each group was assigned a specific treatment (e.g., eating pane fruit but not drinking asmine juice).

The results of each trial are summarized by tables of cartoon faces, and you can tell whether someone had a headache by looking at the cartoon face.

Participants were shown data in a display similar to Figure 2, and were given a print-out of the data to reference while answering subsequent questions. The instructions emphasized that the results had been replicated in much larger studies so that any differences in the frequency of the effect were reliable.

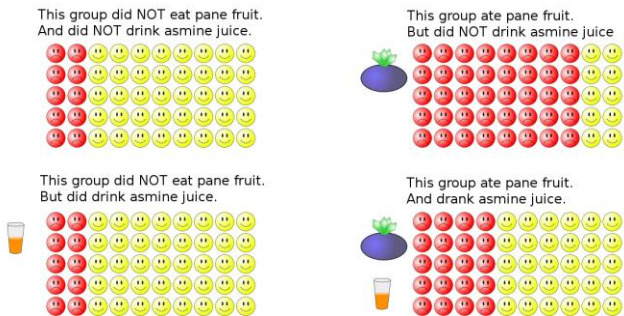

Figure 2: The data shown in the narrow prevention condition. Shaded frowning faces indicate people with headaches, and the lighter smiling faces indicate people without headaches.

Then, participants answered a series of counterfactual questions designed to measure beliefs about how pane fruit and asmine juice influence headaches. Each question asked the participants to imagine a group of people with certain characteristics and to predict whether consuming one of the food products would lead to more, fewer, or the same number of headaches in that group. For example, the *fruit* counterfactual - designed to assess the influence of pane fruit among a group of people who have not drunk asmine juice – asked following question:

Imagine that you go to a small town in the United States. If you brought PANE FRUIT to the town and everyone ate it, do you think that MORE people would have headaches, FEWER people would have headaches, or the SAME NUMBER of people would have headaches?

The other questions assessed when participants believed that asmine juice would prevent headaches. The *juice/fruit* question asked participants to predict the effect of asmine juice among people who live in a town near the rainforest and frequently consume pane fruit. The *juice/no fruit* question measured the influence of asmine juice among people living in a small town in America (who presumably have not eaten pane fruit). The *juice/withdrawal* question measured the influence of asmine juice among a group of people who have headaches for a specific reason other than

eating pane fruit: they have stopped drinking coffee and are experiencing caffeine withdrawal.

Finally, participants were shown a series of statements about pane fruit and asmine juice. The statements were shown one at a time, and participants were asked to endorse whichever statements they agreed with. Table 2 lists these statements in the order that they were presented. Endorsement of the *mediation* statement provided the critical measure of whether participants inferred a hidden mediator. It should be noted that the mediation statement is compatible with broad prevention as well as narrow prevention: a broad preventer might destroy the substance in addition to directly preventing the effect when it is produced by other mechanisms.

Table 2: Participants were asked to indicate whether they agreed or disagreed with the following statements

Type	Statement
prevents	Asmine juice can sometimes prevent or relieve headaches.
develop drug	Your company may be able to turn asmine juice into a drug like aspirin, selling it widely as a headache treatment.
mediation	Pane fruit produces a RARE substance that causes headaches, and asmine juice destroys THAT substance.
combination	There is something special about the combination of asmine juice and pane fruit that prevents headaches.

Results

For the counterfactual questions, participants indicated whether there would be more, fewer, or the same number of headaches after consuming one of the food products. To analyze these responses, we coded responses of “more” as 1, “fewer” as -1, and “same number” as 0.

As expected, most participants predicted that pane fruit causes headaches. For the pane fruit counterfactual, the mean response was .90 ($SD = 0.45$) in the broad prevention condition and .95 ($SD = 0.22$) in the narrow prevention condition. The difference between these experimental conditions was not significant, $t(38) = 0.45$, $p = .66$.

On the other hand, the predicted influence of asmine juice depended on the experimental condition and the specific counterfactual (see Figure 3). Participants in both conditions believed that asmine juice would prevent headaches among groups of people that had eaten pane fruit (*juice/fruit* counterfactual). However, there were noticable differences between the conditions for the other counterfactuals. When participants were shown broad prevention, they believed that asmine juice would prevent headaches in every counterfactual. In contrast, when participants were shown narrow prevention, they were much less likely to believe

that asmine juice would prevent headaches when the headaches were produced by either an unknown (juice|no fruit) or a known non-targeted (juice|withdrawal) cause.¹

Figure 3: Prevention ratings for the counterfactual questions involving asmine juice. Error bars show the standard errors.

To confirm these patterns, we conducted an ANOVA with prevention condition (broad or narrow prevention) and prevention counterfactual (juice|fruit, juice|no fruit, or juice|withdrawal) as the independent variables. The ANOVA found a main effect of prevention condition, $F(1,38) = 17.08$, $p < .001$, and an interaction between prevention condition and prevention counterfactual, $F(2, 76) = 6.28$, $p < .01$. To investigate the source of the interaction, we conducted a separate ANOVA in each prevention condition. These ANOVAs confirmed that there was a non-significant effect of counterfactual question under broad prevention, $F(2, 38) = 1.85$, $p = .17$, and a significant effect of counterfactual question under narrow prevention, $F(2, 38) = 6.34$, $p < .01$.

The percentages of participants endorsing the statements are shown in Table 3. Participants in both conditions were very likely to report that asmine juice sometimes prevents headaches, but participants in the broad prevention condition were more likely to do so, $p < .05$ by Fisher's exact test. This difference might reflect the failure of some participants in the narrow prevention condition to notice that the preventer prevents the effect. Participants in the broad prevention condition were much more likely to believe that asmine juice could be developed into a headache drug and widely marketed, $\chi^2(1, N = 40) = 20.42$, $p < .001$. Participants in the narrow prevention condition were much more likely to believe that pane fruit and asmine juice might produce and prevent headaches via a rare shared mediator, $\chi^2(1, N = 40) = 4.91$, $p < .05$. Neither of the experimental conditions led many participants to suggest that the combination of pane fruit and asmine juice prevented

headaches, and the difference between the conditions was not statistically significant, $p = .41$ by Fisher's exact test.

Table 3: Percentages of participants in each condition who agreed with the statements.

Question	Broad prevention	Narrow prevention
prevents	100%	75%
develop drug	95%	25%
mediation	35%	70%
combination	10%	25%

Discussion

This experiment demonstrates that people will endorse causal mediation in order to explain narrow prevention. The results also confirm that people distinguish between narrow and broad prevention, using preventive scope to guide generalization. Broad prevention was generalized irrespective of context, but narrow prevention was only generalized when the effect was produced by the targeted cause. A narrow preventer was not expected to stop the effect when the effect was produced by an unknown cause or a cause other than the targeted cause.

These findings contribute to a growing body of evidence showing that causal assumptions play a central role in the induction of hidden causes. Models of causal inference that make minimalistic assumptions (e.g., Pearl, 2000; Spirtes, Glymour, & Scheines, 1993/2000) may fail to explain these findings (see Griffiths & Tenenbaum, 2009 for other situations where minimalistic assumptions prove inadequate). In fact, since broad and narrow prevention imply the same conditional independencies among the observable variables,² Pearl's (2000) causal Bayesian network model represents them with the same causal graphs, treating a causal graph with mediation and a causal graph without mediation as equivalent.

Why is independent causal influence so important that its preservation warrants positing a hidden cause? The power PC theory (Cheng, 1997; Novick & Cheng, 2004) uses the assumption of independent causal influence as a defeasible default assumption to justify the inference of causal power. Without this assumption, the causal power of a candidate cause with respect to an effect is indeterminate even if the usual prerequisites for causal inference (e.g., "no

¹ Average causal ratings that are close to zero might be produced by (1) a roughly even mixture of "fewer" and "more" responses, or (2) many "same number" responses. Few participants reported that asmine juice causes headaches ($n = 2$); the answers close to zero were driven primarily by "same number" responses.

² Although the preventer is independent of the effect conditional on the cause being absent in narrow prevention but not broad prevention, causal Bayesian network models do not recognize this distinction. Causal Bayesian network models consider the conditional independencies of variables, not the conditional independencies at certain levels of variables. Since the preventer and effect are dependent for *some* values of the cause in both broad and narrow prevention, conditionalizing on the cause does not render them independent in the sense that causal Bayes nets consider when constructing a causal graph.

confounding”) are satisfied. A difference in the probability of the effect in the presence of the cause and in its absence, for example, could be entirely due to the interaction between the cause and the context. If so, then there would be no reason to expect the cause to produce the effect in a different context. Indeed, without independent causal influence, causal power is bound to specific contexts, and causes will combine in unpredictable ways from one context to the next. This would render generalization unjustified. The assumption of independent causal influence jumpstarts the inference of causal power and supports generalization to transfer contexts via a context-independent causal power.³

Although people view causal mediation as a viable explanation for narrow prevention, the reason for this inference is less clear. There are at least two possibilities. First, people may posit causal mediation liberally, but only endorse causal mediation of a certain form. If so, participants in the broad prevention condition might be equally comfortable with causal mediation except that they prefer explanations where the mediator is common rather than rare. If this is the case, then people use the assumption of independent causal influence to infer the *form* of causal mediation. That is, the violation or non-violation of independent causal influence would determine whether people expect the mediator to be shared between different causes of the effect.

Alternately, people may posit mediation only when causal assumptions are violated. Since causal relationships can be decomposed almost indefinitely, this represents a reasonable strategy to minimize the complexity of causal explanations while maintaining useful assumptions. Broad prevention, which does not violate independent causal influence, can be explained and predicted without causal mediation. Therefore, positing causal mediation provides little practical benefit. For narrow prevention, however, the representation of mediation provides more tangible benefits: it allows people to generalize more accurately. If people can identify the mediator, they can infer whether the preventer will stop other causes from producing the effect. Thus, the violation of the assumption of independent causal influence serves as a criterion for revising one’s causal explanation to achieve more accurate predictions.

In summary, narrow and broad prevention differ in whether they respect the assumption of independent causal influence. In narrow prevention, which violates independent causal influence, people view causal mediation as a plausible explanation. By positing causal mediation, people preserve the assumption of independent causal influence.

³ The assumption of independent causal influence can be replaced, without changing the predictions regarding generalization, by the assumption that the causal factors in the background that interact with the targeted cause occur with the same probability across contexts (Cheng, 2000). Since our dependent measures do not allow differentiation between these assumptions, we treat them as equivalent for our purposes.

Abstract

Human beings show a robust nonindependence effect in causal reasoning: they predict that collateral effects should be correlated even given a common cause. This presents a problem for existing models of causal reasoning, as most predict independence. To deal with this problem, we propose an edge replacement process that builds up apparently probabilistic causal relations using hidden deterministic causes. This model allows us to fit nonindependence effects, and shows promise for modeling other phenomena, such as how causal relations change over time.

Keywords: Markov violations; nonindependence; causal reasoning; models of causal reasoning

Introduction

Causation is only as simple as we make it. Consider the example of sending an email to two colleagues: You push send, which causes them to see text on their screen. The relation seems simple enough, but in reality, there is a complex chain of events that connects cause and effect, which most of us understand only vaguely (Keil, 2003). These details are usually not worth considering, but they are useful when the causal relations fail. For instance, most of us know to check our spam filter when we fail to receive an expected email. Such details also tell you about correlations between events: If one colleague calls to say she has not received the message, you know to call the other one as well. Still, more detail is not always better – it would be absurd reason about email at a molecular level. Choosing the right level of detail is important, and human beings seem to do it easily. Models of causal inference must solve this problem as well.

Causal graphical models (hereafter, “CGMs”), (Pearl, 2000; Spirtes, Glymour, & Scheines, 2000) give us a language in which to express this problem formally. Under this framework, nodes in a graph represent events, and directed edges represent causal relations. Figure 1 gives an example of three graphs that capture the common cause scenario described above: person C sends an email, causing persons E_1 and E_2 to receive it. Under the assumptions of CGMs, unconnected nodes must be statistically independent, but otherwise there are a wide range of possible functional relationships that can be instantiated by an edge. There is also no limit to the number of hidden nodes that can exist in a graph.

Figure 1: Examples of three different graphs that all capture the common cause relation. Minimality prescribes that we should begin by using a).

Thus, CGMs are enormously powerful, defining an infinite space of possible graphs for any given causal relation.

In order to make use of CGMs, we need some way of choosing which graph to use. The principle currently most used is called *minimality*: use the simplest graph that fits the data, in the sense that no other candidate graph has fewer edges. This means that given a common cause of two effects, the minimal graph is shown in Figure 1a. It is often acknowledged (i.e. Pearl, 2000) that minimality creates problems, but in the absence of an alternative, it is widely used.

Within the literature on causal reasoning, the most acute problem with minimality is known as *nonindependence*. The simplest example of this phenomenon is found in a common cause scenario. If two effects of a common cause are related according to the minimal graph (Figure 1a) then the two effects should be independent given their common cause. That is, if C directly causes each of E_1 and E_2 , then $P(E_1|C, \neg E_2)^1 = P(E_1|C) = P(E_1|C, E_2)$. If we see evidence that violates this expectation, then minimality allows us to use

¹This notation means: The probability that E_1 occurs given that C occurred, but E_2 did not.

a slightly more complex graph that better fits the data. But according to minimality, independence should be our initial expectation.

Human beings do not have this expectation. In several experiments (Mayrhofer, Hagmayer, & Waldmann, 2008; Rehder & Burnett, 2005; Walsh & Sloman, 2004) participants robustly predict that $P(C|E_1, \neg E_2) < P(E_1|C) < P(E_1|C, E_2)$, even in novel scenarios, and even when independence is explicitly emphasized. Such nonindependence effects show that if people respect CGMs, they do not respect minimality. This raises the question of what principle, if any, people do respect.

Rehder and Burnett (2005) proposed an “underlying mechanism model” to address this problem, in which people represent hidden intermediate causal structure. In its current form, this model allows only qualitative fits to the data. Our model is one way of formalizing and extending Rehder and Burnett’s proposal in order to make quantitative predictions. Further, Mayrhofer et al. (2008) modeled nonindependence effects using a source of common preventative noise, whose strength they fit to the data. Again, we hope to build on this initial step, and account formally for the source of this noise in a more principled way, while using fewer parameters to fit experimental data.

We propose a generative model of causation, which we call the *causal edge replacement process* (CERP). Theoretically, it is motivated by the hypothesis that causal reasoning involves representations of intermediate causal structure, or mechanisms (Shultz, 1982). Formally, CERP assigns a probability distribution to an infinite space of possible graphs, depending on how likely each is to be generated using repeated application of a specific edge replacement rule, and a restricted function set. The model’s key contribution is that in the generative process, each edge has a *length*; longer edges tend to generate more hidden structure. While the graphs preferred by the model tend to be simple, they are not minimal. In particular, graphs generated by CERP have a characteristic branching structure that gives good quantitative fits to human data on nonindependence. CERP also provides a formal way of addressing questions about causal mechanisms.

We will begin by explaining exactly how the generative model operates, then show how the model fits three independently collected data sets, using the same parameter settings. Finally, we will discuss directions for future work.

Generative model

We will describe the generative model in three independent ways: In this section, we will give an informal verbal overview of the edge replacement process. Figure 2 also shows the process visually. Finally, we will describe the model in complete formal detail.

CERP begins with an edge between two nodes, which represents a causal relation between two events of interest. The process then moves down this edge, randomly generating replacements as it goes. Each replacement incorporates the influence of a new node. Because of the branching structure

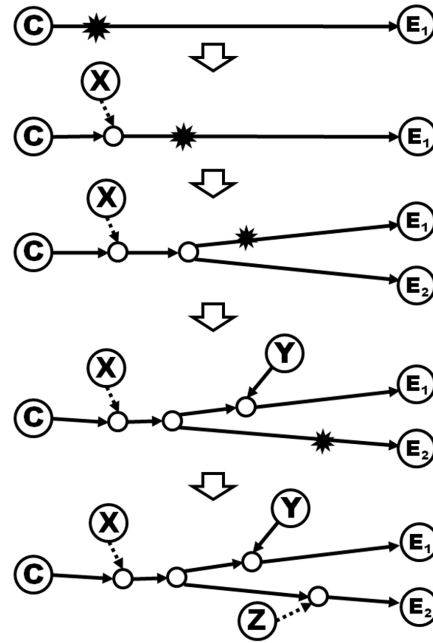

Figure 2: A series of edge replacements leading to a graph. The star indicates the location of the next replacement, as the process moves down each edge. Dashed edges indicate inhibitory relations.

created by CERP, it is helpful to think of causation as flowing down a stream from causes to effects.

To perform a replacement, we first replace the edge with an edge-node-edge path combination that has the same length. We call this middle node the “bridge node.” Then we add a new edge (of randomly determined length) connecting the bridge node and a new node. The meaning of “length” here is more functional than physical – it does not correspond to the spatial distance between cause and effect, but to how vulnerable the relation is to other events. The replacement is randomly determined to be one of three types: If it is an inhibitory replacement, then causation at this point follows an AND NOT relation: causal power will flow through the bridge node only if the new node is off. For instance, in Figure 2, X is generated by an inhibitory replacement. This might be a failure in the server that sends your email. (These specific cover stories are not generated by CERP; they are only used to illustrate the principles involved.) Replacements can also be generative: For instance, E_2 is generated next – it fires whenever causation reaches the bridge node. We call these “side effects”: For instance, sending an email may leave a record on the server. The third type of replacement is also generative, but causation flows inward rather than outward. We call these “alternative generative causes,” because they follow an OR relation: the effect fires either if causation reaches the bridge node, or if the alternative generative cause fires. For instance, see Y in Figure 2: this might repre-

sent the fact that you can cause a given colleague to see the text on their screen via another method, like directing them to a website. In principle, outward inhibitory replacements are also possible, but are usually irrelevant – we only include them for the sake of formal completeness results discussed below. When the new node (not the bridge node) is generated, it is assigned some random probability of firing – this is the only source of randomness in the causal structures defined by CERP. Thus CERP is committed to determinism, in the weak sense that variability arises from hidden causes, not from intrinsic randomness in causal relations.

After a replacement, the same process continues along the old path, and along the new edge created by the replacement. Thus, graphs can become arbitrarily complex if replacements are common enough. The process eventually stops when it reaches the end of all edges, yielding a graph. We can “run” the graph by deciding (again, randomly) whether each exogenous node is on, then propagating causation deterministically through the graph.

Formal Description of CERP

This section describes the model in complete formal detail. Readers who are not interested in implementing CERP can skip this section. A graph with n nodes consists of the following components: 1. An $n \times n$ matrix G that encodes the causal relations (edges) between nodes. (1=generative, -1=inhibitory, 0=no relation) 2. An $n \times n$ matrix L of edge lengths. 3. A vector S of length n that encodes the spontaneous activation probabilities of each node. Together, $\langle G, L, S \rangle$ defines a graph.

The generative process begins with an edge of length 1 between two nodes, which we will call A and B . We perform replacements by moving along each edge and generating replacements according to a Poisson process with rate λ . This is done by sampling x from $Exponential(1/\lambda)$. If $x > L(A, B)$, then stop. Otherwise do a replacement at point x : Create a new node M as the $(n+1)$ th node. With probability ρ , designate a previously generated non-bridge node as E , otherwise create a new node E as the $(n+2)$ th node (For our purposes in this paper, $\rho = 0$). Set $G(A, M) = 1$ and $G(M, B) = G(A, B)$. Set $L(A, M) = x$ and $L(M, B) = L(A, B) - x$. If E already exists, and it is exogenous, set $G(E, M)$, and if it is endogenous, set $G(M, E)$. Otherwise, with equal probability, choose to set either $G(E, M)$ or $G(M, E)$. Set this relation as -1 or 1 with equal probability. Also sample $L(M, E)$ or $L(E, M)$ from $Exponential(\gamma)$. Set $S(n+1) = 0$ and sample $S(n+2)$ from $Beta(\alpha, \beta)$. Finally, set $G(A, B) = 0$, eliminating the original edge. Initiate two new Poisson processes, along MB and ME , and repeat until all processes have stopped.

To sample from the graph, determine whether each node is on, according to S , then propagate causation deterministically through the graph to determine the values of each non-exogenous node. A node is on if and only if all of its inhibitory connections are off, and at least one of its generative connections is on, or it fires spontaneously. This instantiates the OR (for generative) and AND NOT (for inhibitory) func-

tions originally applied to causation by Cheng (1997).

Completeness and Validity

We can use CERP to construct any logical relation: OR can be created by an inward generative replacement, AND NOT from an inward inhibitory replacement, while AND can be created by an inhibitory replacement on the negation of a variable. In particular, the inward inhibitory replacement acts as a “causal transistor,” letting us construct a wide range of logical “circuits.” We can also use the presence of a hidden inhibitor to generate any apparently probabilistic relation between two variables: To generate any $P(B|A)$, perform a hidden inhibitory replacement on the edge AB , with spontaneous activation probability $1 - P(B|A)$. Similarly, for any $P(B|\neg A)$, perform a hidden generative replacement with spontaneous activation probability $P(B|\neg A)$.

Yuille and Lu (2008) show that their noisy-logical graphs can capture any causal-functional relation. If we additionally allow CERP to reuse existing exogenous nodes when performing replacements (i.e. $\rho > 0$), then it is easy to see that CERP can be used to mirror any noisy-logical graph, as we can construct any logical or apparently probabilistic relation as described above. Thus, we can extend Yuille and Lu’s (2008) completeness result to CERP. Some such relations will be generated with low probability by CERP, but all relations will have nonzero probability of being generated. Thus, CERP defines a prior distribution over the hypothesis space of all possible causal-functional relations.

The model also preserves validity: Because it introduces no undirected edges or cycles, it will always produce a directed acyclic graph when given a directed acyclic graph. To introduce a cycle, the model would have to introduce a path from a descendant to an ancestor. But this is not possible, because all new paths are either from nodes that have no ancestors, or to nodes that have no descendants.

Overall, CERP provides a way of expressing causal-functional relations using a compact set of rules. The restriction to deterministic OR and AND NOT functions means that complex relations must be expressed graphically, where the complexity is easier to see and measure, than it is in the complex conditional probability tables often used in existing instantiations of CGMs.

The model has two key components: the idea of edge replacement, and the use of deterministic causal relations. It is conceivable that we could use edge replacement with probabilistic relations. For instance, edges could begin with probabilistic values that change as replacements are made. However, this introduces a great deal of complexity, which is unwarranted unless necessary to fit human data. Given evidence (e.g. Schulz & Somerville, 2006) that even children seem to be determinists in the relevant sense, we believe it is a good assumption. Future work will focus on testing this determinism commitment directly. In this paper, we will instead focus on testing the structural predictions that arise primarily from the use of length in the generative process.

Fitting nonindependence effects

Walsh and Sloman (2004)

Walsh and Sloman (2004) showed a nonindependence effect that provides the simplest test of our model. They told adult participants simple common effect cover stories, in which event C caused both events E_1 and E_2 . For instance, some participants were told that jogging (C) caused both increased fitness (E_1) and weight loss (E_2). They then asked participants to judge $P(E_1|C)$ and $P(E_1|C, \neg E_2)$. Figure 3 shows their data averaged across experiments. Participants reliably judged that $P(E_1|C) > P(E_1|C, \neg E_2)$. This is a nonindependence effect: If both effects are generated independently from the cause (as in Figure 1a), both values should be the same.

CERP’s predictions are also shown in Figure 3. In fitting this and subsequent experiments, we used Monte Carlo sampling on causal structures as generated by CERP. One approach would be to generate a large set of graphs using CERP, keeping only the small subset that are consistent with the cover story and data presented to participants. In this case, we would accept only graphs that had exactly two visible effects. A sufficiently large sample will reflect the properties of the probability distribution defined by CERP. Such an approach is correct but computationally expensive, prohibitively so as we add complexity to the cover story.

We used a more efficient, but equivalent procedure: Begin with a single edge between the cause C and effect E_1 described to participants. Then generate the single visible side effect described to participants. This is equally likely to have been generated from any given point on the path from cause to effect, so we generate the second effect by choosing a random point $x \sim U[0, 1]$.² Call the branch point M , and set the length of ME_1 to $(1 - x)$ in order to ensure that E_1 and E_2 have the same path length from C and hence the same expected $P(E_n|C)$. This is in order to meet the condition, common in nonindependence experiments, that effects are equally likely given the cause. Because of this equivalence, the choice of initial effect in CERP is arbitrary. This process creates three edges: CM , ME_1 , and ME_2 .

At this point, we have generated all the visible causes and effects described to participants. Therefore, we are licensed in using a computational shortcut to do simultaneous inference over all the further (hidden) replacements that could be generated by CERP. In this case, all that matters are inward hidden replacements that occur along each edge. Active replacements on CM (like X in Figures 1 and 2) change both relations (creating a correlation); active replacements on ME_i (like Y and Z in figures 1 and 2) change only the relation CE_i , and inactive replacements have no effect.

We introduce the parameter h to describe a Poisson process that moves along the edge of interest, generating only active inward hidden replacements whose causal power actually reaches the path, with rate $-\ln(h)$. This means that the probability of having zero active replacements along an

Figure 3: Data from Walsh and Sloman (2004), averaged over experiments, along with model predictions. Predictions are robust across alternative parameter settings.

edge of length l is h^l . We also introduce the parameter a to capture the probability that a given visible event fires spontaneously, as a result of causal processes not captured in the graph (Cheng, 1997). Together, h and a replace all the parameters described above in the full formal model. For instance, for most values of h and a , there are many settings of λ , γ , α and β that produce the same predictions. As long as we are not interested in the specific causal structure that generated each effect, this process is equivalent to generating a larger sample of more detailed graphs.³Crucially, it also uses fewer parameters.

After generating causal structures with branch points at various lengths, we used $h = 0.5$ and $a = 0.3$ to generate samples of the co-occurrence of the three events, by generating a set of replacements and propagating causation through the graph. Figure 3 shows the proportion of times that events occurred together, along with human probability judgments. We continued generating samples until we had at least 10000 samples for each entry. Predictions were resistant to changes in parameters; Figure 3 also shows other settings for h .

CERP can also easily make predictions about $P(E|\neg C)$, which Walsh and Sloman did not directly ask participants. However, they did ask participants a related question: the probability of an effect given a disabler that inhibited both effects (0.34). We sampled this by generating an active common inhibitor at a randomly chosen point $y \sim U[0, 1]$, then choosing the branch point x from $U[y, 1]$, because it would be incoherent for the branch point to occur before the common disabler. This gave us a $P(E|y)$ of 0.35. This value is lower than $P(E|\neg C)$ because there is less of the path remaining on which a generative cause could fire.

Overall, the model explains the data well. Because there were few data points (three) in comparison to the number of parameters in the model (two), we will look at more experiments using the same parameters that best fit these data.

²This means: “ x was sampled from a uniform distribution between 0 and 1.” We will use similar notation throughout the paper.

³We verified this by running the full generative model with a variety of parameter settings – several produced the same results as in Figure 3.

Rehder and Burnett (2005)

Another dataset is provided by Rehder and Burnett (2005), who found a nonindependence effect in the domain of feature inference. They told adult participants that one novel feature of a category (C), caused three other novel features ($E_{1,2,3}$). They then asked participants to judge the probability of one feature in a member of the category, given some value of C , and some number of other collateral effects. In Experiment 1, participants were given a cover story involving natural kinds. In Experiment 2, participants were not given a cover story at all – they were told that abstract features caused each other. Across multiple experiments, participants predicted that the values of collateral effects would be correlated, showing a nonindependence effect even with no cover story. The results of their Experiments 1 and 2 are shown in Figure 4.

We modeled this much like Walsh & Sloman, 2004, except that there were two branch points and thus five edges. Again, we ensured that all paths from C to E_n had the same length, because participants were told that all effects had the same probability. All parameters were the same as in fitting Walsh and Sloman: $h = 0.5$, and $a = 0.3$. Because there was always one node with a longer branch than the others, we also randomly permuted the role of each node.

Results are shown in Figure 4. The model provides a good fit to the data, especially when the cause is present. In the absence of the cause, the model predicts slightly higher probability judgments than participants' responses. This is probably due to the effect of categorization: Other data show that participants in this paradigm were significantly less likely to believe that a given instance was actually a member of the category when C was not present (Rehder & Burnett, 2005). This well-known "causal status effect" (Ahn, Kim, Lassaline, & Dennis, 2000) probably lowered their judgments of the other characteristic features of the category. Put another way, we assumed that feature C was uncaused, but participants may have assumed that all features had a hidden common cause that was present only in category members. CERP can model the effect of such an additional hidden common cause, but that was not our goal in the present investigation. We model an experiment below that replicated Rehder and Burnett's findings outside the domain of categorization, where we do not find this problem.

Mayrhofer, Hagmayer, and Waldmann (2008)

One strength of CERP is that it predicts how descriptions of the causal mechanism should affect the degree of nonindependence observed. Mayrhofer, Hagmayer, and Waldmann (2008) did just this. They told adult participants about four telepathic aliens; we will call them C , E_1 , E_2 and E_3 . The "cause" alien sometimes causes the "effect" aliens to think of food when he thinks of food. In the *transmit* condition, the instructions said that C sent his thoughts to each E_n , but sometimes C had difficulty concentrating. In the *receive* condition, instructions said that each E_n read the thoughts of C , but each effect alien sometimes had difficulty concentrating.

Figure 4: Data from Rehder and Burnett (2005) along with model predictions. Lower judgments in the absence of the cause feature are probably due to categorization, which is external to our model.

Like Rehder and Burnett (2005), they asked participants to judge $P(E)$ given different numbers of collateral effects. Data show a much stronger nonindependence effect in the transmit than in the receive condition (See Figure 5).

As before, we used a process which was equivalent to generating a large sample of graphs, and keeping only those consistent with the cover story. The cover story describes three similar effects, so we began by generating all three from the same branch point $x \sim U[0, 1]$. We generated an inhibitor, explicitly mentioned in the cover story ("failure concentrating") at point $y \sim U[0, 1]$, assigning it probability $a = 0.3$ of firing. In the receive condition, we kept only those samples in which $y > x$, since the inhibitor was described as applying to each alien individually. We generated one instance of the inhibitor on each branch. In the transmit condition, we kept only samples in which $y < x$, since only one inhibitor was described. We know of no other way to generate graphs consistent with both CERP and the cover story. Otherwise, we sampled as before, using $h = 0.5$ and $a = 0.3$.

As shown in Figure 5, the model provides a good fit to the data. One exception is the point in the transmit condition in which two collateral effects occur, but the cause does not (the last entry in the "transmit" graph): The model predicted a medium probability judgment, while participants gave a low judgment. This may be due to a random anomaly in human responses, because the data are hard to explain under any account: As collateral effects were added, participants lowered, rather than raised, their probability judgment. This is not replicated in any other condition or experiment.

Mayrhofer et al. fit the qualitative difference between the conditions by adjusting a quantitative parameter: strength of inhibitory noise, which was strong in the transmit condition and weak in the receive condition. As they show, this parameter can be used to fit a wide range of data. Our model used a qualitative structural change instead, while the quantitative parameters have relatively little effect on the predictions, and remained constant between conditions and experiments. The model captures how changes to the mechanism description change the source and structure of the noise.

Figure 5: Data from Mayrhofer et al. (2008) along with model predictions. No parameters were varied between conditions –only the constraints given by the different cover stories.

Conclusion and Further Work

We use CERP to fit three independently collected data sets on nonindependence, using the same parameters between experiments, and even between conditions within experiments. Over all three data sets, we fit 21 data points using 2 free parameters, with a correlation of greater than 0.99.⁴ The power of CERP seems to come not from its use of free parameters, but from the fact that structural aspects may mirror some important aspect of the way that human beings represent causation. Further work will focus on exploring these aspects more closely. For instance, we can generalize our explanation for Mayrhofer et al., 2008’s data to make a novel predictions: Early inhibitors in a causal stream should create more nonindependence than late inhibitors. We call this a *stream location effect*. We have recently tested this on preschoolers, with positive results (Buchanan & Sobel, 2010).

Our main intent with CERP is to test predictions that go well beyond nonindependence effects. For instance, its commitment to a form of determinism (namely, that apparent randomness always comes from hidden causes) has implications for how we reason about data that varies over time. Imagine your car fails to start one morning. Is it more likely to start tomorrow morning, or on a morning one year from now? If the relation were truly random, there should be no difference in judgment between these two times. If we introduce time into CERP, it should be able to rationally justify and fit our

intuition that the car is more likely to start a year from now, than it is tomorrow. This is because variability arises from hidden causes that have persistence in time and space.

Finally, because it can generate any functional relation, CERP represents one way of defining a prior distribution over logical graphs. This may be useful to researchers (i.e. Lucas & Griffiths, 2010) who are interested in how people learn about the functional form of causal relations. An interesting question that arises from this research program is whether something like CERP could itself be learned – for instance, children might start with more general causal expectations, and come to realize that the world follows some or all of the commitments of CERP, such as determinism, and the stream-like character of causation.

Abstract

One of the most fundamental assumptions underlying causal Bayes nets is the Markov constraint. According to this constraint, an inference between a cause and an effect should be invariant across conditions in which other effects of this cause are present or absent. Previous research has demonstrated that reasoners tend to violate this assumption systematically over a wide range of domains. We hypothesize that people are guided by abstract assumptions about the mechanisms underlying otherwise identical causal relations. In particular, we suspect that the distinction between agents and patients, which can be disentangled from the distinction between causes and effects, influences which causal variable people blame when an error occurs. We have developed a causal Bayes net model which captures different error attributions using a hidden common preventive noise source that provides a rational explanation of these apparent violations. Experiments will be presented which confirm predictions derived from the model.

Keywords: causal reasoning; Bayesian modeling; Bayes nets; Markov condition.

Introduction

Causal Bayes net theory is an increasingly popular approach to model causal reasoning in humans, especially in domains in which multiple variables are causally interrelated. Causal Bayes nets can be graphically represented as sets of (observable and hidden) variables that may represent present or absent events, and arrows that express the direction of the causal influences between the interconnected variables (for an example, see Fig. 1).

To make inferences in this network, additional assumptions need to be made about how the three arrows interrelate. A central assumption that turns probabilistic networks into Bayes nets is the Markov condition (see Pearl, 2000). The Markov condition states that for any variable X in a set of variables S not containing direct or indirect effects of X , X is jointly independent of all variables in S conditional on any set of values of the set of variables that are direct causes of X . An effect of X is a variable that is connected with a single arrow or a path of arrows pointing from X to it. The Markov condition implies in the common-cause model that each effect is independent of all the other effects conditional upon the presence or absence of its cause C .

The Markov condition provides Bayes nets with substantial computational power. Assuming conditional independence allows for learning and reasoning about

subsets of variables while ignoring the states of other independent variables. For example, we can infer the presence or absence of an effect from the state of its cause without having to consider the states of the other conditionally independent effects. When using Bayes nets we are not forced to believe that in every situation effects of a common cause are conditionally independent. Whenever we have reasons to question this assumption, it is possible to model violations by adding hidden variables (again obeying the Markov constraint) representing unobserved causal influences. However, the validity of the Markov condition is typically assumed as a default unless we have domain knowledge that suggests hidden variables.

Figure 1: An example of a simple common-cause structure with a cause variable C and three effect variables E_1 , E_2 , E_3 . The state of each effect variable depends statistically only on the state of the cause variable.

Rehder and Burnett (2005) developed a reasoning task which allowed for testing people's intuitions about the Markov condition. For example, subjects had to rate the conditional probability of an effect's presence given the state of its cause C . The crucial manipulation was whether other effects of C were present or absent. According to the Markov condition subject's ratings should be invariant across these conditions. Contrary to this prediction, the ratings were clearly sensitive to the states of other effects of C . The more collateral effects were present, the higher the rating of the conditional probability of the target effect given the presence of C . This Markov violation was extremely robust across many cover stories and domains.

Walsh and Sloman (2007) followed up on this research. They were interested in the boundary conditions of violations of the Markov condition. In one experiment they

presented subjects with a common-cause model in which loud music in an apartment building represented the common cause of the complaints of the neighbors on the left and the right side of the apartment in which the music was playing. Again the crucial test question referred to a case in which loud music was playing but the left neighbor was not complaining. According to the Markov condition this should not affect the rating of the likelihood that the right neighbor is complaining. However, Walsh and Sloman reasoned that the likelihood that complaints of the right neighbor are predicted should depend on the ad hoc explanations of why the left neighbor did not complain. If subjects were instructed that all neighbors were invited to the apartment in which music was playing, subjects should expect both neighbors not to complain (i.e., Markov violation). In contrast, when subjects were told that the left neighbor has left the building there is no reason to expect that the second neighbor will not complain (i.e., no Markov violation). The experiments confirmed these predictions although there was a fairly strong tendency to violate the Markov condition in all conditions. In this experiment the difference between the inferences is due to the fact that the initial causal model was differently augmented and changed in the contrasted conditions by adding further causal variables. In one condition an additional causal event, the invitation, was introduced, in the other condition one effect was effectively removed from the model, thus deleting its diagnostic relevance.

Agents and Causes

We are also interested in conditions moderating the degree of Markov violations. Whereas Walsh and Sloman (2007) have shown that different models containing different kinds of disabling events influence the inferences, our goal is to study the influence of assumptions about causal mechanisms while keeping the causal model on the surface level invariant. Causal Bayes nets combine assumptions about causal mechanisms with probabilistic covariations, but the assumed mechanisms are not elaborated. Tellingly, Pearl (2000) describes causal arrows as *mechanism placeholders*. Although recent empirical studies have casted doubt on the assumption that people have elaborate knowledge about mechanisms (Rozenblit & Keil, 2002), recent research on causal reasoning and language understanding has suggested that people may have abstract notions of basic properties of mechanisms (see Talmy, 1988; Wolff, 2007). Particularly relevant in the present context is the distinction between *agents* and *patients*, which is one of the important distinctions in our causal semantics introduced by Talmy. Agents are causal events that we represent as active in the generation of a causal relation. Patients are passive recipients of causal power. For example, in the familiar Michotte task the ball pushing the second ball is viewed as an agent endowed with force, whereas the ball that is being pushed is represented as a patient exerting resistance (White, 2009).

Agents and causes typically fall together but can be separated. Consider the example of tuners that receive music from a music station. Within a causal Bayes net the station would play the role of a common cause because sending out waves precedes the reception by tuners. However, depending on the focus, it is possible to view the sender as active senders and the tuners as passive receivers, or it is possible to highlight the active role of the tuners as receivers without whom no music can be heard. Thus, effects in a common cause model can be agents or patients depending on the framing. Our key prediction is that the agent role is associated with attributions of causal responsibility and blame. If something goes wrong in a causal transmission, then the agent will be the primary target of error attributions.

Figure 2: An example of a test item used in Waldmann et al. (2007).

Pilot Study

In an initial experiment, we tested this theory (Waldmann et al., 2007). Subjects were presented with instructions about four aliens, Gonz, Murks, Brxxx, and Zoohng, who mostly think of nothing and sometimes think of “POR” (food in alien language; material adapted from Steyvers et al., 2003). In one condition it was pointed out that Gonz is able to transmit its thoughts into the heads of the other alien (sending condition). In the contrasting condition it was pointed out that Murks, Brxxx, and Zoohng are able to read the thoughts of Gonz (reading condition). So, in both conditions the thoughts of Murks, Brxxx, and Zoohng are statistically and causally dependent on the thoughts of Gonz. Hence, both cases can be represented as a common-cause network (see Fig. 1; Gonz as the cause C and Murks, Brxxx, and Zoohng as the effects E_1 , E_2 , and E_3). However, the agent role was manipulated across conditions. Whereas in the sending condition cause and agent fall together, in the reading condition the effects were framed as agents. In the test phase subjects were requested to rate the conditional probability of a target alien, e.g., Zoohng, thinking of POR given the thoughts of the cause and the other effect aliens (for an example, see Fig. 2). Interestingly, the “Markov violation” was significantly stronger in the sending condition than in the reading condition (see interaction of upper two lines in Fig. 3), which confirms our prediction

that errors are associated with the agent. If there is only one agent (sending condition) then the failure of one of the receiving aliens to read his thoughts becomes diagnostic for a failure of the sending agent that also should affect the other aliens. In contrast, if the effects are represented as agents, then the error attributions should be locally attributed to the respective effect. The failure of one reader to read the thoughts of the cause alien should not predict whether the other readers will also fail or not.

Another important finding of the pilot study which we will follow up in Experiment 1 is that Markov violations in the sending condition were only observed when the cause was present but not when the cause was absent (see lower two lines in Fig. 3). Intuitively this can be interpreted as evidence for the assumption that sending errors can only occur when the cause alien is trying to send.

Figure 3: Mean ratings (and standard error) representing the estimates of the relative number of times the target alien thinks of “POR” in ten fictitious situations. The X axis represents the number of collateral effect aliens thinking of “POR”. The upper two lines correspond to the cause alien thinking also of “POR”, the lower two lines to the cause alien thinking of nothing. The dashed lines indicate the sending condition, whereas the solid lines indicate the reading condition.

In the next section we report a model that captures our intuitions about the role of agents in causal models. Subsequently we will report experiments testing the model.

A Bayes Net Model of Error Attributions

In Bayes nets, errors which are due to hidden mechanisms can be represented by hidden nodes in the network. We propose that *each cause* contains a hidden *common preventive noise* (PN) node which is connected to all effects, and can therefore alter the influence of the causes on their effects. Hence, in common-cause model there is one PN attached to its effects. This common noise source summarized *all* influences which potentially decrease the ability of the cause to bring about its effects (e.g., common

preventer; missing enabling conditions, etc.)¹ (see Fig. 4). The strength of this noise source (w_{PN}) and its a priori base rate are domain dependent. In the sending condition, we assume that w_{PN} is pre-set to high values, thus increasing the influence of common preventive noise. In the reading condition, people should primarily attribute errors to the error links that are attached to each effect node and that are in Bayes nets assumed to be independent of each other. Thus, different parameterizations of w_{PN} explain the different degrees of Markov violations in the sending versus reading conditions.

Figure 4: A simple common-cause structure extended by an unobserved common preventive noise node PN. The preventive noise interacts with the causal influence of C. If PN is present the power of C is lowered for all its effects. Thus, if E_1, \dots, E_{n-1} are observed as absent, even if the cause C is present, the presence of PN is likely. This lowers the predicted probability of E_n being present.

Asking people to judge the probability of a target effect alien (E_n) thinking of POR given the thoughts of the other aliens (C, E_1, \dots, E_{n-1}) is formally equivalent with asking the conditional probability of E_n : $P(E_n = 1 | C, E_1, \dots, E_{n-1})$. In a regular common cause structure (without a common noise source) this question simplifies to $P(E_n = 1 | C)$ due to the Markov condition: The presence of the target effect only depends on the state of the cause, not on the states of the collateral effects. Introducing an unobserved common preventive noise node and integrating it out leads to the following derivation²:

$$\begin{aligned}
 P(E_n = 1 | C, E_1, \dots, E_{n-1}) &= \sum_{PN} P(E_n = 1 | C, \mathbf{PN}, E_1, \dots, E_{n-1}) \cdot P(\mathbf{PN} | C, E_1, \dots, E_{n-1}) \\
 &= \sum_{PN} P(E_n = 1 | C, \mathbf{PN}) \cdot P(\mathbf{PN} | C, E_1, \dots, E_{n-1})
 \end{aligned}$$

The second simplifying step in this derivation is possible because in the network with the common preventive noise

¹ Note that this is a specific preventive cause which does not affect the probability of the effect when the cause is absent.

² Actually, also the prior assumptions of the parameter values given by a set of Beta distributions are integrated out. To simplify the discussion we left this out in the description. The complete derivation includes a multiple integral over the parameter vector: $P(E_n = 1 | C, E_1, \dots, E_{n-1}) = \int P(E_n = 1 | C, E_1, \dots, E_{n-1}, \mathbf{w}) p(\mathbf{w}) d\mathbf{w}$

node the Markov condition holds: Given C and PN the target effect E_n is independent of the collateral effects. Thus, reasoning in this simple model can be thought as a two-step process: First the state of the noise is inferred, and then given that state (and given the a priori state of C) the state of the unobserved target effect is inferred.

The model predicts that inferences about the presence of an unobserved target effect in the presence of the cause should be influenced by the number of collateral effects that are present or absent. Absent effects in the presence of the cause should via the PN lower the ratings for the target effect. This influence should increase with increasing numbers of absent effects when the cause is present. When the cause is absent, however, no such pattern should be observed.

Experiment 1

When the cause varies between present (i.e., active) and absent (i.e., inactive), the model predicts an asymmetric influence of PN since in the cause's absence the PN cannot prevent C to bring about the target effect. Thus, the Markov violation in the sender condition should only be observed when the cause is present. In our pilot experiment we have indeed confirmed this prediction. In contrast, our model predicts a symmetric influence of the PN when the cause has two distinct but causally active states (i.e. A/B instead of 0/1). This prediction is tested in Experiment 1.

Method

Participants 56 students from the University of Göttingen participated in exchange for candy.

Figure 5: An example of a test item used in Experiment 1.

Procedure and Material In the instruction phase we presented subjects with instruction about four aliens: Gonz, Brxxx, and Zoohng, who usually think of “TUS” and sometimes think of “POR” (indicated by a bubble containing “TUS” or “POR”; see Fig. 5) (POR and TUS were counterbalanced). In two conditions it was either stated that the upper alien can transmit both thoughts to the lower three (sending condition), or that the lower three aliens can read the thoughts of the upper one (reading condition). It was pointed out that the effect aliens frequently think of

“POR” or “TUS” when the cause alien thinks of “POR” or “TUS”.

In the test phase, subjects were presented with six test panels with all the non-target aliens thinking of either “POR” or “TUS” (for an example, see Fig. 5). The order of test panels was randomized. For each panel, subjects were asked to imagine ten situations with the given configuration, and then to judge in how many of these situations the target alien (indicated by a question mark above its head) would probably think of “POR”. This way we obtained probability assessments from the subjects.

Design The predictions were tested in a $2 \times 2 \times 3$ ANOVA design with “sending” vs. “reading” as a between-subjects factor. The state of the cause alien (“POR” or “TUS” thoughts) and the number of collateral effect aliens thinking of “POR” (0, 1, or 2) were manipulated within subjects.

Results and Discussion

Figure 6 displays the results for Experiment 1. In general, the ratings for the target effect alien thinking of “POR” were higher when the cause alien thinks of “POR” ($F_{1,54}=146.05$, $p<.001$, $\eta_p^2=.73$).

Figure 6: Mean ratings (and standard error) representing the estimates of the relative number of times the target alien thinks of “POR” in ten fictitious situations. The X axis represents the number of collateral effect aliens thinking of “POR”. The upper two lines correspond to the cause alien thinking of “POR”, the lower two lines to the cause alien thinking of “TUS”. The dashed lines indicate the sending condition, whereas the solid lines indicate the reading condition.

As predicted by the model, people’s judgments were symmetrically influenced by the states of the other effects for both states of the cause: In case of C representing “POR” (the upper two lines in Fig. 6) the ratings substantially increased with the number of effect aliens thinking of “POR” ($F_{2,108}=31.47$, $p<.001$, $\eta_p^2=.37$). As in our pilot study this influence was stronger in the sending condition than in

the reading condition yielding a significant interaction ($F_{2,108}=8.94$, $p<.001$, $\eta_p^2=.14$). In case of C representing “TUS” (the lower two lines in Fig. 6) the ratings also increased the more effect aliens thought of “POR” ($F_{2,108}=20.25$, $p<.001$, $\eta_p^2=.27$). As predicted by the model and in contrast to what we observed for the absent state of the cause in our pilot study the influence of the collateral effects was also stronger in the sending condition than in the reading condition when the cause alien thought of “TUS” ($F_{2,108}=4.20$, $p<.05$, $\eta_p^2=.07$). The descriptively weaker two-way interaction in the “TUS” case is predicted by the model as a consequence of the low base rate of “TUS”. No three-way interaction was obtained, as predicted ($F_{2,108}=1.37$, $p=.26$).

The results confirm our model. Subjects’ inferences were influenced by the location of the agent (sending vs. reading) in a fashion predicted by the error attribution model. Moreover, the model’s predictions about the type of states of binary causal variables were confirmed. Our patterns in the sending condition correspond to the findings of Rehder and Burnett (2005), who also found symmetric influences of the states of other effect variables for both states of the cause. Although Rehder and Burnett described these states as present and absent, the two states in their experiments actually also represented two active states on a continuous dimension (typical vs. atypical).

Experiment 2

In our model, the common preventive noise node PN is attached to the specific cause it regulates. Therefore, in a causal chain structure each causal link should have its own PN node (see Fig. 7). This entails that the strength of each PN in the chain should not bias people’s assumptions about the states of other variables. Consequently, our model predicts that in causal chain structures no Markov violation should be observed and that manipulations of people’s assumptions about the location of the agent (i.e., sending vs. reading) should not have any effect. This prediction is tested in Experiment 2.

Figure 7: An extended causal chain model with two indirect causes (IC_1 , IC_2), a direct cause (DC) and a final effect (E). Since the preventive noise (PN) is part of the causal process and therefore attached to each direct cause-effect relation, in each cause variable has its own preventive noise source.

Method

Participants 50 students from the University of Göttingen participated in exchange for candy.

Procedure and Material As in Experiment 1, we presented subjects with instruction about four aliens: Gonz, Brxxx, and Zoohng, who—as in the basic experiment—usually think of nothing and sometimes think of “POR” (indicated by an empty bubble or a bubble containing “POR”, respectively; see Fig. 8). It was pointed out that—in the sending condition—an alien can transmit its “POR”-thoughts to its right neighbor or—in the reading condition—an alien can read the “POR”-thoughts of its left neighbor. Again it was stated that effect aliens frequently think of “POR” when the corresponding cause alien (the left neighbor) also thinks of “POR”.

In the test phase subjects were presented with six test panels with the non-target aliens thinking of “POR” or nothing (for an example, see Fig. 8). The order of test panels was randomized. The target alien was generally the right most alien in the chain. As in Experiment 1, subjects were asked to judge in how many of ten situations the target alien would probably think of “POR”.

Figure 8: An example of a test item used in Experiment 2.

Design The predictions were tested in a $2 \times 2 \times 3$ ANOVA design with “sending” vs. “reading” constituting a between-subjects factor and the state of the direct-cause alien (“POR” or nothing) as well as the number of indirect-cause aliens thinking of “POR” as within-subjects factors (0, 1, or 2).

Figure 9: Mean rating (and standard error) of number of times the target aliens thinks of “POR” in ten fictitious situations plotted against the number of indirect-cause aliens thinking of “POR” (columns). The upper two lines correspond to the direct cause (DC) alien thinking also of “POR”, the lower two lines to the direct cause alien thinking of nothing. The dashed lines represent the sending

condition, whereas the solid lines represent the reading condition.

Results

The results of Experiment 2 are shown in Figure 9. As in Experiment 1, the ratings for the target effect alien thinking of “POR” were higher when the direct-cause alien also thought of POR ($F_{1,48}=191.99, p<.001, \eta_p^2=.80$).

The prediction that different assumptions about the agents in the chain (sending vs. reading) should not matter was clearly supported. As predicted by the model, the sending vs. reading manipulation revealed no interaction with the states of the non-direct causes, neither in the presence of the direct cause ($F_{2,96}<1, p=.5$) nor in its absence ($F_{2,96}<1, p=.66$). However, in contrast to the predictions, significant, although very weak violations of the Markov condition in both the presence (the upper two lines in Fig. 9; $F_{2,96}=11.77, p<.001, \eta_p^2=.20$) as well as the absence of the direct causes (the lower two lines in Fig. 9; $F_{2,96}=6.47, p<.01, \eta_p^2=.12$) could be seen (see also Rehder & Burnett, 2005). The three-way interaction was clearly not significant ($F_{2,96}<1, p=.99$).

Discussion

The results of Experiment 2 show sensitivity to the instructed causal model and support the assumption inherent in our Bayesian model that preventive noise sources are attached to specific causes. Hence, whether preventive noise predicts error correlations is dependent on the underlying causal structure in which these nodes are an intrinsic property of each cause-effect relations.

However, our model cannot account for the small but still significant Markov violations in the data. Possibly subjects doubt that chain variables fully screen off previous influences or there are additional assumptions underlying causal chain representations.

General Discussion

Traditional causal theories view causes as endowed with the power to generate effects. However, little is known about how the mechanisms relating causes and effects are represented, and what influence assumptions about the mechanisms have on causal inferences. We have pinpointed one relevant factor, the distinction between agents and patients which can be separated from the distinction between causes and effects. We have used the example of sending versus reading to disentangle the location of the agent from the location of the cause. Our main hypothesis is that people tend to attribute potential errors to agents rather than patients. This intuition was formalized in a Bayesian model of error attribution which adds hidden preventive noise nodes to capture our intuitions about sources of error. Interestingly, this model explains violations of the Markov condition using a model that honors the Markov condition. Two experiments were conducted which tested and largely confirmed specific predictions of the model.

Traditionally there has been a conflict between covariation and mechanism (or force) theories. The present research shows that it is fruitful to combine the two approaches. Causal models are needed to guide processing of statistical covariations in data. However, the simple assumptions typically underlying these models are insufficient because additional knowledge about the mechanism seems to influence both the assumed hidden and observed structure of the model and the parameterization (see Mayrhofer et al., 2008). Future research will have to further elaborate the intricate relation between mechanism assumptions and causal models.

Acknowledgments

We wish to thank Marie-Theres Kater and Mira Holzer for assistance in data collection, and Noah Goodman, Josh Tenenbaum, and Tom Griffiths for helpful comments on the project. This research was supported by a research grant of the Deutsche Forschungsgemeinschaft (DFG Wa 621/20).

Abstract

This paper presents a preliminary work on a new architecture of executive control (DUCCA), aimed at integration and extension of some leading approaches to executive control. We present DUCCA assumptions and operation and use the architecture to simulate a few effects observed in Stroop-like task, a hallmark test of how control deals with interference. The focus of DUCCA is on how strategic use of general executive mechanisms contributes to Stroop effect. We explain also what is usually neglected in Stroop modeling: the significant individual differences in task performance.

Introduction

Executive control is implemented via numerous brain mechanisms and on different levels of neuronal organization. However, a few general flexible control mechanisms, which are involved in most of situations that require control, were also proposed in control literature (Anderson, Fincham, Qui, & Stocco, 2008; Braver, Gray & Burgess, 2007; Kane & Engle, 2003; Koechlin & Summerfield, 2007). The goal of this paper is to present a new model of executive control, called Dual Cognitive Control Architecture (DUCCA), which integrates several recent theoretical approaches to control and extends them with a few original control mechanisms. The model explains crucial effects related to interference control in Stroop-like tasks with an appeal only to general mechanisms of control, while abstracting from specific (e.g., semantical or stimulus-related) ones.

The first general function of control regards using contextual, episodic, or goal information in order to change the probability distribution of alternative actions into a one that maximizes their task-relevance (Anderson et al., 2008; Koechlin & Summerfield, 2007). Such a function is implemented in cognitive models of executive processing in two ways. In most of connectionist models, a network carrying out non-executive processing is supplemented with task (or goal) units, which modulate processing by propagating additional activation to nodes relevant to a respective task (e.g., Altmann & Davidson, 2001; Cohen, Dunbar & McClelland, 1990; Verguts & Notebaert, 2008). The control in symbolic architectures is usually implemented as control signals, stored in a goal or working memory buffer, which are matched to possible actions in order to select a next operation (Anderson et al., 2008; Meyer & Kieras, 1997). The first original aspect of DUCCA is that it integrates these two approaches into the unitary, general mechanism of top-down control, which may either directly select an action or just modulate a chance of its selection.

The second important function of executive control deals with regulation of its strength, as maintaining control for

long periods of time is metabolically costly and often cognitively inefficient. Early observations indicated that control is amplified after errors. However, results like Gratton effect (i.e., the interference cost in a flanker task is 20 ms smaller in trials following incongruent stimuli, compared to ones following congruent stimuli; Gratton, Coles, & Donchin, 1992), usually observed even if errors are rare, suggested that control can be dynamically modulated on some other basis. Botvinick et al.'s (2001) conflict monitoring theory states that specialized brain mechanism (anterior cingulate cortex; ACC) performs online computing of the level of conflict between alternative responses and it increases the strength of top-down control as such a conflict arises. A more general idea is that ACC learns and reacts to a level of "risk" – conflict related error likelihood and its real-world consequences (Brown & Braver, 2007). Both cited models, however, evaluate only response representations in performing need-for-control monitoring, while conflicts can also be found between covert cognitive processes, which just influence next steps of cognition. Another new mechanism implemented in DUCCA is such a conflict monitoring procedure, which evaluates conflicts in cognitive processing (e.g., between opposing goals), which need not lead directly to any response.

Finally, DUCCA is aimed at taking into account the individual differences in control. Even healthy people differ in efficiency of control, which seem to be correlated with working memory capacity and fluid intelligence (Chuderski & Necka, 2010). Moreover, humans are able to regulate their mode of control by switching between top-down, proactive control and bottom-up, reactive one (Braver et al., 2007). All these differences can be expressed as differences in values of DUCCA internal control parameters, which yield qualitative changes in its simulated behaviour.

Overview of DUCCA

Cognitive operations

DUCCA is modeled as a hybrid production system. Coordination of the working of its modules is inspired by ACT-R architecture (Anderson et al., 2008). However, as the system is focused on executive functioning, "ordinary" cognitive operations have been very simplified. The system stores information received from the environment in a visual attention module, which recognizes 25 (5×5) locations on the computer screen and attends to one of them (via a focus of visual attention) at a time. Model can read symbols and some of their features (e.g., colors) from the focus. Long-term declarative knowledge is organized as a semantic network, which consists of information chunks of defined

categories (which are also chunks). A chunk contains a few slots. Each slot can contain either an atomic symbol or a reference to another chunk. One chunk can be retrieved at a time and placed in a retrieval buffer. Some information relevant to the task is actively maintained in system's focus of working memory (WM). The capacity of the focus is limited to a few (DUCCA's parameter) chunks. Contents of WM focus constitute a *context* of cognitive operations. Another structure is a goal module, which can do only one thing: it represents one chunk as a current goal of the system. Finally, a simplified motor module simulates reactions. Each response is registered and processed by a virtual key set.

Crucial for how DUCCA behaves is its procedural module, consisting of production rules, their utilities, and the mechanism for adapting utilities. Each rule is defined as a collection of conditions and a collection of actions. Conditions are imposed on both foci and the retrieval buffer. For each rule (i), a utility value (U_i) is assigned, which is updated on the basis of feedback. The utility of i tends to the expected value of feedback received after the action i . The higher U is, the more probable is the execution of a respective rule (see below).

DUCCA adapts the value of a recently executed rule in a reinforcement learning procedure, according to formula (1):

$$U_{i,t} = U_{i,t-1} + \frac{f - U_{i,t-1}}{1 + L_i}, \quad (1)$$

where $U_{i,t}$ is a new value of utility of rule i , f is a feedback value (in range zero to one, where zero reflects "complete failure" while one means "full success"), and L_i is the reliability of a recent value of utility ($U_{i,t-1}$), estimated as the number of trials in which reinforcement of rule i has been applied. The rationale for equation (1) is that the more reliable a utility is, the less a current feedback alters this utility value. If a rule is new and L_i equals to zero, then after the first execution of a rule its utility reflects exact value of a feedback. After numerous rule's executions, its utility becomes very reliable and feedback can change it minimally. U values (in $[0,1]$ range) reflect expected probability of reaching a goal if a rule is executed. In simple executive tasks, the reinforcement value f may be usually operationalized as the extent to which a task instruction was fulfilled, as perceived by a subject or signaled by a task.

If the environment and a context unambiguously determine an adequate action, then one rule will be matched and executed in time inversely proportional to its utility. Execution of the rule may: change the goal and/or contents of WM focus, redirect the focus of visual attention, add a chunk to the declarative memory, and send a motor command to the motor module. Then a next cycle of operation starts, until the goal is reached. However, if at least two alternative rules match (i.e., DUCCA detects a conflict related to rule selection), then executive control has to be involved in the choice of one rule from a set of matching ones (*conflict set*).

Control of cognitive operations

The first mechanism of executive control deals with evaluation of the level of detected conflict C , which is calculated according to formula (2) based on nonlinear Luce's ratio:

$$C_i = \left(\frac{\sum_{j \neq i} e^{U'_j/n}}{\sum_k e^{U'_k/n}} \right)^c, \quad (2)$$

where j indexes all production rules in a conflict set, which yield different cognitive or behavioural consequences than a rule i of maximum utility in a conflict set, k indexes all rules in a conflict set, and n is a noise parameter. Conflict measure is thus a proportion of utilities of matching rules which are alternative to the dominant tendency for cognitive or motor processing. Parameter n controls how nonlinear is the computation of C . Note that U 's instead of U_s are used (the calculation of U' is explained below).

The C value determines the strength of top-down control (G) exerted from the goal, according to formula (3):

$$G_t = ag(C + E(1 - C)) + (1 - a)G_{t-1}, \quad (3)$$

where G_{t-1} denotes the strength of control in a previous cycle, E is an error value (meaning the probability that the system committed an error in a previous cycle), g is the maximum strength of control that DUCCA can exert, and a is a control adaptation parameter. C and E work in under-additive interaction. Parameter a can vary between zero (DUCCA exerts fixed strength of control and ignores conflicts and errors) and one (system uses a proportion of its maximum control strength relative to the conflict level). Theoretically plausible values of a lay above zero and below one and they mean that DUCCA adapts control to conflicts and errors, but it does so with some inertia.

The set of DUCCA's rules and their utilities may be understood as a strategy, which maps a set of possible cognitive operations onto a set of probabilities of executing these operations, in a given state of the environment and a given goal and context. Without executive control, a distribution of these probabilities reflects the effects of learning (via U_s). The operation of control consists in changing this distribution into one independent on learning but dependent on how these actions are adequate to a current goal. Due to control, an agent can undertake some arbitrary behavior, even if other well-learned behavioral patterns conflict with it. The second control mechanism operates thus as modifier of rules' utilities, according to formula (4):

$$U'_i = \frac{U_i}{e^{G(1-A_{ij})}}, \quad (4)$$

where modified utility U'_i of rule i , which is used is for conflict evaluation and conflict resolution (see below), is decreased in a function of a current control strength (G) and a value of association A_{ij} between rule i and current goal j . If either rule i is perfectly adequate to goal j (A_{ij} equals one) or control strength G is null, then U'_i equals U_i . In all other cases U_i is decreased in a nonlinear function of G and A_{ij} . If G is very high, the system just selects the rule closest to a goal. Though such a control mechanism can be judged inhibitory, our model is not committed to either an inhibitory or activation nature of control. In terms of probabilities, inhibition of one set of rules is conceptually indistinguishable from activation of an alternative set of rules.

Finally, DUCCA uses modified utilities in order to resolve a conflict among rules present in a conflict set. Analogously as in conflict evaluation formula, nonlinear Luce's ratio is exploited in formula (5) for the calculation of a probability P_i of rule i execution:

$$P_i = \frac{e^{U'_i/n}}{\sum_j e^{U'_j/n}}, \quad (5)$$

where j denotes all rules in a conflict set, and n is a noise parameter (the same as in formula [2]). When n is very high, the rule with maximum U' always wins, while at n close to zero P equals to one divided by a number of rules in a conflict set. An important DUCCA's assumption (opposite to ACT-R theory) is that conflict resolution consumes time relative to the conflict level. Latency of conflict resolution is a multiplication of conflict value C and a scaling parameter s (i.e., $Lat = s \times C$).

Executive control in DUCCA stems from a dynamical interaction of external stimulation and its consequences (rules' utilities and goal-rule associations) and two internal mechanisms strategically adapting to the pattern of cognitive processing (conflict evaluation plus control strength modification and utility learning).

Modeling of Stroop

Stroop-like tasks, which are widely used to examine operations of executive control (MacLeod, 1991), impose interference by presenting bivalent, incongruent stimuli, which activate two cognitive processes: one dominant and the other much weaker. The task is to complete the non-dominant process. The well-known example is naming a color of a colored word that itself means an incongruent color. Interference effect, namely a positive difference between RTs for incongruent stimuli and neutral ones (e.g., colored letters X), reflects the unavoidable additional time needed for control processes to override interference from a dominant process. At the same time, control processes are usually successful, as error rates in Stroop-like tasks are low (2-10% on average). Often, a facilitation effect is also observed: people are faster for congruent stimuli (e.g., when word and its color match) than for neutral ones (MacLeod, 1991).

Some existing models

A seminal connectionist model (Cohen et al., 1990) represented alternative processing pathways as interconnected nodes in a network. Nodes for non-dominant process were associated more weakly than those of the dominant one. For the non-dominant pathway to win, an additional task-unit had to activate that pathway. A version of the model supplemented with conflict monitoring node (Botvinick et al., 2001), which controlled the amount of activation spread by the task-node in a function of conflict within a response layer, replicated above mentioned Gratton effect. It was also able to simulate an observed decrease in interference with increase in proportion of non-neutral (congruent plus incongruent) stimuli as well as smaller than interference a facilitation effect (Tzelgov, Henik, & Berger, 1992). In another

model, Verguts and Notebaert (2008) implemented conflict-modulated Hebbian learning rule, which adapted specific network connections involved in conflict resolution. The model was able to account for a decrease in interference for items often presented in incongruent contexts, in comparison to stimuli usually presented as congruent (i.e., for a so-called item-specific proportion congruency effect).

However, connectionist models are often judged atheoretical (e.g., Altmann & Davidson, 2001). They represent a modeled mechanism as just a several links between a few abstract nodes of no internal structure. A node for "redness" would be exactly the same as a node for "left keypress", even if they belong to different categories of phenomena. These models are not related to any cognitive theory (e.g., of language or memory) either. In consequence, models of tasks imposing different constraints (e.g., Stroop, flanker, or antisaccade tasks) may be described by the same network.

Some other Stroop-like models do make assumptions on related cognitive processing and focus also on more specific aspects of Stroop performance. Altmann and Davidson (2001) modeled Stroop interference as an effect of the competition between syntactic properties of the words (lemmas) and embedded this linguistic mechanism in a broader cognitive architecture (i.e., ACT-R). The model was able to explain why the separation of incongruent aspects of stimulus in time decreased interference. Lovett (2005), exploiting ACT-R's idea of utility learning of production rules, was able to explain strategical preferences of participants in choosing dominant and non-dominant processes. However, all these models would have difficulty in explaining interference effects in Stroop isomorphic tasks, which do not relate so much on linguistic properties (e.g., flankers task) or memory retrievals (e.g., Navon task).

Specific processes surely explain some part of a variance in Stroop interference, but the general executive mechanisms beyond specific processes may be responsible for the significant part of that variance. Our architecture is aimed to describe these mechanisms. However, it explains them with higher theoretical plausibility than most of connectionist models do. The model identifies different categories of cognitive structures (e.g., rules, chunks, goals) and it can ascribe meaningful contents to particular representations. Moreover, the architecture isolates executive aspects common to different tasks from task-specific characteristics. Finally, it can easily be extended with additional theoretical assumptions (e.g., ones concerning language or memory).

DUCCA's model of Stroop

We developed a model of a *generalized* Stroop-like task in order to account for a variety of results, observed within different experimental conditions and numerous versions of Stroop tasks (i.e., we abstracted from task-specific aspects).

DUCCA was supplemented with task-specific rules and chunks. There are three crucial rules for response choice: "trained", "target", and "others". The first rule leads to a skilled action, which is not proper for a task instruction. For this rule, the maximum utility ($U_{trained} = 1.0$) was set, reflecting that for adult participants such a rule had received millions of positive feedbacks. The second rule leads to instructed, but relatively poorly trained action. Its utility should be

much lower than $U_{trained}$ but still significantly above 0 (here, $U_{target} = .6$). “Others” represents all task-unrelevant possible processes, including ruminations and mental slips, and it should have a utility close to 0 (here, $U_{others} = .1$), as ruminations and slips rarely lead to positive feedbacks.

The model contains some visual and memory chunks. One important aspect of perceived stimuli is that each congruent and incongruent stimulus is bivalent: one its aspect is matched by the rule “trained”, while the other aspect is matched by the rule “target”. Rule “others” matches any stimulus. Memory chunks associate stimuli with proper responses. We skip other details of chunks’ description.

Though the rule “target” has a low utility, it is fully associated with the goal ($A_{target} = 1.0$). The rule “trained” has goal association much lower than A_{target} , but still significantly above 0 (here, $A_{trained} = .2$), as it is somehow related to what happens during the task (e.g., when congruent stimuli are frequent, it may be beneficial to use sometimes the dominant rule). Thus, in every congruent and incongruent trial there is a competition between useful rule “trained” and goal-relevant rule “target”. This is modulated by the strength of control (G): the stronger control is the higher is choice probability of the rule “target”. Though the rule “others” is not associated with the goal ($A_{others} = .01$), it may sometimes be chosen, depending on the amount of noise. When the model perceives a neutral stimulus, the rule “trained” cannot be effectively applied and only the rules “target” and “others” fall into the conflict set.

Choosing a reaction means that either the rule “trained” or the rule “target” retrieves a chunk from the declarative memory, according to stimulus features present in the visual buffer. Perceiving a feedback is applied in a simplified form, as the information about correctness of the response is displayed on the screen and processed directly.

Simulation results and discussion

The noise was set to relatively low value of 0.15, as all modeled experiments involved young and healthy participants. Parameter g equalled to 3.625 (i.e., the mean value between high- and low-WM groups, see last section). Value of c was set to 0.6, reflecting relative sensitivity to conflicts. Two time scaling parameters for each simulation were optimized to fit observed data. As these data come from differing tasks (a flanker task and two different versions of Stroop task) and experimental conditions, we did not try to fit data precisely, but we were looking for qualitative replication of the wide range of effects, instead.

Gratton effect The original Gratton et al.’s (1992) effect in flanker task is often replicated within Stroop paradigm (e.g., Kerns et al., 2004). However, for comparison with other models, we aimed to replicate the original effect (see Figure 1, left panel). In the first simulation study, 5000 runs of the model were administered with 50/50 proportion of congruent vs. incongruent trials. The ordering of trials was random. The simulated Gratton effects is presented in Figure 1, right panel. Though the model generated slightly larger interference effect, influence of previous trial was the same as in the original experiment. The Gratton effect in DUCCA comes from the rise in conflict level (C) after incongruent

trial. In a subsequent trial, C is higher than it would be if a previous trial was congruent. So, the control strength (G) is higher and it makes (via U ’s) the firing of the rule “target” faster, leading to decrease in RT in incongruent trials. It also makes the execution of the rule “trained” slower. As this rule may often be fired in congruent trials, it thus results in increased RT in these trials.

Figure 1: Left panel: data adapted from Gratton et al. (1992) on latency in congruent (C) and incongruent (I) trials as a function of a previous trial. Right panel: simulated data.

Practice on a non-dominant process The seminal study on a relation between the level of automaticity of a non-dominant process and Stroop interference was administered by MacLeod and Dunbar (1988). The participants were asked to name colors arbitrarily associated with shapes by an instruction (a task to be practiced). The shapes were colored. As expected, when color-to-name and actual color mismatched, responses took longer when colors matched or a shape was non-colored. On some days, only practice trials (naming shapes) were applied. General result was that practice on non-dominant process decreased (and after some enormous number of practice trials – even reversed) an interference cost. Here, we replicated the effect of five days of training (about 2000 practice trials) on interference (see Figure 2).

Figure 2: Left panel: data adapted from Experiment 3 by MacLeod and Dunbar (1988) on latency in congruent (C) and incongruent (I) trials as a function of practice on a non-dominant task. Right panel: simulated data.

In this simulation, which regarded a task with highly artificial non-dominant action, we used a lower value of U_{target} equal to 0.1. The practice runs resulted in decrease in utility of the rule “trained” (as it lead to errors during practice) and in increase in U_{target} . This “automatization” effect was caused by model equation (1). The change in U_s caused the decrease in an interference cost, as the lower difference in utility between both rules increased a conflict value C . The increased conflict engaged more efficient control because of larger value of G . Then, 480 test runs were carried to simulate the presented data.

Proportion of incongruent stimuli, facilitation, and individual differences in Stroop performance Kane and Engle (2003; Experiment 4) observed decrease in Stroop interference as a result of decreasing proportion of congruent stimuli, when neutral stimuli were absent. Moreover, it appeared that this proportion influenced the difference in accuracy in incongruent trials between low- and high-working memory capacity (WMC) participants, screened with operation span task. When proportion was low (20% congruent), both WMC groups scored around six percent of errors, with no significant advantage of WMC-high group. When incongruent trials were rare (80% congruent), error rate increased, but much more for WMC-low subjects (see Figure 3, left panel). Kane and Engle interpreted this as a result of more frequent slips of attention control of WMC-low group. In 20% congruent sequence, stimuli exogenously kept the control focused on non-dominant process and the differences in quality of internal control did not matter much. When incongruent trials were rare, only internal control could keep focus on non-dominant process and weak control of WMC-low group more often made it loose the task goal and commit more errors on incongruent trials.

Figure 3: Left panel: data adapted from Kane and Engle (2003) on error rate in incongruent trials as a function of proportion congruent and WMC. Right panel: relevant data simulated with high/low parameter g value.

Interestingly, WMC differences did not interact with the effect of congruent trials proportion on latency: interference effect increased with increasing proportion of congruent trials, but WMC-low participants presented higher effect than WMC-high ones in both conditions of proportion congruent (see Figure 4, left panel). Kane and Engle observed also (Experiment 2) the differences in facilitation effect.

Surprisingly, WMC-low persons exhibited a larger effect (72 ms) than WMC-high ones (41 ms). On congruent trials, WMC-low participants might have more often used the dominant process to emit a response. Although use of this process did not cause errors in congruent trials, as both processes lead to the same response, it could have speeded up WMC-low participants' RTs comparing to RTs of WMC-high ones (who probably avoided the dominant process).

Figure 4: Left panel: data adapted from Kane and Engle (2003) on interference effect a function of proportion congruent trials and WMC. Right panel: data simulated with high/low parameter g value.

The complicated pattern of results presented in this subsection constitutes a tough test for any Stroop model. We simulated those data using either 36 congruent and 144 incongruent trials (20% congruent condition) or vice versa (80% congruent condition), following Kane and Engle's procedure in Experiment 4. The value of g parameter was set to lower value of $g = 3.5$ in order to reflect WMC-low group or set to higher value of $g = 3.75$, to reflect WMC-high group. 4320 runs of the model yielded simulated data.

All observed effects were qualitatively replicated. As in Kane and Engle's study, the effect of the proportion congruent was observed in latencies as well as in errors. In all conditions, increase in parameter g caused reasonably lower interference effects in latencies. However, the difference in g resulted in difference in accuracy on incongruent trials only when incongruent stimuli were rare. Simulated data are presented in right panels of Figures 3 and 4. In a simulation of Experiment 2, which differed slightly from Exp. 4, neutral trials were included and the values of $g = 3$ and $g = 4$ were set for WMC-low and WMC-high groups, respectively. The facilitation effect (68 ms) appeared much smaller than the interference effect (137 ms) and it fitted observed results. Also, WMC-low group scored larger facilitation effect (76 ms) than WMC-high persons (60 ms).

Figure 5 presents the indices of strategical adaptation to different (20% vs 80% congruent) task conditions. The model adapted mean level of control, rising its average level from 80% congruent to 20% congruent condition. Due to utility learning, in the more difficult condition the model amplified a utility of non-dominant rule and lowered the one of dominant rule, what increased internal conflict and thus recruited additional control. Such a strategical adaptation was less efficient when maximum strength of control was

limited (i.e., when g value was low), matching the results of WMC-low participants.

Figure 5: Internal dynamics of the model expressed as fluctuations in exerted control (G) and changes in utilities of the rules “trained” and “target” in two task conditions.

Two major quantitative deviations from data may be noticed: much smaller effect of proportion of congruent stimuli on latency interference and more errors committed by the model than by participants. These deviations probably result from the fact that our model captures only general aspects of control, while experimental situation involve many other general processes (e.g., expectations about the probability of events, changes in speed-accuracy trade-offs, decreased vigilance, and so on) as well as some task specific processes, all influencing interference effects. However, as a hybrid and general architecture, DUCCA can potentially implement all these processes within more complex models.

Summary and conclusions

DUCCA, a new general architecture of executive control was presented. It was applied in order to simulate Stroop-like task. We used only a few simple assumptions of how control operates and still were able to replicate most of general effects observed in Stroop paradigm: asymmetrical interference and facilitation effects, the Gratton effect, an influence of practice on Stroop effect, decrease in interference as proportion of congruent trials decreases, and the complex pattern of individual differences related to WMC.

The presented work is on a preliminary stage. Taking into account semantics and item-specific effects in executive control, linking executive mechanism to brain structures, and explaining the common variance in several executive tasks and its role in complex cognition constitute the most important future directions of DUCCA development.

Modelling the Correlation Between Two Putative Inhibition Tasks: An Analytic Approach

Abstract

A process of response inhibition is often held to be recruited in situations where it is necessary to withhold or inhibit a prepotent response. Individual differences in the efficacy of this function have been held to underlie individual differences in behaviour on tasks such as the Stroop colour-naming task and the stop-signal task. These claims, however, have been supported only with correlational analyses and informal argument. This paper considers the operationalisation of response inhibition by exploring existing mathematical and process models of both the Stroop and stop-signal tasks. We identify parameters that might underlie individual differences in the performance of the tasks and consider potential relations between those parameters. It is shown that (a) at least three potential inter-relations between parameters of the task models may lead to inter-task correlations, and (b) the observed correlations arise when attentional bias parameters in the models are equated but not when inhibition parameters are equated. We conclude that the ascription of such correlations to a process of response inhibition is premature.

Keywords: Cognitive control; Response inhibition; Stroop task; Stop signal task; Individual differences.

Introduction

In much everyday behaviour, and in many psychological tasks, it is necessary to resist temptation or to avoid producing a prepotent response. Consider the well-known Stroop colour-naming task, where the subject is required to name the colour of the ink in which a word is printed. If the word is itself the name of a colour (e.g., RED printed in green ink) then the subject must actively or deliberately resist the temptation to read the word if they are to successfully name the ink colour.

It is commonly argued that the ability to inhibit a prepotent response is facilitated by a cognitive control process referred to as *response inhibition*. Critically, response inhibition is not a task-specific construct, limited to (e.g.) the Stroop task. Rather, it is held to be one of several general “executive” processes that are invoked across a range of tasks. Moreover, individual differences in the ability to inhibit a prepotent response are held to reflect individual differences in the efficacy of response inhibition. For example, in a well-known study of cognitive control by Miyake, Friedman and colleagues (2000), 137 subjects completed a battery of tasks, three of which were assumed specifically to tap response inhibition. Miyake and colleagues found significant pair-wise correlations in performance on the response inhibition tasks, and

confirmatory factor analysis supported their model of executive function as comprising at least three separable components, one of which was response inhibition.

The three tasks held by Miyake et al. to tap the latent construct were the Stroop task (as discussed above), the stop-signal task of Logan (1994), and an antisaccade task (Roberts et al., 1994). In the stop-signal task subjects complete a series of trials in which they must normally respond as quickly as possible to a stimulus (e.g., by indicating whether an auditorily presented noun denotes a type of animal). On a small proportion of trials the stimulus is followed by a second “stop” stimulus (e.g., a beep), indicating that on this particular trial a response should be withheld. In the antisaccade task trials involved visual presentation of a fixation point at the centre of a monitor screen. This was followed by a brief cue appearing to the left/right of the screen and then an even briefer target appearing on the opposite side of the screen. Subjects were required to make a choice decision based on a feature of the target. To do so, they needed to avoid making a saccade to the cue, as this would prevent them from being able to make a saccade back to the target before it was replaced by a mask. Response inhibition was indexed by Miyake et al. (2000) in the Stroop task by the difference in response times between incongruent and neutral trials. In the stop-signal task it was indexed by the number of stop trials on which a response was (incorrectly) produced. In the antisaccade task it was indexed by the proportion of correct target decisions. As noted above, significant pair-wise correlations were found between these measures. This result was effectively replicated in a subsequent study with 220 subjects which used the same tasks but slightly different dependent measures (Friedman & Miyake, 2004).

The studies of Miyake, Friedman and colleagues appear to provide strong support for the response inhibition construct and for its variability across individuals. However in both cases the evidence is purely correlational. Neither study attempts to provide a mechanistic account of response inhibition as it might be manifest in the various tasks. Clearly, if response inhibition is a cognitive control process that plays a causal role in the performance of the Stroop, stop-signal and antisaccade tasks (amongst others), then that process should be shared by computational accounts of the three tasks. Moreover, if the efficacy of that construct can vary across individuals, then that process should be parameterised in the computational accounts. Lastly, if pair-wise correlations in performance of the tasks are to be attributed at least in part to the efficacy of response

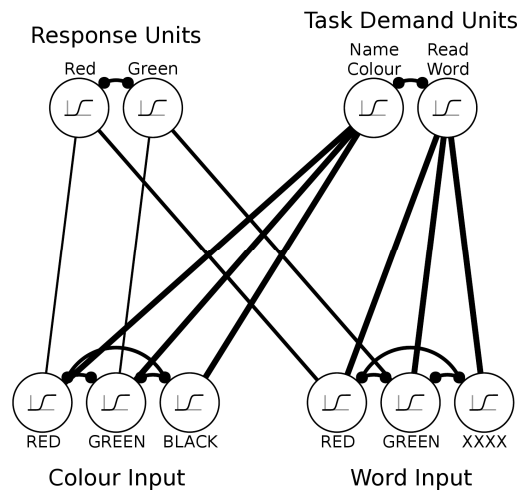

Figure 1: The architecture of the Cohen & Huston (1994) model of the Stroop task. The response function for each node is a sigmoid. Relative line thickness indicates connection strength. Lateral inhibition (shown by arrows with circular end points) operates between nodes in each group.

inhibition, then varying the response inhibition parameter in the computational accounts should also result in pair-wise correlations.

The difficulty, however, is that a cursory analysis of existing process models of the tasks used by Miyake, Friedman and colleagues suggests that their dependent measures are not obviously related to a common mechanism of response inhibition. Consider the widely accepted interactive activation model of the Stroop task of Cohen and colleagues (e.g., Cohen & Huston 1994; see Figure 1). In the model, interference on incongruent trials arises from competition between two response pathways – a word-reading pathway which is highly practiced and hence strong, and a colour-naming pathway which is less practiced and hence somewhat weaker. In order to generate a color-naming response on an incongruent trial it is necessary to selectively amplify the inputs to the color-naming pathway via task-demand units. This process, often referred to as attentional biasing, allows activation from the colour-naming pathway to dominate activation from the word-reading pathway. While individual differences in interference are not generally the focus of this model, they may be captured by assuming that individuals who show relatively little interference are better able to maintain strong excitation of the color-naming task-demand unit. This in turn might result either from greater input to the color-naming task demand unit from external sources (e.g., attentional processes) or conceivably from stronger lateral inhibition between task-demand units. Therefore in this model at least the dependent measure of Miyake et al (2000) indexes an aspect of task-demand, and not response inhibition.

The goal of this paper is to formalise this analysis and extend it to a second putative response inhibition task,

namely the stop-signal task, for which a relatively well-developed “off-the-shelf” computational account is also available (Boucher et al., 2007). We analyse potential sources of correlations in performance across the two tasks by couching both models within a common architecture. In so doing we question the standard concept of response inhibition and propose instead that correlations between performance on the Stroop and stop-signal tasks might be due to a somewhat different factor related to the strength or potency of the currently selected goal.

The Task Models

In order to address the correlation between the Stroop and stop-signal tasks, we converged on an interactive activation architecture based on the existing published models. This architecture was then simplified to extract a small set of equations that relate the relevant parameters of cognitive control in these two tasks to the dependent measures used by Miyake et al. These equations were then used to generate distributions of the dependent measures by varying the critical parameters and calculating the resulting correlations.

Stop-signal task

The version of the stop-signal task used by Miyake et al. consisted of two blocks. The principal task was an animacy-categorisation task. The first block only had categorisation trials and was intended to ensure that generating a response was indeed the prepotent response. The second block included 25% stop-trials. For our analytic modelling efforts the following components are relevant. First, the first block produced a mean response time. This was used on a subject-by-subject basis to adjust the onset of the stop-signal on stop-signal trials in the second block. For each subject this onset was their mean response time less 225ms. The stop-signal was therefore presented at (RT–225) ms post-stimulus. We assume a similar approach in the model. Second, the dependent variable was the proportion of categorisation responses generated on stop trials. This value represents errors due to failure to inhibit.

The architecture for our model is inspired by several preceding models. First, Boucher et al. (2007) used a simple interactive race model in which a “go” and a “stop” unit compete through lateral inhibition. Critical for their simulations is that the inhibition from stop unit to go unit is much larger than the reverse connection. This makes the model interactive for only a brief time. Second, the location of the units is downstream in the basal ganglia. This is also assumed in a related go/nogo-model of Frank and colleagues (2004). Third, in the go/nogo-model the nogo-signal comes through the subthalamic nucleus. This nucleus has been shown to form part of a response inhibition pathway that included the inferior frontal gyrus (Aron et al, 2004). It has been postulated that choice responses can be optimised through this pathway (Davelaar, 2009; Frank, 2006). This leaves us with the architecture shown in Figure 2a. It is assumed that the two units are located in the striatum and receive input from earlier processing levels

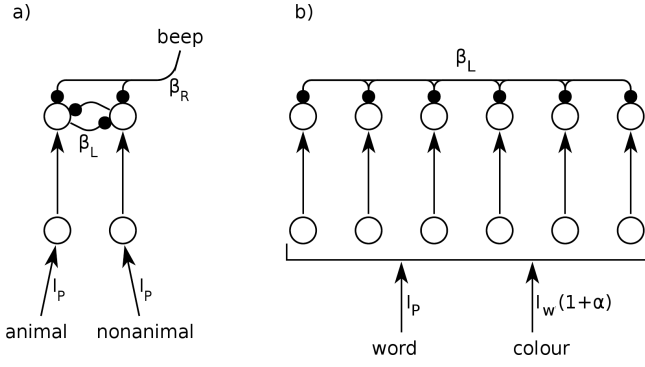

Figure 2: a) Basic architecture of the stop-signal model.
b) Basic architecture of the Stroop model.

regarding the animacy of the stimulus. The two units are forward connected to two output units that are connected via lateral inhibition. These are assumed to be localised in the globus pallidus interna and substantia nigra. This is a straightforward model of response selection. The stop-signal is assumed to inhibit the final responses via the IFG \rightarrow STN \rightarrow SN/GPi-pathway. The strength of the response inhibition parameter β_R is one source of individual differences in stop-signal performance.

Stroop task

The Stroop task used by Miyake et al. involved naming the colour of a word of which the ink could be in one of six colours. Relevant for the current analytic modelling effort is that the dependent measure is the difference in voice key response time between the mean RT on incongruent trials and neutral trials (which consisted of coloured asterisks). The architecture for the Stroop model follows the incarnations of Cohen and colleagues discussed above. In particular, compared to the neutral trial, an incorrect unit gets activated in response to reading the colour-word. The lateral inhibition between the response units slows down the responses in incongruent trials. Some extension to this model is needed, however. Recent analyses have shown that the Cohen models are unable to produce the correct relation between the stimulus-onset asynchrony in versions of the Stroop task when the word and its ink colour are presented asynchronously (Stafford & Gurney, 2007). The solution to this problem was to treat the output units of the Cohen model as the input units to the basal ganglia, i.e., the striatum (see Figure 2b). This automatically leads to a consistent architecture for both the Stroop task and the stop-signal task.

Simplifying the Overarching Model

Some simplifications are necessary in order to provide an analysis of the correlation between the two tasks and the relevant parameters. First, we focus only on the abstracted basal ganglia pathway shown in Figure 2. Second, we assume no lateral inhibition in the input level and lateral inhibition of strength β_L at the output level. For the stop-signal model, an extra inhibitory connection of strength β_R

to both units is assumed. Whereas in the stop-signal task, the animacy judgement is unambiguous (and prepotent), there is overlap in the Stroop task. This means that in the stop-signal task the only components doing the work are a single response unit and the β_R . In the Stroop task, there are two critical trial types. In the neutral condition the neutral response unit is activated in absence of any inhibition. In the incongruent condition the response unit receives input from the target channel and inhibition from the distractor channel via lateral inhibition. The amount of activation that goes through the target channel is under attentional control. Whereas earlier models of the Stroop task implemented a tradeoff in attention to both channels, recent functional imaging work did not find any support for a deactivation of the distractor channel (Egner & Hirsch, 2005). Instead, only a positive enhancing effect of attention was found in a Stroop-like task. Thus we assume an attentional parameter, α , which enhances the target channel. We assume that the prepotent inputs for both tasks are identical and that the weaker target channel propagates a weaker signal.

This leads to the following equations that govern the input activation of the target unit in all tasks and conditions:

Stop-signal task

$$X(t) = \begin{cases} I_P(t) & \text{when } t < \overline{RT} - 225\text{ms} \\ I_P(t) - \beta_R & \text{when } t > \overline{RT} - 225\text{ms} \end{cases} \quad (1)$$

Stroop task

$$X(t) = \begin{cases} (1+\alpha)I_w(t) & \text{neutral condition} \\ (1+\alpha)I_w(t) - \beta_L I_P(t) & \text{incongruent condition} \end{cases} \quad (2)$$

In order to obtain response time, we assume a linear output activation function:

$$\frac{d}{dt} F(x) = X(t) \quad (3)$$

This choice is justified by the observation that simple and choice reaction time models operate optimally when they are in the linear part of a sigmoidal output function (Bogacz, et al., 2006). By assuming linear output activation functions, we thus assume optimal responding.

Finally, we assume that the response threshold, θ , is the same for both tasks. For the stop-signal task, a response deadline is included of 1500ms (as used in Miyake et al., 2000).

Given the above assumptions, the response time in the stop-signal task is:

$$RT_{SS} = \begin{cases} \frac{\theta - I_P \cdot 225}{I_P - \beta_R} + 225 & \text{for } I_P > \beta_R \\ \infty & \text{otherwise} \end{cases} \quad (4)$$

This is tested against the response deadline. An erroneous response is produced if the response time is less than this deadline. The difference in RTs between incongruent and neutral trials in the Stroop task is:

$$\Delta RT_{Stroop} = \theta \cdot \left\{ \frac{1}{(1 + \alpha) \cdot I_W(t) - \beta_L \cdot I_P} - \frac{1}{(1 + \alpha) \cdot I_W(t)} \right\} \quad (5)$$

For both equations θ was fixed at one and noise was added.

One immediate observation of interest is that architecturally, the mechanisms producing incorrect stop-trials and slowed down Stroop trials are not identical. In fact, Stroop performance is determined by the lateral inhibition between two information channels, whereas stop-errors are due to a pathway that inhibits both competing channels.

Our focus is on four parameters: the prepotent response parameter, I_P , the response inhibition parameter, β_R , the attention parameter, α , and the lateral inhibition parameter, β_L . There are a number of constraints on the parameters and points to note. First, note that I_P is shared between the models and moreover that this is the *only* parameter that is shared. Thus, it is expected that this parameter will be the locus of (at least some of) the correlation between the two tasks. Second, the following constraints hold:

- $(1 + \alpha) \cdot I_W > \beta_L \cdot I_P$ in order to ensure that response accuracy in the Stroop task is above 50%
- $\beta_L < \beta_R$. This is justified based on the findings of Boucher et al. (2007)
- $I_W < I_P$, by definition

We focus on the following three potential sources of correlation between the proportion of stop-errors and the size of the Stroop interference effect:

1. Pre-potency of input. The pre-potency of the input, I_P , is an obvious choice from the architectural viewpoint, as it is the only parameter that features in both models. Therefore varying I_P across subjects should produce the positive correlation between the two tasks. The pre-potency, however, is not a factor that is mentioned as an executive function by Miyake et al (2000) and in fact would in most accounts be categorised as the parameter that has to be overcome via executive control.

2. Correlated executive functions. To overcome the pre-potency in the stop-signal task, response inhibition, β_R , is the relevant parameter, while for the Stroop task, the attentional control, α , is the relevant parameter. Obviously, varying these parameters across subjects should not produce a correlation in performance measures. However, one could argue that executive functions are themselves partly correlated (as is done by many authors including Miyake et al., 2000). If this is the case, then a correlation between the two tasks may not be due to shared variance in inhibition parameters, but due to a correlation between the executive functions of inhibition and attentional focus. One possibility that we will come back to in the discussion is that both of these concepts might be subsumed under a more general notion of the strength or potency of the goal, as both tasks require the need to exert control based on the recognition of a stimulus (stop-signal or colour-word).

3. Correlated inhibition. Perhaps the most natural way of addressing the correlation is to assume that response inhibition in the stop-signal model, β_R , and lateral inhibition

in the Stroop model, β_L , are correlated. However, note that the dependent variables are such that greater (response) inhibition in the stop-signal task leads to fewer errors and hence lower levels of the dependent measure, whereas greater (lateral) inhibition in the Stroop task leads (perhaps counter-intuitively) to slower responses in the incongruent condition and higher levels of the dependent measure. Thus, correlated inhibition will lead to a correlation in the dependent measures, but this will be a *negative* correlation – not a positive one! Thus correlated inhibition can only result in the observed positive correlation between dependent measures on the stop-signal and Stroop tasks if the inhibition parameters are *negatively* correlated.

Sampling Studies: Methods and Results

Several sampling studies were conducted based on the above analysis. The aim of these studies was to assess effects of the three potential sources of correlation identified above on the cross-task correlation in dependent measures. To this end, equations 4 and 5 were used to obtain dependent measures for each task as all parameters except I_W were varied uniformly using boundaries that (a) were found to be adequate to produce values for the dependent measures that were within the range of the actual empirical results and (b) adhered to the set of constraints above. I_W was fixed to 0.6. The choices of uniform distributions and the precise value of I_W are arbitrary and do not impact on the conclusions drawn from this work.

We imposed associations among parameters as follows:

1. To address the pre-potency view, only the I_P distribution was varied between-subjects and each subjects' I_P value was used in both task models. For each virtual subject, the other three parameters were randomly sampled 100 times corresponding to 100 trials within a task. The proportion of stop-errors was calculated as the mean number of times that a response time in the stop-signal task was shorter than 1500 ms. The Stroop mean interference was calculated over the 100 3-parameter combinations (together with the subject's I_P). One hundred subjects were simulated and a Pearson product-moment correlation coefficient was calculated over the resulting set of 100 data pairs.
2. To address the correlated executive function view, β_R and α were used as between-subjects parameters (I_P and β_L varied within-subjects). There were two versions: uncorrelated and correlated β_R and α .
3. Finally to address the correlated inhibition view, we correlated β_R and β_L between-subjects (I_P and α varied within-subjects).

In all cases additional noise was added to the correlated parameter in order to lower the resulting correlation in dependent measures and obtain a value of approximately 0.18 as found in the behavioural studies of Miyake et al. (2000).

Scatter plots showing the correlation between dependent measures for four situations are shown in Figure 3. Positive correlations can be obtained between the dependent measures either when I_P is fixed within-subjects (exploring

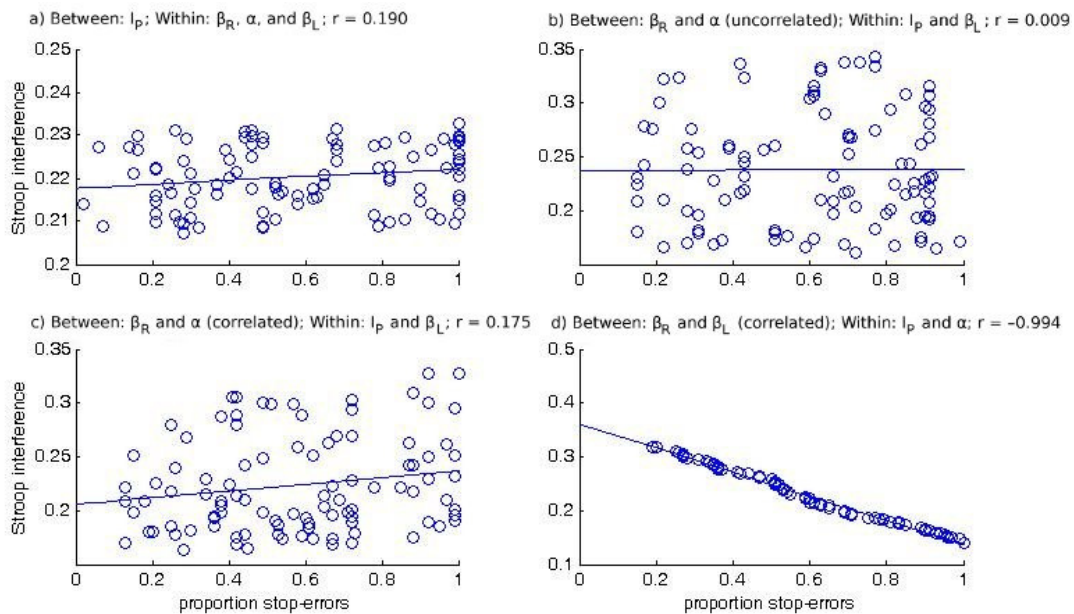

Figure 3: Scatter plots of dependent measures under different conditions. a) When I_p is fixed within-subjects (the pre-potency view) the correlation is positive. b) If β_R and α vary within-subjects but are uncorrelated, then there is no correlation. c) The correlation is positive when β_R is correlated with α (the correlated executive functions view). d) When β_R and β_L are positively correlated the correlation between dependent measures is negative.

the pre-potency view; Figure 3a), or when β_R is correlated with α (exploring the correlated executive functions view; Figure 3c). If β_R and α vary within-subjects but are uncorrelated, then there is no correlation between the dependent measures (Figure 3b). When β_R and β_L are correlated, then as anticipated the correlation between dependent measures is negative (Figure 3d).

Discussion

We set out to address the correlation between two well-known tasks that have been discussed as tapping executive inhibition. Correlations between performance on the stop-signal and the Stroop tasks have been found in several behavioural studies and both tasks have been the subject of detailed computational modelling. The modelling has been at the same architectural level, thus allowing the integration of those models into a larger more general model. As the parameters in the models are tied to specific mechanisms, we can address the source of the correlation between the tasks at a parameter level without having to make imprecise verbal assumptions about the relation between mechanisms operating in the two tasks. The general model itself can be simplified without loss of argument and applied to the complex enterprise of not only modelling individual differences in task performance, but also the correlations among tasks.

If the argument is that co-variability in the stop-signal and Stroop task is due to shared variability of a single executive function referred to as response inhibition, then our results question this strong statement. First, the only mechanism that is truly shared between the tasks is the strength of the

pre-potent response channel. Given that this channel is the one that is the target of executive control and thus cannot be considered to be an executive control function itself, we see no basis to assume that a shared inhibition-type of executive function underlies the behavioural correlation. Second, the mechanisms that have been assumed and shown in modelling to be critical in overcoming the pre-potency are different between the tasks, thus a single inhibition-type of executive function is not an appropriate label. Instead, if these mechanisms are correlated, then a more appropriate label might be “goal potency”. We elaborate on this view below. Third, if the shared inhibition function is taken literally and the inhibition mechanisms are correlated, then the simulation suggests that a negative correlation should be found between the tasks. However, the behavioural studies show a positive correlation between the tasks. This is in the context of literature that claims a positive correlation between each task and a latent inhibition factor. These points together argue against the use of a response inhibition construct in the individual differences literature as a mechanistic explanation for the behavioural correlation.

We suggested that the correlation between the tasks is due to the potency or strength of the current goal. More specifically, the computational studies are consistent with either a unitary mechanism that affects the rate of activation accumulation or one that relates to the level of the maximum possible activation. Both of these are emergent from an activation-based framework in which perceptual or cognitive information is actively maintained through self-excitatory loops (Davelaar, et al., 2005). Whether they can be distinguished remains to be demonstrated. However we

note that in a further part Miyake et al.'s (2000) study, it was shown that the common factor underlying performance on the stop-signal and Stroop tasks dissociated from a factor common to performance on several other tasks that were held to require a further executive function, referred to as *task-shifting*. A full account must therefore relate, in computational terms, the function isolated in this study and a task-shifting function. This is particularly important as Gilbert and Shallice (2002) consider task-shifting in the context of the Stroop task, and account for it in a model closely related to the Cohen and Huston model that forms the basis for part of this work.

The idea of goal potency has some support from other areas of cognitive neuroscience. Thus, Duncan et al. (2008) refer to the inability to execute a goal on presentation of a stimulus, even though knowledge about the rules regarding stimulus and response is present, as *goal-neglect*. Individuals differ in the degree to which they exhibit goal-neglect. If goal-neglect (or a factor underlying it) lies behind our factor, then one would expect that the proportion of stop-errors and the size of the Stroop interference effect should both be positively correlated with measures of goal-neglect. We know of no study that has investigated the correlation between stop-errors and goal-neglect.

We have focused only on the stop-signal and the Stroop task. As noted in the introduction, Miyake et al. (2000) also considered the antisaccade task. This task requires an eye-movement away from a distractor stimulus when this stimulus appears. In the Miyake et al. study the dependent measure for this task was the proportion of correct trials. Thus, overcoming pre-potency increases the score. This is important, as for the stop-signal and Stroop tasks, overcoming the pre-potency decreases the corresponding dependent measure. Consequently one might expect a negative correlation between the measures. Instead a positive correlation was found between the antisaccade task and both tasks. This is inconsistent within the response inhibition view. However, processes of active maintenance or activation accumulation can account for positive correlation where overcoming prepotent responses would expect negative correlations. In all but the antisaccade task, the stimulus conveys information that is used in activation of the relevant goal. In the antisaccade task, the first stimulus is a distractor and does not convey positive information, while the second is the target. Therefore being able to quickly activate information will produce less accurate responses. This leads to more activation producing lower levels of the dependent measure (accuracy) in the antisaccade task, together with more activation leading to lower levels of the dependent measures in the stop-signal (proportion stop-errors) and Stroop (interference effect) tasks. Our argument therefore is that the latent factor in the Miyake et al. studies reflects an activation-based function, and not an inhibition function.

This work also demonstrates more generally the importance of using explicit formal analyses to uncover the mechanisms underlying latent cognitive constructs.

Estimation of Trade-off between Costs of Preprocessing and Primary Processing

Abstract

People often conduct preprocessing to simplify primary processing. Usually, there is a trade-off between the costs of performing preprocessing and primary processing. Therefore, the utility of preprocessing differs depending on the task complexity. We conducted three experiments to find out whether people could adaptively estimate the utility of preprocessing and then take rational action. The overall result was that in performing a high complexity task, almost all the participants made a rational choice. However, for a low complexity task, the participants gradually learned to conduct preprocessing despite it not being effective. These results were explained based on theoretical perspectives proposed in previous studies.

Keywords: Strategy selection; Task environment; Cost; Time; Preprocessing

Introduction

When people engage in a task, they often create and conduct an additional preliminary task in order to conduct the main task more easily by using the result of the additional task. For example, people create preliminarily index cards for documents so that needed documents can be easily found. Moreover, people program preliminarily macros on a computer so that data can be easily processed later. In this study, we call such preliminary processing “preprocessing”. People conduct preliminarily preprocessing so that primary processing in the task can be easily carried out. Preprocessing is often performed in our daily lives.

Kirsh (1996) referred to a “complementary action” which redesigns a task environment before engaging in the task in order to complete the task easily. He explained: “Complementary actions are a part of a strategy for restructuring the environment to improve the speed, accuracy, and robustness of cognitive processes” (p. 442). Such complementary actions taken before engaging in a task are also considered to be preprocessing. Moreover, Martin and Schwartz (2009) described preprocessing as an expertised action and call it an “adaptive pattern” in their manuscript. They stated that “in the adaptive pattern, people take an initial period to explore or adapt their ideas, practices, and/or environment. They are slower to start, but they can make up the lost time if they make an appropriate adaptation” (p. 372).

When preprocessing is conducted, the cost in primary processing is reduced. However, since conducting the preprocessing itself incurs a cost, there is a trade-off between the costs of preprocessing and primary processing. In such a situation, the utility of preprocessing seems to differ depending on the task complexity. When primary processing is conducted in a task without preprocessing, the task completion time increases with the task complexity. In contrast, when preprocessing is conducted for a certain period of time, it is considered that the increase in total task completion time for preprocessing and primary processing will be reduced, compared to the increase in the task completion time without preprocessing. Figure 1 illustrates our basic concept, showing

the utility of preprocessing in relation to the task complexity. As shown in Figure 1, from the point where the task complexity (the amount of processing) exceeds a threshold level, the effectiveness of the preprocessing becomes significant. The utility of preprocessing differs depending on the task complexity; therefore, people should decide whether or not preprocessing is worthwhile depending on the situation.

Many researchers have studied cost estimation in situations where there is a trade-off between the costs of two different types of processing, e.g., a trade-off between processing using external resources (called external processing) and internal processing (Gray & Fu, 2004; O’Hara & Payne, 1998). In these studies, it was revealed that people adaptively estimate the costs of external processing and internal processing, and effectively adjust the usage of external resources depending on the cost of their use. Moreover, Matthew and Anderson (2009) found that people could adaptively determine whether or not external resources should be used depending on the task complexity. These studies show that people can adaptively estimate and allocate the costs of external processing and internal processing. On the other hand, in the current study, we investigate cost estimation in a situation where a different task needs to be conducted as preprocessing in order to reduce the cost of primary processing. The purpose of this study is to investigate whether people can adaptively estimate the utility of preprocessing and take rational action when there is a trade-off between the costs of preprocessing and primary processing as described above.

Figure 1: Concept diagram of trade-off between costs of preprocessing and primary processing

Experimental task

In the following experiments, we used a routine task of transcribing scores from test sheets to a tally sheet. In this task, fifty test sheets were prepared. On each test sheet, a student ID number was printed in the upper left and a test score in the center. In the experiments, three trials were conducted. In each trial, all the scores on the fifty individual test sheets had to be transcribed to a tally sheet to correspond to each student ID number.

Task complexity Each student ID number consisted of an eleven-digit number that encoded four categories, Grade, Major, Course, and Individual number. We set up a situation in which there were two grades, two majors, and five courses, and also there were twenty students in each course. Each student ID number on the test sheet was represented differently from that of the tally sheet, but could be collated by a certain transformation rule. In order to find the right place to fill out in the tally sheet, the student ID number on the test sheet needed to be transformed by the rule so that the transformed number could be found in the tally sheet (Figure 2). In the high task complexity condition, the participants had to calculate the student ID numbers on the test sheets for the transformation using a certain formula. On the other hand, in the low complexity condition, a student ID number correspondence table was given to the participants for the transformation so that they could find the referred numbers in the tally sheet without performing a calculation.

Figure 2: Transformation of student ID number; In the high task complexity condition, a transforming formula was used as follows: (1) add Major number to Course number ($24 + 19 = 43$). (2) multiply the first digit by the second digit of the result of (1) ($4 \times 3 = 12$). (3) subtract the result of (2) from the result of (1) ($43 - 12 = 31$). In the low task complexity condition, a correspondence table was used to transform the student ID numbers.

Preprocessing To carry out the preprocessing, a desk space was available for participants. Initially, the test sheets were arranged in random order and handed to the participants. They could rearrange the test sheets on the desk space so that they could group the test sheets according to the categories of Major and Course numbers. By preliminarily grouping the test sheets, the participants could transform the student ID numbers of a bundle of multiple test sheets in the same Major and Course number at one time. There was no need to transform each student ID number on each test sheet one by one. Therefore, the participants could reduce the number of transformations of the student ID numbers by preliminarily grouping the test sheets as a preprocessing task.

Experiment 1

Purpose

We investigated the relationship between the task performance and the task complexity, i.e., the task completion time and the number of errors respectively, when preprocessing is conducted or not.

Method

Participants Forty-six university students participated in this experiment.

Material A set of fifty test sheets made from A4 sized paper was prepared for each trial. Three trials were performed and a different set was used in each trial. All three sets were

controlled using the number of times, and the order in which the operations of carrying and borrowing were required for the calculation to transform the student ID numbers. The tally sheet was made of A3 sized paper. A scenario with two grades, two majors, and five courses were conjectured with twenty students belonging to each course. Therefore, 400 empty cells ($= 2 \times 2 \times 5 \times 20$) were placed on the tally sheet. By transcribing all the scores to the tally sheet, fifty cells out of the 400 blank spaces had to be filled in. A desk with space large enough to accommodate ten A4 sized papers was used for preprocessing. Also, another desk was used for primary processing, that is, transcribing the scores to the tally sheet with a pencil.

Factorial design The experiment had a three-factor mixed design. The factors were: (1) Task complexity (high and low) between participants; (2) Preprocessing (preprocessing and no preprocessing) between participants; (3) Trial (1, 2, and 3) within participants.

Procedure In order to confirm participants' ability to calculate, they were required to solve computational problems that consisted of a total of 25 addition and multiplication problems. The main task was conducted three times with different sets of the test sheets and the tally sheets. At the beginning of each trial, the participants were informed of their task completion time and the number of errors in the previous trial as feedback. As a preprocessing condition, the participants had chosen a particular way of grouping the test sheets in the first trial and were instructed to rearrange them in the same way throughout the three trials.

Result

In order to maintain homogeneity of the participants' calculation ability, two participants whose computational time in the calculation problems fell outside 2 SD from the mean computational time for each condition were eliminated from the analysis. In addition, it was assumed that the participants who made too many errors in the task could not conduct the task appropriately, therefore three participants whose mean number of errors throughout the three trials fell outside 2 SD from the mean number of errors in each condition were eliminated from the analysis. Moreover, one participant who violated the instructions, i.e., conducted the transforming calculation on the desk space for preprocessing, was eliminated from the analysis. In the following experiments, the identical criteria were used for selecting appropriate participants. As a result, the performance of forty participants, of whom ten were assigned to each condition, was analyzed.

There was no significant difference in performing the calculation problems between the four conditions ($F(3,36) = .07, n.s.$). Therefore, the calculation abilities of the participants among the four conditions were considered equivalent.

Task completion time On the task completion time, a 2 (Task complexity: high/low) \times 2 (Preprocessing: preprocessing/no preprocessing) \times 3 (Trial) ANOVA was conducted. As a result, there was no significant three-way interaction ($F(2,72) = 2.17, n.s.$). There was a significant two-way interaction between task complexity and preprocessing ($F(1,36) = 9.80, p < .005$). There was neither significant two-way interactions between task complexity and trial

($F(2, 72) = 1.83, n.s.$) nor between preprocessing and trial ($F(2, 72) = .46, n.s.$). Figure 3 illustrates the mean task completion time in Experiment 1 based on the basic concept depicted in Figure 1. In Figure 3, the preprocessing time was measured from the time when the test sheets were put on the desk space for grouping (preprocessing) until they were lifted up for transcribing the scores to the tally sheet (primary processing).

Next, we conducted a simple main effect test on the preprocessing factor. As a result, (1) in the high task complexity condition, there was a marginally significant difference showing that the task completion time was faster in the preprocessing condition than in the no preprocessing condition ($F(1, 36) = 3.19, p < .10$), whereas (2) in the low task complexity condition, it was significantly faster in the no preprocessing condition than in the preprocessing condition ($F(1, 36) = 6.98, p < .05$).

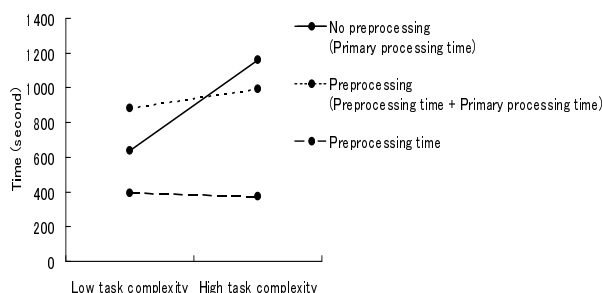

Figure 3: Task completion time in Experiment 1 represented by the basic concept

Number of errors We defined a transcribing error as being a transcription of an incorrect score or a transcription to an inappropriate cell. On the number of errors, a 2 (Task complexity: high/ low) \times 2 (Preprocessing: preprocessing/no preprocessing) \times 3 (Trial) ANOVA was conducted. As a result, there was no significant three-way interaction ($F(2, 72) = .61, n.s.$). There was a significant two-way interaction between task complexity and preprocessing ($F(1, 36) = 4.37, p < .05$) and a marginally significant interaction between task complexity and trial ($F(2, 72) = 2.56, p < .10$). There was no significant interaction between preprocessing and trial ($F(2, 72) = 1.98, n.s.$).

Next, we conducted a simple main effect test on the preprocessing factor. As a result, (1) in the high task complexity condition, the number of errors was significantly smaller in the preprocessing condition than in the no preprocessing condition ($F(1, 36) = 11.12, p < .005$), whereas (2) in the low task complexity condition, there was no significant difference between the preprocessing and no preprocessing conditions ($F(1, 36) = .14, n.s.$).

Discussion

As a result of Experiment 1, it is revealed that conducting preprocessing is effective for the high complexity task, and contrarily, not conducting preprocessing is effective for the low complexity task. These results proved that our transcribing task is an appropriate task for embodying a trade-off between preprocessing and primary processing.

In the following Experiment 2, using the same task, we in-

vestigated whether people could adaptively estimate the utility of preprocessing and take rational action depending on the task complexity.

Experiment 2

Purpose

Using the transcribing task, we investigated whether people could adaptively estimate the utility of preprocessing and take rational action depending on the task complexity.

Method

Participants Twenty-seven university students participated in this experiment.

Material Identical materials were used as in Experiment 1.

Factorial design The experiment had a two-factor mixed design. The factors were: (1) Task complexity (high and low) between participants; (2) Trial (1, 2, and 3) within participants.

Procedure Basically an identical procedure to that of Experiment 1 was followed. In Experiment 2, the participants were instructed: "it is allowed to rearrange and group the test sheets, but it is not a requirement to do so." In addition, when the participants chose to conduct preprocessing at the beginning of each trial, they were allowed to decide their own way of rearranging the test sheets.

Result

Three participants were excluded from the analysis based on the same criterion as in Experiment 1. As a result, the performance of twenty-four participants, of whom twelve were assigned to each condition, was analyzed. First, there was no significant difference in performing the calculation problems between the two conditions ($t(22) = .23, n.s.$).

Preprocessing and minimal transformation strategy In Experiment 2, we calculated the ratio of participants conducting preprocessing for each condition. Moreover, there was a rearranging strategy with which the participants could transform the student ID numbers with the minimum number of times in primary processing. This strategy could minimize the cost of primary processing. In particular, this strategy was to group the test sheets according to the categories of Major and Course numbers first. We calculated the ratio of participants using this minimal transformation strategy for each condition. Figure 4 shows the ratio of participants conducting preprocessing and the ratio of participants using the minimal transformation strategy. In the low task complexity condition, the participants gradually learned to conduct preprocessing from the first to third trial. On the other hand, in the high task complexity condition, the participants conducted preprocessing from the first trial. Moreover, the minimal transformation strategy was used more in the high task complexity condition than in the low task complexity condition.

Discussion

As a result of Experiment 2, when the participants were allowed to choose whether to conduct preprocessing or not, the participants conducted ineffective preprocessing in the low complexity condition. Moreover, the minimal transformation

Figure 4: Ratio of participants conducting preprocessing and ratio of participants using minimal transformation strategy in Experiment 2

strategy was used more for the high complexity task than for the low complexity task.

At this point, we have questions. Was it possible the participants were trying to reduce fatigue by grouping the test sheets as a routine work throughout the trials although they realized that conducting preprocessing was ineffective for the low complexity task? Moreover, was it also possible for them to try to reduce the number of errors by grouping the sheets although they noticed that conducting preprocessing increased the task completion time for the low complexity task? To answer these questions, in Experiment 3, we conducted a questionnaire directly asking the participants which makes the task faster and more accurate, preliminarily grouping the test sheets as preprocessing or not. Furthermore, in Experiment 2, at the beginning of each trial, the participants were told the task completion time and the number of errors in the previous trial as feedback. Throughout the trials, the task completion time gradually decreased because of the learning effect. Consequently, the participants might have misunderstood that preprocessing is effective because of the effect of this feedback. Therefore, in Experiment 3, we gave no feedback to the participants.

Experiment 3

Purpose

We replicated Experiment 2 and confirmed whether people could adaptively estimate the utility of preprocessing and take rational action in the low complexity task.

Method

Participants Seventeen university students participated in this experiment.

Material Identical materials were used as in Experiment 2.

Procedure Basically an identical procedure to that of Experiment 2 was followed. In Experiment 3, at the beginning of each trial, we gave the participants a questionnaire asking them to estimate the utility of preprocessing for the task completion time and the accuracy. The participants were instructed to choose one out of four choices: (1) preprocessing is effective, (2) no preprocessing is effective, (3) no difference, and (4) impossible to estimate. When the participants chose to conduct preprocessing at the beginning of each trial, they were allowed to decide their own way of rearranging the test sheets. In addition, the participants were instructed to

estimate the task completion time and the number of errors after each trial had been completed. They were neither informed of the actual task completion time nor the number of errors as feedback. Moreover, in Experiment 3, we set up the fourth trial in which the participants were not allowed to conduct preprocessing in order to compare the performance with the performance when preprocessing was conducted in the former three trials. Also, the participants were instructed to estimate the task completion time and the number of errors after the fourth trial had been completed.

Result

Two participants were excluded from the analysis based on the same criterion as in Experiment 1. As a result, the performance of fifteen participants was analyzed.

Preprocessing and minimal transformation strategy

Figure 5 shows the ratio of participants conducting preprocessing and the ratio of participants using the minimal transformation strategy. The participants gradually learned to conduct preprocessing from the first to third trial. Moreover, the ratio of participants using the minimal transformation strategy was low.

Figure 5: Ratio of participants conducting preprocessing and ratio of participants using minimal transformation strategy in Experiment 3

Estimation of preprocessing utility Figures 6 and 7 show the numbers of choices made in the questionnaire at the beginning of each trial for the task completion time and the accuracy. With each subsequent trial, the participants shifted towards estimating that conducting preprocessing is effective in producing a more rapid performance. They also either estimated that preprocessing was effective or produced no difference in performance accuracy.

Figure 6: Respondents estimation for task completion time

Actual/ Estimated performance In Experiment 3, almost all participants conducted preprocessing as in Experiment 2. Consequently, we compared the participants' performance when preprocessing was conducted in the first three trials with their performance in the fourth trial where they were not allowed to conduct preprocessing. In particular, the mean

Figure 7: Respondents estimation for accuracy

performance of nine participants, who had conducted preprocessing in all the first three trials, and four participants, who had conducted preprocessing in the second and third trials, was calculated. The result was regarded as the representative performance for when preprocessing was conducted. The performance of these thirteen participants in the fourth trial was regarded as the representative performance for when preprocessing was not conducted. Moreover, we compared the participants estimated performance when preprocessing was conducted in the first three trials with their estimated performance in the fourth trial.

Actual/ Estimated task completion time Figure 8 shows the actual task completion time and the estimated task completion time when preprocessing was conducted and when it was not conducted. As a result, the actual task completion time was significantly faster when preprocessing was not conducted than when conducted ($t(12) = 4.49, p < .001$). Moreover, we conducted a t-test on the participants estimated task completion time when preprocessing was conducted and when it was not conducted. As a result, there was a marginally significant difference showing that their estimated time was faster when preprocessing was conducted than when not conducted ($t(12) = 1.89, p < .10$).

Figure 8: Comparisons of actual task completion time (left) and estimated task completion time (right) when preprocessing was conducted and when it was not conducted

Actual/ Estimated number of errors We conducted t-tests on the actual number of errors and on the participants estimated number of errors when preprocessing was conducted and when it was not. As a result, there was neither significant difference in the actual number of errors ($t(12) = .66, n.s.$) nor in their estimated number of errors ($t(12) = 1.54, n.s.$).

Discussion

First, as a result of Experiment 3, when the participants were allowed to choose whether to conduct preprocessing or not, the participants conducted ineffective preprocessing as in Ex-

periment 2. This result eliminated the possibility that the feedback from their previous performance had encouraged the participants to mistakenly elect to perform preprocessing. Second, the ratio of participants using the minimal transformation strategy was also as low as in Experiment 2. Third, the results of the questionnaire indicated the participants overestimated the utility of preprocessing for the task completion time and the accuracy. This result eliminated the possibility that the participants conducted preprocessing as a strategy for reducing fatigue and reducing the number of errors, because they had reported that conducting preprocessing could reduce the task completion time in the questionnaire. Moreover, we compared the performances when preprocessing was conducted and when it was not conducted in the within-participant experiment. As a result, we confirmed the result was consistent with that of Experiment 1. Contrarily, the participants estimated the actual task completion time faster when preprocessing was conducted than when not conducted. This result is consistent with the result of participants' estimation for the task completion time in the questionnaire given at the beginning of each trial.

General Discussion

The purpose of this study was to investigate whether people can adaptively estimate the utility of preprocessing and take rational action. First, Martin and Schwartz (2009) investigated preprocessing to create representational tools before engaging in a task. However, they evaluated the performances of preprocessing and primary processing separately and did not address the issue of a trade-off between the costs of the two types of processing. They used a learning task to investigate how learning experiences in preprocessing influence the following behavior for learning. In contrast, in this study, we used a problem solving task. In order to investigate the utility of preprocessing, it is crucially important, especially in problem solving tasks, to consider the trade-off between increasing the cost of preprocessing and decreasing the cost of primary processing.

As a result of our experiments, in the low complexity task, preprocessing was aggressively conducted despite it not being effective. In our experimental task, preprocessing was performed with a desk space as an external resource. Brown, Collins, and Duguid (1989a, 1989b) suggested that people actively use external resources at the initial stage as an initial human impulse. In addition, Kirsh (2009) referred to the activity-centric model as an instinctive human behavior of using external resources without thinking. The human nature to instinctively use external resources described in the research of Brown et al. and Kirsh may explain the participants' behavior in our experiments.

Sirouzu, Miyake, and Masukawa (2002) experimentally confirmed such a human nature. They suggested that people actively use external resources as their "proto-plan". In their experiment, the existence of external resources prevented the participants from noticing the availability of usable internal processing. In contrast, in our experiments, the participants conducted preprocessing although they were explicitly offered the choice of using preprocessing or not. Moreover, Sirouzu et al. (2002) stated that the participants divided a sin-

gle over-all task into multiple simpler sub-tasks using an external resource so that they could visually confirm the completion and the result of each sub-task, and plan the next step. In our experiments, the participants could divide one transcribing task into two different tasks: rearranging the test sheets (preprocessing) and transcribing scores (primary processing). The participants could take advantage of the result of preprocessing, allowing them to conduct primary processing smoothly and easily. It is considered that the effect of such task decomposition causes the overestimation of the utility of preprocessing. Kirsh (1996) explained such human action of task decomposition as a complementary action, which enables the externalization of plans into sub-goals in order to easily achieve a final goal and that this is a central element of human activities.

The result of our experiments about the estimation of a trade-off between two types of processing is not consistent with the findings of Matthew and Anderson (2009). In their experiment, the participants had to choose between solving each problem using a calculator as an external resource or by using mental calculation. The participants were able to make the correct choice whether to use the external resource or not, dynamically and instantly, depending on the task complexity. Matthew and Anderson (2009) used calculation problems that each took around ten seconds to solve. In contrast, in our experiments, we used the transcribing task that took around ten minutes to complete. In order to conduct preprocessing, the participants had to create an additional sub-task as a preliminary task, once stepping away from the primary task, and thus conduct two different types of tasks sequentially. One reason why the participants failed to estimate the costs might be because the cost estimation in our task was much harder than such estimation in the previous study.

Another reason may depend on the participants' time perception. The task completion time in the low complexity task was estimated to be faster when preprocessing was conducted than when not conducted. This trend in estimation was opposite to that of the actual task completion time. In studies of time perception, it has been verified that the more cognitive processing people perform, the less attention they direct to time, so that they underestimate time duration. This phenomenon is explained by the attentional model (Hicks, Miller, & Kinsbourne, 1976; Zakay, 1993). Hicks et al. (1976) investigated the attentional model using a card sorting task. As a result, it was revealed that the more stacks the cards were sorted into, the faster the task completion time was estimated to be, because more cognitive processing was performed as there were more stacks to sort. In our experiments, when preprocessing was conducted, the participants had to sort the test sheets. Therefore, there is a possibility that the participants estimated the task completion time faster when preprocessing was conducted than when not conducted because they performed more cognitive processing when preprocessing was conducted than when it was not conducted in the low complexity task.

Last, the minimal transformation strategy was used more in the high complexity task than in the low complexity task. Cary and Carlson (1999) found that in a situation where high internal costs were demanded, the participants tended to use a

strategy to minimize their internal costs. On the other hand, in a situation where low internal costs were demanded, the participants chose a strategy of following structures in the problem, and did not focus on reduction of internal processing. In our experiments, in the high complexity task, the participants rearranged the test sheets according to the categories of Major and Course numbers first. Using this strategy, the participants successfully transformed the student ID numbers for referring to the numbers on the tally sheet using the minimum number of times and minimized internal cost. On the other hand, in the low complexity task, the participants tended to rearrange the test sheets according to the category of Grade number first, affected by the structure of the student ID number in which the first two digits represented the Grade. This meant that they used a strategy to follow the structure of the problem. Our results were consistent with the findings of Cary and Carlson (1999).

Increasing Information Access Cost to Protect Against Interruption Effects during Problem Solving

Phillip L. Morgan (MorganP4@Cardiff.ac.uk)

Park Place, Cardiff, CF10 3AT, UK

Abstract

The aim of this experiment was to examine whether increasing the cost of accessing the goal-state during problem solving would induce a more internalized strategy that would protect against the negative effect of interruption. The soft constraints hypothesis (Gray, Sims, Fu & Schoelles, 2006) predicts that a more memory-based strategy will be developed with increasing information access cost (IAC). Three levels of access cost were used in the Tower of Hanoi (ToH) with three types of interrupting task (simple ToH, mental arithmetic and a blank screen control). Increasing access cost to a mouse movement and a few seconds delay to view the goal-state encouraged a strategy that not only improved resumption from memory but also reduced the number of moves required to solve the primary task. These effects came at no extra time cost and occurred irrespective of the type of interrupting task. The theoretical implications of these findings are discussed together with issues of using access cost as a method for alleviating the negative effects of interruption.

Keywords: Interruption; Problem Solving; Goal-State Access Cost

Introduction

Interruptions are intrinsic to our everyday and working lives (e.g., telephone calls, emails), and although often useful (e.g., responding to another important task), they are also often associated with performance decrements when returning to the interrupted task. Difficulties include: problems remembering what one was doing or intended to do prior to being interrupted (e.g., Edwards & Gronlund, 1998; Morgan, Patrick, Waldron, King & Patrick, 2009); and delays in resuming the interrupted task (e.g., Hodgetts & Jones, 2006; Monk, Trafton & Boehm-Davis, 2008). Whilst these issues are sometimes tolerable (e.g., when taking a telephone call whilst buying groceries), interruptions can be a nuisance, expensive or even life threatening in many other contexts, including, offices, aircraft flight-decks, and hospitals (see Trafton & Monk, 2008). Thus, investigating methods for minimizing interruption effects has become an important topic. Methods include: using an 'interruption lag' to briefly delay the onset of an interruption and allow an opportunity to prepare for resumption of a problem solving task (Hodgetts & Jones, 2006); and a reminder cue to support memory of a delayed intention in a prospective memory task (McDaniel, Einstein, Graham & Rall, 2004). A recent study by Morgan et al. (2009) developed another method that involved increasing goal-state access cost (the time, physical and mental effort

costs associated with accessing information). This encouraged a more memory-based strategy that was effective in protecting against forgetting following interruption. The aim of this paper is to investigate the efficacy of this method in a problem solving task rather than the copying task used by Morgan et al. (2009).

The predicted advantage of increased access cost on promoting a more internal cognitively-based strategy derives from the soft constraints hypothesis (Gray et al., 2006). This theory posits that whilst certain elements of a task environment are fixed (i.e., hard constraints) and dictate what behavior is possible, task strategies are flexible and therefore adapt in a rational manner. People strive to minimize the time spent performing tasks at a local rather than global level (Gray et al., 2006), so strategy adjustments are made at the 1/3 to 3-second level of task performance favoring those that are more effective at this millisecond level (Gray & Boehm-Davis, 2000). On one hand, if information is readily available in the task environment, a strategy that relies less on internal memory (which is fallible and subject to error) will prevail (e.g., Anderson & Douglass, 2001). In contrast, if there is an unacceptable cost associated with accessing information in the task environment, cognition will adapt and adjust to a more memory-based strategy to minimize this cost.

Such strategy change has been demonstrated in a variety of studies (Gray & Fu, 2004; Gray et al., 2006; Morgan et al., 2009; Waldron et al., 2007) using the Blocks World Task (BWT) developed by Ballard, Heyhoe & Pelz (1995), that involves copying a target pattern of colored blocks to a workspace window. Increasing the cost of accessing the target pattern with a mouse movement and a brief time delay induced a shift to a more memory-based strategy (e.g., Gray & Fu, 2000; Gray et al., 2006) and improved recall of information (Waldron, Patrick, Morgan & King, 2007). Morgan et al. (2009) found that such an induced memory-based strategy protected against forgetting following both visuo-spatial copying and mental arithmetic interrupting tasks. This was particularly effective when the interruption occurred on approximately half of the trials.

In contrast, little is known about the effect of goal-state access cost on problem solving. Some studies have manipulated the availability and effort required to use the task environment as an external memory resource. For example, the use of internal memory increased when the ability to make paper notes was made more difficult whilst

solving demanding mental arithmetic problems (Cary & Carlson, 2001). Similarly, when the current-state had to be requested during performance of 'balls and boxes' problems, participants tended to execute more moves per request (Pfeiffer, 2004). Also, O'Hara and Payne (1998) demonstrated how increasing the cost of implementing an action during problem solving leads to improved planning. The results from these studies suggest increased use of internal memory to avoid additional costs of interacting with the environment. One recent problem solving study found that High goal-state access cost led to more 'planning before action' as opposed to 'planning during action' (Waldron, Patrick & Duggan, unpublished) although it had no effect on number of moves to solution. However the effect of High goal-state access cost on mitigating the negative effect of interruption has not been examined during problem solving.

Experiment

To fill this research gap, the aim of the experiment was to examine whether increasing goal-state access cost induces a more memory-based strategy in a ToH task and whether such a strategy can improve performance following interruption. It was predicted that High access cost would accomplish this by encouraging a more internalized rather than display-based strategy with more planning before action (Davies, 2003; Waldron, Patrick & Duggan, unpublished).

There were two subsidiary aims. First, Morgan et al. (2009, Experiment 3) demonstrated that High access cost induced a memory-based strategy that was powerful enough to abolish the effects of forgetting following different types of interrupting tasks compared to a no interruption condition, even when one task (another BWT) arguably had similar processing requirements to the primary task. There is mixed evidence regarding the effects of interruption similarity on post-interruption performance. Some studies report greater disruption following a similar interrupting task (e.g., Edwards & Gronlund, 1998; Gillie & Broadbent, 1989) whereas others argue against this so called 'interruption similarity' effect (e.g., Latorella, 1996). Given that it is difficult to unequivocally separate tasks on dimensions of similarity, we examined the effects of increasing goal-state access cost on performance following two different types of interrupting tasks: one involving another ToH (arguably similar to the primary task) and the other involving mental arithmetic.

Second, we wanted to assess whether the typical cost of High access cost on reducing speed of completing the BWT (Morgan et al., 2009) would be less pronounced or even eliminated in the ToH. Performing the BWT under a High access cost places a high demand on memory and participants spend time encoding and rehearsing block information, suffering the time cost of uncovering the goal-state at each visit, and making more move errors that have to be corrected. In contrast, the ToH is not as memory demanding given that the goal-state often consists of a small array of objects (e.g., 4-discs) that are bounded by a simple

constraint (e.g., a larger disc cannot be placed on top of a smaller disc). Also, the hierarchical nature of the ToH in terms of goal and subgoals means that many moves are interdependent, and therefore the goal-state does not need to be re-visited as often as in the BWT. Furthermore, the proposed benefit of High goal-state access cost in the ToH is due to its encouragement to develop a more effective problem solving strategy that should lead to fewer moves and possibly reduced time to solve the problem.

Method

Participants

Fifty-four Cardiff University Psychology students participated for course credit and were randomly assigned to one of three goal-state access cost conditions. There were six men and forty-eight women with an age range of 18 to 37 years ($M = 20.56$, $SD = 2.95$).

Materials, Design & Procedure

There were 18 primary task four-disc ToH problems, each with a different start and goal-state disc configuration (see Figure 1 for an example start-state). Disc movement was controlled by clicking on a disc on one peg (e.g., A), holding down the mouse button, and dragging the disc to a destination peg before releasing the mouse button (e.g., at B or C). If a larger disc was dragged over a smaller disc, the larger disc would be returned to its source peg and a message reading 'illegal move' would appear on the screen. All primary task ToH problems required a minimum of 15 moves for error-free completion and all major subgoals occurred at the same point within the solution sequence (if solved error-free: subgoal 1, moves 1 – 8; subgoal 2, moves 9 – 12; and subgoal 3, moves 13 – 15). The main subgoals within the ToH task involve getting the largest-out-of-place discs to their goal destination peg(s) in the order 'largest first' through to 'smallest last'.

Figure 1. An example of the start-state of a four disc ToH task

Note. Disc numbers are used to represent colors (1 = green, 2 = blue, 3 = yellow, and 4 = red)

Goal-state access cost was manipulated between-subjects on three levels: Low (goal-state always visible), Medium (goal-state covered with a grey mask with a mouse movement to uncover) and High (as Medium but with an additional 2.5-second lockout cost to uncover). Each of nine ToH problems was interrupted once with one of three different interruption types (manipulated within-subjects). The ToH interruption consisted of 3-disc ToH problems that could be solved in a minimum of seven moves using the

same disc movement procedure as in the primary task. The mental arithmetic (MA) interruption involved solving a series of self-paced double-digit addition problems (e.g., $34 + 45 = ??$). Answers were entered using a keyboard. In the control condition (referred to as blank screen interruption hereafter), there was no task during the interruption. Each interruption occurred immediately following the first move of the first, second or third major subgoals, giving three interruption points. Both interruption task type and interruption position were counterbalanced.

Two types of measure were used to examine the effects of goal-state access cost and interrupting task on the ability to resume the primary task from memory. First, we calculated the number of interrupted trials resumed without first revisiting the goal-state and, for those trials, the number of moves executed subsequently. Second, we calculated both the number of moves and the time required to complete the ToH problem following interruption. Given that interruptions were equally distributed across the three points of interruption, fair comparisons could be made between both the different levels of access cost and the different interrupting tasks. Finally, it was important to confirm that any benefit of increased goal-state access cost on performance following interruption was due to increased use of a more internalized problem solving strategy with reduced reliance on the external problem space. For this we used an important measure of planning in problem solving (e.g., Davies, 2003, 2005; Ward & Allport 1997), which was the amount of time spent at the beginning of a ToH problem before the first move was executed. This was predicted to increase with increasing access cost.

Participants were tested individually. They were instructed on task procedures and informed that they could be interrupted at any time. The main experiment started after completion of one non-interrupted 15-move practice trial and one attempt at performing each interrupting task. The experiment lasted approximately 30 minutes.

Results and Discussion

First, the effects of goal-state access cost and interruption type on the ability to resume the primary ToH task from memory were considered, followed by an examination of their effects on various post-interruption performance measures. Finally, we assessed whether any beneficial effect of High access cost on these performance measures could be accounted for by participants using a more memory-based problem solving strategy.

Effects of Goal-State Access Cost and Interruption Task on Performance after Interruption

We predicted that the main benefit of a higher access cost would be a tendency to adopt a more internalized problem solving strategy with participants choosing to rely less on the external problem space, even following interruption. As such, it was anticipated that participants in the High access cost condition would resume the primary task without revisiting the goal-state (and suffering the associated time

cost) more often than the Medium access cost condition. (Note that the Low access cost condition could not be considered for any resumption measure because the goal-state was permanently uncovered.) The results supported this prediction (Table 1) with a 2 (goal-state access cost: Medium and High) \times 3 (interruption type: blank screen, ToH, MA) ANOVA revealing that more trials were resumed from memory by participants in the High compared to the Medium access cost condition, $F(1, 34) = 67.43$, $MSE = 3.28$, $p < .001$. There was also a main effect of interruption type, $F(2, 68) = 9.47$, $MSE = 6.57$, $p < .001$, due to less use of the goal-state to aid resumption following a blank screen interruption compared to a ToH interruption. Furthermore, and as predicted, Bonferroni post-hoc tests revealed that participants in the High access cost condition resumed more often without first viewing the goal-state than those in the Medium access cost condition following all interruption types ($ps < .001$).

Table 1. Effect of goal-state access cost and interruption task on resumption performance

	Goal-State Access Cost		Interruption Type		
			Blank	ToH	MA
Number of trials resumed without revisiting the goal-state (max = 3)	Med	<i>M</i> <i>SD</i>	1.17 .86	.11 .32	.61 .78
	High	<i>M</i> <i>SD</i>	2.56 1.17	1.46 .94	2.28 .83
Number of participants resuming at least one trial without viewing goal-state	Med		13/18	2/18	8/18
	High		17/18	16/18	17/18
Number of moves executed without revisiting the goal-state	Med	<i>M</i> <i>SD</i>	4.19 1.56	- -	2.57 1.97
	High	<i>M</i> <i>SD</i>	6.78 3.30	- -	6.55 3.87

Therefore it is evident that participants in different access cost conditions adopted different resumption strategies involving the need to view (or not) the goal-state to resume. For example, most participants in the Medium access cost condition were unable to resume at least one ToH interruption trial without first revisiting the goal-state window (Table 1). In contrast nearly all participants in the High access cost condition resumed at least one ToH trial from memory. This demonstrates the protective effect of High goal-state access cost on memory for the goal-state and/or a future move(s) following a ToH interruption *and* the ineffectiveness of Medium goal-state access cost following the same type of interruption. This beneficial effect of High access cost was reduced with the two other

interrupting tasks although it was still apparent for an MA interruption (Table 1).

Another indicator of participants relying less on the external display and more on an internal representation to continue an interrupted task is the number of moves they make before re-inspecting the goal-state (Table 1). A 2 (goal-state access cost) x 2 (interrupt type: blank screen and MA) ANOVA revealed a main effect of goal-state access cost, $F(1, 22) = 7.09$, $MSE = 7.54$, $p < .05$, with participants in the High access cost condition making more moves after interruption before goal-state re-inspection than those in the Medium access cost condition. There was no effect of interruption type and goal-state access cost and interruption type did not interact ($ps > .05$).

These results are testimony to the marked effect of High goal-state access cost on the ability to maintain an internal representation of the goal-state and/or a future move or series of moves throughout the course of an interruption, even when interruption involved a different task.

Whilst the above measures concerned interruption trials that were resumed without first viewing the goal-state window (and are thus restricted to the Medium and High goal-state access cost conditions), it is also important to establish the effects of all three levels of access cost on post-interruption performance (Table 2). Specifically, we were interested whether High access cost with its more internal memory-based strategy (1) led to fewer moves and (2) affected the time to complete interrupted ToH problems.

Participants in higher access cost conditions completed interrupted ToH problems in fewer moves (Table 2). A 3 (goal-state access cost: Low, Medium and High) x 3 (interruption type: blank screen; ToH, MA) ANOVA confirmed a significant main effect of goal-state access cost $F(2, 51) = 4.35$, $MSE = 2.53$, $p < .05$, $f = .41$ with participants in the High access cost condition completing problems in fewer moves than participants in the Low access cost condition ($p < .05$). However, participants in the High access cost condition did not perform significantly better than those in the Medium access cost condition ($p > .05$), and participants in the Medium access cost condition did not perform better than those in the Low access cost condition ($p > .05$). There was a non-significant main effect of interruption type ($p > .05$) and a non-significant interaction ($p > .05$).

Time to complete problems following interruption was similar across goal-state access cost conditions (Table 2), and there was a non-significant main effect ($p > .05$). There was, however, a significant effect of interruption type, $F(2, 102) = 7.77$, $MSE = 52.77$, $p < .01$, $f = .39$. Not surprisingly, participants were significantly faster to complete following a blank screen than a ToH interrupting task ($p < .01$) and were marginally faster following mental arithmetic than a ToH interrupting task ($p = .06$). Goal-state access cost and interruption type did not interact ($p > .05$).

Table 2. Effect of goal-state access cost and interruption type on performance following resumption

	Goal-State Access Cost		Interruption Type		
			Blank	ToH	MA
Number of moves to complete the primary task following interruption	Low	<i>M</i>	10.39	11.70	11.26
		<i>SD</i>	2.98	3.49	3.05
	Med	<i>M</i>	9.52	10.93	10.19
		<i>SD</i>	1.57	3.20	2.33
	High	<i>M</i>	9.28	9.89	9.52
		<i>SD</i>	2.25	1.93	2.29
Time to complete the primary task following interruption (s)	Low	<i>M</i>	20.65	25.79	22.16
		<i>SD</i>	9.28	8.84	8.18
	Med	<i>M</i>	19.09	23.19	21.36
		<i>SD</i>	7.79	9.23	9.52
	High	<i>M</i>	17.28	24.42	19.74
		<i>SD</i>	7.38	12.76	5.97

Thus, the more memory-based strategy associated with High goal-state access cost was sufficient to effect an improvement in problem solving efficiency following interruption compared to a Low access cost. In contrast, the cost of a mouse movement in the Medium access cost condition was not sufficient to improve performance compared to the Low access cost condition. Furthermore, the improvement under a High access cost on resumption *and* performance thereafter comes at no extra time cost compared to lower access cost conditions. This is especially encouraging given the extra time cost associated with such a condition in a more memory-demanding visuo-spatial copying task (e.g., Morgan et al., 2009).

Effects of Goal-State Access Cost on Planning

It is important to confirm that the improvements in performance following interruption during High goal-state access cost can be accounted for by a change of task strategy. One important measure of planning is the amount of time taken to execute the first move at the start of a ToH, which we predicted would be greatest in the High access cost condition. A significant main effect of goal-state access cost, $F(2, 51) = 4.82$, $MSE = 4.59$, $p < .05$, $f = .44$, revealed that participants in the High access cost condition indeed took more time to execute the first move ($M = 6.31$, $SD = 2.7$) than those in Medium and Low access cost conditions, $ps < .05$ ($M = 4.53$, $SD = 1.45$ and $M = 4.27$, $SD = 2.08$ respectively). Time spent planning in the Medium and Low access cost conditions did not differ statistically ($p > .05$).

General Discussion

The current experiment demonstrates the efficacy of imposing higher costs on accessing the goal-state in problem solving to promote a more efficient memory-based strategy that protects against the negative effects of different types of interruption. High goal-state access cost was superior to lower access cost conditions on nearly all measures following any type of interrupting task. The

benefit of a High access cost to induce a more memory-based strategy to protect against forgetting following interruption has been demonstrated with a simple BWT copying task (Morgan et al., 2009), but this paper highlights for the first time how these effects extend to a problem solving task. This is especially interesting given the different nature of the BWT and a ToH problem solving task. The BWT has a relatively flat and repetitive goal structure (e.g., locate a block in one position and move it to another position), whereas the ToH has a hierarchical goal structure and can be performed using a variety of different strategies that usually become more sophisticated with practice (e.g., Anzai & Simon, 1979).

The findings provide further support for the soft constraints hypothesis (e.g., Gray et al., 2006), particularly its claim that strategy selection is dependent upon the time costs imposed by interacting with the external task environment. We have shown that when the ToH goal-state is masked and cannot be viewed without suffering a mouse movement and a brief time cost, problem solving strategy becomes more internalised and less display-based. Whilst this strategy selection is based upon a very subtle change to the task environment, it is powerful enough to protect against forgetting following interruption and improves problem solving efficiency.

The results can also be interpreted within the theoretical framework of the memory for goals model (Altmann & Trafton, 2002). This is a model of goal suspension and resumption that posits: for a goal to govern behaviour it has to be repeatedly *strengthened* so that its activation level within internal memory exceeds that of an interference threshold set by all other goals in memory. A goal must be *primed*, that is, associatively linked to a reminder cue (either externally or internally based) that must be available both immediately prior to and following interruption, otherwise the goal will decay and become forgotten. Upon encountering this cue again, the decaying representation of the suspended goal will be reactivated such that it again governs behavior. Our data suggest that suspended goals may have undergone a greater amount of strengthening in the High access cost condition and we may speculate that the current-state disc configuration might have provided adequate priming cues. However, the memory for goals model suggests that an interruption lag is a critical period to strengthen and prime a to-be-suspended goal so that it can be retrieved from memory after interruption. The current findings, together with those reported in Morgan et al. (2009), suggest that an interruption lag may not be critical if the task performer is equipped with a more memory-based strategy *throughout* performance of the primary task. High goal-state access cost is a subtle yet powerful method to induce such a strategy and thus may either be an alternative method to an interruption lag or a complementary method to support its proposed benefit.

The findings are also important from a practical perspective, especially regarding principles relating to cognitive engineering and display design. These principles

stress the importance of making available as much information as possible to perform a task (see Wickens & Hollands, 2000), at least within the realm of human capabilities (e.g., Rasmussen & Vicente, 1989). For example, ecological interface design recommends that complex relationships between variables should be made immediately available and information within the interface should be easily extractable (Vicente & Rasmussen, 1992). Similarly, information fusion involves synthesising information from a wide range of sources and displaying it to the user in an immediately available format (e.g., Dasarathy, 2001). Whilst adopting these principles has benefit in many situations, they also risk a passive and more display-based approach to monitoring and processing information that may ultimately result in the user moving 'out-of-the-loop' (e.g., Bainbridge, 1987). A recent study by Waldron et al. (2008) using a flight simulation found that making positional information temporarily rather than permanently available improved memory for aircraft location. Given the additional findings of the current experiment and related studies (e.g., Morgan et al., 2009; Waldron et al., 2007) we perhaps radically suggest that paradoxically making information harder to access may sometimes improve performance, such as when resuming some tasks following interruption. This will depend on what is the criterion measure of performance and the advantage will be greatest when recall is important to post-interruption performance. There are of course exceptions to this suggestion. For example, it is unlikely that the benefits of increased goal-state access cost would outweigh the costs of having to continually access information in fast-paced, safety-critical task environments such as an aircraft flight-deck.

Future experiments will be necessary to fully test the boundary conditions associated with the benefit of increased goal-state access cost in problem solving and other task environments, both with and without interruptions. Furthermore, it is practically important to compare the advantages and disadvantages of using access costs with other methods for mitigating interruption effects.

Abstract

This paper investigates the effectiveness of creative versus uncreative leadership using EVOC, an agent-based model of cultural evolution. Each iteration, each agent in the artificial society invents a new action, or imitates a neighbor's action. Only the *leader's* actions can be imitated by all other agents, referred to as *followers*. Two measures of creativity were used: (1) *invention-to-imitation ratio*, i_{Leader} , which measures how often an agent invents, and (2) *rate of conceptual change*, c_{Leader} , which measures how creative an invention is. High i_{Leader} increased mean fitness of ideas, but only when creativity of followers was low. High i_{Leader} was associated with greater diversity of ideas in the early stage of idea generation only. High c_{Leader} increased mean fitness of ideas in the early stage of idea generation; in the later stage it decreased idea fitness. Reasons for these findings and tentative implications for creative leadership in human society are discussed.

Keywords: agent based modeling; broadcasting; creativity; culture; cultural evolution; imitation; leadership.

Introduction

It is widely assumed that effective leaders are creative (Basadur, 2004; Bellows, 1959; Puccio, Murdock, & Mance, 2006; Simon, 1988; Sternberg, Kaufman & Pretz, 2003). Creativity, however, has drawbacks (Cropley, Cropley, Kaufman, & Runco, 2010). For example, a creative solution to one problem may generate other problems, and similarly, a creative solution to one element of a situation may have unexpected negative consequences with respect to other elements. Moreover, time spent creatively finding a solution for oneself is time not spent imitating and passing on solutions already found by others.

Previous investigations of the pros and cons of creativity using an agent-based simulation approach addressed the question: in an ideal society, what proportion of individuals should be 'creative types' (Leijnen & Gabora, 2009; Gabora, Leijnen & Ghyczy, in press)? The rationale was that in a group of interacting individuals only a fraction of them need be creative for the benefits of creativity to be felt throughout the group. The rest can reap the benefits of the creator's ideas by simply copying, using, or admiring them. After all, few of us know how to build a computer, or write a symphony or novel, but they are nonetheless ours to use and enjoy. Numerical simulations showed that if the proportion of creators is low, the mean fitness of ideas in the

artificial society is highest when creators dedicate themselves fully to invention. However, as the proportion of creators increases, for optimal results, creators should spend more time imitating. Creative agents amounted to 'puncture points' in the fabric of society that interfered with the dissemination of proven effective ideas.

In the current investigation we focused exclusively on the extent to which creativity is desirable in a leader, where leadership is equated with having substantial influence over others. Previous results indicated that the presence of a leader accelerates convergence on optimal ideas, but does so at the cost of consistently reducing the diversity of ideas (Gabora, 2008b,c). In these previous simulations, the leader was no more nor less creative than the rest of the agents, referred to here as *followers*. The goal of the work reported here was to investigate how creative versus uncreative leadership affects the group as a whole.

The Modeling Platform

Our investigation was carried out using an agent-based simulation referred to as 'EVolution of Culture', abbreviated EVOC (Gabora, 2008b, 2008c). EVOC is an elaboration of Meme and Variations, or MAV (Gabora, 1994, 1995), the earliest computer program to model culture as an evolutionary process in its own right (as opposed to modeling the interplay of cultural and biological evolution). The approach was inspired by Holland's (1975) genetic algorithm, or GA. The GA is a search technique that finds solutions to complex problems by generating a 'population' of candidate solutions through processes akin to mutation and recombination, selecting the best, and repeating until a satisfactory solution is found. The goal here was to distill the underlying logic of not biological evolution but cultural evolution, i.e. the process by which ideas adapt and build on one another in the minds of interacting individuals. EVOC (as did MAV) uses neural network based agents that could (1) invent new ideas by modifying previously learned ones, (2) evaluate ideas, (3) implement ideas as actions, and (4) imitate ideas implemented by neighbors. Agents do not evolve in a biological sense—they neither die nor have offspring—but do in a cultural sense, by generating and sharing ideas for actions. EVOC (like MAV) successfully models how 'descent with modification' occurs in a cultural context. The approach can thus be contrasted with computer

models of how individual learning affects biological evolution (Best, 1999, 2006; Higgs, 2000; Hinton & Nowlan, 1987; Hutchins & Hazelhurst, 1991).

EVOC consists of an artificial society of neural network based agents in a two-dimensional grid-cell world. It is written in Joone, an object oriented programming environment, using an open source neural network library written in Java. This section summarizes the key components of the agents and the world they inhabit.

The Agent

Agents consist of (1) a neural network, which encodes ideas for actions and detects trends in what constitutes a fit action, and (2) a body, which implements actions.

The Neural Network. The core of an agent is an autoassociative neural network, as shown in Figure 1. It is composed of six input nodes that represent concepts of body parts (LEFT ARM, RIGHT ARM, LEFT LEG, RIGHT LEG, HEAD, and HIPS), six matching output nodes, and six hidden nodes that represent more abstract concepts (LEFT, RIGHT, FORELIMB, HINDLIMB, SYMMETRY and MOVEMENT). Input nodes and output nodes are connected to hidden nodes of which they are instances (e.g. RIGHT FORELIMB is connected to RIGHT.) Activation of any input node activates the MOVEMENT hidden node. Same-direction activation of symmetrical input nodes (e.g. positive activation—which represents upward motion—of both forelimbs) activates the SYMMETRY node.

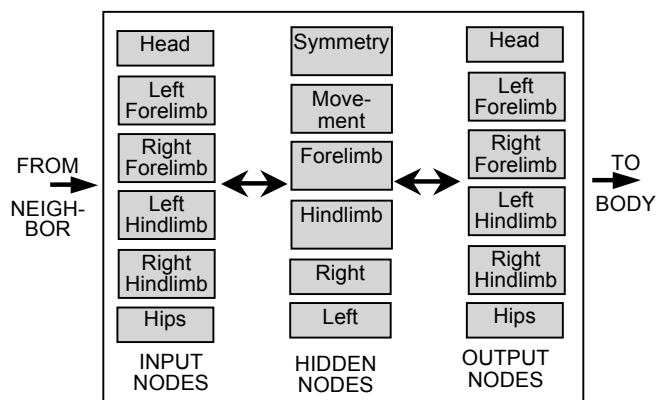

Figure 1. The neural network. See text for details.

The neural network learns ideas for actions. An idea is a pattern consisting of six elements that dictate the placement of the six body parts. Learning and training of the neural network is as per Gabora (1995). During imitation, the input is the action implemented by a neighbor. During invention, the pattern of activation on the output nodes is fed back to the input nodes, and change is biased according to the activations of the SYMMETRY and MOVEMENT nodes. In EVOC, the neural network can also be turned off to compare results with a data structure that cannot detect trends, and thus invents ideas merely at random.

The Body. If the fitness of an action is evaluated to be higher than that of any action learned thus far, it is copied from the input/output nodes of the neural network that represent *concepts of* body parts to a six digit array that contains representations of *actual* body parts, referred to as the *body*. Since it is useful to know how many agents are doing essentially the same thing, when node activations are translated into limb movement they are thresholded such that there are only three possibilities for each limb: stationary, up, or down. Six limbs with three possible positions each gives a total of 729 possible actions. Only the action that is currently implemented by an agent's body can be observed and imitated by other agents.

The Fitness Function

Agents evaluate the effectiveness of their actions according to how well they satisfy needs using a pre-defined equation referred to as a *fitness function*. The fitness of an action with respect to the need to attract mates is calculated as in (Gabora, 1995). The fitness function rewards actions that make use of trends detected by the symmetry and movement hidden nodes and used by knowledge-based operators to bias the generation of new ideas. It generates actions that are relatively realistic mating displays, and exhibits a cultural analog of *epistasis*. In biological epistasis, the fitness conferred by the allele at one gene depends on which allele is present at another gene. In this cognitive context, epistasis is present when the fitness contributed by movement of one limb depends on what other limbs are doing.

The World

MAV allowed only worlds that were square and toroidal, or 'wrap-around' (such that agents at the left border that attempt to move further left appear on the right border). Moreover, the world was always maximally densely populated, with one agent per cell. In EVOC the world can assume any shape, and be as sparsely or densely populated as required, with agents placed in any configuration. EVOC also allows for the creation of complete or semi-permeable permanent or eroding borders that decrease the probability of imitation along a frontier (although this was not used in the experiments reported here).

Incorporation of Cultural Phenomena

Agents incorporate the following phenomena characteristic of cultural evolution as parameters that can be turned off or on (in some cases to varying degrees):

- **Imitation.** Ideas for how to perform actions spread when agents copy neighbors' actions. This enables them to share effective, or 'fit', actions.
- **Invention.** This code enables agents to generate new actions by modifying their initial action or a previously invented or imitated action. (See Gabora 1995 for further details.)

- **Knowledge-based Operators.** Since a new action (or, in invention, new idea for an action) is not learned unless it is fitter than the currently implemented action, new actions provide valuable information about what constitutes an effective idea. This information is used by knowledge-based operators to probabilistically bias invention such that new ideas are generated strategically as opposed to randomly. For example, if successful actions tend to be symmetrical (e.g. left arm moves to the right and right arm moves to the left), the probability increases that new actions are symmetrical. Also, if movement is generally beneficial, the probability increases that new actions involve movement of more body parts. (See Gabora 1995 for further details.)
- **Mental simulation.** Before committing to implementing an idea as an action, agents can use the fitness function to assess how fit the action would be if it *were* implemented.
- **Broadcasting.** Broadcasting allows the action of a *leader*, or broadcaster, to be visible to not just immediate neighbors, but all agents, thereby simulating the effects of media such as public performances, television, radio, or the internet, on patterns of cultural change. Each agent adds the leader as a possible source of actions it can imitate. The leader itself is thus the only agent that can only acquire actions from its immediate neighbors. The leader can be specified by the user or chosen at random. Broadcasting can be intermittent, or continued throughout the duration of a run. It can also be turned off altogether.

A Typical Run

Each iteration, every agent has the opportunity to (1) acquire an idea for a new action, either by *imitation*, copying a neighbor, or by *invention*, creating one anew, (2) update the knowledge-based operators, and (3) implement a new action. To invent a new idea, for each node of the idea currently represented on the input/output layer of the neural network, the agent makes a probabilistic decision as to whether change will take place, and if it does, the direction of change is stochastically biased by the knowledge-based operators. If the new idea has a higher fitness than the currently implemented idea, the agent learns and implements the action specified by that idea. To acquire an idea through imitation, an agent randomly chooses one of its neighbors, and evaluates the fitness of the action the neighbor is implementing. If its own action is fitter than that of the neighbor, it chooses another neighbor, until it has either observed all of its immediate neighbors, or found one with a fitter action. If no fitter action is found, the agent does nothing. Otherwise, the neighbor's action is copied to the input layer, learned, and implemented.

Fitness of actions starts out low because initially all agents are immobile. Soon some agent invents an action that has a higher fitness than doing nothing, and this action gets imitated, so fitness increases. Fitness increases further as

other ideas get invented, assessed, implemented as actions, and spread through imitation. The diversity of actions initially increases due to the proliferation of new ideas, and then decreases as agents hone in on the fittest actions.

The Graphic User Interface

The graphic user interface (GUI) makes use of the open-source charting project, JFreeChart, enabling variables to be user defined at run time, and results to become visible as the computer program runs. The topmost output panel is shown in Figure 2.

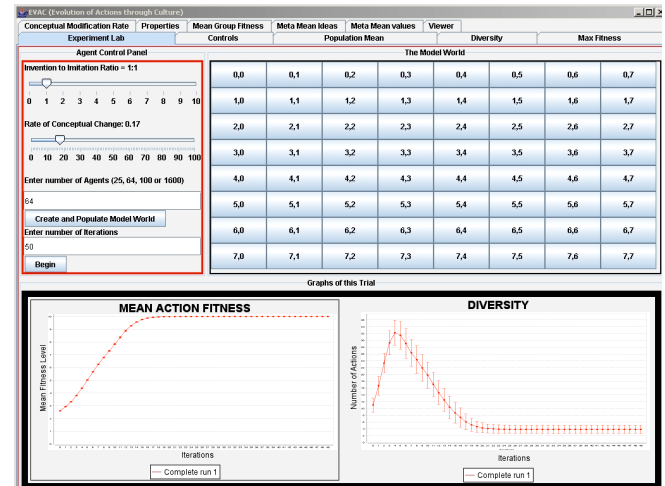

Figure 2. Output panel of GUI. See text for details.

At the upper left one specifies the *Invention to Imitation Ratio*. This is the probability that a given agent, on a given iteration, invents a new idea for an action, versus the probability that it imitates a neighbor's action. Below it is *Rate of Conceptual Change*, where one specifies the degree to which a newly invented idea differs from the one it was based on. Below that is *Number of Agents*, which allows the user to specify the size of the artificial society. Below that is where one specifies *Number of Iterations*, i.e. the duration of a run. Agents can be accessed individually by clicking the appropriate cell in the grid on the upper right. This enables one to see such details as the action currently implemented by that agent, or the fitness of that action. The graphs at the bottom plot the mean idea fitness and diversity of ideas. Tabs shown at the top give access to other output panels.

Experiments

We now present the creative leadership experiments performed with EVOC. Unless stated otherwise, graphs plot the average of 100 runs, the world consists of 100 cells, one agent per cell, a 1:1 invention-to-imitation ratio, and a 1/6 probability of change to any body part during invention (The rationale behind this is that since, with six body parts, on average each newly invented action differs from the one it was based on with respect to one body part.)

The current experiments made use of EVOC's broadcasting function. As described above, broadcasting enables the action implemented by a leader to be visible throughout the artificial society. While experiments reported elsewhere investigated the impact of varying the number of leaders on the fitness and diversity of ideas (Gabora, 2008c), in the experiments reported here, simulated societies consist of one leader and ninety-nine followers. The leader is chosen randomly and broadcasts throughout the entire run.

Experiment 1a: Effect of Varying Inventiveness (i) of Leaders and Followers on Fitness of Ideas

The first experiment investigated the effect of varying the ratio of iterations spent inventing versus imitating, or invention-to-imitation ratio, abbreviated i , of both the leader and the followers, on the fitness of ideas produced by the artificial society. The inventiveness of the leader, abbreviated i_{Leader} was systematically varied from 0.0 to 1.0. When i_{Leader} was 1.0, the leader invented a new action every iteration. When i_{Leader} was 0.0, the leader never invented new actions; it only imitated its neighbors' actions. (It was still the leader because its actions were visible to, and could be imitated by, all other agents in the society, not just its immediate neighbors, as was the case for followers).

In the first set of runs, followers only imitated; they never invented, i.e., $i_{Followers} = 0.0$. As shown in Figure 3, with uncreative followers, the degree of creativity of the leader matters a lot; the mean fitness of ideas in the artificial society is positively correlated with creativity of the leader.

Figure 3. Mean fitness of actions with leaders of varying invention-to-imitation ratios, and followers that only imitate, i.e. that never invent (e.g. $i = 0.0$).

In the second set of runs, shown in Figure 4, followers were able to invent. More specifically, $i_{Followers} = 0.05$; thus each iteration, each of the 99 followers had a 5% chance of inventing. Comparing figures 3 and 4 it is clear that while the degree of creativity of the leader had a large impact when followers are uncreative, it had almost no impact when followers were themselves creative. With creative followers, the mean fitness of ideas generated by the society increased over the duration of a run at more or less the same pace no matter how creative the leader was.

Figure 4. Mean fitness of actions with leaders of varying invention-to-imitation ratios, and followers that invent as well as imitate ($i = 0.05$).

Experiment 1b: Effect of Varying Inventiveness (i) of Leaders and Followers on Diversity of Ideas

The second part of this experiment involved investigating the effect of varying the invention-to-imitation ratio, i , of both the leader and the followers on the *diversity* of ideas produced by the artificial society. As in experiment 1a, i_{Leader} was systematically varied from 0.0 to 1.0. The result obtained with $i_{Followers} = 0.0$ is shown in Figure 5.

Figure 5. Diversity of actions in the artificial society with leaders of varying invention-to-imitation ratios, and followers that only imitate ($i = 0.0$).

In the short run, creative leadership was associated with increased diversity of actions. However in the long run, no matter how creative the leader, all agents converged on the same action, despite that there were seven other equally optimal actions they could have converged upon. Results with higher values of $i_{Followers}$ (not shown) were qualitatively similar. Action diversity was initially substantially higher, but it still always eventually converged to 1.

Experiment 2: Effect of Varying Leaders' Rate of Conceptual Change (c)

There are two ways an agent's creativity can be manipulated in EVOC. The first way involves changing i , the invention-

to-imitation ratio, as in the first set of experiments. It is possible to vary not just how frequently an agent invents, but how creative its newly invented ideas are. This second measure, referred to as the *rate of conceptual change*, abbreviated c , is implemented as follows. Invention occurs by taking the current action, and modifying it. When c is low, the newly invented action varies little from the previous action upon which it was based. When c is high, the newly invented idea varies dramatically from the previous idea upon which it was based.

As mentioned previously, the default value of c , the probability of change to any body part during invention, is $1/6$ for any agent that invents, whether it is a leader or a follower. Previous experiments revealed this to be the rate that optimizes the rate of increase in mean fitness of actions (Gabora, 1995). Since ideas are ideas for actions, and since actions involve at most six body parts, on average, each newly invented action involves a change to the motion of one body part. Thus $c = 1/6$ means that each body part changes what it is doing with a $1/6$ probability, or 17% of the time. In this second set of experiments, shown in Figure 6, c_{Leader} was systematically varied from 0% to 100%. Since the followers only imitated, $c_{Followers} = 0$. Because that means there are no new actions for the leader to imitate, i_{Leader} was set to 1.0.

Figure 6. Mean fitness of actions in the artificial society with leaders of varying rates of conceptual change, and followers that only imitate.

Unlike in experiment one, the optimal degree of creative leadership with respect to this second measure of creativity depended on what phase of the creative process the society was at. Early on in a run, a form of leadership that entails the highest possible rate of conceptual change (100%) was most beneficial. However, as the run progressed a transition occurred, after which point a much lower rate of conceptual change (approximately 40%) was most beneficial.

Discussion

The experiments reported here investigated the impact of creative versus uncreative leadership on the mean fitness and diversity of ideas for actions in an agent-based artificial

society. The first experiment looked at the effect of varying the invention-to-imitation ratio of both leader and followers. The mean fitness of actions was positively correlated with the creativity of the leader, but only when the followers were uncreative. The more creative the followers, the greater the extent to which the beneficial effect of creative leadership was washed out. One must be cautious about extrapolating from a simple simulation such as this to the real world. For example, real-world creativity is correlated with emotional instability, affective disorders, and substance abuse (Andreason, 1987; Flaherty, 2005; Jamieson, 1993) which presumably would interfere with effective leadership, and which were not incorporated in these simulations. However, the result suggests that creativity may be a relatively unimportant quality for a manager of a creative team, but an important quality for a manager of an uncreative team.

The first experiment also investigated the effect of varying the invention-to-imitation ratio of both leader and followers on the diversity or number of different of actions implemented by agents. Previous results with EVOC had suggested that the beneficial effect of leadership on mean fitness of ideas is tempered by decreased diversity of ideas, and this echoed previous simulation findings that leadership can have adverse effects when agents can communicate (Gigliotta, Miglino, & Parisi, 2007). We wanted to know whether the decreased diversity associated with the presence of a leader was still observed when leaders are highly creative or highly uncreative compared to followers. We found that while in the early stages of a run, creative leadership (as well as the degree of creativity of followers) was associated with higher diversity, eventually all agents converged on what the leader was doing no matter how creative the leader (or how creative the followers). This suggests that in the long run leadership diminishes cultural diversity regardless of how creative the leader is. It is worth noting, however, that in this artificial world, unlike the real world, agents had only one task to accomplish. Further experiments will investigate whether these results hold true when the fitness function varies over time.

The second set of experiments investigated the effect of not how often the leader invents, but how creative any particular invention is, referred to as the rate of conceptual change. We found that early on in the creative process, when the fitness of the ideas that are getting generated was still relatively low, it was best if the leader was very creative (high rate of conceptual change). However, later in the creative process, once relatively fit ideas were being generated, a less creative leader was better (low rate of conceptual change). This result may reflect that the fitness function used here exhibits the cultural equivalent of the biological phenomenon of epistasis, wherein what is optimal for one element of an idea depends on what is going on with respect to another element. Initially, the higher the rate of conceptual change, the more quickly fitter actions are found. However, once relatively fit actions have been found, a high rate of conceptual change breaks up co-adapted epistatically

linked elements and thus interferes with convergence toward optimal actions. In future experiments we will investigate whether these findings hold true when a different fitness function is used. However we believe that many real-world problem solving situations involve this kind of epistasis. Thus, although once again one must be cautious about extrapolating from the results of simple simulations such as this to the real world, our results suggest that a new startup company benefits most from highly creative leadership, while a more established company, or one that has stabilized on an established product line, benefits most from a more conservative form of leadership.

Abstract

There is an increase in deception studies investigating which non-linguistic and linguistic cues best predict deception. Even though these studies have shown participants consistently use specific cues to deception when they are asked to deceive somebody in a particular situation, it is less clear how these findings translate to non-experimental settings, for instance, do these cues also apply in cases of global deception in social networks. This paper investigated whether fraudulent events can be related to linguistic cues of deception within records of a large corporate social network. Specifically, we investigated the Enron email dataset using a model of interpersonal language use. Results suggest that during times of fraud, emails were composed with higher degrees of abstractness.

Keywords: deception, social cognition, computer mediated communication, corpus linguistics.

Introduction

Humans lie because it helps them manipulate the impressions people have of them. Apologizing for being late (even though you could have been on time), telling a police officer you really thought the speed limit was 40 (even though you knew it was 35), and thanking the waitress for guiding you to your table (even though you had waited for 20 minutes and she just did her job), all help to establish an interpersonal glue between you and your social environment. We tell many lies, on average one or two a day (DePaulo & Kashy, 1998).

Of course, there are gradations in the acceptability of twisting the truth. Some lies are blatant transgressions with potentially far reaching consequences, such as cases related to fraud, others are harmless and would have very little or no consequences. Most research in the cognitive sciences on deception centers on lies with little consequences. In fact, very little research has been done on cases of deception with

far reaching consequences, for the liar or the recipient of the lie.

Liars leave non-linguistic and linguistic footprints in their attempts to hide the truth, both in cases of blatant and not so blatant half-truths (DePaulo, et al., 2003). Several experiments have investigated these footprints using a paradigm whereby a participant in a deception condition is asked to tell a lie and/or to tell the truth. For instance, Newman, Pennebaker, Berry and Richards (2003) conducted a study in which they asked pro- (and anti-) abortion participants to produce both pro- and anti-abortion stories. They found that deceptive communication had fewer first-person singular pronouns, fewer third-person pronouns, more negative emotion words (e.g., *hate*, *anger*, *enemy*), fewer exclusive words (e.g., *but*, *except*), and more motion verbs (e.g., *walk*, *move*, *go*). Apparently liars wanted to dissociate themselves from their words (fewer first person pronouns), and made an attempt to create a story that seemed less complex (fewer exclusive words) and more concrete (more action words).

Hancock, Curry, Goorha, & Woodworth (2008) came to a very similar conclusion. They investigated deception in asynchronous computer-mediated communication. Participants were asked to write stories on five different topics. Half of the participants were asked to not tell the truth. Hancock et al. (2008) found that lies consisted of fewer words, more questions, fewer first person pronouns and more words pertaining to senses (e.g., *see*, *listen*) than truthful discussions.

Both Newman et al. (2003) and Hancock et al. (2008) found pronoun use, lowered word quantity, emotion words and lower cognitive complexity to be linguistic cues affiliated with deception. Both the experimental design and the findings of these two studies are prototypical for much of the empirical work on deception.

DePaulo et al. (2003) conducted a meta-analysis of experimental literature that investigated cues to deception. They reviewed 116 studies that looked into deceptive cues when people told lies. Results showed, for instance, that liars raised their chins more, pressed their lips more, and had larger pupil dilations than truth tellers. Moreover, lies had more verbal and vocal uncertainty, less verbal and vocal immediacy, were more ambivalent, less plausible and had less logical structure, with less contextual embedding.

However, DePaulo, et al. (2003) warned that these (and other) deception cues were moderated by motivation and transgressions. That is, when participants were more motivated to succeed and when the lies were about transgressions, the deception cues were more pronounced. These moderators are important to note. In fact, it is worth pointing out that the deception studies DePaulo et al. reviewed typically consisted of college students (87.1%), who lied to strangers (88.80%), with lies about transgressions (85.34%).

Indeed, the cues found in the studies DePaulo et al. (2003) used in their meta-analysis are extremely helpful to gaining further insight into deception. In these cases of deception researchers can compare the repertoires of deception cues that humans can use in their lying acts. At the same time, these cues come from unidirectional individual cases in which the participant is asked to act out a lie. It might well be the case that in ecologically situated settings no cues, or different cues, may be observed.

Furthermore, lies often do not impact only the liar. Instead, important cases of lying involve more than a single individual who is aware of the lie. Such instances, where a group of people become part of a collective deception are of a more global nature affecting a social network of people, whereby the individual feelings of guilt and shame are reduced due to a diffusion of responsibility. Examples of deception within a social network include cases of false bookkeeping, mislabeling of accounts, and corruption (Clinard & Yeager, 2006).

Knowing whether (and which) cues to deception can be found in social networks might not answer the question what deception cues humans will use, but it does answer the question whether (and which) deception cues humans generally use. Moreover, such an investigation would be informative in identifying deception strategies in cases of fraud detection or counterintelligence.

This study investigated whether deception in corporate social networks could be detected using linguistic cues.

Enron Email Dataset

The ideal corpus for a study on deception in corporate social networks is the Enron email dataset (Klimt & Yang, 2004). This dataset consists of email messages from various Enron executives/employees obtained from the accounts of 150 executives.

Enron Corporation is most famous for the elaborate network of accounting fraud spread throughout the organization. The company formed in 1985 through the

merger of Houston Natural Gas (HNG) and InterNorth Inc. After years of extensive reorganization and rebranding by CEO Kenneth Lay, Enron formed into one of the world's leading natural gas, electricity, and communication companies. Despite its six-year title within Fortune magazine as "America's Most Innovative Company," Enron's network of accounting fraud prompted an SEC inquiry that ultimately lead to the dissolution of the accounting firm Arthur Andersen and a declaration of bankruptcy by Enron Corporation in 2001.

The Enron email dataset is extremely useful for the purposes of this study. First, the dataset is highly diverse, consisting of over 20,000 different senders. Second, the emails cover a relatively large time span (1999-2001). Most importantly perhaps, there is detailed information available on Enron Corporation, its rise and fall and its fraudulent activities (Diesner, Frantz, & Carley, 2005).

While the advantage of this corpus lies in its ecological validity as well as its diversity in senders, receivers, and topics, the disadvantage is that it is very difficult to determine which emails are deceptive and which emails are not. That is, even though Enron as a whole has been known for its deception, that deception cannot be uniquely attributed to specific people or specific topics. As a result, the best way to identify deception is to use those time stamps during which it was clear – in hindsight – that fraudulent activities took place.

There are a number of studies that have analyzed the Enron dataset. Most of these studies looked at the dynamics of the structure and properties of the organizational communication network (Diesner, et al., 2005). Very few studies have looked at deceptive cues in this email corpus. Keila and Skillicorn (2005) is an exception. They used the four deception categories mentioned earlier (first person pronouns, exclusive words, negative emotion words, and action verbs) to categorize the corpus into emails of interest (which were labeled as unusual and deceptive if they showed evidence of the four categories). Keila and Skillicorn's analysis used singular value decomposition (SVD) as the primary analysis technique and successfully showed how emails can be clustered on the basis of the four deception categories. Importantly, Keila and Skillicorn did not test whether these linguistic cues predicted deception.

The current paper tested exactly this question: can a relation be found between linguistic cues in the Enron email data set and fraudulent events? Because we are dealing with interpersonal communication, we investigated this question using the Linguistic Category Model (LCM).

Linguistic Category Model

There is a range of algorithms we could apply to a corpus like the Enron email dataset (Jurafsky & Martin, 2008). However, because we are dealing with a large number of emails sent by different people on a variety of topics covering a time span of many months, it is desirable to use an algorithm based on a model of interpersonal communication. There are very few computational models

Table 1. Overview categories in the Linguistic Category Model (LCM).

Verbs in this category:	DAV	IAV	SAV	SV	ADJ
Refer to a particular activity.	+	-	-	-	-
Refer to a physically invariant feature of the action.	+	-	-	-	-
Refer to a general class of behaviors.	-	+	-	-	-
Have an action with a clear beginning and end.	+	+	-	-	-
Have associated semantic valence, positive or negative.	-	+	+	-	-
Refer to a single behavioral event.	+	+	+	-	-
Refer to a specific object.	+	+	+	+	-
Refer to a specific situation.	+	+	+	-	-
Refer to a specific context.	-	-	-	-	-
Require context for sentence comprehension.	+	-	-	-	-
Express the emotional consequence of an action.	-	-	+	-	-
Refer to mental and emotional states.	-	-	-	+	-
Readily take progressive forms.	+	+	+	-	-
Are freely used in imperatives.	+	+	+	-	-
Require interpretation beyond description.	-	+	+	+	+

available in the field of social cognition (Newman, et al., 2003).

One successful model of interpersonal language is the Linguistic Category Model (LCM, Semin, 2000; Semin & Fiedler, 1988, 1991). The model consists of a classification of interpersonal (transitive) verbs that are used to describe actions or psychological states and adjectives that are employed to characterize persons. This classification gives insight into the meanings of verbs and adjectives that people use when they communicate about actors and their social events. The model makes a distinction between five different categories of interpersonal terms (Semin & Fiedler, 1991):

- (a) Descriptive Action Verbs (DAV) refer to single, specific action with a clear beginning and end, such as *hit*, *yell*, and *walk*.
- (b) Interpretative Action Verbs (IAV) refer to different actions with a clear beginning and end, but do not share a physical invariant feature, such as *help*, *tease*, *avoid*.
- (c) State Action Verbs (SAV) refer to behavioral events, but refer to the emotional consequence of an action rather than the action itself, such as *surprise*, *amaze*, *anger*.
- (d) State Verbs (SV) refer to enduring cognitive or emotional states with no clear beginning or end, such as *hunger*, *trust*, *understand*.
- (e) Adjectives (ADJ) refer to a characteristic or feature qualifying a person or concept, such as *distracted*, *optimal*.

These five categories can be seen as a continuum from concreteness (DAV) to abstractness (ADJ). The distinction between the categories is obtained on the basis of a number of conventional grammatical tests and semantic contrasts (Miller & Johnson-Laird, 1976). An overview of the five categories is presented in Table 1.

Several studies have shown that the LCM can adequately capture differences in interpersonal language use predicted

by theories in social psychology (see Stapel and Semin, 2007).

Semin and Fiedler (1991) proposed an aggregate of the five categories in the form of an abstractness score. This score was formed by the following straightforward formula:

$$\text{Abstractness score} = \frac{\text{DAV} + (2 \times (\text{IAV} + \text{SAV})) + (3 \times \text{SV}) + (4 \times \text{ADJ})}{\text{DAV} + \text{IAV} + \text{SAV} + \text{SV} + \text{ADJ}}$$

Semin and Fiedler (1991) make the important claim that items scoring high on abstractness (i.e., through abstractness score, or a high frequency of abstract categories, such as adjectives):

- 1) generate much disagreement;
- 2) are difficult to verify; and
- 3) are low in informativeness of the situation.

These claims are relevant for the purposes of the current paper. We hypothesize that when fraudulent events take place it is more likely that the language used is difficult to verify, is low in informativeness of the situation, and is likely to be subject to disagreement (because it is harder to verify and is low in informativeness). In short, we predict that fraudulent events relate to higher abstractness scores in interpersonal communication.

In the computational implementation of the LCM model we identified all verbs and adjectives that matched the criteria identified by Semin and Fiedler (1988; 1991). This set of words was then sent through the CELEX database (Baayen, Piepenbrock & Van Rijn, 1993) to obtain derivations and inflections. The final LCM result was a list of 31,444 words in total, classified in five categories: DAV (17,884), IAV (9,224), SAV (1,533), SV (433), and ADJ (2,370). In addition, adjectives were broken down by the same categorical separations as the verb categories: DA-ADJ (467), IAV-ADJ (1,564), SAV-ADJ (220), SV-ADJ (119).

Table 2. Overview of Enron Corporation events used in Study 1 and 2. Superscripts mark multiple events.

Variable	Description of Variable	Month and Year
Layoffs	Employees within Enron Corp. were laid off.	12/01
CEO	Indicating involvement of the CEO within any coded event.	3/00, 8/00, 11/00, 1/01-4/01, 8/01 ⁶ , 10/01 ³ , 11/01
Fraudulent Paperwork Filed Signed	Filing and/or signing of fraudulent paperwork (by the CEO or COO.)	3/00 ² , 8/00
Fraudulent Comments	Enron made fraudulent comments, to the employees and/or investors.	1/01 ² , 9/01 ²
Discussion of Ethics	A discussion of ethics occurred between Enron executives or between the CEO and employees	7/00, 3/01, 5/01, 8/01 ² , 9/01, 10/01
Selling Enron Shares	Selling of Enron stock by high-level executives occurs.	11/00, 5/01, 6/01, 7/01 ² , 8/01 ² , 9/01 ²
Rolling Blackouts Initiated	Intentional initiation of rolling blackouts in California.	1/01
Meetings with Nat'l Political Figures	High-level Enron executives met with national political figures incl. the Secr. of the Treasury and the Secr. of Commerce	2/01, 3/01, 4/01, 8/01, 10/01 ⁴ , 11/01
Financial Support of Political Candidate	High-level Enron executives (CEO & President) provided financial support for a newly elected national political figure.	1/01
Profit Announced	Profits were announced for the quarter.	4/01
Loss announced	Losses were announced for the quarter.	10/01
SEC Inquiry Developments	Beginning of the SEC inquiry and the point at which the SEC inquiry became a formal investigation.	10/01 ²
Shredding Occurs	Shredding of Enron documents in Enron and/or Arthur Andersen accounting firm.	10/01 ²
Shredding Stopped	Shredding of Enron documents stopped in Enron and/or Arthur Andersen.	10/01, 11/01
Fraud Announced	Enron admitted to having overstated the company's profits	11/01
Bankruptcy Filed	Bankruptcy was filed.	12/01

The content of each of the 255,637 messages was extracted, and the frequency of words in each of the five LCM categories was determined. These frequencies were normalized to account for the number of words in an email. Sixteen events related to the rise and fall of Enron Corporation, and occurring during the time of the emails, were identified. These events are given in Table 2. Note that some events are directly related to fraudulent activities (e.g., Fraudulent paperwork filed signed; Fraudulent comments; Shredding occurs) and others indirectly (Selling Enron shares; Rolling blackouts initiated; Financial support of political candidate). These events were dummy-coded using a 1 for the presence and a 0 for the absence of an event in the month and year (Cohen, Cohen, West, & Aiken, 2003). This resulted in a database of the sender, the normalized frequency of the LCM categories in each email, and the events linked to the time the email was received.

A mixed-effect regression model analysis was conducted on the normalized frequency of LCM categories, with events as fixed factors, and email sender and email date (year and quarter) as random factors (Louwerse & Jeuniaux, 2010). The model was fitted using the restricted maximum likelihood estimation (REML) for the continuous variable (the normalized frequency of the LCM category). F-test denominator degrees of freedom were estimated using the Kenward-Roger's degrees of freedom adjustment to reduce the chances of Type I error. It is important to point out that mixed effect regression models are very robust with regards

to unequal cell sizes, which are a necessary consequence of this dataset.

Given the sheer size of the LCM wordlist, the diversity of topics, senders, and dates (the latter two controlled for in the mixed effect regression model) it is surprising to find any fraudulent event being predicted by the data. Nevertheless, as Table 3 shows, several events can be successfully related to linguistic cues. Recall that, according to the LCM, emails scoring high on abstractness are difficult to verify and are low in informativeness of the situation. Table 3 supports this idea. For instance, during the times that shredding occurred, shredding stopped, and fraud was announced, emails scored higher on abstractness.

Moreover, the most abstract category according to the LCM model is the adjectives. Discussion of ethics, financial support of political candidate, shredding occurs, shredding stopped, fraud announced, and bankruptcy filed, all predicted a higher frequency of adjectives.

Even though these results generate new research questions, there is evidence that the LCM model allows for predicting fraudulent events. Earlier in this study, however, we reviewed studies that found categories such as pronoun use, word quantity, emotion words and cognitive complexity to be affiliated with linguistic cues to deception. Although we do not have access to the exact linguistic cues of some of these categories, we can create an algorithm that approximates these cues. This is what was done in a second study.

Study 2

In the second study we used some of the categories that Newman et al. (2003) and Hancock et al. (2008) reported to be linguistic cues to deception in their experiments: first person pronouns, third person pronouns, causal adverbs, negation (both analytic and synthetic negation), the connective “but”, and the length of the email in number of words.

As in Study 1, each of these seven categories was compared with the dummy-coded events in Table 2 using a mixed-effect regression model, thereby controlling for sender and date of the emails.

Table 4 shows the results of this analysis. Events such as fraud announced, bankruptcy filed, fraudulent paperwork filed/signed, and layoffs were related to first person pronouns in emails. However, this relation was in the opposite direction of the one found by Newman et al. (2003) and Hancock et al. (2008).

Fraudulent comments, meetings with national political figures, SEC inquiry developments, and stopping of shredding were related to a higher frequency of negations (analytic negations). It is also noteworthy in these findings that negations were predicted by the stopping of shredding, but not by the occurring of shredding.

Overall, these findings are less uniform than the findings presented in Study 1. This lack of uniformity may be due to the incompleteness with respect to several of the linguistic cues assessed by Newman et al. (2003) and Hancock et al. (2008). Furthermore, the dataset analyzed here did not necessarily represent individual views on situations, unlike the situational data analyzed by Newman et al. (2003) and Hancock et al. (2008). Despite these discrepancies, the findings of the second study are helpful, as a tool of comparison to those in the first study.

Discussion and Conclusion

This study investigated whether linguistic cues can be linked to fraudulent events in a corporate social network. Various studies have looked at linguistic cues to deception. However, unlike the study presented here, these studies used carefully controlled experiments in which participants were asked to give their individual views to a receiver. Most notably, participants were placed in a lying or truthful condition. These studies provide an excellent insight in ways to deceive others, but it is at least an empirical question whether the same linguistic cues can predict deception in more ecologically valid situations. Moreover, it is worth determining whether linguistic cues of deception can be identified in large social networks.

The results of the two studies presented here on the Enron email dataset, a large record of a corporate social network, suggest that abstractness of an email is most indicative of fraudulent events.

By no means are we arguing that by using the LCM model we can predict whether an email consists of fraudulent information or not. At the same time, our results suggest that during times of fraudulent activities messages are sent out with a higher level of abstractness than during times such fraudulent activities are absent or less prevalent.

The work presented here can be extended along a number of dimensions. First, it might well be possible that the LCM categories used here allow for a different abstractness formula that better predicts the result.

To our knowledge this is the first study that has analyzed the impact of fraudulent events on the interpersonal language use of a large social network. Even though the results invite further research, the findings presented here are encouraging, and provide valuable information to the field of deception and interpersonal language use.

The Cognitive Cost of Ethnocentrism

Artem Kaznatcheev (artem.kaznatcheev@mail.mcgill.ca)

Department of Physics and School of Computer Science,
McGill University, 3600 University Street, Montreal, QC H3A 2T8 Canada

Abstract

Recent computational studies suggest that ethnocentrism, commonly thought to rely on complex social cognition, may arise through biological evolution in populations with minimal cognitive abilities. We use the methods of evolutionary game theory and computational modelling to examine the evolution of ethnocentrism. Since ethnocentric agents differentiate between in- and out-group partners, and adjust their behavior accordingly, they are more cognitively complex than humanitarian or selfish agents that always cooperate or defect, respectively. We associate a fitness cost with this complexity and test the robustness of ethnocentrism, concluding that ethnocentrism is not robust against increases in cost of cognition. Our model confirms that humanitarians are suppressed largely by ethnocentrics. Paradoxically, we observe that the proportion of cooperation is higher in worlds dominated by ethnocentrics. We conclude that suppressing free-riders, such as selfish and traitorous agents, allows ethnocentrics to maintain higher levels of cooperative interactions.

Keywords: Ethnocentrism; humanitarianism; cooperation; agent-based simulation; minimal cognition; Prisoner's Dilemma; evolution; free-rider-suppression hypothesis

Introduction

Seeing one's own group (in-group) as superior and other groups (out-groups) as inferior is a widespread syndrome of discriminatory behaviors (LeVine & Campbell, 1972). This perspective is associated with behavior including in-group favoritism (ethnocentrism) and out-group hostility (xenophobia) (Cashdan, 2001; Hewstone, Rubin, & Willis, 2002; Brown, 2004). Although the behavior is commonly thought to involve substantial cognitive ability (Sherif, 1966; LeVine & Campbell, 1972; Hewstone et al., 2002), extensive psychological evidence suggests that the presence of a strong in-group bias can be observed in individuals with minimal cognition and highly abstract social input (Tajfel, 1970; Tajfel, Billig, Bundy, & Flament, 1971). This is supported by observed ethnocentrism in human placenta (Haig, 1996), ants (Keller & Ross, 1998), and microbes (Lenski & Velicer, 2000), and suggests that ethnocentrism may have a basis in biological evolution. Cognitively, the ability to distinguish in- and out-group members and adjust behavior accordingly may be sufficient to foster this effect.

Recent computational studies (Hammond & Axelrod, 2006; Shultz, Hartshorn, & Hammond, 2008; Shultz, Hartshorn, & Kaznatcheev, 2009) have focused on the emergence of in-group favoritism through agent-based simulations of individuals with minimal cognitive ability. Agents interact via a one-time prisoners dilemma (PD) game that affects the reproductive potential of the

participants. Agents can either defect against, or cooperate with, other in- or out-group agents, permitting four strategies: (1) a humanitarian strategy of universal cooperation, (2) an ethnocentric strategy of in- but not out-group cooperation, (3) a traitorous strategy of cooperation exclusively with the out-group, and (4) a selfish strategy of constant defection. Hammond and Axelrod (2006) showed that, after a transient period, ethnocentric agents dominate the population. Shultz et al. (2008) examined the transient period to uncover evidence for early competition between the ethnocentric and humanitarian strategies. More recently, Shultz et al. (2009) focused on explaining the mechanism behind ethnocentric dominance over humanitarians. In particular, they introduced the direct and free-rider-suppression hypotheses. The direct hypothesis is that ethnocentric clumps of agents directly suppress contacted clumps of humanitarian agents from different groups. The contrasting free-rider-suppression hypothesis is that ethnocentrics are more effective than humanitarians at suppressing groups of free riders — selfish and traitorous agents from the same group.

This paper extends beyond previous work by closely examining the cognitive mechanisms required for ethnocentrism. In particular, we measure the cost in fitness an agent is willing to pay in order to have the higher (yet still simple) cognitive processes required to discriminate between in- and out-groups. By varying the cost of cognition we also eliminate ethnocentric agents and confirm the direct hypothesis as the mechanism of ethnocentric dominance over humanitarians. Tracking the proportion of cooperation also reveals a novel and important role for the free-rider-suppression hypothesis — maintaining cooperative interactions.

Cognitive Complexity

An easy way to understand the complexity of reasoning carried out by simple abstract agents is to represent their decision procedure by finite state machines (FSMs). To use FSMs, it is important to understand what information agents receive and what actions they perform based on that information. During an interaction the agent receives some information about its partner and then makes a decision to cooperate or defect. In particular, the agent receives a signal S if the agent's partner is from the same abstract group (in-group) and N otherwise (out-group). In response, the agent outputs a D to defect in the PD interaction, and C to cooperate. Note that the agent does not receive any direct information

Figure 1: Finite state machines representing the 4 possible strategies. Transitions are represented by arrows, with label S corresponding to an input of same-tag and N to different-tag. The agent’s action is represented in the center of the state, C for cooperate and D for defect.

on its partner’s strategy, and instead relies on potential correlations of a partner from the same group having the same strategy.

The four strategies are represented by FSMs in figure 1. Circles correspond to states, that are labeled by their output, either C or D . Arrows represent transitions, labeled by S or N . The initial state is signified by the smaller arrow with no pre-state. Humanitarian agents that always cooperate, and selfish agents that always defect are easy to represent. In particular, they are single state machines that output C or D (respectively) regardless of the input they receive. These two strategies are shown schematically in figures 1a and 1b. Ethnocentric and traitorous agents, however, require two states as shown in figures 1c and 1d. The extra state represents the greater complexity in making a decision based on input received, compared to not making a decision at all (the single state agents). Since implementing this rudimentary decision-making requires extra energy expenditure on the part of the agents, we represent this extra cost as a small fitness decrement k for ethnocentric and traitorous agents. This cost is especially important for studying the co-evolution of cooperation and ethnocentrism. To follow an ethnocentric strategy the agents have to invest a bit of their fitness into developing more sophisticated cognitive processes.

Method

Prisoner’s Dilemma

In virtually any competitive social situation, interacting agents have a basic decision to make: cooperate

		Agent 2	
		C	D
Agent 1	C	$b - c$	$-c$
	D	b	0

Table 1: Payoff matrix for one agent (agent 1) interacting with another (agent 2).

with each other, or not. In evolutionary game theory such interactions are usually modelled by the Prisoner’s Dilemma (PD). In PD, two agents independently decide whether to cooperate with or defect against the other. When cooperating, an agent pays a cost c to provide a greater benefit b to its partner. When defecting, an agent pays no cost and provides no benefit, but can still receive benefit if its partner cooperates. Table 1 shows the payoff for one agent (agent 1) interacting with another (agent 2). The payoff matrix reveals that an agent can always receive a higher payoff by defecting instead of cooperating. In game theoretic terminology, mutual defection is the Nash equilibrium. However, if both agents manage to coordinate cooperation, then they are both better off than if they had mutually defected — mutual cooperation Pareto dominates mutual defection. Due to this paradox, the PD game is regarded as a paradigmatic example of the problem of achieving mutual cooperation (Axelrod & Hamilton, 1981). The game provides a simple model of an environment where one action (defection) is better for the individual and the other (cooperation) is better for the population.

The simplest approach to studying the evolutionary dynamics of the PD is in a well mixed population. If agents are paired randomly from a mixed population and interaction results modify individual reproductive potential, eventually defectors will dominate the population. To allow cooperation to emerge it is essential to introduce positive correlations between the strategies of paired agents. To study the emergence of cooperation, researchers explore various ways to create these correlations. In our model we consider an interplay of spatial structure and arbitrary tags.

Model

Our model, and the Hammond and Axelrod (2006) model it is based on, expand beyond random interactions to facilitate the emergence of cooperation. Instead of randomly choosing interaction pairs, agents populate a toroidal square lattice (50 by 50 cells) and interact with their four adjacent neighbors. Each individual is simple, only perceiving whether it shares a common tag with neighbors (from a total of 4 tags), allowing for two interaction strategies: an in-group (igs) and an out-group (ogs) strategy. The four strategies are summarized in figure 1 and table 2. The outcomes of PD interactions

Name	igs	ogs	Figure
Humanitarian	C	C	1a
Ethnocentric	C	D	1c
Traitorous	D	C	1d
Selfish	D	D	1b

Table 2: The four possible strategies. The igs column correspond to the in-group strategy, ogs to out-group strategy.

(with $b = .025$ and $c = .01$) are added to the agents potential to reproduce (ptr, which is reset to .1 at the start of each cycle). At the end of a cycle, each agent has a chance equal to its ptr to clone itself (with a constant mutation rate (.005)) and a constant probability (.1) of dying. If an agent expires its location is vacated until habitation by a new agent. Regardless of the agent’s survival, if the agent cloned itself the child is placed in one empty cell adjacent to the parent (potentially including the parent’s cell if the parent expired after cloning itself). To start the world, and if the population ever reaches zero, the world is seeded with 80 individuals distributed randomly across the torus and uniformly across the 16 strains (4 possible tags, 2 possible igs, 2 possible ogs). The simulation runs for 3000 cycles.

To account for the potential cost of extra cognitive abilities we introduce a new parameter k . This parameter is varied in different simulations from 0 to .01 to show the impact of cognitive costs on the evolution of ethnocentrism. The effect of the cost of cognition is to lower the base ptr of ethnocentric and traitorous agents. In particular, at the start of every cycle the ptr is reset to .1 for humanitarian and selfish agents and to $.1 - k$ for ethnocentric and traitorous agents. The rest of the simulation is unmodified. By adjusting k we can quantify how much the extra cognitive powers of ethnocentrics are worth in terms of the currency of evolution — reproductive fitness.

During the simulation we collect two primary types of data. We record the distribution of agents by strategy, and track the number of cooperative and non-cooperative interactions. If an agent chooses to cooperate during its interaction, we increment the number of cooperations for the cycle. The proportion of cooperation is then the number of cooperations divided by twice the number of interactions (to account for both agents having to make a decision during each interaction). When comparing simulations with different values of k we take the mean data from the last 500 cycles, since the dynamics stabilize by then. To account for the stochastic nature of our model, we present all results with standard error from averaging over 30 worlds (a world is a single instance of the simulation with specific parameter setting and initial random seed).

Figure 2: Number of ethnocentric and humanitarian agents vs. cost of cognition. The points represent the mean number of agents over the last 500 cycles of the simulations: red is ethnocentric agents, blue is humanitarian. The error bars represent standard error from averaging over 30 different worlds.

Results

Our primary result is the variation in the number of ethnocentric and humanitarian agents and the proportion of cooperation for different values of the cost of cognition, k . As in previous studies (Hammond & Axelrod, 2006; Shultz et al., 2008, 2009) the number of selfish and traitorous agents is negligible, and hence we concentrate our presentation on the number of humanitarians and ethnocentrics in the population. Figure 2 shows the number of ethnocentrics (in red) and humanitarians (in blue) in simulations with increasing costs of cognition. Unsurprisingly, as the cost of cognition increases the number of ethnocentric agents decreases, and humanitarians take their place. This is consistent with the assessment of Shultz et al. (2009) that humanitarians are directly suppressed by ethnocentrics. A surprising result, is how low the cost of cognition ($.004 \leq k \leq .0045$) is at the point where the humanitarian strategy becomes fitter. In particular, this transition point is more than an order of magnitude lower than the default ptr (.1) and less than half of the cost of cooperation (.01). The third interesting result, is the quick phase transition from ethnocentric to humanitarian dominance. With $k \leq .0035$ the number of humanitarian agents is relatively stable around 200, from $k = .004$ to $k = .0065$ we observe quick change, and then for $k \geq .007$ the humanitarian population stabilizes around 1000 individuals. Together, these results suggest that ethnocentrism is not very robust against variance in the cost of cognition. In particular, for widespread ethnocentrism to emerge, the cost of differentiating between in- and out-groups needs to be

Figure 3: Proportion of cooperative interactions vs. cost of cognition. The points represent the mean proportion of cooperative interactions over to last 500 cycles. The error bars represent standard error from averaging over 30 different worlds.

extremely low in comparison to other relevant parameters (default ptr, cost and benefit of cooperation, etc.).

In figure 3 we show the proportion of cooperative interactions as the cost of cognition increases. Although the change in cooperation is not as drastic as the changes in strategy distribution, it is still statistically significant. In particular, we observe the same phase transition, with proportion of cooperative interactions stable around .955 while $k \leq .0035$ and stable around .915 when $k \geq .0065$. The counter-intuitive result in figure 3 is that as humanitarian agents start to dominate the population, the proportion of cooperation decreases. This raises the important question of what is more important: overall cooperation or the individual fairness of predominantly humanitarian agents?

For contrast, we also present two figures of strategy distribution by cycle. In figure 4a we show a cost of cognition $k = .002$, a bit before the phase transition. In figure 4b we examine a point after the phase transition, $k = .007$. The drastic change from ethnocentric (green) dominance to humanitarian (blue) dominance is self-evident. Further, in the humanitarian-dominated world of $k = .007$ selfish (red) agents perform around 5 times better than in the ethnocentric dominated world. This supports the intuition that ethnocentrics are better at suppressing selfish agents.

For other nearby choices of basic parameters (b , c , base ptr, and death rate) the qualitative results are similar, although the exact quantitative aspects change. As in reports (Shultz et al., 2008, 2009), we omit them for brevity.

(a) $k = .002$

(b) $k = .007$

Figure 4: Number of agents of various strategies vs. evolutionary cycle. The lines represent the number of agents of each strategy: blue — humanitarian; green — ethnocentric; yellow — traitorous; red — selfish. The width of the line corresponds to standard error from averaging 30 different worlds. The two figures correspond to different costs of cognition, k .

Discussion

The relatively low cost of cognition (around $.004 \leq k \leq .0045$) required to transition from ethnocentric to humanitarian dominance suggests that ethnocentrism is not very robust. In particular, the emergence of ethnocentric cooperation is unlikely to have caused significant investment of fitness in cognitive development. Alternatively, the mechanisms for differentiating between in- and out-groups and making basic decisions would need to be already in place by other means, and are unlikely to have co-evolved with cooperation. Making the distinction between in- and out-groups does not require fitness investment for humans, but for more rudimentary organism, it is likely that it would. Although the cognitive abilities required for ethnocentrism are as simple as distinguishing in- and out-groups, this simplicity can be deceiving. Our results stress that for ethnocentrism to evolve, these simple cognitive abilities must also be extremely cheap in terms of fitness invested.

The results in figure 3 suggest that displacing ethnocentric agents by humanitarian ones can lead to a decrease in overall proportion of cooperative interactions. In particular, it is important to reexamine the negative perception of ethnocentrism. Although unfair from the individual point of view, ethnocentrism might be essential to sustain the levels of cooperation required for complex structures such as multi-cellular organisms or human society. Thus, a tempting answer to the question of Shultz et al. (2009): “why is ethnocentrism more common than humanitarianism?” is that humanitarianism cannot maintain as high levels of cooperation.

A further connection to previous work (Shultz et al., 2009) is a reevaluation of the direct and free-rider-suppression hypothesis. Although Shultz et al. (2009) ruled out the free-rider-suppression hypothesis in favor of the direct hypothesis, they did not examine the proportion of cooperation. The direct hypothesis provides a good explanation of why ethnocentrics dominate humanitarians, but the free-rider-suppression hypothesis explains the increased levels of cooperation in largely ethnocentric populations. When humanitarians replace ethnocentric as the dominant strategy, significantly higher levels of selfish agents evolve in the population. The decrease in cooperation caused by higher levels of selfish agents exceeds the increase in cooperation caused by humanitarians cooperating across groups. This results in an overall reduction in the cooperative interactions. Thus, ethnocentric agents ability to better suppress free-riders is important for maintaining higher levels of cooperative behavior.

Although the decision making employed by our abstract agents is extremely simple, it is not beyond the scope of what contemporary cognitive science regards as cognition. Our research explores rudimentary cognition in a social and evolutionary context. In particular we

hope that this paper highlights the importance of considering possible fitness investment in even the simplest forms of cognition. By exploring further we hope to gain a better understanding of the evolution and potential social effects of simple information processing.

Abstract

The matching effect is the empirical finding that romantic couples have a high correlation in physical attractiveness. It remains a debate as to whether this correlation is based purely on similarity preference - the matching hypothesis - or marketplace forces. We present a new marketplace model for romantic relationships. Previous models granted every person access to his/her own attractiveness. In reality, people have only a vague idea of their own attractiveness ratings. We introduce a concept analogous to self-esteem to model this phenomenon. Further, we extend beyond previous models by dealing explicitly with both the initialization and development of a relationship. Our model accounts for the experimental tendency to choose more attractive partners, while still explaining observed intra-couple attractiveness correlation and the difference in correlation between casual and serious daters.

Keywords: mate selection; matching hypothesis; self-esteem; social cognition

Introduction

The study of dating behavior in humans has both shed light on and raised many questions about the dynamics of human relations. A common parameter across myriad studies of human partner selection has been the physical attractiveness of individuals (Cash, 1981). Walster, Aronson, Abrahams, and Rottman (1966) attempted to address the tyranny in the advantages of attractive individuals by proposing the matching hypothesis. Basing their hypothesis on the Level of Aspiration Theory (Lewin, Dembo, Festinger, & Sears, 1944), they predicted that, in making a realistic social choice, an individual would choose a partner similar in social desirability. Simply, when faced with a realistic choice, one would choose a romantic partner of nearly identical physical attractiveness.

The theoretical sanctuary that the matching hypothesis offers from physical misgivings has not been well supported by direct experimental tests (Kalick & Hamilton, 1986). When homely men estimated attractive women as more likely to reject them compared to their handsome brethren, no significant difference in their choice of prospective partners was observed: both groups opted to choose the more attractive women (Huston, 1973). Even

the most promising early experiments (Berscheid, Dion, Walster, & Walster, 1971) showed only a weak matching effect (Wetzel & Insko, 1982) that was overpowered by the attractiveness effect. So, why has the matching hypothesis survived?

Direct experiment is not the only way to test the hypothesis; one can also observe existing couples. The matching theory has been consistently supported when the correlation between the attractiveness of male and female partners in real couples was studied (Kalick & Hamilton, 1986). In average couples correlations of .38 (Murstein, 1972a), .39 (Price & Vandenberg, 1979), .42 (Feingold, 1981) and .53 (Citelli & Waid, 1980) were found. Further studies (White, 1980) expanded their investigation to differentiate between the type (and associated longevity) of relationships, observing intra-couple attractiveness correlations of .18 for casual dates, compared to the correlation of .56 and .63 for serious daters and engaged or married couples, respectively. The strong correlations in real couples provide the main evidential support for the matching hypothesis.

The stark dichotomy between direct experiment and observations of existing couples raises the question: is the matching hypothesis a good model for human courtship? By itself the matching hypothesis fails to match experiment but corresponds well to correlation studies in existing couples. It is the goal of this paper to provide a synthesis of the hypothesis and the apparent preference for the most attractive partner into a single computational model.

The computational approach was famously pursued by Kalick and Hamilton (1986). The Kalick and Hamilton simulation assumed every person has access to both their own attractiveness rating and their partner's attractiveness rating. Experimentally, the latter assumption is valid. Cunningham and Wu (1995) found a correlation of .9 between a single rating and the average rating of pictures of women. This correlation remains high if either the female picture of the rater is from a different culture. The assumption of access to own attractiveness, however, is not supported by experiment. Rand

and Hall (1983) found that people are very inaccurate at rating their *own* attractiveness. Females tend to have a .5 correlation between their self-perception of attractiveness and the rating of male judges. Males have only a .1 correlation between self-attractiveness ratings and the ratings of female judges. The inability of people to accurately judge their own attractiveness cannot be disregarded when simulating the matching hypothesis. Hence, for a model to have ecological validity, it must incorporate the inaccuracy of judging self-attractiveness.

Our model incorporates this self-perceptive inaccuracy through the effect of a variable self-esteem (or body-image) rating. We use a simple model of self-esteem based on sociometer theory (Leary, 2005). As suggested by naturalistic studies, self-esteem mediates self-perception of attractiveness (Fleming & Courtney, 1984; Feingold, 1988; Leary, 2005) and changes based on acceptance (or rejection) in the initiation of relationships and by the dissolution of relationships (Helgeson, 1994; Leary, 2005; Pass, 2009; Pass, Lindenberg, & Oark, 2010). We also extend beyond previous models by dealing explicitly with both the initialization and development of a relationship. This allows us to study the expected difference in attractiveness correlation between casual and serious daters (Cavior & Boblett, 1972; White, 1980) and track the effects of break-ups on self-esteem.

Method

The method of simulation is widely used to help understand certain types of complex systems. Models of human courtship lend themselves particularly well to simulation, since the goal is to define relatively simple rules for individual parts (people) and observe a more complex behavior and trend in the whole system (group). In our model, each individual i is parametrized by two values: a static $\alpha_i \in (0, 1)$ to represent the person’s attractiveness and a dynamic $s_i \in (-1, 1)$ (referred to as ‘self-esteem’). Together these parameters are used to derive $A_i \in (0, 1)$ — the person’s perception of their own attractiveness. The two parameters that describe a person (α_i and s_i) are generated randomly from a uniform distribution. If two individuals i and j form a couple, then the relationship carries an extra parameter, $l_{ij} \in \mathbb{N}$, called longevity. Longevity counts the number of ‘dates’, or amount of time, i and j have been in a relationship. The longevity parameter is used to track the longest lasting couples and is reset to zero upon relationship dissolution.

Individuals are not explicitly given a gender, but the simulation is constructed such that males only ever show up in the list of male individuals (or the male side of a relationship) and vice-versa for females. For simplicity, the simulation is restricted to have the same number of male and female individuals. At the start all individuals are initialized as singles (not part of a couple) and only

heterosexual relationships were considered. The simulation proceeds in discrete steps (epochs). On each epoch we follow the procedure:

1. existing couples are examined for a potential break up,
2. agents from dissolved couples are reintegrated into the pool of singles,
3. new couples are formed from the pool of singles, and
4. statistical data collected.

Any changes to self-esteem are incorporated at the instant they occur.

Formation and dissolution of relationships

The probability of date formation is based around the empirical observations that individuals seek the most attractive partners regardless of their own attractiveness (Huston, 1973; Kalick & Hamilton, 1986). In the simulation, each single man i is paired with a single woman j and each decides if they want to accept the date based on a probability of acceptance equal to the attractiveness of their potential partner ($P(m_{ij}) = \alpha_j$). If both partners accepts, then the pair become a couple, l_{ij} is initialized and self-esteem is modified as detailed in the next subsection.

For established couples, the break up probability is based on equity theory and the matching hypothesis. Since a break-up is seldom mutual (Hill, Rubin, & Peplau, 1976) we compute a separate break up probability for each member of the couple. Given a couple of woman x and man y the break up probability, $P(b_{xy})$ and $P(b_{yx})$, is calculated for each person, respectively, according to equation 1. The probability of i breaking up with j is linearly dependent on the absolute difference between i ’s perceived attractiveness, A_i , and his partner’s actual attractiveness α_j . The dependence on absolute difference in perceived attractiveness is based in equity theory (Murstein, 1972b; Walster, Hatfield, Walster, & Berscheid, 1978) and the empirically observed importance of similar physical attractiveness to the longevity of relationships (Hill et al., 1976; Feingold, 1988). The values of 0.15 and 0.85 are arbitrary, but by rescaling time we can always assume the values we chose add up to 1.

$$P(b_{ij}) = 0.15 + 0.85|A_i - \alpha_j| \quad (1)$$

If the couple ij remains, then one more ‘date’ is added to their longevity ($l_{ij} \leftarrow l_{ij} + 1$). If at least one of i or j decides to break up with the other then the relationship ends, both individuals are added to the singles list before new couples are formed, and l_{ij} is reset to zero. The impact on individual’s self-esteem depends on whether the dissolution was mutual or unilateral.

Self-esteem effects

The primary effect of the self-esteem variable s_i is on i 's perception of its own attractiveness. Our model of the effect of self-esteem on self-perception is grounded in the Fleming and Courtney (1984) finding that self-ratings of attractiveness loaded heavily on self-esteem factors. In particular, we use equation 2 to determine an individual's self-perceived attractiveness A_i in terms of their actual (externally determined and static) attractiveness α_i and their varying self-esteem s_i .

$$A_i = \begin{cases} \alpha_i + (1 - \alpha_i)s_i, & s_i \geq 0 \\ \alpha_i(1 + s_i), & s_i < 0 \end{cases} \quad (2)$$

Equation 2 is the simplest choice of equation that ensures that any value of actual attractiveness $\alpha_i \in (0, 1)$ and self-esteem $s_i \in (-1, 1)$ results in a perceived self-attractiveness A_i in the correct range of $(0, 1)$. From the upper clause of equation 2 we can see that a positive s_i produce a linear increase in perceived attractiveness from $A_i = \alpha_i$ for $s_i = 0$ to $A_i = 1$ for $s_i = 1$. Thus, $s_i > 0$ corresponds to an overly high self-esteem or even arrogance and an overestimation of one's own physical attractiveness. In the lower clause of equation 2 we see that $s_i < 0$ produce a linear decrease in perceived attractiveness from $A_i = \alpha_i$ for $s_i = 0$ to $A_i = 0$ for $s_i = -1$. Negative s_i model a low self-esteem. A perfect judgement of one's own attractiveness is achieved with the 'perfect' esteem of $s_i = 0$.

Through its effect on A_i , self-esteem is important for the duration of relationships. However, in the formation of couples we only consider the actual attractiveness α_i and self-esteem plays no role. We do not incorporate self-esteem in the selection of a mate because Walster (1970) established that self-esteem has no effect on the tendency to prefer the most attractive choice of partner.

The key difference between α_i and s_i is that α_i is static throughout the simulation and s_i varies depending on social interactions. In other words, a person's physical attractiveness is not affected by social interactions, but their self-esteem, self-image, or body-image is affected (Leary, 2005; Pass, 2009). To lower an agent i 's self-esteem by a factor x without exceeding the range of $(-1, 1)$ we use $d_i(x)$:

$$d_i(x) = \begin{cases} s_i - x, & s_i \geq 0 \\ s_i - (1 + s_i)x, & s_i < 0 \end{cases} \quad (3)$$

and to raise it by a factor x we use $u_i(x)$:

$$u_i(x) = \begin{cases} s_i + (1 - s_i)x, & s_i \geq 0 \\ s_i + x, & s_i < 0 \end{cases} \quad (4)$$

If an agent has a positive self-esteem ($s_i \geq 0$) and we lower it by x with equation 3 then we simply subtract x

from the agent's esteem. If an agent has a negative self-esteem ($s_i < 0$) then we need to worry about potentially reducing it past -1 and so we do as equation 2: lower self-esteem linearly from $d_i(0) = s_i$ to $d_i(1) = -1$. The same procedure is used in equation 4 except with negative and positive esteem swapped and raising instead of lowering. $u_i(x)$ and $d_i(x)$ allow us to increase and decrease an agent i 's self-esteem in a simple and consistent way without leaving the range $(-1, 1)$.

During the relationship forming stage, if both agents accept the relationship then each receives a self esteem boost: $s_i \leftarrow u_i(0.3)$. This corresponds to the feeling of well being individuals receive from the social acceptance of relationship formation as predicted by sociometry theory (Leary, 2005). On the other hand, if agent i proposes the relationship, but agent j declines, then agent i suffers a self-esteem loss from rejection (in our model: $s_i \leftarrow d_i(0.2)$) and agent j receives a small self-esteem boost from the flattery and reassurance of their attractiveness ($s_j \leftarrow u_i(0.1)$) (Pass et al., 2010). If both agents reject the potential pairing then self-esteem is left unchanged because neither individual proposed a relationship.

The most drastic effects on self-esteem are in the case of unilateral termination of a relationship (Helgeson, 1994). If one of the individuals decides to break up with the other, then the dumped agent's self-esteem is lowered to a new level: $s_i \leftarrow d_i(0.4)$. However, if both individuals want the relationship to end, then neither self-esteem is affected. Although the specific values 0.1, 0.2, 0.3, and 0.4 in our model are chosen for simplicity, the relative ordering of them is meant to correspond to the general ordering observed by Helgeson (1994): break-ups are the most damaging ($d_i(0.4)$), with rejection less damaging ($d_i(0.2)$) and the awards for acceptance higher for a new relationship ($u_i(0.3)$) compared to just the flattery of an offer ($u_i(0.1)$).

Results

To provide an idea of how effective the model is while keeping errors and simulation times reasonable, the simulation was run 50 times with 300 men and 300 women courting for 50 epochs. The main observed quantity was the mean intra-couple attractiveness correlation for the couples in each epoch. Figure 1 provides a visualization of the collected data. The mean correlation was collected for all of the couples in each epoch (blue), as well as the top 30% by longevity (red). Effectively, the blue points represent the 'average' daters and asymptote at around $r = .23$. The top 30% correspond to the 'serious' daters and asymptote near $r = .60$ which is in the observed range of .56 to .63 for serious and engaged or married couples (White, 1980). The large gap between the attractiveness correlation in average and serious daters is consistent with White's (1980) em-

Figure 1: The intra-couple attractiveness correlation versus epochs with statistical error. The blue data points are the correlations of all of the couples in an epoch. The red data points are of the oldest 30% of the couples. The data were generated by averaging over 50 simulations of 50 epochs with 300 men and 300 women courting

pirical results. The lower correlation value of our model also matches empirical data much better than the unreasonably high correlations of earlier models (Kalick & Hamilton, 1986).

Discussion

Earlier simulations (Kalick & Hamilton, 1986) yielded an intra-couple attractiveness correlation of approximately .9, .85, and .55 for the matching hypothesis, combined, and mate attractiveness selection rules respectively. Kalick and Hamilton (1986) concluded based on these simulations that the matching hypothesis alone could not explain intra-couple attractiveness correlations as they were simply too high. By introducing modified rules that incorporated both formation and development of relationships, our model provided realistic correlations of .23 for average daters and .60 for serious and engaged or married couples. We matched experimental results of attractiveness selection by allowing partners to favour accepting dates with more attractive partners. We incorporated the matching hypothesis in the break-up probability instead of relationship formation. This allowed our model to track both the formation and development of relationships. Allowing couples to break-up also addressed an important shortcoming of earlier models (Aron, 1988). By allowing individuals to be single instead of eventually forcing everyone into a relationship we ensure that there is always choice of potential partners.

Our model has provided promising results, but only a portion of its potential has been examined. The model and simulation were used to show how the matching hypothesis can be present in a place other than the probability of date acceptance. This approach accounts for matching effects (especially in long-lived couples) while

allowing for the experimental tendency to choose more attractive partners. The simulation could be extended to allow one of the sexes to select a potential partner (instead of random assignment). We believe that such a modification is essential to account for the asymmetry in male and female perception of self-attractiveness. In particular, if males select a potential partner more often, then they will face rejection more often than females and produce more variation in self-esteem and hence a lower correlation between self-perceived and externally judged attractiveness. However, the most important part of the model that needs more attention and study is the self-esteem variables and the choices of weights in various equations. As it stands, lack of knowledge about the self-esteem factor is the largest limitation of the model. To truly test and understand the model and simulation, experiments are essential.

The structure of the simulation and relative simplicity of the model, lends itself nicely to empirical studies. Our model's predictions could be tested with human participants. The attractiveness score of each individual could be evaluated by a panel of judges or by querying participants of the other gender. Individuals' self-esteem parameter could be estimated by comparing their own evaluation of attractiveness, A_i , to the attractiveness assigned by judges, α_i . The dates and choices to break up or accept partners can be carried out as in existing studies. The computer simulation can be run with the same initial population of parameters and results compared. By doing parameter fitting on the inputs for equations 3 and 4 we could estimate the effects of rejection and acceptance on self-esteem.

A further contribution of our simulation is the clarity a formal model brings to theories of human romantic relationships. This clarity allows us to easily generate hypotheses and, more importantly, to relate our model to work in the nearby fields of evolutionary and cognitive psychology. In particular, we hope that — using attractiveness as a proxy for fitness (Singh, 1993; Hönekopp, Rudolph, Beier, Liebert, & Müller, 2007) — future work can connect our social/psychological model to evolutionary and cognitive models. The methods of evolutionary game theory have already been used to study parts of equity theory such as the evolution of fairness in the ultimatum game (Nowak, Page, & Sigmund, 2000; Bolton & Ockenfels, 2000) and the predominance of ethnocentrism (Hammond & Axelrod, 2006; Shultz, Hartshorn, & Kaznatcheev, 2009). Recently, Kaznatcheev (2010) incorporated cognition into these evolutionary models. Recasting our model of mate selection in such a setting can provide important insights into the basis of romantic relations. By looking at the evolutionary and cognitive underpinning of mate selection (Miller & Todd, 1998), future work could explain not only *how* romantic relationships progress, but *why* this is the case.

Our model offers a new and alternative look at the dynamics of romantic relationships. Unlike earlier studies (Kalick & Hamilton, 1986), not only the initialization of a relationship is examined, but also its longevity. As any romantic can tell you, knowing how to start a relationship is nothing compared to keeping an existing one going. Hopefully, this model and simulation can illuminate the mysteries of dating and help us understand human interaction a little better.

Determining the Internal Consistency of Attitude Attributions

Kyle E. Jennings (jennings@berkeley.edu)

Department of Psychology, University of California, Berkeley
Berkeley, CA 94720-1650 USA

Abstract

In the attitude attribution paradigm, observers must estimate the true attitude of an author who was assigned to advocate a particular position. Observers' tendency to attribute an attitude in line with the expressed position despite its having been assigned is called the correspondence bias. While there is strong evidence that such attributions are externally invalid, it is less clear whether they are internally consistent. This research develops a Bayesian model that specifies what attitude an observer should attribute, given assumptions about the prior attitude distribution, and perceptions of the degree of compliance shown in the essay and the strength of the situation. The model reproduces classical findings regarding chosen vs. assigned positions, prior attitude probability, and degree of compliance, and also fits newly collected data. The results suggest that future research should examine observers' assumptions and perceptions, and focus less on the reasoning process itself.

Keywords: Correspondence bias; Attitude attribution; Normative standard; Bayesian modeling.

People's tendency to neglect situational influences on behavior has been a subject of long-standing interest to social psychologists. Many of the earliest and most famous demonstrations of this error make use of the attitude attribution paradigm (Jones & Harris, 1967), wherein participants read an essay that expresses an opinion on an issue, and must estimate the author's attitude. Complicating this judgment is the fact that the author was assigned what position to express, which pits two competing explanations—holding the attitude, or complying with the request—against each other. Participants tend to make attitude attributions in line with the essay even when the position was assigned, which is called the correspondence bias (Gilbert & Jones, 1986).

It is not straightforward to say whether people's responses in the attitude attribution paradigm are in fact biased. On the one hand, when participants rate essays that other study participants wrote under constraint, the attributed attitudes are more in line with the essay than with the authors' self-reported attitudes (e.g., Reeder, Fletcher, & Furman, 1989). On the other hand, if people's attributions are internally consistent with their own perceptions and assumptions, it is hard to call their attributions completely biased (Jones, Worchel, Goethals, & Grumet, 1971; Morris & Larrick, 1995; Forsyth, 2004). These two views involve two different standards for correctness, known as correspondence and coherence (Hammond, 1996), which concern the external validity and internal consistency of the judgment, respectively. To avoid confusion between correspondence *criteria* and the correspondence *bias*, the terms external validity and internal consistency will be used. Though people's judgments probably lack external validity, it is not clear whether they are at least internally consistent.

Checking internal consistency requires knowing what information is relevant to a judgment, and how that information determines the correct answer. This paper develops a Bayesian model relating assumptions and perceptions to attitude attributions. Since the model is grounded in mathematics, the steps between premises and conclusions can be more readily verified than with verbally justified standards (Morris & Larrick, 1995). Additionally, the model is agnostic to what process people might use to make judgments, helping researchers advocating different mechanisms at least agree on the correct outcome.

Normative Model

In the attitude attribution paradigm, observers know what essay was written, and the circumstances under which it was written. Their judgment of whether the essay author holds the expressed attitude is (Morris & Larrick, 1995):

$$P(\text{attitude} \mid \text{essay, circumstances})$$

Letting A , E , and C stand for the attitude, essay, and circumstances, and strategically applying Bayes' rule,¹ this equals:

$$P(A) \cdot \frac{P(C \mid A)}{P(C)} \cdot \frac{P(E \mid A, C)}{P(E \mid C)}$$

Intuitively, these terms express the prior probability of the attitude, the co-occurrence of the circumstances and the attitude, and the relative likelihood of a person writing the essay, comparing someone with the attitude to the average person.

The model can be applied in two ways. First, it can be interpreted schematically in order to draw conclusions about the general direction of normative inferences. For instance, the standard shows that the conventional wisdom that the essay communicates no information about the author's attitude in light of the circumstances is correct only if two conditions are met. First, the co-occurrence term must be one, meaning that positions must be assigned without respect to the author's attitude. Studies that merely say that the position to advocate was assigned leave open the possibility that the author's attitude was considered when making the assignment, in which case a correspondent inference may be justifiable. Second, the likelihood term must also be one, meaning that the constraint must be seen as equally compelling regardless of the author's attitude (with completely compelling being a special case of this). As other researchers have argued (e.g., Jones

¹ $P(A \mid E, C) = P(A, E, C) / P(E, C) = P(E \mid A, C) P(A, C) / P(E, C) = P(E \mid A, C) P(C \mid A) P(A) / [P(E \mid C) P(C)]$. See also Jennings (2010).

Figure 1: Illustration of $p(e | a, p = 2, s = .5)$. Left panel shows two essay distributions, for $a = -2$ and $a = 2$. Right panel shows likelihood distribution over attitudes for $e = 2$. As shown in the middle panel, these two distributions are really slices of the same three-dimensional function.

et al., 1971) or found (e.g., Forsyth, 2004), observers do not seem to hold this belief.

Though these conclusions are powerful, it is possible to do better. The second way to apply a model such as this one is to use it to quantitatively assess the internal consistency of people's judgments, which is done by measuring quantities on both sides of the equation. Previous authors have done this using alternative Bayesian standards (Trope, 1974; Morris & Larrick, 1995; Forsyth, 2004). However, every previous model has required participants to think in terms of discrete probabilities (e.g., the probability that the author holds the attitude expressed in the essay), while nearly all other studies of attitude attribution ask participants to estimate the author's attitude on a Likert-type scale. Achieving a match to what participants customarily estimate requires switching from the probabilities of dichotomous events to probability *densities* over continuous variables, as follows:

- “Pro” and “con” attitudes are generalized to real-valued attitudes along a “con” (negative) to “pro” (positive) continuum, with attitudes further from zero being more extreme. The variable a will refer to the author's attitude, while e will refer to the position expressed in the essay.
- The circumstances (C) are decomposed into two things: p , the position that the author was asked to express, and s , the strength of that request. The variable p can vary as discussed above, while s can vary between zero (no inducement) and one (a completely compelling inducement).

Using the above variables, $P(A | E, C)$ becomes $p(a | e, p, s)$. Converting the prior, co-occurrence, and relative likelihood terms into probability distributions and multiplying the three over the range of a gives the probability of each possible attitude. The expected value of this distribution will be the attitude attribution, and the confidence in this attribution will be proportional to the distribution's standard deviation.

Completing the normative model requires specifying the forms of the three terms. The prior distribution, $p(a)$, is just the assumed attitude distribution in the population. The co-

occurrence term expresses how the circumstances vary with the author's attitude. Assuming a random assignment process, then this term equals one. This leaves the likelihood term, $p(e | a, p, s) / p(e | p, s)$. Since the denominator does not involve a , the expression can be written:

$$p(a | e, p, s) \propto p(a) \cdot p(e | a, p, s)$$

These terms will be called the posterior, the prior, and the (essay) likelihood, respectively.

The final task is to specify a form for the likelihood, $p(e | a, p, s)$. This can be done by determining the distribution of essay positions that an author with attitude a would write when asked to express position p , facing an inducement of strength s . Instead of requiring participants to estimate this themselves, the form of the function will be specified mathematically. Past research has found that observers expect constrained authors to express an attitude somewhere in between their own attitude and the position that was assigned (Miller & Rorer, 1982), which Reeder et al. (1989) refer to as the central tendency assumption. Thus, an author with (say) a strong con attitude who was asked to express a strong pro position would attempt to write a neutral essay. This expectation can be modeled by saying that when a , p , and s are known, $p(e | a, p, s)$ is a normal distribution, with:

$$\mu = a \cdot (1 - s) + p \cdot s$$

With no inducement ($s = 0$), $\mu = a$, the author's own attitude. With a completely compelling inducement ($s = 1$), $\mu = p$, the requested position. For other values of s , μ is a weighted compromise between a and p . While one could imagine ways that the distribution's standard deviation might depend on a , p , and s , for parsimony it will be assumed to be constant.

The above model of authors' responses specifies the distribution of e , given that the other variables are known. However, when applied, e is known but a is unknown. This does not present a problem, as illustrated in Figure 1. The left graph shows the essay distributions for two values of a (-2 and 2), where $s = .5$ and $p = 2$. The right graph shows the

Figure 2: Model of the choice (left) and no choice (right) conditions for Jones and Harris (1967), Study 1. In the bottom panel, black arrows show original results, and black lines show the model's results.

likelihood distribution over the range of a , where $e = 2$. The middle image shows how the two are related, with two points shown on all three graphs ($e = 2$, $a = \pm 2$) for reference.

As already mentioned, this model improves upon previous Bayesian models of attitude attribution in that its output is the same kind of variable as participants usually estimate. In addition, the model's inputs correspond to perceptions that are relatively straightforward for participants to reason about (the position expressed in the essay, e , whether the essay is weaker or stronger than was expected of the author, $e - p$, and how constraining the situation was, s). When testing scenarios schematically, this makes it possible to continuously vary the model parameters, or to test specific combinations of parameters, rather than having to make verbal arguments about, say, the relative sizes of $P(\text{Essay} | \text{Attitude})$ and $P(\text{Essay} | \text{Attitude})$. When testing the internal consistency of participants' actual judgments, it becomes possible to directly ask for the relevant quantities. The tradeoff is that the model assumes people believe that constrained authors will express a position between their own attitude and the request. However, other models of how authors respond could be translated into likelihood functions, and the results compared.

Illustrations

Choice and Prior Probabilities

Correspondent inference theory (Jones & Davis, 1965) was intended to be a normative standard for how people should make attributions, and aims to specify which behaviors justify the inference of information about a person that would not have been assumed previously (Jones & McGillis, 1976). Jones and Harris (1967) was an attempt to show that while both constrained behavior and expected behavior do not contribute new information, an expected behavior performed under constraint will still lead to a corresponding attribution, simply because the underlying disposition would be expected

anyway. It is for this reason that they used advocacy for "Castro's Cuba"—a highly unexpected behavior in 1960's America—as the critical test. As predicted, they found that people made attributions corresponding to the constrained behavior when the behavior was expected (arguing against Castro). What they were surprised to find was that though people did not make completely corresponding attributions when the behavior was unexpected (arguing for Castro), their attributions did not revert to the level that would be obtained had the behavior been completely disregarded. This is the result that triggered the volumes of research on the correspondence bias that continues to this day.

This paper's model can reproduce the pattern of results that Jones and Harris obtained, using two reasonable assumptions. First, assume that the prior attitude distribution was strongly right skewed (i.e., very few people supporting Castro).² Second, for parsimony, assume that the pro and con essays were equivalently strong, and no weaker or stronger than requested.

To reproduce the "choice" condition, the model is run with strength set to zero ($s = 0$), which is illustrated in the left half of Figure 2. The top panel of this graph shows the prior distribution, $p(a)$, while the middle panel shows the likelihood functions for the con (dashed line) and pro (dotted line) essays. These lines show $p(e | a, p, s)$, where $e = \pm 3$,³ $s = 0$ since authors could choose what to express (making the requested position, p , irrelevant), and a varies across the x -axis to encompass the range of attitudes shown. The bottom panel shows the posterior distributions, $p(a | e, p, s)$, which are the result of multiplying the prior distribution by either likelihood distribution. In this case, the prior distribution has only a small effect on the posterior distributions, and the expected

³Note that attitude values are always rescaled to a -4 [con] to 4 [pro] for consistency of comparison across studies.

	Con		Pro	
	Strong	Weak	Weak	Strong
Requested position (p)	-2	-2	2	2
Essay position (e)	-3	-1	1	3
Attribution (a), weak constraint ($s = .25$)	-2.78	-0.56	0.56	2.78
Attribution (a), strong constraint ($s = .75$)	-2.16	0.72	-0.72	2.16
Essay position (e)	-3	-2	2	3
Attribution (a), strong constraint ($s = .75$)	-2.16	-0.72	0.72	2.16

Table 1: Model-predicted attributions for strong and weak essays under weak and strong situational constraint. Weak situation shows no reversal for the weak essays, but strong situation does. The same pattern can be obtained by keeping situation strength constant but making the weak essays less weak.

values of the distributions (shown by the black, vertical lines) are a very close match to the results that Jones and Harris originally obtained (shown by the black arrows).

Jones and Harris found nothing counterintuitive about their results for the choice condition, but were surprised by the results in the no choice condition, which can be replicated by choosing an appropriate value for s . Not shown in the figure is the case where the situation is seen as completely constraining ($s = 1$). Under conditions with no behavioral freedom, everyone is equally likely to have written the requested essay, and so the two likelihood functions are flat lines. As such, both posterior distributions are equal to the prior distribution, making the normative attribution for both essays equal to the mean attitude in the population. This result is what Jones and Harris were expecting to find. Since this is not what they obtained, values of s less than one must be tried.

A good fit to the original results was obtained with $s = .6$. The right half of Figure 2 shows this case, where it can be seen that though the prior distribution is the same and the likelihood functions have the same locations, the likelihood functions are also more spread out (since constrained behavior is less informative than freely chosen behavior). Even though the pro and con likelihood functions are equal and opposite, the posteriors are not, which is a result of multiplying by the asymmetric prior.

As the bottom panel shows, the expected values of either posterior (black, vertical lines) are quite close to the results that Jones and Harris obtained (black arrows). In particular, for the “con” essay, the model-derived and actual attributions are still in the direction of the essay. For the “pro” essay, however, multiplying by the prior probability has brought the model-derived results closer to the midpoint, and like the actual results, still somewhat correspondent with the essay itself. It is also worth noting that the “pro” posterior is more spread out than the “con” posterior, just as Jones and Harris found greater variance in this condition than in the other conditions of their study.

As the above shows, the model can reproduce the important features of the original demonstration of the correspondence bias, with only one parameter varying between the choice and no choice conditions. As such, it establishes that the results

in Study 1 of Jones and Harris (1967) could be the result of an internally consistent reasoning process, given the assumption that the participants did not believe that the author’s situation in the no choice condition was completely constraining. In fact, according to the model, the *only* internally consistent way for perceivers to make attributions other than to the mean attitude in the population is if they believe that the situation leaves room for choice, and that this choice depends on the compatibility of the author’s attitude and the assigned position. Though these attributions are probably externally invalid, the possibility that they are internally consistent suggests that defects in observers’ reasoning processes are not necessary to explain the results. Likewise, people may make perfectly reasonable assumptions about how situational constraints in general would influence essay authors. The source of “bias” may simply be that people applied those assumptions using an insufficiently strong appraisal of the power of the author’s particular situation.

Degree of Compliance

Thus far, it has been assumed that perceivers believe that the essay written was no weaker or stronger than was requested. However, compliance needn’t be all-or-nothing. Jones et al. (1971) manipulate the strength of the essay in order to understand how behavioral extremity affects attributions. One of their key results is that when people read an essay written under constraint and expressing a weak position, they attribute the *opposite* attitude to the author as was assigned. When the essay position was strongly argued, they attribute a corresponding attitude. In an attempt to replicate this result, Miller (1974) found that people made less extreme attributions when reading a weak essay than when reading a strong essay, but did not find any reversal. In both cases, however, the degree of compliance affected the attributions.

The model is able to reproduce these result patterns by varying the situation strength parameter, s , and leaving everything else constant. Model-predicted attitude attributions for weak and strong levels of constraint are shown in the top and middle of Table 1. Reversal occurs for the strong constraint, but not for weak constraint. Intuitively, this is because stronger constraints make it less likely that a person

Figure 3: Illustration of strong and weak “con” essays for weak constraint (left, $s = .25$) and strong constraint (right, $s = .75$). In both cases, the requested position, p , is -2 and the essay positions, e , are -3 and -1 for the strong and weak essays.

would deviate from the requested position. Therefore, when someone does deviate from the requested position by writing a weaker-than-expected essay, it is reasonable to conclude that this person must hold an attitude very different than what was requested. This is illustrated in Figure 3. As can be seen, the likelihood functions are both further from the requested positions and more spread out at higher constraint.

Varying situation strength is not the only way to replicate the different patterns of results. The bottom two rows of Table 1 show what happens when the weak essays are made less ambivalent, but the strong level of constraint kept consistent. This change removes the reversal that had been obtained with the weak essays. In speculating on the failure to replicate the Jones et al. (1971) weak essay reversal, Miller (1974) does in fact note that his weak essays were not as weak as those in Jones et al. While both Jones et al. and Miller speculate that strong essays “engulf the field” whereas the weak essays allow the perceiver more latitude to notice the situation, the model suggests that no such perceptual metaphors are necessary. Instead, both outcomes are reasonable conclusions of an internally consistent logic that does not depend on any distortions in perception, failure to notice the situation, or alteration in the underlying behavioral model being used to make the attribution. This example also makes clear that there are often multiple internally-consistent ways to obtain the same pattern of results. The model makes it possible to explore many sources of a result, thereby suggesting hypotheses for behavioral research.

Empirical Results

In addition to fitting previous research results, the model fits new data (collected for a different purpose).⁴ Partici-

⁴These data are part of an in-progress replication of Miyamoto and Kitayama (2002), which uses their essays as stimuli. In addition to having “pro” and “con” essays, the study varies essay length.

pants ($N = 246$) read essays for and against the death penalty, and then learned that the author was randomly assigned the position to take. Participants then rated what they thought the author’s attitude was, how confident they were in their answer, and other perceptions (detailed next). Replicating past results, there was a significant difference between the pro and con essay attributions ($M = -0.90$ vs. $M = 0.98$, $t(244) = -8.44$, $p < .0001$). Model-based predictions were then tested, after reversing all of the relevant quantities for participants in the “con” essay condition.

As the model of the Jones and Harris (1967) results showed, a skewed prior attitude distribution should result in asymmetric attitude attributions. In particular, attributions for essays expressing rare opinions should be closer to the midpoint that attributions for essays expressing common positions. Additionally, as judged by the variance of the posterior distributions, people should be less confident in their attributions when the expressed position is rare. This was tested by looking at participants’ self-reported prior attitude distributions, which were elicited by having people apportion 100 percentage points to three equal-sized intervals encompassing the measurement scale. A “skew” was calculated for each participant by taking the log ratio of the lower and upper intervals of their priors. Negative ratios imply more probability mass near the “pro” end of the scale, and positive ratios imply more probability mass near the “con” end of the scale. Supporting the model’s predictions, the correlation of attribution and skew was $r = -.14$ ($p < .05$), and the correlation of confidence and skew was $r = -.20$ ($p < .01$).

Next, the co-occurrence between the situation and attitudes was examined. As mentioned at the outset, if assignment is non-random, people might believe that the essay author’s own attitude and the assigned position are related. To test

Since the effects listed next are not qualified by length, the length manipulation is not discussed further.

this, people were compared by whether they indicated (as intended) that the author had no control over assignment. There was a significant difference ($M = 0.73$ vs. $M = 1.21$, for no control vs. control, respectively, $t(244) = 2.16$, $p < .05$).

Finally, the likelihood model predictions were examined. As shown with the modeling of the Jones et al. (1971) and Miller (1974) result patterns, the model predicts that overcompliance and attribution extremity should be positively related, and that perceived situation strength and attribution extremity should be negatively related. Participants estimated overcompliance via a question asking how much weaker (or stronger) the essay was than what they believed was expected, and strength was measured via a question about how much overall choice the author had (reversed). After partialing out the effects of skew and strength, attribution and overcompliance were positively related, $pr = .14$ ($p < .05$). After partialing out skew and overcompliance, attribution and strength were negatively related $pr = -.16$ ($p < .05$). Because higher strengths lead to more spread out likelihood functions, the model also predicts that confidence and strength should be negatively related, which was supported $r = -.24$ ($p < .001$).

Though these results do not prove that people's attributions are internally consistent, they do demonstrate promise. Future work will systematically test the match between model predictions and empirical results in greater detail.

Conclusions

Using a simple yet plausible model of how people respond to instructions to advocate a particular opinion, this work derives a model that can postdict prior attitude attribution results, and that fits newly-collected data. Though the correspondence bias can be seen when people's attributions are compared to the ground truth, this work suggests that these attributions could be internally consistent with other beliefs and perceptions that people have. Future work should investigate why these beliefs (e.g., about how people respond to requests) and perceptions (e.g., of the request strength or the essay extremity) don't match reality. The likelihood model could also be extended to encompass other essay features, such as argument quality (cf. Miller & Rorer, 1982; Gawronski, 2003).

Early in the history of correspondence bias research, Jones et al. (1971) conceded that correspondent inferences for constrained behavior are only wrong if every person in that situation would comply. Short of this extreme, they say that "it would be very difficult if not impossible to determine whether [a correspondent inference] should be judged as attributional distortion" (p. 77). The model presented here helps answer this question by encoding a set of assumptions mathematically, and then using the logic of Bayes' rule to understand the implications of those assumptions. It is likely that many attitude attribution findings can fruitfully be reexamined in light of the added precision that this model provides.

Abstract

This study investigates the roles of cohesion and coherence in evaluations of essay quality. Cohesion generally has a facilitative effect on text comprehension and is assumed to be related to essay coherence. By contrast, recent studies of essay writing have demonstrated that computational indices of cohesion are not predictive of evaluations of writing quality. This study investigates expert ratings of individual text features, including coherence, in order to examine their relation to evaluations of holistic essay quality. The results suggest that coherence is an important attribute of overall essay quality, but that expert raters evaluate coherence based on the absence of cohesive cues in the essays rather than their presence. This finding has important implications for text understanding and the role of coherence in writing quality.

Keywords: Coherence; Writing Quality; Cohesion, Linguistics, Computational Algorithms, Models.

Introduction

Writing affords the opportunity to thoroughly articulate ideas and synthesize a variety of perspectives allowing for persuasive communication that transcends both time and space (Crowhurst, 1990). As such, the ability to convey meaning proficiently in written texts is a critical skill for academic and professional success. Indeed, college freshmen' writing skills are among the best predictors of academic success (Geiser & Studley, 2001), and even outside of academia, writing skills continue to be important and are an important attribute of professional competence (Light 2001). As such, developing a better understanding of good and poor writing is an important objective, both for theoretical and applied reasons.

The overarching objective of this study is on the identification of essay features that are predictive of overall writing quality. Our goal is to better understand and model writing proficiency. We are particularly interested in the roles that cohesion and coherence play in writing quality. Cohesion refers to the presence or absence of explicit cues in the text that allow the reader to make connections between the ideas in the text. For example, overlapping words and concepts between sentences indicate that the same ideas are being referred to across sentences. Likewise, connectives such as *because*, *therefore*, and *consequently*, inform the reader that there are relationships between ideas and the nature of those relationships. Whereas cohesion refers to the explicit cues in the text, *coherence* refers to the understanding that the reader derives from the text, which

may be more or less coherent depending on a number of factors, such as prior knowledge and reading skill (McNamara, Kintsch, Songer, & Kintsch, 1996; O'Reilly & McNamara, 2007).

There is a strongly held sense that essay quality is highly related to the cohesion and coherence of the essay. This is reflected in the literature about writing (e.g., Collins, 1998; DeVillez, 2003), as well as textbooks that teach students how to write (Golightly & Sanders, 1990). However, there are few studies that have empirically investigated the role of cohesion cues and by consequence, coherence, in essays. Whereas there is a strong assumption that coherence is an important aspect of writing, few studies have documented this assumption or tied the notion of coherence to explicit linguistic features of the essay. Indeed, our own examinations of linguistic features of good and poor essays have turned up no evidence that cohesion cues are positively related to essay quality for either first language writers (McNamara, Crossley, & McCarthy, 2010) or writers for whom English is their second language (Crossley & McNamara, in press). Therefore, the question of whether coherence or cohesion play important roles in essay writing and judgments of essay quality remains open.

In contrast, the role of cohesion in text comprehension is much better understood and there are numerous empirical studies on the topic (for a recent review, see McNamara, Louwerse, McCarthy, & Graesser, 2010). These studies show that increasing the cohesion of a text facilitates and improves text comprehension for many readers (Gernsbacher, 1990) and is particularly crucial for low-knowledge readers (McNamara et al., 1996).

From this literature on text comprehension, we glean two competing hypotheses for the effects of cohesion on estimates of essay quality (i.e., the coherence of the essay in the mind of the essay rater). On the one hand, cohesion underlies coherence, and thus should be important. On the other hand, the effects of cohesion on comprehension depend on the knowledge and reading skill of the reader. Indeed, a reverse cohesion effect, or an advantage for low cohesion text, can occur for high knowledge readers (McNamara, 2001; McNamara et al., 1996; O'Reilly & McNamara, 2007). High-knowledge readers, unlike low-knowledge readers, can successfully make the inferences needed to bridge the conceptual gaps that are in low-cohesion text. In fact, high-knowledge readers may benefit from low cohesion texts because gaps in cohesion force the reader to make connections in text that are not explicitly

available (McNamara, 2001; O'Reilly & McNamara, 2007). Hence, when the material covered in a text is familiar to the reader (as is often the case for narratives), cohesion cues may be unnecessary, and perhaps even distracting. Overall, text comprehension literature leads to the conclusion that cohesion may play an important role in facilitating coherence if the rater of the essay has less knowledge about the topic, but cohesion cues may be inversely related to essay scores if the rater has more knowledge about the topic.

We recently explored this topic by examining the effects of cohesion devices on human evaluations of writing quality. McNamara et al (2010) used linguistic indices of cohesion and language sophistication provided by the computational tool Coh-Metrix (Graesser, McNamara, Louwerse, & Cai, 2004) to analyze a corpus of 120 argumentative essays written by college undergraduate and scored by expert raters using a holistic rubric. The essays were scored on a 1-6 scaled SAT rubric and then categorized into two groups: essays judged as low versus high quality. The results indicated that there were no differences between these two groups according to indices of cohesion (e.g., word overlap, causality, connectives). By contrast, indices related to language sophistication (lexical diversity, word frequency, and syntactic complexity) showed significant differences between the groups. A follow-up discriminant function analysis (DFA) showed that these indices successfully classified the essays into their respective groups at a level well above chance. The results of the McNamara et al. study provide initial indications that text cohesion may not be indicative of essay quality. Instead, expert raters in the McNamara et al. study judged essays as higher quality when they were more difficult to process (less familiar words, more complex syntax).

While McNamara et al. (2010) showed that cohesion cues were not related to the overall scores assigned by essay raters, it did not investigate the role of the raters' judgments of the coherence or cohesion of the essay, nor did it investigate whether cohesion cues are related to raters' judgments of coherence and cohesion. Hence the purpose of the current study is two-fold. First, we examine the assumption that judgments of essay coherence are predictive of the overall score for an essay. While this is a commonly held belief, we are aware of no empirical support for this assumption provided in the literature. Second, we examine whether cohesion cues as measured by Coh-Metrix are related to raters' estimates of an essay's coherence. Whereas McNamara et al. (2010) did not find a relation between indices of cohesion and the overall essay scores, it remains an open question as to whether cohesion indices might be related to more direct ratings of an essay's coherence.

Method

Our method of inquiry involves an analysis of argumentative essays by expert scorers on atomistic features of essay quality (i.e., introductions, thesis statement, topic sentences, relevance, coherence) as well as a holistic evaluation of essay quality. Thus, unlike McNamara et al.

(2010), we do not rely solely on computational indices to model overall essay quality, but instead concentrate on the evaluation of human judgments of individual text features in relation to overall text quality. Included in the individual text features evaluated by human experts are two measures of coherence. If the ratings of coherence are predictive of overall essay quality, we will also use computational indices of cohesion to model these human ratings. We can, thus, examine the importance of cohesion and coherence in writing quality and examine which cohesive devices may be predictive of human ratings of coherence. Such an analysis will also afford the opportunity to examine whether indices of cohesion correlate with human ratings of coherence, providing us with an opportunity to gain a better understanding of the role cohesion plays in high-knowledge readers (i.e., the expert raters in our study).

Corpus

As in McNamara et al. (2010), our analyses were conducted using a corpus of essays collected from undergraduate students at Mississippi State University (MSU). The MSU corpus was designed to account for learner variables such as age (adult students) and learning context (freshman college composition class). The corpus was also designed to consider task variables such as medium (writing), first language (English), genre (argumentative essays), essay length (between 500 and 1,000 words), and topics (3 prompts on equality, television, and creativity). The final corpus consisted of 184 essays. The essays were untimed and written outside of the classroom. Thus, referencing of outside sources was allowed, but was not required. Students were allowed to select the essay prompt. Therefore, there are an unequal number of essays per prompt. Although 100 of the essays used in our current analysis were also used in the McNamara et al. study, these 100 essays were evaluated by different raters in the current study. The raters used both an atomistic and holistic survey instrument.

Rating Rubric

The essay-rating rubric used in this analysis was designed to parallel the rubric used initially by Breetvelt, van den Bergh, and Rijlaarsdam (1994) and later adapted with a focus on structure and argumentation by Sanders and Schilperoord (2006). Three experts in language processing with Ph.D.s in either linguistics or cognitive psychology developed the rubric. It was then subjected to usability tests by expert raters with at least three years experience in essay scoring. The final version of the survey instrument has three subsections: structure, content, and conclusion. The structure subsection contains questions related to essay structure and continuity. The content subsection contains questions related to the introduction, thesis, coherence, topic and evidential sentences, relevance, register use, and mechanics. The conclusion subsection contained questions related to the conclusion type, conclusion summary, and closing. In addition, the survey instrument included a holistic grading scale based on a standardized rubric

commonly used in assessing Scholastic Achievement Test (SAT) essays. This holistic scale was the same scale used by McNamara and colleagues (2010). The holistic scale and all of the rubric items had a minimum score of 1 and a maximum score of 6. The atomistic rubric ratings included the following:

Structure: Clarity of division into introductions, argumentation, and conclusion.

Continuity: Strength of connection of ideas and themes within and between the essays' paragraphs (cohesion).

Introduction: Presence of a clear, introductory sentence.

Thesis Statement: Strength of the thesis statement and its attached arguments.

Reader Orientation: Overall coherence and ease of understanding.

Topic Sentences: Presence of identifiable topic sentences in argumentative paragraphs.

Evidential Sentences: Use of evidential sentences in the argumentative paragraphs that support the topic sentence or paragraph purpose.

Relevance: Degree to which argumentation in the paper contained only relevant information.

Appropriate Registers: Degree to which the vocabulary in the essays followed the expected register.

Grammar, Spelling, and Punctuation: Accuracy of grammar, spelling, and punctuation.

Conclusion: Clarity of the conclusion.

Conclusion Type: Identifiable conclusion type.

Conclusion Summary: Presence of summary within the conclusion including arguments and the thesis of the essay.

Closing: Clarity of closing statements within the essay.

Essay Evaluation

Two expert raters with master's degrees in English and at least 3 years experience teaching composition classes at a large university rated the 184 essays from the corpus using the rubric. The raters were informed that the distance between each score was equal. Accordingly, a score of 5 is as far above a score of 4 as a score of 2 is above a score of 1. The raters were first trained to use the rubric with 20 essays. A Pearson correlation for each rubric evaluation was conducted between the raters' responses. If the correlations between the raters did not exceed $r = .50$ (which was significant at $p < .05$) on all items, the ratings were reexamined until scores reached the $r = .50$ threshold. Raters followed similar protocol for the holistic score, but were expected to reach an $r \geq .70$.

After the raters had reached an inter-rater reliability of at least $r = .50$ ($r = .70$ for the holistic score), each rater then evaluated the 184 essays that comprise the corpus used in this study. Once final ratings were collected, differences between the raters were calculated. If the difference in ratings on survey feature were less than 2, an average score was computed. If the difference was greater than 2, a third expert rater adjudicated the final rating. Correlations between the raters (before adjudication) are located in Table

1. The raters had the lowest correlations for judgments of continuity and the highest correlations for essay structure.

Table 1: Pearson Correlations between Raters

Item	<i>r</i>
Structure	0.647
Continuity	0.307
Introduction	0.330
Thesis Statement	0.513
Reader Orientation	0.367
Topic Sentences	0.510
Evidential Sentences	0.404
Relevance	0.306
Appropriate Registers	0.394
Grammar, Spelling, Punctuation	0.599
Conclusion	0.596
Conclusion Type	0.355
Conclusion Summary	0.525
Closing	0.445
Holistic Score	0.533

Results

We used a multiple regression analysis to examine the predictive strength of the atomistic writing features in explaining the scoring variance in the holistic scores assigned to the essays. We used a training set to generate a model to examine the amount of variance explained by each writing feature. The model was then applied to a test set to calculate the accuracy of the analysis. Accordingly, we randomly divided the corpus into two sets: a training set ($n = 123$) and a test set ($n = 61$). The training set was used to identify which of the atomistic features most highly correlated with the holistic scores assigned to the essays. These features were later used to predict the holistic scores in the training and test sets using the generated model.

We controlled the number of variables included in the regression analysis in order to reduce the likelihood that the model was over-fitted. If too many variables are used, the model fits not only the signal of the predictors, but also the unwanted noise. The model may, thus, lack accuracy when applied to a new data set. We selected a ratio of 15 observations to 1 predictor, which is standard for analyses of this kind (Field, 2005). Given that the training set contained 123 essays, we determined that we could include eight features in our regression analysis.

Pearson Correlations

All features on the rubric correlated significantly with the holistic scores assigned to the essays in the training set. The strongest correlations were for Reader Orientation (coherence), Relevance, and Continuity (cohesion). The weakest correlations were for Thesis, Conclusion, and Introduction. All the features along with their r values are presented in Table 2 (all $p < .001$).

Table 2: Pearson Correlations Atomistic to Holistic Scores

Variable	<i>r</i> value
Reader Orientation	0.803
Relevance	0.710
Continuity	0.650
Conclusion Type	0.640
Structure	0.633
Evidential Sentences	0.629
Grammar, Spelling, & Punctuation	0.590
Appropriate Registers	0.589
Topic Sentences	0.583
Closing	0.578
Conclusion Summary	0.551
Thesis Statement	0.548
Conclusion	0.526
Introduction	0.389

Collinearity

The features Structure and Conclusion were both highly correlated ($> .70$) with the feature Conclusion Type. Because both of these features had lower correlations with the holistic score as compared to Conclusion Type, the Structure and Conclusion variables were dropped from the multiple regression analysis. Thus only the variables Reader Orientation, Relevance, Continuity, Conclusion Type, Evidential Sentences, Grammar, Spelling, & Punctuation, Appropriate Registers, and Topic Sentences were included in the regression.

Multiple Regression Training Set

A linear regression analysis (stepwise) was conducted including the eight variables. These eight variables were regressed onto the raters' holistic evaluations for the 123 writing samples in the training set. The variables were checked for outliers and multicollinearity. Coefficients were checked for both variance inflation factors (VIF) values and tolerance. All VIF values were at about 1 and all tolerance levels were well beyond the .2 threshold, indicating that the

model data did not suffer from multicollinearity (Field, 2005).

Five variables were significant predictors in the regression: Reader Orientation ($t = 6.668, p < .001$) Conclusion Types ($t = 5.068, p < .001$), Evidential Sentences ($t = 3.495, p < .001$), Topic Sentences ($t = 3.180, p < .010$), and Appropriate Registers ($t = -1.419, p < .050$). Three variables were not significant predictors: Relevance ($t = 1.841, p > .050$), Continuity ($t = 1.760, p > .050$), and Grammar, Spelling, & Punctuation ($t = 1.486, p > .050$). The latter variables were left out of the subsequent analysis. The linear regression using the eight variables yielded a significant model, $F(5, 117) = 89.693, p < .001, r = .891, r^2 = .793$, demonstrating that the combination of the five variables accounts for 79% of the variance in the human evaluations essay quality for the 123 essays examined in the training set. All the features retained in the regression analysis along with their r values, r^2 values, unstandardized Beta weights, standardized Beta weights, and standard errors are presented in Table 3.

Test Set Model

To further support the results from the multiple regression conducted on the training set, we used the B weights and the constant from the training set multiple regression analysis to estimate how well the model would function on an independent data set (the 61 essays and their holistic scores held back in the test set). The model produced an estimated value for each writing sample in the test set. We used this correlation along with its r^2 to demonstrate the strength of the model on an independent data set. The model for the test set yielded $r = .922, r^2 = .850$. The results from the test set model demonstrate that the combination of the five variables accounted for 85% of the variance in the evaluation of the 61 essays comprising the test set.

Linguistic Features Analysis

Our regression analysis demonstrated that text coherence is an important predictor of human judgments of essay quality. Our subsequent goal was to identify which linguistic features are attributable to the coherence construct used by the human raters.

Table 3: Linear Regression Analysis to Predict Essay Ratings Training Set

Entry	Variable Added	R	R^2	<i>B</i>	B	SE
Entry 1	Reader Orientation	0.803	0.645	0.458	0.413	0.069
Entry 2	Conclusion Type	0.850	0.723	0.296	0.257	0.058
Entry 3	Evidential Sentences	0.871	0.758	0.271	0.182	0.078
Entry 4	Topic Sentences	0.882	0.778	0.222	0.160	0.070
Entry 5	Registers	0.891	0.793	0.201	0.152	0.069

Notes: Estimated Constant Term is 23.79; *B* is unstandardized Beta; B is standardized Beta; SE is standard error

To accomplish this goal, we conducted an analysis of the Reader Orientation scores using computational indices provided by Coh-Metrix that have theoretical correlates with cohesion features. Our goal in this second analysis is to examine if computational indices related to cohesion can successfully model the human coherence ratings from our essay analysis. We used the same corpus as the principle study, but concentrated solely on the human ratings for the Reader Orientation item (i.e., the coherence feature that was predictive of overall essay quality).

We selected a range of measures related to cohesion from the Coh-Metrix tool. The constructs measured included semantic coreference (LSA indices), causal cohesion, spatial cohesion, temporal cohesion, connectives and logical operators, anaphoric resolution, word overlap, and lexical diversity (see Crossley & McNamara, 2009; Graesser et al., 2004, for an overview of the cohesion indices in Coh-Metrix). Each construct was measured using multiple Coh-Metrix indices.

We first divided the corpus into a training (N = 123) and test set (N= 61). We then conducted Pearson correlations to relationships between the Coh-Metrix Indices and the human ratings of coherence.

Pearson Correlations. Among the selected cohesion constructs, only a few reported multiple indices that demonstrated significant correlations with the human ratings of coherence. The constructs that reported multiple significant indices included anaphoric reference (i.e., the proportion of anaphoric references between sentences), causal cohesion (i.e., the incidence of causal verbs and particles), incidence of connectives (i.e., positive temporal connectives, subordinating conjunctions, causative subordinators), and overlap measures (the overlap nouns, stems, and arguments between sentences). However, these correlations were negative (with the exception of Subordinating Conjunctions; i.e. *until*, *though*, *since*). Measures for semantic coreference, logical operators, lexical diversity, spatial cohesion, and temporal cohesion did not report significant indices. The indices with the highest correlations from the significant measures are presented in Table 3 along with their *r* and *p* values. The negative correlations indicate that the essays rated high in coherence included fewer cohesion cues.

Table 4: Correlations Coh-Metrix Indices to Raters' Coherence Scores

Variable	r value	p value
Anaphoric reference	-0.349	< .001
Ratio of causal particles and verbs	-0.259	< .010
Incidence of positive temporal connectives	-0.237	< .010
Subordinating conjunctions	0.240	< .010
Causative subordinators	-0.211	< .050
Content word overlap	-0.187	< .050

Discussion

This study has demonstrated that human ratings of coherence are an important indicator of holistic evaluations of essay proficiency. However, how human raters construct a coherent mental representation of a text seems opposed to many intuitive notions of coherence. For instance, we might expect that cohesive devices such as word overlap, causal particles and verbs, resolved anaphors, and positive temporal connectives would help the rater to develop a more coherent textual representation. However, in the case of the expert raters used in this study, the opposite was true. The absence of cohesive devices was associated with a more coherent mental representation of the text.

Our results indicate that coherence is an important element of human judgments of essay quality. In fact, overall text coherence is the most predictive feature of holistic essay scores. The coherence of a text (and by extension its understandability) was more predictive of writing quality than conclusion types, the use of evidential sentences, the use of topic sentences, and the use of appropriate registers. The overall coherence of a text was also the primary predictor of essay quality and explained 65% of the variance in the human ratings of writing quality. Human ratings of cohesion (continuity), although not retained in our regression analysis, also significantly correlated with essay quality.

However, our analysis using cohesion indices provided by Coh-Metrix demonstrated that our human judgments of coherence were not positively related to indices related to text cohesion indicating that cohesive devices may not underlie the development of coherent textual representations. Indeed, the majority of cohesive devices negatively correlated with human judgments of coherence. The exception is the use of subordinating conjunctions, which were positively correlated with human ratings of coherence. Yet, subordinating conjunctions also play a syntactic role and, by their nature, create more complex syntactic structures that result in a greater number of words before the main verb. Thus, it is likely that the subordinating conjunction index is actually detecting syntactic complexity, which does positively correlate with estimates of essay quality (McNamara et al., 2010).

So the question becomes: What factors are informing expert raters' mental representations of the text? One conclusion that the results of this study support is that factors important in text comprehension may have similarly important roles when raters evaluate the quality of essays. Specifically, the background knowledge of expert raters may influence text coherence in assessments of essay quality. Expert essay raters tend to be highly educated with advanced degrees and with experience in grading essays and other types of writing. The prompts used in the current study as well as prompts commonly used in essay writing assessments generally deal with topics that are relatively familiar to most educated individuals. As such, we can assume that essay raters will not tend to be low knowledge readers. Low knowledge readers lack sufficient knowledge

to generate inferences to bridge conceptual gaps in text, and, as a result, they tend to benefit from explicit text cohesion (i.e., word overlap, resolved anaphors, causal cohesion, connectives). By contrast, high knowledge readers benefit from texts low in cohesion because the cohesion gaps in the texts induce them to generate appropriate inferences to fill in the conceptual gaps. High knowledge readers can do this successfully because they have sufficient background knowledge to make appropriate inferences. When successful inferences are generated, the coherence of the mental representation can increase due to connections between the new information and their prior knowledge (McNamara, 2001; McNamara & McDaniel, 2004; O'Reilly & McNamara, 2007). Thus, more cohesive devices in essays may produce a less coherent mental representation in expert raters.

Conclusion

We conclude that coherence is an important attribute of writing quality. Essay raters' evaluations of coherence were highly related to their overall holistic scores for the essays. Nonetheless, we have found here that coherence is not necessarily defined through the use cohesion devices, and in fact may be inversely related to the presence of cohesion cues. Thus, the question becomes: What textual features of an essay lead to higher versus lower estimates of essay coherence? Our results demonstrate that the indices currently available from which to measure cohesion are not strongly linked to human judgments of coherence. However, it is highly unlikely that textual features do not affect coherence. Thus, our task becomes the identification of these features and the derivation of computational algorithms that accurately model them.

Acknowledgments

This research was supported in part by the Institute for Education Sciences (IES R305A080589 and IES R305G20018-02). Ideas expressed in this material are those of the authors and do not necessarily reflect the views of the IES. The authors would like to thank Brad Campbell and Daniel White for their help in scoring the corpus of essays.

An acquired taste: How reading literature affects sensitivity to word distributions when judging literary texts

Justine Kao, Robert Ryan, Melody Dye & Michael Ramscar

Department of Psychology, Stanford University,
Jordan Hall, Stanford, CA 94305

Abstract

This study examines how reading habits affect people's sensitivity to word distributions in literary and non-literary writing. We manipulated eight literary and non-literary passages, creating modified versions that had lower word chunk frequencies but higher individual word frequencies than the originals. Subjects were then asked to rate the passages' quality of writing. Results showed that subjects with more experience reading literary writing (literary readers) gave higher ratings to original literary passages, while subjects with less literary reading experience (non-literary readers) preferred modified versions. Subjects with both types of reading habits rated original versions of non-literary passages higher. This indicates that literary readers are sensitive to frequencies of word chunks containing words that appear more frequently in the literary genre, while non-literary readers are not. We suggest that, over time, people can acquire slightly different representations of the probabilistic structure of language through their specific linguistic exposure.

Introduction

With one careful, calculated sip, a wine connoisseur can detect the subtle differences of quality between wines, and may even note the year and vineyard in which the grapes were grown. We, on the other hand, may stumble upon a thirty-year-old Bordeaux and not be able to tell it apart from a ten-dollar bottle. Appreciation for wine, like appreciation for high fashion or opera, is an acquired skill. Many fine things in life require years of experience to generate true appreciation. In what follows, we ask whether or not this "connoisseur phenomenon" translates to appreciation for literature as well. Is the ability to detect skill and beauty in literature also an acquired taste? If so, what is being acquired through the act of reading? Will avid readers have a stronger appreciation for good-quality writing, or be more sensitive to subtle changes of word choice?

As writing becomes an increasingly important form of communication and a central aspect of our lives, many studies have been conducted on the ways in which we are affected by what we read. Previous research shows that frequent readers are more sensitive to ambiguities in literary texts and are more likely to provide nuanced interpretations of them than infrequent readers (Dixon et al., 1993). Further, students who read recreationally perform better on

reading comprehension and vocabulary tests (Anderson et al., 1988; Capielwski & Stanovich, 1992), suggesting a relationship between reading enjoyment and competence. Still another study shows that frequent readers of literary writing have higher empathy and social measures than readers of non-literary writing (Mar et al., 2006). These results suggest that certain effects on our social, reasoning, and linguistic skills may be closely connected to the kinds of reading we engage in.

While these studies focus on higher-order social and cognitive effects of reading, we are interested here in examining how reading shapes readers' sensitivity to distributions of words. More specifically, we seek to explore whether readers' experience reading literary or non-literary writing shapes their sensitivities to word and chunk frequencies, and further, whether these fine-tuned sensitivities affect their judgments of quality when rating texts from different genres.

The Probabilistic Nature of Natural Languages

A slew of recent studies have shown that language users are sensitive to the distributional patterns of sounds, words, and even larger linguistic structures such as word sequences, or word 'chunks,' in the language they speak (see e.g., Altmann & Steedman, 1988; Bell et al., 2009; Bod et al., 2003; Bybee, 2002, 2006; Bybee & Hopper, 2001; De Long et al., 2005; Hale, 2003; Levy, 2008; Otten & Van Berkum, 2008; Pierrehumbert 2001, 2003; Ramscar et al., in press; Perruchet & Pacteau, 1990; Servan-Schreiber & Anderson, 1990). In many ways, the idea that we pay attention to how words are used is hardly surprising. It seems obvious, for example, that "a daunting task" sounds more "right," or more familiar, than "a daunting job." In fact, although *job* is a much higher frequency word than *task*, "a daunting task" appears 191 times on the Corpus of Contemporary American English (COCA), while "a daunting job" occurs only 6 times. We are sensitive to the different frequencies of the two chunks and prefer the one with the higher frequency. Since there is no real reason why it is less appropriate to describe a job as daunting, the preference for "a daunting task" over "a daunting job" does not seem to be driven by the appropriateness of the phrases' inherent meanings, but rather how the words are usually used.

The reason why we can sense these subtle mismatches is because words do not co-occur with each other with equal frequency. Indeed, the distribution of words in languages is

highly systematic (Baayen, 2001), and listeners are clearly sensitive to how words co-occur in sensible, and less sensible ways (see e.g., Wicha, Bates, Moreno, & Kutas, 2003). These kinds of co-occurrence patterns offer a rich and readily available source of information for anyone learning to understand the way that language relates to the world, and there is considerable evidence to support the idea that people are sensitive to this information.

However, it is critical to note that every person's internal model of his or her language is trained on a slightly different corpus. In other words, each person hears and reads different things throughout his or her life, and over time these differences in the input may result in different representations of the language. In written language, for example, genres of writing have been observed to differ on a number of linguistic dimensions. Research on corpus comparison and genre detection makes use of the idea that word distributions – how words are used and which words are used – differ across genres (Biber 1988, 1993; Eisenbeis & Avery, 1972; Karlgren & Cutting, 1994; Lee & Myaeng, 2002, Xiao & McEnery, 2005). Work in literary theory has also suggested that literary texts often use low-frequency words to foreground certain elements of writing (Miall & Kuiken, 1994, Mukarovský, 1964), while non-literary texts tend to use more conventional words to convey meaning clearly. Given that there is marked variation in the distributions of words that people will be exposed to over the course of their lives, it seems likely that people will have different sensitivities to word distributions depending on their “training sets.” We examine this possibility through the lens of writing genres.

‘Literary’ and ‘Non-literary’ Words

For our purposes here, we class writing into two primary domains: literary and non-literary. Much of what people read can be identified as one of the two, with fiction and poetry belonging to the former category, and newspaper articles and textbooks to the latter. Based on whether a word occurs more frequently in literary writing or non-literary writing, we can refer to it as a ‘literary’ word or a ‘non-literary’ word. For example, “abruptly” is a literary word (37 per million in the fiction corpus and 6.7 per million in the newspaper corpus), while “actively” is a non-literary word (2.54 per million in fiction and 9.97 in newspapers) (Corpus of Contemporary American English (COCA)).

As we will illustrate in a later section, literary texts tend to contain more literary words, while non-literary texts tend to contain more non-literary words. Since literary and non-literary words are *defined* by how often they occur overall in literary and non-literary writing, this may not seem entirely surprising. However, it sheds light on the deeper point that the words in a given piece of writing will have different distributions depending on the corpus you examine (e.g., the frequency and usage of “abruptly” will differ sharply between a “non-literary” newspaper corpus and a “literary” fiction corpus).

This has implications for how people may be affected by their reading practices. Given that some people's reading habits may make them more familiar with one “corpus” than another (i.e., they may be more widely read newspapers and journal articles than fiction and poetry), this difference in exposure should translate into a corresponding difference in their probabilistic representation of the distributions of words within their language. In other words, readers within different genres will have learned somewhat different distributional patterns, and these differences should be similar to the ones that we can actually research and quantify by analyzing different corpora.

This leads to testable predictions. For example, we would expect that literary readers would be more sensitive to the probabilistic distributions of literary words than non-literary readers, and we would also expect them to have a better understanding of the environment – or linguistic context – in which such words are likely to occur. Thus, they should show higher sensitivity than non-literary readers to the frequencies of *chunks* of words in literary texts.

Reading Habits and Judgment: Experiment

In order to test the predictions detailed above, we selected four excerpts of choice contemporary fiction writing and four excerpts of non-literary writing. We then systematically manipulated the frequencies of several chunks (short sequences of words) within each passage, creating modified versions of each of the eight passages. Our method of modification is detailed in the section “Manipulation of passages.” After creating the 8 modified versions, we had 16 testing passages total: 4 literary and 4 non-literary *original* passages, which contain higher overall chunk frequencies but lower overall word frequencies, and 4 literary and 4 non-literary *modified* passages, which contain lower overall chunk frequencies but higher overall word frequencies. We hope to examine whether subjects' evaluations of writing quality differ for the original and modified versions, and further whether literary and non-literary readers' evaluation of literary and non-literary texts also diverge.

We hypothesize that for literary texts, literary readers will give higher ratings to literary passages containing chunks that have higher frequencies, because these chunks will be more familiar in the corpus they have been trained on, and thus more representative of their internal models of language (e.g., they should recognize “adamantine luster” as a frequent literary pairing and prefer it over “adamantine milk,” which is not a frequent literary pairing). By contrast, we hypothesize that non-literary readers, who lack the same levels of exposure to ‘literary’ words and their contexts, will only be sensitive to individual word frequencies, and will prefer more highly frequent words even when they are used in contexts (e.g., “adamantine milk”) that would seem anomalous or even jarring to a literary reader. In terms of quality ratings, this suggests that literary readers will prefer the original literary passages with higher chunk frequencies,

whereas non-literary readers will prefer the modified literary passages with higher individual word frequencies.

With regards to the non-literary texts, the picture is less clear. It may be that we should expect the opposite effect: that literary readers will prefer modified passages while non-literary readers will prefer the originals. However, it also seems likely that our literary readers, who read for pleasure, may read more widely than our non-literary readers, and be sensitive to our non-literary manipulations as well.

Participants

Participants were 31 Stanford University undergraduates recruited for credit for an introductory psychology course. All subjects were monolingual English speakers.

Materials

Four excerpts from literary writing and four excerpts from non-literary writing, each ranging from 80 to 130 words in length, were selected as materials. The literary passages were selected from four separate stories in *“The Vintage Book of Contemporary American Short Stories,”* a collection of short stories featuring distinctive short fiction in American English published within the last 25 years. Three journalistic, or non-literary, English passages were selected from articles in the New York Times during the past year, and one non-literary passage was chosen from a reading comprehension article in a 2009 GRE prep book. Passages from each genre varied in style and content. We chose materials from these sources because they reflect high quality of writing, offer a variety of styles and themes, and are not famous or widely enough read to be likely to be recognized by our subjects during the survey.

Methods

Assessment of Passages

To explore the degree to which literary texts tend to contain more literary words and non-literary texts tend to contain more non-literary words, we examined the 400 million word COCA corpus (Davies, 2009) recording the frequency of each word in each passage in the fiction corpus, the newspaper corpus, and the corpus as a whole. The average log frequencies of the passages in the three corpora are shown in figure 1. This analysis revealed that within the specific corpora, the literary passages had significantly higher average frequencies in the fiction corpus than in the newspaper corpus ($t(670)=2.3148$; $p < 0.05$) whereas the average frequencies of the non-literary texts in the fiction and newspaper corpora were not significantly different ($t(584)=-1.0288$; $p>0.05$). This suggests that words occurring in literary texts are more frequent in literary than non-literary texts, while words in non-literary texts are more evenly distributed across literary and non-literary texts. This idea is supported by an analysis of the overall corpus, which revealed the literary passages to have higher average frequencies than the non-literary passages

($t(627)=2.2786$; $p<0.05$). Together these findings suggest that literary texts make specialized use of a specific subset of the overall corpus, rather than employ a markedly different vocabulary. Consistent with this idea, a 2 (literary versus non-literary text) \times 2 (fiction versus newspaper corpus) ANOVA of the average frequencies of the texts revealed an interaction between text type and corpus type ($F(1, 627)=13.324$, $p<0.001$), and a main effect of text type ($F(1,627)=121.926$, $p<0.001$).

A more fine-grained analysis of the texts further supported the idea that the distribution of vocabulary items is specialized in different kinds of writing. When we compared the pair-wise frequency of each word in each specific corpus, we found (unsurprisingly) that the pair-wise frequencies of the words in the literary passages were significantly higher in the corpus for fiction writing than in the corpus for newspaper writing ($t(335)=11.4987$; $p<0.001$), but also that the reverse was true for each of the words in non-fiction passages ($t(292)=-4.7295$; $p < 0.001$). In other words, what appears to set literary and non-literary writing apart is not that they make use of specialized sets of words, but rather that words are used in specialized ways in different kinds of writing, and, at least in this sample, the distribution of vocabulary within literary writing in English appears to be particularly distinctive.

Figure 1. Average log frequencies of passages in different corpora

Manipulation of Passages

After analyzing the passages, we then manipulated the frequencies of three to seven chunks (strings of words) within each literary and non-literary passage, lowering chunk frequency while simultaneously retaining (or even raising) average individual word frequency. Measures of individual word frequency were taken from COCA, while chunk frequency was based on the number of ‘hits’ a chunk returned on Google. The reason why we used Google to measure chunk frequencies is because its magnitude allows us to find ‘hits’ for word sequences that are several words long, while many longer word sequences would return 0 counts even in large corpora like COCA, and thus fail to

measure the differences in frequencies of longer word chunks.

In the following example, (a) is the original chunk, and (b) is the modified chunk.

- (a) On the further *side* of the field¹
- (b) On the further *part* of the field

While *side* and *part* have highly similar meanings in this context, *side* has an average frequency of 317/ million in COCA, while *part* has frequency of 479/ million, suggesting that *part* is a more frequent word in English than *side*.

In terms of chunk frequencies, “further side” returns 259,000 hits on Google, whereas “further part” returns 374,000 hits, suggesting that in English, “part” is more likely than “side” given “further” (Miller & Chomsky’s² famous point about the lack of evidence for specific strings in English can be illustrated by considering that there are insufficient instances of “part of” and “side of” in the 400 million words of COCA to facilitate an analysis). Finally, the highly frequent “of” is the most likely word to follow both “side” and “part” in English, and by both our COCA and Google measures, the likelihood of “of” given “part” is three times that of “side” (“part of” has 132176 Google hits compared to 40446 for “side of,” and “part of” occurs on average 330 times per million words in COCA, as compared to 101/million for “side of”).

Thus, the “average probabilities” of English suggest that, as a string of words, (b) is much more likely than (a). However, the original chunk (a) returned 898 hits on Google, while the modified chunk (b) returned 0 hits. Thus, although both (a) and (b) appear to be similar in meaning and equally “grammatical,” and although the average frequency of all words, and the average transitional probabilities between them in English as a whole are higher in (b), given that its chunk frequency is considerably lower, it appears that the likelihood of actually encountering (b) in English is lower than it is for (a).

Since we wished to manipulate word and chunk frequencies while keeping the meaning of the passages relatively constant, chunks were selected for modification in the manner just described based on whether or not they contained a word that could be replaced with a synonym that had a similar or higher frequency.

Procedure and design

All surveys were designed and distributed using the Qualtrics online survey software. Each survey had four literary and four non-literary passages, half of which were original excerpts, and half of which were modified as described in the section above. Two versions of the survey were distributed: either the odd-numbered passages were modified and the even-numbered passages were kept as the original, or vice versa. Participants were randomly assigned one of the two versions.

Participants were surveyed individually on a computer. They were asked to read the instructions in the survey carefully, and the time it took each subject to complete the survey was recorded to make sure they spent enough time reading the passages and answering questions.

Participants were presented with each passage in the same order and asked to read carefully. While each participant read the passages in the same order, the order of the passages was counterbalanced with respect to passage type. For example, in the version of the survey in which the odd-numbered passages were modified, the passages appeared in the order of: modified literary, original non-literary, modified literary, original literary, modified non-literary, original non-literary, modified non-literary, original literary. This design should weaken the effects of passage type ordering on subjects’ preferences.

After subjects finished reading the passage as a whole, the same passage appeared again, but this time with a selection highlighted. They were asked to rate the quality of the highlighted section on a 7-point scale, with 7 being “Very well-written,” and 1 being “Very poorly written.” Each passage was equally divided into three sections, separately highlighted and presented to the subjects for rating.

After participants finished reading and rating all eight passages, they were asked to provide an estimate of how many hours a week they usually spent reading literary texts (including poetry, magazine stories, creative non-fiction, and novels) and non-literary texts (including text books, newspaper articles, and academic papers). In order to arrive at a score of how much more experience each subject had reading literary writing compared to reading non-literary writing, the hours reading literary texts was divided by the hours reading non-literary texts, a ratio we will refer to as the ‘literary reading bias.’ We use this as our measure for subjects’ reading habits because it reflects the relative amount of time they read literary texts versus non-literary texts, which for our purposes is the salient feature of their reading habits.

Results

A repeated measures ANCOVA of participant ratings of the modified and non-modified passages with literary reading bias as a continuous covariate revealed a significant interaction between literary reading scores and within-genre preference ($F(1, 21) = 3.095$; $p < 0.05$; see figure 2). To facilitate further analysis, subjects were divided equally into two groups based on their literary reading bias, with subjects whose scores were above the median placed in one group, and subjects whose scores were below the median placed in the other. The within-genre preference of each subject was measured using the difference between his or her average ratings for original and modified passages of each genre. The two groups’ average preferences within each genre are shown in figure 2.

Further, participants who read more fiction relative to non-fiction writing showed a stronger preference for the

¹ Taken from “Emergency,” by Denis Johnson

² Miller & Chomsky, (1963)

unmodified literary texts compared to participants who read more non-fiction ($t(29) = 1.7377$; $p < 0.05$), and a one-sample t-test revealed that participants who read more fiction showed an overall preference for the original literary passages ($t(14) = 1.856$; $p < 0.05$). For non-literary passages, there was no significant difference between the within-genre preferences of subjects in the two groups ($t(29) = 0.6556$; $p > 0.5$), and while both groups showed a preference for the original non-literary passages, these preferences were not significant.

Figure 2. Literary and non-literary readers' preference for original passages in the two genres

Discussion

As predicted, there was a significant interaction between subjects' reading habits and their reading preferences. How might one explain these results?

Only people who are exposed to the distributional properties of those words in literary contexts appear be sensitive to our manipulations, which is consistent with our assessment of the passages, where we found that literary writing uses words in ways that are literary specific. On the other hand, both literary and non-literary readers were sensitive to the manipulation of non-literary passages. One reason may be that non-literary writing makes use of less specialized distributions, as shown in our corpus analysis. Literary writing can be thought of as a specialized form of writing that re-employs and expands upon distributional information also present in non-literary writing, which makes literary readers still reasonably familiar with the distributions of words in non-literary texts, whereas the same cannot necessarily be said for non-literary readers and literary texts. Another reason may be that our social and cultural lives naturally enforce a non-literary expertise on all readers, while literary expertise is more a matter of individual practice.

One potential weakness for our study was that we relied on self-report to measure our subjects' reading habits. There may be issues of accuracy in recall, given that subjects were trying to judge the exact number of hours they spent reading in a given week. For this reason, we used the

ratio between reported literary and non-literary reading hours as a means of comparing our subjects. This ratio should, at the very least, reflect the subject's subjective sense of how much time he or she devoted to reading literary writing relative to non-literary writing, and hopefully separates out fiction and poetry readers from magazine and front-page readers.

In future studies, it may be possible to use more "objective" measures of reading habits—for instance, by examining the number of literary and non-literary authors each subject can identify (Mar et al., 2006), or by having subjects track their reading habits over time. Alternatively, we might conduct a study in which we ask a certain group of subjects to exclusively read literary texts for an extended period, while having another group read exclusively non-literary texts, and then measure the effect.

Our preliminary findings on the subject suggest that each person's model of the language they speak may be affected and "trained" over time by the specific linguistic samples they encounter. Intriguingly, differences in these individual language models appear to correspond with differences in "subjective" perceptions and judgment. Here, we examined how prior reading exposure may affect our perception and judgments of reading new texts. If our findings generalize to different genres of writing, spoken language, or even other modes of art and communication, we may be able to begin to explain individual differences in judgment and perception, and also how one can acquire taste through experience.

Abstract

In spoken dialogue between people and machines, the computer must understand not only what the speaker means but also what she does not. The computer begins with a considerable disadvantage: even the best speech recognition technology can provide error-ridden transcriptions of human speech under real-world telephone conditions. The work recounted here examines how, and how well, people use context to interpret noisy transcribed utterances in a challenging domain. Models learned from this experiment highlight two aspects of this human skill: the ability to detect a context-supported match, and the ability to know when the quality of attempted matches is so poor that it should be questioned. These models can then be applied by a spoken dialogue system to find the correct interpretation of users' spoken requests, despite incorrect speech recognition.

Keywords: spoken dialogue systems; natural language processing; machine learning; Wizard of Oz studies, learning.

Introduction

A computer system intended to replicate a human skill faces two considerable limitations: it works from a different input modality and it is restricted to a preprogrammed set of alternative actions. The thesis of our work is that people should be studied for their skill at the target task as if they were similarly restricted, that is, as if they had only the system's input and alternatives. The domain of investigation here is a spoken dialogue system (*SDS*). Subjects were given the same data that would be available to the *SDS*: error-ridden strings representing transcribed speech plus a large database of possible matches (Passonneau et al., In Press). The resultant data was then used to identify the best performers, and to learn models of them destined for the system. There were two principal results. First, subjects ably guessed what the speaker meant, that is, they could often identify the correct item from the context provided by a database query on the error-ridden string. Second, the people most skilled at this task excelled because they could also identify what the speaker had *not* meant, that is, they knew when no item returned from the database was a correct match. Such recognition is essential to move dialogue forward constructively.

Ideally, an *SDS* offers people a natural way to communicate with a computer and benefit from its expertise. In an *SDS*, automated speech recognition (*ASR*) transcribes human spoken input into a string of words, which is then as-

signed an interpretation. Under real-world telephone conditions, however, even state-of-the-art *ASR* can exhibit a word error rate (*WER*) as high as 68% (Raux et al., 2005). High *WER* is common when the environment is noisy, the language the system is expected to understand is flexible and based on a large vocabulary, or the user population is diverse in gender, age, and native language. These are all characteristic of our target domain: telephoned book requests from patrons of the Andrew Heiskell Braille and Talking Books Library.

Although people manage dialogue well in the presence of noise, computers do not. Our subjects used *ASR* output from a spoken title to query our copy of Heiskell's book database. For example, for one book title, the *ASR* output string was "ROLL DWELL." A database query on this string returned three likely matches (in real time): "CROMWELL," "ROBERT LOWELL," and "ROAD TO WEALTH."

This is a difficult task. (The reader is invited to guess whether any of these actually matches the spoken title.) Our experiment studies how people manage this task. The resultant data is then used to train accurate models of human behavior, and to identify the features that make people proficient. Such models are ultimately intended as an integral part of an *SDS*, to make it more robust to noisy *ASR* in the context of database queries. The next sections of this paper describe related work, our target system, and the experimental design and results. These are followed by a description of the models learned from the data collected during the experiment, and a discussion of their import and application.

Related Work

The Wizard of Oz (*WOz*) paradigm is a well-known approach to iterative prototype design. It gathers information about the characteristics of a successful system before the system's development (Dix, et al. 2003). In a *WOz* experiment, only a user-system interface is provided. Users believe they are interacting with a computer system through this interface, but instead a person (the *wizard*) is "behind the curtain." This permits the system designer to observe human responses to certain system functionalities, to study user behavior and expectation, and to assess interface design features before the construction of an initial prototype.

WOz can also be used to study the wizard, to provide data on how the system should behave. In particular, *wizard ab-*

lation is a Woz study in which a wizard relies on system input and output rather than her own communication resources (Levin and Passonneau 2006). Wizard ablation supports the collection of dialogues that illustrate the decisions people make when confronted by the same input/output data and choices as an SDS. Data collected under wizard ablation supports supervised learning to predict wizard actions. The resultant model can then be incorporated into a system to improve its behavior. Woz studies that directed their attention to the wizard during full spoken dialogues include efforts to predict: the wizard's response when the user is not understood (Bohus 2004), the wizard's use of multimodal clarification strategies (Rieser and Lemon 2006), and the wizard's use of application-specific clarification strategies (Skantze 2005). The experiment presented here is restricted to single utterances, rather than full dialogues. It also differs in that it analyzes several wizards' behavior. It recognizes differences among wizards and identifies distinctive and successful behavior, so that the system will ultimately benefit only from models of the most skilled wizards.

To limit communication errors incurred by faulty ASR, an SDS may use enriched strategies to detect and respond to incorrect recognition output (Bohus 2004). It may repeatedly request user confirmation to avoid misunderstanding, or ask for confirmation using language that elicits responses from the user that the system can handle (Raux and Eskenazi 2004). When the user adds new information in response to a system prompt, two-pass recognition can consider the extra information contained in such user responses to restrict the language expected in the second pass and thereby achieve better recognition (Stoyanchev and Stent 2009). In a highly interactive setting, an SDS might benefit when it takes this approach one step further and uses context-specific language for incremental understanding of the noisy input throughout the dialog (Aist, et al. 2007). This paper explores the use of system-internal resources, such as a database search, to respond to faulty ASR. It embeds a wizard into a system, and then observes and models her ability to use such context to respond appropriately.

Peripherally related are other approaches that increase understanding between an SDS and the user through the adaptation of an SDS's response based on a user model. In automated tutoring, for example, it is essential to validate the user when she is correct and to elicit more reasoning when she is not (Franceschetti, et al. 2003, Ohlsson, et al. 2003). In particular, affect-adaptive systems can improve learning efficiency by responding to uncertainty in the transcribed speech (Forbes-Riley and Litman 2009).

Ordering Books with CheckItOut

CheckItOut is a research SDS for book requests from patrons of the Andrew Heiskell Braille and Talking Books Library, a branch of the New York Public Library and part of the National Library System. Patrons of the library request books by telephone and receive them by mail. Regular newsletters provide patrons with the titles and catalogue numbers of new books. To gauge the kinds of interactions

patrons have with Heiskell's librarians, we transcribed 82 telephone calls from a larger set we had recorded. Forty four percent of the book requests were by catalogue number, 28% by title or a combination of title and author, and 28% were more general. *CheckItOut* is therefore designed to accept book requests by catalogue number, author, or title.

CheckItOut builds upon the Olympus/Ravenclaw architecture and dialogue management framework (Bohus, et al. 2007, Bohus and Rudniky 2003). Olympus/Ravenclaw has been the basis for approximately a dozen research SDSs in different domains. During a dialogue with *CheckItOut*, the user first identifies herself as a patron of the library, and then requests at most four books. *CheckItOut* references two databases: a sanitized version of Heiskell's database of 5,028 patrons, and its entire book database with 71,166 titles and 28,031 authors. These force *CheckItOut* to manage a large vocabulary; titles and author names alone contribute 54,448 distinct words. Moreover, Heiskell's patrons include many elderly and non-native speakers. The experiment described next observes how human wizards respond to the same challenges that *CheckItOut* confronts.

Experimental Design

The experiment described here seeks to uncover how people marshal system resources (e.g., the ASR string and database results), and which strategies achieve the best performance. Here the focus is on single turn interactions that request books by title, the *CheckItOut* request type most likely to elicit problematic ASR output.

In an offline pilot study, 3 native speakers of English read 50 titles to generate 3 sets of ASR output strings (Passonneau, et al. 2009). Each subject received a different ASR set and was asked to find the corresponding title from a text file that listed all 71,166 titles. WER was 69% – 83%, depending on the speaker. Despite the high WER, these subjects identified the correct title 74% of the time.

Given this demonstration of human skill, we designed a Woz study to identify which aspects of human performance come into play when a wizard seeks to match noisy ASR against a list of *candidates* (possible title matches) (Passonneau et al. In Press). The experiment was designed to identify what makes a good wizard, and to extract any additional insights a wizard may offer when supported by database search with the quality common in modern systems.

During the experiment, users and wizards were isolated from one another in separate rooms. Each had her own graphical user interface (*GUI*) and microphone. In a *title cycle*, the user read a book title into a speech recognizer through the microphone, and the corresponding ASR was displayed on the wizard's GUI. The wizard then formulated a query for the database. Once the search returned a list of candidates, the wizard had four options: make a *confident choice* among the candidates, make a *tentative choice* among the candidates, ask a *question* through her microphone, or *give up*. (Wizards were also permitted to ask the user to repeat the title, but were discouraged from doing so.) If the wizard chose a candidate, it then appeared on the us-

user's GUI, and the user scored it as correct or incorrect. That score was also displayed on the wizard's GUI, so that the wizard knew if her most recent title choice was correct or incorrect. If the wizard asked a question instead, the user heard it through her headset and rated it on her GUI. The possible ratings with respect to the current book request were "relevant and I can answer it," "relevant but I cannot answer it," irrelevant," and "uncertain." Question ratings were not shared with the wizard. After the wizard saw the user's score or was notified that the user had judged the question, the wizard signaled the beginning of a new cycle.

The speech recognizer continually transcribed the speech signal from the user's microphone, and the wizard's GUI provided a live feed of the resultant ASR strings. For each request, the wizard submitted a database query after very limited editing of those strings (e.g., removing "um"). The return from the database was displayed on the wizard's GUI as a list of candidates in descending order of search confidence. This confidence was measured using Ratcliff/Obershelp pattern recognition (*R/O*) which evaluates the similarity of the ASR string to a book title from the database (Ratcliff and Metzner 1988). Confidence scores were not displayed on the wizard's GUI.

Given an ASR query, the database produced one of the four following kinds of returns, based on the *R/O* scores:

- *Singleton*: the single top-scoring candidate, if any were very good ($R/O \geq 0.85$)
- *AmbiguousList*: two to five moderately good candidates ($0.85 > R/O \geq 0.55$)
- *NoisyList*: six to nine poor but non-random candidates ($0.55 > R/O \geq 0.40$)
- *Empty*: No candidates ($\max R/O < 0.40$)

Our focus here is not on the database search, but on the wizard's actions given noisy ASR and an adequate but imperfect database return. Words in each candidate that exactly matched a word in the query appeared darkest on the GUI. All other words appeared in grayscale in proportion to their degree of character overlap with the words in the query.

Two of the seven subjects were non-native speakers of English (one Spanish, one Romanian). Each pair of students (a total of 21 possible pairs) met five times. In each meeting, one student was the user and the other was the wizard in a session of 20 title cycles. Then the pair immediately exchanged roles to run a second session of 20 title cycles. Thus, each student was the wizard on 100 title cycles and the user on 100 title cycles with every other student, for a possible 4200 title cycles in all. Users were permitted to end a session early after fewer than 20 title cycles if they experienced severe system problems.

Beyond the mechanics of this process, it was important to create a dialogue-like environment and to encourage the best possible performance from our subjects. To make her speech more conversational and less like simply reading a list, the user prepared immediately before each session. She read brief synopses of the 20 titles (chosen at random from the database) and then ordered them in some way (e.g., genre or theme) relevant to their content. To encourage

thoughtful decisions, no time limits were imposed upon either the wizard or the user. Finally, we devised a score that subjects were asked to maximize throughout the experiment, with prizes to be awarded for the top two scorers. The wizard scored +1 for a correctly identified title, +0.5 for a relevant question and -1 for an incorrect title. To encourage co-operation between users and wizards, the user also scored +0.5 for a successfully recognized title.

Results

The analysis in this section provides essential support for automatically learning models of intelligent behavior worthy of incorporation into an SDS. Given the permitted early termination, there were 4172 title cycles (instead of 4200). In them, the average WER was 69%. Nonetheless, the distribution of database returns was 46.7% Singleton, 53.26% AmbiguousList and 2.83% NoisyList. (Although in pilot tests 5% - 10% of the returns were empty, during the experiment itself none were.)

Figure 1 shows the overall distribution of wizard actions for our subjects, W1 through W7. Each of them saw a similar distribution of database returns: Singleton ($\mu = 278.57$, $\sigma = 21.16$), AmbiguousList ($\mu = 300.57$, $\sigma = 16.92$), and NoisyList ($\mu = 16.86$, $\sigma = 4.78$). The correct title was among the candidates returned by the database 71.31% of the time. Singleton returns were the correct title 92.05% of the time. AmbiguousList and NoisyList returns contained the correct title 53.74% of the time.

Ideally, a wizard should identify the correct title if it appears among the candidates, and otherwise ask a thoughtful question that could constructively advance the dialogue. As one might expect from our pilot study, wizards knew what the user meant when they saw it. If the correct title was among the candidates, wizards identified it confidently 68.72% of the time and tentatively 26.53% of the time — 95.25% in all. Recall, however, that AmbiguousLists and NoisyLists were sorted by search confidence. When the database returned multiple candidates, the top candidate was the correct title 41% of the time. It was second 5.81%, third 2.61%, fourth 2.20%, and later (fifth through ninth) 1.67% of the time. This did indeed help the wizards, who correctly offered the first title 98.34% of the time (74.24% confidently, and 24.10% tentatively). Of course, preference for

Figure 1: Distribution of wizard actions

the top returned candidate is readily programmed into an SDS. Instead we focus here on what wizards did when the title was not among the candidates.

Wizards were less skilled at recognizing what the user had not meant. Indeed, their performance differed primarily on their response when the correct title was not among the candidates — most wizards were less accurate then, and their performance was less uniform. Despite careful instructions to the subjects that had explained this option, wizards asked a question in only 22.32% of the cases where the correct title was not among the candidates. Instead they made a tentative guess (67.71%), chose confidently (7.78%), or gave up (2.20%). Table 1 shows each wizard’s number of title cycles, session score, and *accuracy*, the proportion of title cycles where she identified the correct title or correctly recognized that the title was not among the candidates (by asking a question or giving up). It also shows the frequencies with which she offered the top candidate and correctly recognized that the title was not among the candidates

Wizards are ranked in Table 1 in descending order of session score and accuracy. Those values are highly correlated ($R = 0.91$, $p = 0.0041$). W4 scored highest, primarily because of the frequency with which she asked a question when the candidates did not include the correct title (correct non-offers = 64%). Table 2 shows the distribution of what should have been the correct action across all 4172 title cycles. The correct action was either to offer the title as the correct candidate at a given position (Return 1 through Return 9) or to ask a question or give up when the title was not among the candidates. Table 2 makes clear that the simple strategy “always guess the top candidate” (as our wizards often did) would achieve about 65% accuracy. Note too that those wizards who relied on it most (W3 and W6) were also the least accurate overall, while the wizard who relied on it least (W4) was the most accurate. Clearly, given a reasonable but fallible database search on noisy ASR, an SDS should emulate W4, not simply choose the top candidate.

Learning to be Like a Wizard

Wizards collaborate with the SDS — the system manages input and output (except for the wizard’s questions), while the wizard exploits the available information (ASR string and database return) to make a decision. Our experimental design also captured data that described the system and the wizard’s session history. That data was then used to train models of wizard actions selection. Such models could be used to implement the best wizard behavior within an SDS.

The experiment collected data on 60 features available at run time, selected for their likely relevance to wizard action choices. They described the ASR (e.g., number of words in the ASR string), the recognition process (e.g., recognizer’s confidence score when it produced the ASR string), the speech signal (e.g., speech rate as number of 10ms speech fragments per word), the ability of the SDS to interpret the ASR string (e.g., number of parses in the natural language understanding component), and Olympus/ Ravenclaw confidence scores that combine recognition with language un-

Table 1: Raw session score, accuracy, proportion of offered titles listed first in the database search return, and frequency of correct non-offers for seven participants.

Subject	Cycles	Session score	Accuracy	Chose #1	Correct non-offer
W4	600	0.7585	0.8550	70%	64%
W5	600	0.7584	0.8133	76%	43%
W7	599	0.6971	0.7346	76%	14%
W1	593	0.6936	0.7319	79%	16%
W2	599	0.6703	0.7212	74%	10%
W3	581	0.6648	0.6954	81%	20%
W6	600	0.6103	0.6950	86%	3%

derstanding. (Much of this system information was not available to the wizard.) Other features described the session history (e.g., number of correctly identified titles so far), the database return (e.g., return type of Singleton, AmbiguousList, NoisyList), or the similarity between the ASR string and the candidates (e.g., number of matching words). Because the number of candidates differed across title cycles, these features were averaged over multiple candidates.

As a machine learning technique, we chose decision trees to model wizard behavior because they are easy to interpret and compare, and relatively transparent. A decision tree maps feature values to a target value (here, wizard action). A decision tree is a tree-like structure of nodes with directed links between them. Each node is a branch test based on feature values. To simulate the modeled behavior, a program traces a path from the *root* (the top node), following the branch tests until it reaches a *leaf*, a non-branch node that provides a target value. With a version of C4.5 (Quinlan 1993), we trained two kinds of decision-tree models: an *overall model* that used data from all the wizards to predict wizard action in general, and seven individual *wizard models*, one for each wizard.

Cross-correlation over the features indicated that many of the initial 60 features were heavily correlated. We manually isolated groups of correlated features with $R^2 > 0.5$, and retained only one representative feature from each group. We grouped features that described the similarity between ASR string and candidates, features that described the database

Table 2: Distribution of correct wizard actions

Correct action	N	%
Return 1	2722	65.2445
Return 2	126	3.0201
Return 3	56	1.3423
Return 4	46	1.1026
Return 5	26	0.6232
Return 6	0	0.0000
Return 7	7	0.1678
Return 8	1	0.0002
Return 9	2	0.0005
Question give up	1186	0.2843
Total	4172	1.0000

search returns, features that described confidence scores from various system components, and features that described the speech signal. This left 28 features. Before training each model we also ran CfsSubsetEval, an attribute selection algorithm that evaluates subsets of features based on both their individual predictive power and the degree of redundancy among them (Hall 1999). This further reduced the number of features to between 8 and 12 per model. (Many of the same features survived into more than one model.) To reduce overfitting, we also activated pruning to remove subtrees likely to provide little additional power because they cover too few training instances.

To confirm the learnability and quality of the decision trees, we also trained logistic regression and linear regression models on the same data. Here, regression captures the change in wizard action based on the changes in feature values (Witten and Frank 2005). Linear regression fits data to a linear function, and represents the wizard’s four actions numerically in decreasing value: confident choice, tentative choice, question, and give up. Logistic regression predicts the probability of an action based on fit to a logistic curve. This generalizes the linear model to predict categorical data, here, the wizard’s four actions. All models were produced with the Weka data mining package (Hall, et al. 2009) under 10-fold cross-validation.

Ability to predict wizard action was uniform across learning methods. On the overall model, logistic regression had 75.2% accuracy while the decision tree’s accuracy was 82.2%. The linear regression model had root mean squared error of 0.483, while the decision trees’ was 0.306. Predictive ability for the individual wizard models was similarly comparable. Thus the remainder of this discussion is restricted to decision trees.

Table 3 describes the learned models for individual wizards (ranked by wizard accuracy from Table 1). It shows size in number of nodes, number of included features, accuracy, and the F measure on confident choice. Note that model accuracy does not correlate with wizard rank; model accuracy indicates only how well the tree predicts the wizard’s action from the training data. The simplest wizard strategies (e.g., always select the top candidate) are clearly easier to predict, but not necessarily better. (Compare, for example, W4 and W6.)

Recall from Figure 1 that confident choice was more common than tentative choice, which was in turn more common than question or give up. As a result, the individual models consistently predicted a confident choice with $0.80 \leq$

$F \leq 0.87$, but less consistently predicted tentative choices with $0.60 \leq F \leq 0.89$, and could predict question only for W4, the top-scoring wizard who most often asked questions.

The features that appeared most often in the individual models primarily described the database return, the ASR string’s similarity to the candidates, the wizard’s recent performance, and the quality of the speech recognition and language understanding. (Note that the last two were not available to the wizard.) The five features that appeared most often at the root or top-level nodes were

- *ReturnType* (Singleton, AmbiguousList, NoisyList)
- *RecentSuccess*, how often the wizard had chosen the correct title within the last three title cycles
- *ContiguousWordMatch*, the maximum number of contiguous word matches between a candidate and the ASR string (averaged across candidates)
- *NumberOfCandidates*, how many candidates were returned by the database
- *Confidence*, an Olympus/Ravenclaw metric on confidence for recognition and language understanding

Careful inspection of the model for the most accurate wizard (W4) indicates that, if ReturnType was NoisyList, she asked a question. If ReturnType was AmbiguousList, her decision involved the five features above, plus the acoustic model score (another internal system measure that indicates the quality of the speech recognition), the length of the ASR string in words, the number of times the wizard asked the user to repeat, and the maximum size of the gap between matching words in the ASR string and the candidates. To further focus our analysis on W4’s distinctive behavior, we trained an additional decision tree to model how W4 chose between selecting a title and asking a question. The resulting model on 600 data points (each corresponds to a title cycle) consisted of 37 nodes and 8 features, with $F = .91$ for selecting a title and $F = 0.68$ for asking a question. The root of this tree differs from all other wizard models — it is the number of frames (10ms speech segments used to produce the ASR string), a measure of the length of the ASR. On short ASR strings (as measured both in number of frames and number of words) with AmbiguousList or NoisyList returns, W4 asked a question when $\text{RecentSuccess} \leq 1$ or $\text{ContiguousWordMatch} = 0$, and the acoustic model score was low. (Short titles are more readily confused.) On long ASR strings, W4 asked a question only when $\text{ContiguousWordMatch} \leq 1$, $\text{RecentSuccess} \leq 2$, and either the return was a NoisyList, or Confidence was low and there was more than one candidate. In summary, the factors that drove W4 to ask a question include the length of the ASR string, the quality of the ASR transcription, the database return type, the similarity between the ASR string and the candidates, and how well she had performed on recent title cycles. These can all be captured by system-internal features.

Discussion and Future Work

As used here, wizard ablation embeds a wizard within an SDS to study her choices when placed in the same environment as a machine. Given noisy ASR and the results of a

Table 3: Learned decision trees model individual wizards.

Tree	Rank	Size	Features	Accuracy	F conf
W4	1	55	12	75.67	0.85
W5	2	21	10	76.17	0.85
W1	3	7	8	80.44	0.87
W7	4	45	11	73.62	0.83
W3	5	33	10	77.42	0.84
W2	6	35	10	78.49	0.85
W6	7	23	10	85.19	0.80

database search, the best wizards do not always guess based on search return. Instead they sense that the knowledge they have is a poor fit with what the recognizer “heard.” In that case, a good wizard infers that the correct title is not among the returned candidates, and asks a thoughtful question to move the dialogue forward. (The mystery book at the beginning of this paper, by the way, was the third title listed.)

Experiments like this provide insight into how people match noisy input with returns from database search. The experimental design led wizards to prefer the first candidate listed — they read it first, and it was typically correct if the return included the correct title. Thus a wizard’s skill at finding the title when it is present is less noteworthy than W4’s ability to question the relevance of all the candidates.

The focus here has been on a single book request by title. Current work extends this approach to full dialogue. Wizards will see ASR and query results, and will have a pre-defined set of system-actions from which to choose. Dialogue interactions will include greeting, user identification, and four book requests by author and catalogue number, as well as by title. In full dialogue, context will have more relevance and can be measured more realistically by metrics in addition to RecentSuccess. Analysis of wizards’ questions from this experiment will motivate a pre-defined set of questions for wizards in the full dialogue study.

This work successfully learned models that predict wizard action primarily from system features. (The only prevalent wizard-specific feature was RecentSuccess, which is readily replaced by the system’s recent success.) Similar learned models will be incorporated into CheckItOut. Our next experiment will train models to predict wizards’ actions during full dialogue with our baseline version of CheckItOut, and then refine the system with the learned models. We predict that evaluation of the refined, wizard-informed CheckItOut will provide better performance.

Abstract

We introduce an approach for how spatial reasoning can be conceived as verbal reasoning. We describe a theory of how humans construct a mental representation given one-dimensional spatial relations. In this construction process objects are inserted in a dynamic structure called a “queue” which provides an implicit direction. The spatial interpretation of this direction can be chosen freely. This implies that choices in the process of constructing a mental representation influence the result of deductive spatial reasoning. To derive the precise rules for the construction process we employ the assumption that humans try to minimize their cognitive effort, and a cost measure is introduced to judge the efficiency of the construction process. From this we deduce how the queue should be constructed. We discuss empirical evidence for this approach as well as a computational implementation of the construction process.

Keywords: Verbal Reasoning; Spatial Reasoning; Mental Models; Cost Function; Computational Framework

Introduction

One dimensional spatial relations like “right of”, “left of”, “in front”, “behind”, “north of” have in common that they are transitive and, thereby, allow us to create a linear order between objects linked by one of these relations. Let us demonstrate this by an example. Consider the following two sentences, also called premises.

1. The apple is to the left of the mango.
2. The mango is to the left of the kiwi.

These premises allow us to create a linear order of the objects named in the premises, apple–mango–kiwi. This order enables us to draw conclusions about information not directly given in the premises: we can infer that the apple is to the left of the kiwi. The ability to infer information about relations between objects not explicitly yielded by the premises is the subject of theories about relational reasoning (cf. Johnson-Laird & Byrne, 1991; chapter 5). The bases of such inferences are internal representations that reflect information conveyed verbally by the premises. There are several theories on how

this is accomplished. Syntactic-based approaches (Braine & O’Brien, 1998; Rips, 1994; Hagert, 1984; Henst & Schaeken, 2005) suggest that the reasoning process is based on operations similar to the syntactic rules of formal logic. A set of rules is applied to draw inferences from given premises in order to derive new information implicitly provided by the premises. Model-based approaches, such as the mental model theory (MMT) on the other hand, suggest that reasoners infer new information by inspecting a mental model, representing the “state of affairs”, described by the premises (Johnson-Laird & Byrne, 1991).

Polk and Newell (1995), however, point out that the deduction process does not necessarily require deduction-specific mechanisms to operate on internal representations. Especially in reasoners that are not specifically trained on deductive reasoning more general cognitive mechanisms might guide the reasoning process. They introduced a third approach, called **verbal reasoning**, that assumes the cognitive processes in deductive reasoning to be based upon the same processes as language comprehension and generation. Verbal reasoning describes reasoning as transformation of verbal information provided by the premises of an inference problem. Linguistic skills operate in order to encode and re-encode a reasoning problem until the conclusion becomes obvious or until the reasoner gives up. Polk and Newell (1995) hypothesize that when task-relevant information is provided verbally, the crucial role in reasoning is played by the verbal processes of encoding and re-encoding accordingly and that inferences follow comparatively easily from the encoded information.

In the following, we sketch how spatial reasoning can be conceived in Polk and Newell’s framework of verbal reasoning, which covers reasoning about relations. In particular, we propose new theoretical assumptions for the special case of reasoning with spatial relations. The key assumption is that the process of constructing a mental representation – a mental model – from the premises influences deductive spatial reasoning. This implies that the process of encoding the

spatial information is critical for the result of the spatial reasoning process. We discuss empirical evidence as well as a computational implementation of the process.

A cognitive model

We are proposing a theory on how humans create a mental model from a set of spatial relations. The theory is based on the idea of cognitive efficiency, that is humans try to minimize their cognitive effort, therefore a cost measure is introduced to judge the efficiency. From this we derive how a mental model should be constructed. This mental model can then be used to reason about spatial relations and its properties imply consequences for the reasoning process.

Basic assumption for the cognitive model

Since we consider arbitrary one-dimensional relations as basis for the model we assume that models consist of a “queue” of objects and an interpretation what this queue represents. The queue describes in which order the objects are aligned but what this order represents depends on the relation that is considered. So while the order is implicit the interpretation of the order is not. The queue is constructed by forming links between objects. The links signify which objects follow each other in that ordered arrangement. These links between the objects are one directional which means that when inspecting the queue we can move from one object to the next object in the order but not to the preceding object. To access the queue one needs to access the first element of the queue. Therefore the beginning of the queue is marked by a start pointer.

The queue can be accessed from this starting point which is directed at the first object. From there all other objects in the mental model can be reached by following the links between objects.

This amounts to the following assumptions about the queue:

1. There exist a starting point or first object.
2. Each object is linked to the next object in the linear order. Only the last object is not linked to other objects.
3. While this structure has an implicit direction, the interpretation of this direction depends on the context.

Mental Cost

We now introduce a cost measure that allows us to judge how to create the queue efficiently. The main assumption is that an existing link should not be broken if that is avoidable and as few new links as possible should be formed to minimize cognitive work.

So a cost efficient model is one that can be built by a minimal number of broken links. Since in the end of the construction process the complete mental model is supposed to have as many links as objects costs can only be reduced by altering as few links as possible during the construction process. Therefore it is most cost efficient if we can insert new

objects creating just one new link and not changing any existing links. The only way to accomplish this is by attaching them at the very end, following the last object in the queue. So if an object can be inserted at the very end of the queue it should be inserted there.

The starting point is also considered a link. This is due to the fact that one has to know how the queue starts in order to access it. Therefore knowing which object is the first constitutes a link, connecting the start of the queue to that object.

Moving through the queue on the other hand takes very little cognitive effort as long as we move in the implicit direction of the queue. Due to the fact that the links only have one direction moving in the opposite direction through the queue is impossible.

Construction of mental models from spatial information

The question now is how a mental model is constructed from the premises of a reasoning problem. How are objects inserted in the queue and where does the cost measure come into play?

In this process the first premise that is considered has a special function and dominating effect on the construction of the rest of the arrangement. We consider the first premise independently of the following premises and postulate the following two rules for the construction process.

- 1^{fp} First object inserted in the queue is the starting point of the queue.
- 2^{fp} The second object is linked to the first object. The relation between the first and the second object thereby creates the interpretation of the link and the implicit direction of all the following objects in the queue.

If we know, for example, that the second inserted object is supposed to be to the right of the first (starting) object, then the link is interpreted as “to the right”.

When we look again at our example from the introduction this gives us two options for the first premise: “The apple is to the left of the mango.” We can choose the apple as the starting point (marked by the asterisk) and insert the mango second:

apple* → mango

The implicit direction of the queue is interpreted as moving from the leftmost object to the right. However, if we use the mango as a starting point (marked by the asterisk) inserting the apple second we get:

apple ← mango*

In this case the implicit direction of the queue is interpreted as moving from the rightmost object to the left. So even though the premise describes only one arrangement of fruits there are two options for representing this arrangement in our queue.

Once the interpretation of the implicit direction of the queue is fixed by inserting the second object the rest of the

objects are inserted according to this interpretation. This amounts to the following options for inserting objects in an existing queue from the second premise on:

1. The first object of the premise has to be found in the queue.
- 2.(a) If the new object is to be placed behind this object (with regard to the implicit direction of the queue) it can be either inserted into the queue directly behind the object or at any point further to the end of the queue.
- (b) If the new object is to be placed in front of the object (with regard to the implicit direction of the queue) it can be either inserted into the queue directly in front of the object or at any point further to the beginning of the queue.

The question is which of these choices is more cost efficient. As a cost measure we use primarily the number of links that need to be formed. If this does not show any difference between the options the required movement through the queue is used as an secondary cost measure.

Let us first look at the costs resulting from inserting a new object into the queue between two objects that are linked. To insert a new object between two existing objects in the queue the first object, that was linked to the second object before, is now linked to the new object. The new object is linked to the second object. This requires forming two new links. If the object is inserted at the beginning of the queue the starting point needs to be redefined which we will consider as creating a new link.

Using this information we will now judge the cost created by the insertion options described in 2.(a) and (b). Let us first look at option (a): If the object is inserted between two objects of the queue two new links need to be formed. If the object is inserted at the end of the queue, only one new link needs to be formed. So in case (a) it is most cost efficient to insert the object at the very end of the queue. Now we consider (b): The new object can only be inserted between two objects or at the starting point of the queue. Since we consider the starting point a link to the beginning of the queue both options require two new links to be formed. So it is the most cost efficient not to move around the queue but to insert the object directly in front of the found object. Using this analysis we postulate the following rules:

- 1^{ins} If the new object is to be placed behind an object of the queue it will be inserted *at the end* of the queue.
- 2^{ins} If the new object is to be placed in front of an object of the queue it will be inserted into the queue *directly in front* of this object.

If we apply these rules to the second premise of the first example we create one of the following two models depending on the direction of the queue.

$$\text{apple}^* \rightarrow \text{mango} \rightarrow \text{kiwi} \quad (1)$$

$$\text{apple} \leftarrow \text{mango} \leftarrow \text{kiwi}^* \quad (2)$$

While the results look similar, the costs for building these models differ. In case (1) we were able to use rule 1^{ins}, creating only one more link. In case (2) however, we needed to redefine the starting point. This resulted in creating two new links. So the cognitive costs for building the first model are lower.

Let us look at another example that is not quite as simple:

1. The apple is to the left of the mango.
2. The apple is to the left of the kiwi.

Here the premises describe an indeterminate order: there are two possible orders of these three fruits: apple–mango–kiwi and apple–kiwi–mango. So the question is, whether one of these orders is preferred over the other? Knauff, Rauh, and Schlieder (1995); Rauh et al. (2005); Jahn, Knauff, and Johnson-Laird (2007) have empirically shown that such preferences exist in human reasoners.

Since the first premise is the same as in the example with the determinate order we receive the same two options for models when applying the rules for the first premise. If we apply the rules of insertion to the second premise we get one of the following models.

$$\text{apple}^* \rightarrow \text{mango} \rightarrow \text{kiwi} \quad (3)$$

$$\text{apple} \leftarrow \text{kiwi} \leftarrow \text{mango}^* \quad (4)$$

Here we see a difference between the two models depending on the implicit direction of the queue. This is due to the fact that the arrangement is indeterminate and because the two queues have opposite interpretations of the implicit direction different rules are applied to form the queues. There is also a difference in the cost for building these models. In (3) we were able to apply rule 1^{ins}, again creating only one new link. In (4) we needed to apply rule 2^{ins}, redefining the starting point, creating two new links. So the cognitive costs for creating the last model (4) are higher than the ones for creating model (3).

Once a model has been constructed it can be used to make inferences. If we build the model

$$\text{apple}^* \rightarrow \text{mango} \rightarrow \text{kiwi}$$

from the premises of the first example we can answer the question "Is the apple to the left of the kiwi?" by finding the apple in the queue and then moving further down the queue till we find the kiwi.

Predictions based on the construction process:

From the model we can derive several behavioural predictions:

- If the model is indeterminate (allowing more than one model) the direction of the queue influences which model will be built.

- It should be easier to infer information that can be obtained following the implicit direction of the queue than infer information that require to go against that direction.
- The same mechanism is used for all one dimensional spatial relations, not just in the left/right direction.

Computational implementation and computational complexity estimation

The model construction process can be easily implemented as a computer model using the data structure linked list, consisting of nodes containing data and a pointer to the next node in the list. There is also a start pointer pointing at the first node of the list. If we compare that to our mental model the pointers from one node in the list to the next represent the link between the objects. The data represent the objects. It is therefore easy to model a queue such as the one we proposed in a computer program.

Computer science provides standard rules for analysing the efficiency of algorithms. However, the traditional cost analysis of the algorithm used to insert objects into a linked list provides different results than the above cost analysis. This is because in computational complexity theory every operation has the same weight. There are no operations that are harder or easier to perform than other operations.

Let us look again at the possibilities for insertion in an existing queue from above, 2(a) and (b). Which of these options is the most cost efficient? When inserting a node behind a node of the list as in 2(a), and we insert it directly behind the found node, we have the cost of assigning one pointer and reassigning another (if not the end of the list). If we move further down the list, the costs of moving through the list have to be added to the costs of assigning pointers and moving one node down the list costs as much as assigning one pointer. So inserting a node between two nodes further down the list is always more expensive than inserting it right behind the found node. Attaching the node to the end of the list is not a good idea either: if the end of the list is more than one node away, the cost of moving through the list and assigning the pointer will be higher than the cost of just inserting the new node right behind the found node. And since there is no way of knowing how far away the last node is, the cost efficient solution is to insert the new node right behind the found node.

When inserting a node in front of a found node of the list as in 2(b), the same costs result for inserting the new node right in front of the node and for inserting it at the beginning of the list as the starting pointer of the list can always be accessed at no extra cost. In both cases one pointer needs to be assigned and one pointer needs to be redirected. If it is inserted at any other point of the list the costs are higher since we first have to move to that point from the beginning of the list. So in this cost analysis it would be most efficient to insert the object either at the beginning of the list or directly in front of the found object.

Based on this analysis we derive alternative rules for inserting nodes into a list:

- 1^{alt} If the new node has to be placed behind a node of the list it should be inserted into the list *directly behind* the node.
- 2^{alt} If the new node has to be placed in front of a node of the list it should be inserted into the list *either directly in front* of this node or at the *very beginning* of the list.

If we apply these rules to the second premise of the second example we receive the following models.

$$\text{apple}^* \rightarrow \text{kiwi} \rightarrow \text{mango} \quad (5)$$

$$\text{apple} \leftarrow \text{mango} \leftarrow \text{kiwi}^* \text{ OR } \text{apple} \leftarrow \text{kiwi} \leftarrow \text{mango}^* \quad (6)$$

The model (5) was built using rule 1^{alt}, the models in (6) are the two options following from rule 2^{alt}. The insertion of the last object has the same computational cost in all three of these models.

The models also show that rules based on a classic computational cost measure produce different results than our rules based on a cognitive cost measure. Model (5) differs from model (3) above and only one of the models of (6) is similar to the model (4). Of course this does not mean that a computational model would have to follow the alternative rules. It can also be implemented using the insertion rules that resulted from the cognitive model.

So one of the questions is whether it is justified to assume that forming a link is more cost intensive than moving through the queue. If not, the traditional computational complexity measure might provide better predictions than our model.

Empirical Evidence

We report an experiment that shows that rules derived from our cognitive cost measure predict human behaviour better than the rules derived from the traditional computer science cost measure. In this experiment we investigated what kind of mental model participants construct when they are faced with indeterminate problems that allowed more than one model to be constructed.

Participants, Materials, Procedure, and Design

Thirty-five participants (3 male; age: $M = 22.4$; $SD = 3.2$) from the University of Giessen had to solve sixteen determinate (like in example 1) and sixteen indeterminate problems (like in example 2). The three-term problems had two premises each and we used only the relation “left of”. The problems were presented to the participants in a random order on a computer screen. Each premise was presented sequentially (in a self-paced manner). After having read the premises a conclusion was presented and the participants were asked if this conclusion was correct or not. For determinate problems the conclusion was either true or false. For indeterminate problems we used two different types of conclusions which could either hold in a model constructed according to rule 1^{ins} or to rule 1^{alt}.

Results and Discussion

Separate ANOVAs for the percentage of correct responses and reaction times of correct responses with the within-subject factor conclusion acceptance (hits, correct rejections) and insertion principle (indeterminate/rule1^{ins} vs. indeterminate/rule1^{alt}) were calculated, respectively. Level of significance was 5%.

Figure 1: The left two bars show the mean number of correct responses for the determinate problems. In half of the problems the correct response was “yes” (hit), in the other half it was “no” (correct rejection). The right two bars show how often the participants accepted a conclusion that hold in the model built by rule 1^{ins} or rule 1^{alt}, respectively. Error bars indicate standard errors.

ANOVA of the percentage of correct responses yielded a significant main effect of conclusion acceptance [$F(2,32) = 54.79, p < .01$]. Percentage of correct responses of determinate/valid and determinate/invalid items did not differ ($p > .75$). The high percentage of correct responses for the determinate items ($M = 92.19; SD = 11.14$) indicate that the participants understood the task and were able to perform well. Because the determinate items were easiest constructed from the left to the right for both cost functions we assume that they were indeed constructed from left to right. We also assume that the indeterminate items were constructed from the left to the right as well, since the decision has to be made directly after reading the second premise before knowing whether the item is determinate or indeterminate. We find a higher percentage ($t(34) = 5.49; p < .01$) of yes-answers for the items where the conclusion was true if the model was built by rule 1^{ins} than for items where the conclusion was true if the model was built by rule 1^{alt} (see Figure 1). This indicates that indeed the rules derived from our cognitive cost functions are more often applied than the alternative rules derived from the classical computer science cost function.

ANOVA of the reaction times of correct responses also yielded a significant main effect of conclusion acceptance [$F(2,18) = 4.25, p < .05$]. Reaction times for determinate/valid items ($M = 3618$ ms, $SD = 1427$) were significantly lower compared to determinate/invalid items ($M =$

4887 ms, $SD = 2691$; $t(34) = -4.67; p > .01$). Reaction times for indeterminate/rule1^{ins} items ($M = 4156$ ms, $SD = 3066$) were significantly lower compared to indeterminate/rule1^{alt} items ($M = 5057$ ms, $SD = 3457$; $t(20) = -2.29; p > .05$). This implies that conclusions of the determinate/valid items were easier to confirm than the ones of the determinate/invalid items and the conclusions of the indeterminate/rule1^{ins} items were easier to accept than the ones of the indeterminate/rule1^{alt} items. These easier items were those where the confirmation could easily be made by following the implicit direction of the queue provided that the queue was indeed constructed from left to right.

Other evidence

Further evidence for our model comes from the experiments of Jahn et al. (2007). Their participants inserted an object to an existing array, as opposed to adding it to one end of the array, more often for objects that would have been added to the left end of an array than for entities that would have been added to the right end of an array (Jahn et al., 2007, Experiment 2, Table 4). The authors come to the conclusion that: “Given that the participants constructed arrays from left to right, they evidently found it easier to add a new entity to the right-hand end of an array than to the left-hand end of an array [...]” (Jahn et al., 2007, p. 2081)

For a queue that is constructed from left to right our model predicts this behaviour, since rule 1^{ins} is applied to the objects inserted on the right of a reference object and rule 2^{ins} is applied to objects inserted on the left of a reference object. So the results of Jahn et al. (2007) confirm the predictions of our model.

Discussion

We introduced an approach how spatial reasoning can be modelled as verbal reasoning. The main idea is that the deduction process does not necessarily require deduction-specific mechanisms to operate on internal representations. Instead we assume that a simple order of objects (represented by words) and some genuine verbal cognitive mechanisms might guide the reasoning process. Following Polk and Newell (1995) we assumed that the cognitive processes in deductive reasoning can be based upon the same processes as language comprehension and generation.

From our point of view our approach is a helpful addition to the long lasting controversy between models and rules in reasoning (e.g. Johnson-Laird, Byrne, & Schaeken, 1994; Rips, 1994; Hagert, 1984). In fact, models are often identified with visuo-spatial processing and rules with linguistic or sentential mechanisms (e.g. Goel, Buchel, Frith, and Dolan (2000)). Our study, however, shows that this distinction does not reflect the actual differences between the two approaches. In fact, our approach is a model-based approach, because at no point during the inference process rules of inferences are used, instead the new information must be derived from the queue - the model. And our results suggests that such models can be the basis of verbal reasoning, so no visuo-spatial

process are involved in the inference.

Our work has also shown that the approach and the related cost measure leads to good predictions about what kind of model will be created. It predicts behaviour better than the classical computer science approach to cost calculation. But there remain some open questions about the cost measure. One problem of our approach results from the fact that it is easier to move through the queue than alter the existing links, no matter how far we have to move. Another possibility is that if the queue becomes larger there might exist a critical distance when it requires more mental effort to move this distance through the queue than altering a link. This would imply that if the queue reaches a certain number of objects, new objects would not necessarily be attached to the end of the queue any more.

Another question is whether the starting point of a queue is really a link like all the other links in the queue. However, since this link is different concerning its cognitive nature it might be weaker or stronger than the links between object in the queue.

A third limitation of our project is that we only used problems with two premises, although we believe that the postulated rules also apply if there are more than two premises and three objects, as long as the premises all contain relations describing the same dimension. And it is possible to mix relations of the same dimension such as left and right, as done in many experiments (Jahn et al., 2007; Ragni, Fangmeier, Webber, & Knauff, 2006).

Finally, we postulate that the implicit direction of a queue can be chosen freely. But what is this choice based on? In a behavioural experiment, in which many spatial reasoning problems need to be solved, subjects are likely to choose the direction that produces the lowest cost for the items seen so far. Also, once a choice has been made on which direction to use, subjects are likely to stick with it. This also keeps the mental costs low because the tactic used is not constantly being analysed. Also, when using material with a left-right dimension as in the examples there seems to be a general preference for constructing a left to right queue (Jahn et al., 2007; Rauh et al., 2005; Ragni et al., 2006). This could be a cultural preference such as reading. Also other orders we see in daily life are arranged left to right.

Overall, we were able to present some evidence for our assumption that the process of constructing a “verbal mental model” from premises influences deductive spatial reasoning. The chosen interpretation for the implicit direction of the queue has consequences on what kind of conclusions can be easily made. And, most importantly, for indeterminate problems, we can predict which model is preferred over the other and which model is more difficult to consider as a possible interpretation of the premises. While our model can not necessarily be generalized to other domains of reasoning we feel that it can describe some aspects of human reasoning with spatial relations and that it demonstrates that spatial reasoning can also be conceived as verbal reasoning.

Abstract

How we engage in mental state reasoning remains a contentious issue, reflected in the debate between theory-theorists, who argue that we deploy theory-based rules, and simulation theorists, who argue that such reasoning is subserved by simulation processes. The present study examined whether theory-based or simulation-based reasoning is adopted in regret-oriented counterfactual scenarios involving mental state inferences. Participants thought aloud while reasoning through such scenarios from the perspective of themselves, themselves and another, or two other individuals. The scenarios also manipulated the controllability of event outcomes. Results revealed more theorizing in the uncontrollable than the controllable scenarios, and more simulation in the controllable than uncontrollable ones. More theorizing was also observed in the “other-and-other” than the “self-only” condition. These findings highlight the value of adopting a hybrid model of mental state reasoning, where theorizing and simulation are integrated within a common framework, with such processing being deployed in a context-sensitive manner.

Keywords: Simulation theory; theory-theory; counterfactual thinking; regret; think aloud protocols; mental models.

Introduction

The theory-theory (TT) versus simulation theory (ST) debate focuses on how we understand and reason about our own and others’ *mental states* relating to beliefs, desires, intentions and the like. The TT approach (e.g., Carruthers, 1996) argues that we apply both tacit and non-tacit “theories” when understanding mental states. In contrast, ST posits that such understanding is attained either: (i) by “offline” simulation (e.g., Goldman, 2006), in which we take our own beliefs and desires offline, input those of another individual, and run a simulation process; or (ii) by imagining how we would feel in a given situation and by assuming that since other individuals are similar to ourselves then they would feel the same as we do (e.g., Gordon, 1986). Recently, a new variety of theorists have emerged who argue for a *hybrid* approach, in which both theory and simulation are adopted, dependent on the

situation (e.g., Mitchell, Currie, & Ziegler, 2009). As we will demonstrate, this hybrid approach has considerable appeal, not least because it can capture the way in which mental state reasoning is sensitive to a multiplicity of factors associated with the prevailing situation, such as its familiarity. The factor of interest in the present paper relates to the protagonist’s capacity to have control over the outcome associated with a situation.

Previous Attempts to Arbitrate Between TT and ST

Since the emergence of the TT/ST debate, psychologists and philosophers have been keen to find a test case to arbitrate between these accounts. This pursuit has largely focused on empirical findings that derive from comparisons between autistic individuals (who have various deficits in mental state understanding) and those without autism. The debate surrounding the correct theoretical interpretation of mental state reasoning deficits in autism appears to have reached an impasse (e.g., Carruthers, 1996, has argued that evidence from autism supports TT, while Goldman, 2006, argues that it corroborates ST), such that researchers have started to explore other ways to address the TT/ST debate.

Recent work in this latter vein reported by Kühberger, Kogler, Hug, and Mösl (2006), examined the TT/ST debate using the “position effect” (i.e., a bias to select the rightmost object in an array of identical objects when asked to make a preference judgment). In Experiment 1, participants observed a target person viewing a line of pantyhose and had to imagine viewing the items in the same manner. It was found that participants could predict the target’s preference for the rightmost item, which seems to support ST since the availability of sufficient imaginative input (i.e., reasoning from the perspective of the target) enabled participants to predict the position bias. In Experiment 2, participants were given a verbal description about an actor rather than observing them, which failed to produce the results of Experiment 1. In Experiment 3, participants were informed about the position effect (but what it entailed was not explained), and were told to ignore it when making their selection. The fact that most people still demonstrated the

bias was interpreted as indicating deployment of an incorrect theory.

Although, Kühberger et al. claim their results support ST, we wonder whether they speak more to a hybrid account in which TT operates under some conditions and ST under others (e.g., Experiment 3 suggests an incorrect theory can be overridden by simulation). We also note a limitation of the study, which is that it focuses on epistemic mental states (i.e., beliefs), which are rather divorced from the richness of everyday mental state understanding. In order for TT and ST concepts to be useful for examining mental state reasoning (rather than just the currency of an esoteric philosophical debate; cf. Ratcliffe, 2007), such concepts must show general applicability to a wide variety of everyday mental state reasoning contexts.

In this paper we propose that counterfactual reasoning about mental states may provide a new test case for arbitrating between TT and ST. Counterfactual reasoning involves imagining how events associated with regret or disappointment could have turned out differently. Such reasoning is commonplace in everyday life and is vital for understanding how other people may be feeling in response to negative outcomes of real-world situations.

Mental Models and Counterfactual Thinking

The conceptual analysis of counterfactual reasoning is currently dominated by those adopting a mental models framework (e.g., Byrne, 2002, 2005), where mental models reflect representations of actual and counterfactual possibilities. Two particular phenomena in counterfactual reasoning that have been addressed by mental model theorists are: (i) the “action effect”, which concerns the observation that greater regret intensity is elicited by acts of commission than acts of omission in the short term (e.g., Kahneman & Tversky, 1982), with the reverse being evident in the long term (e.g., Gilovich & Medvec, 1994); and (ii) the “temporal order effect”, whereby we are more likely to reason about undoing the final event in a sequence of events that led to a negative outcome (e.g., Byrne, Segura, Culhane, Tasso, & Berrocal, 2000).

Atkinson, Bell, and Feeney (2009) explored both effects in a study using regret-oriented scenarios. To examine the action effect participants were asked to decide which of two protagonists would feel more regret, an actor or non-actor. To investigate the temporal order effect, participants were asked who would feel worse, the actor who was mentioned first or second. The study also manipulated the time that participants had available to register their response: either they had as long as they wished or they had to answer as quickly as possible. It was found that there was no effect of response time on the emergence of the temporal order effect. However, the action effect was disrupted in the speeded condition, with the actor being selected significantly less often than in the delayed condition. The finding that the action effect and temporal order effect are differentially influenced by the response-time manipulation is claimed by Atkinson et al. to be a consequence of

reasoners needing to build complex representations when displaying the action effect (cf. Feeney & Handley, 2006). In particular, for the action effect to arise the reasoner has to compare events associated with both the actor and the non-actor.

We concur with Atkinson et al.’s interpretation, and also believe that their findings are relevant to understanding the role of theorizing and simulation in counterfactual reasoning. The observation that participants readily select the second actor in the temporal order scenario, regardless of time constraints, suggests that participants may be applying a straightforward, theory-based “rule” that the second actor would feel more regret. For the action effect, however, we propose that with sufficient time participants are likely to engage in mental simulation to pursue comparisons between the levels of regret felt by the actor and non-actor - in line with Atkinson et al.’s claim that participants flesh out mental models in these cases.

We illustrate this latter point with reference to a classic action/inaction scenario (Gilovich & Medvec, 1994):

“Dave and Jim do not know each other but both are enrolled at the same elite East Coast University. Both are only moderately satisfied where they are and both are considering transferring to another prestigious school. Each agonizes over the decision, going back and forth between thinking he is going to stay and thinking he will leave. They ultimately make different decisions: Dave opts to stay where he is and Jim decides to transfer. Suppose their decisions turn out badly for both of them: Dave still doesn’t like it where he is and wishes he had transferred, and Jim doesn’t like his new environment and wishes he had stayed”.

When considering the mental models constructed when reasoning about Dave, Feeney and Handley (2006) argue that participants construct the actual state of affairs in which he stayed and was unhappy and the counterfactual state in which he moved and was happy. However, we propose that a third possibility may be constructed for the short term of Dave moving and being unhappy:

Actual: Stays – Unhappy [Regret]

Counterfactual: Moves – Happy [No regret]

Counterfactual: Moves – Unhappy [Regret]

When fleshing out this model set it is apparent that three possibilities have to be constructed. These would not be easy to derive from theory-based processing alone, which underpins our proposal that simulation may be necessary for participants to imagine options that the protagonist may be considering - along with their related emotional impact. We further propose that when individuals are presented with a counterfactual scenario they will typically evoke a two-stage reasoning process. The first stage involves bringing to mind an initial model based on theory-driven processing (e.g., “If failing to take an action turns out badly then one will feel regret”). Assuming that a response can be generated at Stage 1 without any perceived need for further processing then this will be done on the basis of the initial model. However, if more processing seems to be needed then individuals may

engage in simulation. This Stage 2 process would be more cognitively effortful than theorizing as well as more sequential and controlled in nature.

Predictions of the Study

These aforementioned ideas allow us to develop predictions in relation to the experiment we report below. One focus of the research concerned the distinction between “controllable” and “uncontrollable” outcomes within regret-oriented counterfactual situations. Scenarios involving uncontrollable outcomes limit the consideration of how the outcome could have turned out better. We therefore predict that such scenarios will be susceptible to reasoning based on the application of theory-based inferences. For controllable outcomes, however, although theory-based reasoning is available as a starting point, there is also the potential for the reasoner to flesh out possible ways in which events could have turned out differently. We therefore predict increased simulation-based reasoning when participants engage in mental state understanding in the controllable case relative to the uncontrollable case.

Most philosophers have focused on arbitrating between TT and ST with reference to situations involving reasoning about another person. However, it is also interesting to examine people’s reasoning about their own mental states. Evidence that there are differences in how we reason about ourselves compared to others comes from a study by Girotto, Ferrante, Pighin, and Gonzalaz (2007), who presented participants with a scenario where they could win a prize by solving a problem. One key experiment involved two conditions. In the “actor” condition participants were presented with two sealed envelopes; one they were told contained an easy problem, one a difficult one (in fact, both contained an insoluble problem). In the “reader” condition, participants read about a protagonist who had to make the same choice as in the actor condition, with an identical outcome (i.e., failure to solve the problem). Participants were either assigned to the actor or reader condition and were afterwards asked to name one way in which the outcome could have turned out better. Responses were coded as either modifying choices (e.g., selecting the other envelope), or as modifying problem features (e.g., having more time). Girotto et al. found the actors were more likely to alter problem features, while readers were more likely to alter a choice, such as the selection of the envelope.

The finding that participants reason about different aspects of a scenario in the self/actor versus other/reader condition suggests that different processes may be occurring. The increased likelihood of undoing a problem feature in the actor condition indicates the consideration of more possibilities than in the reader condition, which tended to involve just choosing the other envelope. This points to the idea that more possibilities are considered when reasoning from the perspective of oneself than that of another, with the implication being that more simulation may arise in the former than the latter situation.

We also note that when people engage in counterfactual reasoning about another individual then theory-based reasoning may take precedence as people tend to possess a wealth of generalized rules concerning how people will feel in regret-oriented situations (e.g., “A person will be upset if they miss out on something they desire greatly”). However, when reasoning about ourselves we may be more likely to progress onto the simulation stage since we possess more specialized knowledge concerning ourselves and the nuances of our own reactions to events. In this way, people who are engaged in self-oriented reasoning may move away from the application of generalized folk psychological theories toward the simulation of multiple eventualities.

In sum, by using regret-oriented counterfactual scenarios involving mental state reasoning we assumed that we would gain useful insights to address two issues surrounding the TT/ST debate. First, such scenarios should usefully inform whether theory-based or simulation-based reasoning dominate in mental state understanding, or whether both forms of reasoning are deployed. Second, the manipulation of factors such as outcome controllability and the self/other distinction should clarify whether contextual and instructional aspects of the presented scenarios determine whether individuals are more likely to theorize or simulate.

Method

Participants

Participants were 90 individuals at Lancaster University who received either course credit or payment. None had prior knowledge of research on reasoning or theory of mind.

Design

A 2 x 3 mixed between-within participants design was adopted. The between participants factor was the perspective that participants had to reason from, which had three levels: self; self-and-other; other-and-other. The within participants factor was outcome controllability, with two levels: controllable versus uncontrollable.

Materials and Pre-Test

Participants received two controllable and two uncontrollable scenarios. Controllable scenarios concerned: (i) two individuals performing poorly on a University assignment (assignment scenario); and (ii) individuals changing or not changing a minor subject to a major at University and then not enjoying the course and receiving a poor course grade (course scenario). The uncontrollable scenarios concerned: (i) losing a game of table football by scoring an own goal, followed by one’s opponent scoring a winning goal (football scenario); and (ii) an individual missing their flight by 5 mins, with the plane having been delayed, and another individual missing their flight by 30 mins, with the plane leaving on time (plane scenario).

In the self-only and self-and-other conditions the participant had to take on the role of one of the individuals within the scenario. In those conditions that involved other individuals, we presented “personas” (i.e., brief bio-sketches

of the named individuals) in an effort to increase the realism of the scenarios. For the self-and-other and other-and-other conditions participants were required to state who they thought would feel more regret, upset or frustration (dependent on scenario). For the self-only condition participants had to state how much regret/upset/frustration they would feel with essentially equivalent scenarios.

To validate our controllability manipulation we gave 13 participants the scenarios from the self-only condition. After reading each scenario they had to use a 10-point scale to rate it for familiarity in their everyday life, and for the controllability of the outcome. We also included a mutability question in which participants were asked simply to list all the ways in which the situation could have turned out for the better. Using paired samples t-tests we found that controllable scenarios were rated as significantly more controllable ($M = 6.54$) than the uncontrollable scenarios (mean = 5.31), $t(12) = 2.66$, $p = .02$. There was no difference, however, in ratings of familiarity (means of 5.58 versus 4.88 for controllable vs. uncontrollable), $t(12) = 1.17$, $p = .26$. For the mutability measure there was a mean of 2.38 mutations for controllable scenarios and 2.69 mutations for uncontrollable scenarios, which was unreliable, $t(12) = 1.67$, $p = .12$. Overall, these pre-test data reveal a solid effect of controllability in the predicted direction, but no confounding effects of mutability or familiarity.

Procedure

Participants were randomly assigned to one of the three perspective conditions and were given associated instructions. They were then presented with a booklet containing the scenarios and were asked to think-aloud whilst reasoning about each one. Scenario order was independently randomized for each participant.

Results

Data Coding

To code the data we adopted Ball and Christensen's (2009) scheme in which each line was coded as reflecting theory-based or simulation-based reasoning. An "ambiguous" code was used when: (i) lines were evenly split across categories (there were 13 instances of these); or (ii) it was difficult to be certain whether theory-based or simulation-based reasoning was being adopted. Theory-based reasoning concerned instances in which the participant adopted tacit or non-tacit theories to make inferences about their own or others' mental states. Such reasoning tended to involve the participant stating general rules regarding mental states, typically involving a grammatical construction such as "The person will feel x because of y". The following excerpt illustrates theorizing taking place, with a participant adopting a tacit rule that captures the notion that action will elicit greater regret in the short term than inaction:

"I think Mike's gonna feel the more regret in the short term coz he's actually chan- he actually made a bad decision whereas Timmy's decided - Timmy's chosen

not to make the decision, so he doesn't know whether or not he'd prefer the other - you can assume he can".

Simulation occurred when participants took their own beliefs and desires offline and inputted those of other individuals (e.g., Goldman, 2006). This simulation process typically involved the participant running through their own or another individual's mental states in relation to the possibilities arising within the scenario so as to determine how they or others would feel (cf. Gordon, 1986). The following excerpt demonstrates such simulation, with the participant imagining themselves in a given situation and stating how they would feel and also how the protagonist might feel, rather than simply stating a rule such as "People feel upset when they receive a poor grade":

"I myself am not particularly competitive erm, so I might be kind of disappointed and think, 'Oh well, that's kind of surprising, I'll erm, I'll have to find out why I went wrong'. But perhaps Jim might be slightly more likely to think, 'Oh I should have worked harder I should have'".

For each scenario the application of this coding scheme by the first author resulted in a percentage of theorizing and simulation for each participant as a function of all coded lines, including ambiguous ones. An independent coder checked a 10% sample of transcripts after first being trained in the application of the coding scheme. Inter-rater reliability was good, with 74% agreement. All areas of disagreement were resolved through discussion between the coders.

Theory-Based Reasoning

Table 1 presents the percentage of theory-based reasoning as a function of controllability and perspective. A 2 x 3 mixed design ANOVA revealed a main effect of controllability, $F(1, 87) = 15.81$, $MSE = 589.91$, $p < .001$, $\eta_p^2 = 0.15$, with theory-based reasoning being more prevalent in uncontrollable than controllable scenarios. There was also a main effect of perspective, $F(2, 87) = 11.41$, $MSE = 1238.82$, $p < .001$, $\eta_p^2 = 0.21$, with the other-and-other condition evoking the greatest level of theorizing and the self-only condition the least. The controllability by perspective interaction was not reliable, $F(2, 87) = 0.75$, $MSE = 589.91$, $p = .48$, $\eta_p^2 = 0.02$. Post hoc comparisons showed significant differences between the self-only condition and the other-and-other and self-and-other conditions ($ps < .01$). No difference was found between the self-and-other and other-and-other conditions ($p = .23$).

Table 1: Mean percentage of theorizing as a function of outcome controllability and perspective (SDs in brackets).

Perspective	Outcome Controllability		<i>M</i>
	Controllable	Uncontrollable	
Self-only	33 (33)	46 (40)	40
Self-&-other	49 (29)	69 (23)	59
Other-&-other	65 (25)	75 (28)	70
<i>M</i>	49	63	

Table 2: Mean percentage of simulation as a function of outcome controllability and perspective (SDs in brackets).

Perspective	Outcome Controllability		<i>M</i>
	Controllable	Uncontrollable	
Self-only	52 (38)	40 (37)	46
Self-&-other	24 (27)	20 (21)	22
Other-&-other	20 (21)	15 (24)	18
<i>M</i>	32	25	

Simulation-Based Reasoning

Table 2 presents the percentage of simulation as a function of controllability and perspective. A 2 x 3 mixed design ANOVA revealed a main effect of controllability, $F(1, 87) = 3.97$, $MSE = 555.95$, $p = .049$, $\eta_p^2 = 0.04$, with greater simulation in controllable than uncontrollable scenarios. There was also a main effect of perspective, $F(2, 87) = 12.63$, $MSE = 1122.86$, $p < .001$, $\eta_p^2 = 0.23$, with more simulation in the self-only condition relative to the other-and-other and self-and-other conditions. No interaction was observed between perspective and controllability, $F(2, 87) = 0.57$, $MSE = 555.95$, $p = .57$, $\eta_p^2 = 0.01$. Post-hoc comparisons revealed a significant difference between the self-only condition and the self-and-other other-and-other conditions ($ps < .001$), but no difference between the self-and-other and other-and-other conditions ($p = .90$).

Discussion

To our knowledge this is the first study to examine the TT/ST debate through the prism of mental state reasoning with counterfactual scenarios. The results from our protocol analysis indicate that although theorizing dominated overall, there were nevertheless differences across conditions when theorizing and simulation data were analyzed separately.

Looking first at the controllability factor, our results indicated that theorizing was more prevalent in uncontrollable than controllable scenarios, with the reverse being the case for simulation. The observation that people theorize more and simulate less in uncontrollable scenarios relative to controllable ones is consistent with the view that uncontrollable scenarios evoke less consideration and modeling of alternative possibilities. In essence, participants appear to be minimizing cognitive effort in these cases. For the controllable condition, simulation may have been facilitated because it was possible to consider more alternatives to reality, thereby provoking a more detailed examination of how an individual might feel in a situation. Participants also appeared to be more likely to engage in reasoning about *how* they might feel in such scenarios, using this to infer how the protagonist might feel.

How do these findings concerning the effect of outcome controllability on mental state reasoning fit in with other theories? Mitchell et al.'s (2009) hybrid account argues that simulation is used by default, but in cases where a situation is familiar they suggest that people might use rule-based theorizing as a shortcut strategy. However, our controllable and uncontrollable scenarios were equated for familiarity in

a pre-test. As such, since controllability was not confounded with familiarity it is not immediately apparent how Mitchell et al.'s account might address the observed influence of controllability on rates of theorizing and simulation. It may be the case, however, that both theorizing and simulation reflect different strategies for engaging in mental state understanding, with one or other strategy being elicited by different factors in the prevailing context, including familiarity and event controllability - and potentially other cues (e.g., the emotionality of the situation).

Our study also set out to examine whether differences arise in how people reason about themselves versus others. Our analysis showed that the self-only condition elicited more simulation and less theorizing than the other-and-other condition, with the self-and-other condition occupying a middle position on both the theorizing and simulation measures. One reason for relatively more simulation arising in the self-only condition may be that it is triggered by direct emotional engagement with presented scenarios arising from specific memories of personal experiences.

Overall, our findings indicate that both theorizing and simulation occur in mental state reasoning about regret-oriented counterfactual scenarios. This supports a hybrid view of mental state understanding along the general lines espoused by Mitchell et al. (2009), and suggests the traditional TT/ST debate may be misconceived in its attempt to emphasize the deployment of a unitary reasoning approach based purely around *either* theorizing *or* simulation. Our results also have implications for mental models accounts of counterfactual reasoning. So far these accounts have been dominated by studies of the action effect (e.g., Feeney & Handley, 2006), and the temporal order effect (e.g., Atkinson et al., 2009), with less work examining issues relating to the controllability of regret outcomes. Our research suggests that an initial model may be formed by theory-based reasoning, with subsequent models being fleshed out through a mental simulation process involving the identification of multiple alternative possibilities. Although speculative, these ideas resonate with previous findings relating to the action effect, and represent a useful area for future research.

Reflecting on our results more generally, we wonder whether they also speak to dual-process accounts (e.g., Evans, 2003, 2006), which contend that human reasoning involves the interplay between two distinct reasoning processes. On the one hand Type 1 or heuristic processes are fast, automatic, high capacity and involve low cognitive effort. On the other hand, Type 2 or analytic processes are slow, controlled, low capacity and involve high cognitive effort. Under some dual-process accounts, Type 1 processes act by default to provide an initial response that can be overturned through the application of Type 2 processes (e.g., Evans, 2006). We suggest that theory-based reasoning may map onto Type 1 processing, and simulation-based reasoning may map onto Type 2 processing. Our findings suggest that there was little simulation that was not also driven by an initial phase of theorizing, which implies that

theorizing may be primary, and that if further processing is required this arises through simulation and may serve either to confirm or override a theory-based decision.

Evidence for this dual-process view of mental state reasoning comes from Atkinson et al.'s (2009) study, where the absence of an influence of speeded responding on the temporal order effect suggests the rapid and automatic deployment of a rule-based process, in line with TT assumptions that we possess a set of folk psychological theories. Furthermore, Atkinson et al.'s observation that speeded responding modulated the emergence of the action effect is indicative of slower, controlled, Type 2 processing linked to simulation. These dual-process arguments also resonate with Apperly and Butterfill's (2009) claims for two processing systems in mental state reasoning, with the proposal being that infants possess a cognitively efficient but inflexible method for tracking belief states that runs parallel to a later-developing adult system which is more flexible but cognitively demanding.

We conclude by returning to the two issues mentioned in our introduction that we hoped our research might address, that is: (i) whether mental state understanding is based on *either* theory-based reasoning *or* simulation-based reasoning - or whether both types of processing are deployed; and (ii) whether the manipulation of factors such as outcome controllability and the self/other distinction might determine the propensity for individuals to theorize or simulate. In relation to the first issue, we have demonstrated by means of think-aloud protocols and the adoption of counterfactual thinking scenarios that both theory-driven and simulation-driven reasoning play out in mental state understanding, with all participants deploying theorizing *and* simulation to greater or lesser degrees for many of the scenarios. In relation to the second issue, we have shown that people are more likely to engage in simulation when thinking about themselves rather than when thinking about other individuals. Furthermore, they are more likely to engage in simulation when reasoning about controllable than uncontrollable regret outcomes. Moreover, these two factors (i.e., perspective and controllability) appear to combine additively to determine the relative levels of simulation and theorizing that arise in mental state reasoning.

Standard, unitary TT and ST accounts do not seem to be able to accommodate our observations that the processes underpinning mental state understanding are influenced by content, context and perspective effects. Although these accounts may be able to develop ways to explain the present evidence, it remains for the proponents of these theories to take up this challenge. In contrast, hybrid accounts that embrace both TT and ST seem better able to deal with our findings. We suggest that hybrid theories represent an important new direction in research examining the processes associated with mental state reasoning.

Abstract

Inference on the basis of recognition alone is assumed to occur prior to accessing further information (Pachur & Hertwig, 2006). A counterintuitive result of this is the “less-is-more” effect: a drop in the accuracy with which choices are made as to which of two or more items scores highest on a given criterion as more items are learned (Frosch, Beaman & McCloy, 2007; Goldstein & Gigerenzer, 2002). In this paper, we show that less-is-more effects are not unique to recognition-based inference but can also be observed with a knowledge-based strategy provided two assumptions, limited information and differential access, are met. The LINDA model which embodies these assumptions is presented. Analysis of the less-is-more effects predicted by LINDA and by recognition-driven inference shows that these occur for similar reasons and casts doubt upon the “special” nature of recognition-based inference. Suggestions are made for empirical tests to compare knowledge-based and recognition-based less-is-more effects.

Keywords: Heuristics; Recognition; Less-is-more; LINDA

The Less-is-more Effect

Suppose an individual is presented with the two cities *Milan* and *Modena* and asked to choose between the two along some criterion, for example to decide which has the larger population. In the classic work of Goldstein and Gigerenzer (2002), it is assumed that the participant will guess if they recognize neither of the items, they will use whatever additional knowledge is available to make a decision if they recognize both of the items and if they recognize only one of the items, they will choose this item as the larger without consulting any other cues or searching for further information about it (the *Recognition Heuristic* or *RH*). Recognition-driven inference of this type predicts a *less-is-more effect*, whereby individuals who recognize many of the items often perform worse than individuals who recognize fewer of the items (Goldstein & Gigerenzer, 2002). A number of studies have shown that this effect can be observed empirically (Frosch, Beaman & McCloy, 2007; Goldstein & Gigerenzer, 2002; Reimer & Katsikopoulos,

2004). It occurs because items that are more prominent (e.g., larger, more populous cities) are more likely to be encountered, hence more likely to be recognized. Recognizing one of the two items is thus a useful cue for choosing the recognized item; whereas if both items are recognized, additional knowledge is needed to make the decision and such additional knowledge may be very limited in discriminative power. In the terms provided by Goldstein and Gigerenzer (2002) a less-is-more effect, superior performance by an individual who recognizes fewer of the options, is expected when the recognition validity (the probability that a correct decision is made based upon recognition alone) exceeds the knowledge validity (the probability that a correct decision is made based upon the best available knowledge about the items).

The assumption underlying the RH is that items scoring higher on the criterion under consideration (larger cities, more successful ice-hockey teams, better tennis players etc.) are ordinarily encountered more frequently. The counter-intuitive nature of the less-is-more effect makes its prediction by recognition-driven inference interesting, and has been used as a rhetorical device to promote the heuristic (Borges, Goldstein, Ortmann & Gigerenzer, 1999; Gigerenzer, 2007). Counter to this, failures to observe the effect have been cited in attempts to refute the RH (e.g., Boyd, 2001; Dougherty, Franco-Watkins & Thomas, 2008; Pohl, 2006). In describing the RH, Goldstein and Gigerenzer (2002) use the example of recognizing a city because it has appeared frequently in newspaper reports, a larger city is more likely to be so mentioned. Any individual who is presented with a city they recognize (but know nothing more about) and one they do not is therefore well-advised to choose the recognized city if judging which of the two is more populous. However, the recognizability of a particular city, for example, is a function of several factors, including its physical distance from the individual as well as its size. An appropriate analogy here might be the force of gravity. Local towns, like nearby planetary bodies, might have intrinsically less “pull” or prominence than distant

cities (or distant galaxies) but their appearance in local news reports is enhanced by their closer physical proximity and both of these factors influence recognizability. A further moderating factor is the way in which the individual might shape the environment their own ends. In the newspaper example, the individual receiving the newspaper is implicitly assumed to be a fairly passive processor of the information contained within the newspaper and no consideration is given to the potential difference between an individual who actively seeks out a newspaper and one who does not or to potential differences between choice of reading matter (e.g., the *New York Review of Books* versus the *National Enquirer*) which may have very different content, and each of which might be sought out, or passively encountered, to different degrees by different individuals or groups of individuals.

A basic premise in what follows is that, for any given individual, there are several subgroups of items which the individual is able to recognize and about which they may also have partial knowledge. This is particularly likely if they are local to the individual in some way or if they form part of a set of items of special interest to that individual. For example, American cities include large, famous cities such as *New York* and *New Orleans*, and small cities associated with famous universities, such as *New Haven* and *Palo Alto*. The relative recognition of various subgroups (such as those with famous Universities) may not be simply correlated with size. Any individual with specialist knowledge or affiliation with any special-interest group, e.g., membership of a European academic community, might be more likely to recognize small but academic cities in the USA than all but the most famous large USA cities. For this fictional individual¹, there is a weaker relationship between recognition and magnitude for the subset of US cities with famous Universities than for the subset of US cities that do not possess famous Universities.

This assumption that differential access to various subgroups of items may occur between individuals is not reliant upon anecdotal evidence or arguments of plausibility as above. By-item analysis of data taken from an experiment by McCloy, Beaman, Frosch and Goddard (in press) shows, when a group of 40 participants were asked to indicate which of a group of famous individuals they recognize, a significant interaction between the reason for the individual's celebrity and the participant's gender, $F(3, 43) = 13.44$, $p < .001$. For example, males recognized, on average, sports personalities 78% of the time (females = 55%) and rock stars 75% of the time (females = 66%). In contrast, females recognized fashion and show-business professionals 57% of the time (males = 33%). In what follows, we consider similar situations where, for an individual within the environment, there is no simple correlation between recognition and magnitude because subsets of the items are prominent for reasons unconnected to magnitude (e.g., the age, gender or special interests of the individual). The question we wish to address is whether

less-is-more effects still occur in such situations and what forms of decision-rule, if any, will give rise to such effects.

LINDA

To formally examine the appearance of less-is-more effects, we suppose a pool of N items, split into several subsets A, B, C, \dots . Within each subset the participant is able to recognize a, b, c, \dots items, respectively. In a typical test of recognition-driven inference, the experimenter selects items quasi-randomly from the pool. Since the constraints on the experimenter are unknown, a random selection from N is assumed and the basic case considered is where pairs of items are chosen, and the participant's task is to say which is larger. For purposes of exposition, attention is also restricted to situations in which there are just three subsets. The models can easily be extended to other cases (e.g., the participant is asked to choose between more than two items (Frosch et al., 2007; McCloy, Beaman & Smith, 2008) and/or the pool is split into more than three subsets).

On a given trial, suppose the participant recognizes i items from subset A , j items from subset B , and k items from subset C . Only two items are presented, so $0 \leq i + j + k \leq 2$. p_{ijk} is the probability of recognizing 0-2 items from $A-C$. p_{ijk} is dependent on how many items the participant can recognize in each of the subsets, but is independent of the decision rule adopted. The probability of success is α_{ijk} , given the recognition of i, j and k items from their respective subsets. α_{ijk} is dependent upon the decision rule adopted and distinguishes between models. The overall probability of success for any model is given by:

$$\sum_{ijk} p_{ijk} \alpha_{ijk} \quad (1)$$

The distinguishing feature of the RH model is that the participant chooses the recognized item when only one item is recognized. So $\alpha_{000} = 0.5$ (no item recognized, pure guess); α_{100} , α_{010} , and α_{001} reflect the success of the recognition heuristic; α_{110} , α_{101} , α_{011} , α_{200} , α_{020} , α_{002} reflect use of knowledge. The alternative against which the RH is to be compared we refer to as LINDA (Limited INformation and Differential Access). As the name implies, this model requires two basic assumptions:

1. *The limited information assumption.* For each recognized item, the individual has reliable but limited information about its size (e.g. that the size is above the population median).
2. *The differential availability assumption.* Some subsets are more accessible than others so that subset A contains items that are more readily recognizable than subset B and so forth. The extent to which items in A are larger than items in B implements the recognition-criterion correlation which is the basis of the RH.

The limited information assumption is that some information is available at the time of decision-making against which to evaluate the usefulness of choosing the recognized item in any given case. This is strictly limited: above or below *median knowledge* corresponds in

¹ Who bears a strong resemblance to the second author.

information theoretic terms (Shannon & Weaver, 1948) to only 1 bit of information. The reliability of this information may also vary. The differential availability assumption states merely that, within any subset, a given individual may recognize more or less items. Thus, a member of the UK academic community may recognize more US cities with famous Universities than a UK-based baseball fan. The baseball fan, by contrast, may recognize more US cities with famous baseball teams.

Existence-Proofs for Knowledge-Based Less-is-more Effects.

For the LINDA model, consider the situation where the individual has accurate median knowledge of items from pool N , i.e., they accurately know whether each recognized item is above or below median. Subset A includes items in the top quartile of the size distribution, subset B includes items in the second highest quartile of the size distribution, and subset C contains all the remaining items. It is assumed for purposes of exposition that median knowledge is perfect, i.e., that the knowledge about a recognized item is accurate. This assumption can be relaxed but the general conclusions reported here hold for all reasonably high levels of accuracy (to just above chance). The size of the pool from which the test items are drawn is set at 100 but the same pattern of results is obtained for all large values of N . The key prediction is the relation between the proportion of correct decisions (calculated by equation (1)) and n , the number of items in the pool the participant can recognize. A less-is-more effect occurs, according to Goldstein & Gigerenzer's (2002) definition whenever performance of the inference task is demonstrably superior under conditions where fewer items from the pool of test items are recognized. McCloy et al. (2008) use a stricter definition, arguing that less-is-more effects should be restricted only to those areas of the graph where learning more items will continue to impair performance. We use the latter definition for our examples, although note that when this definition holds it necessarily implies that Goldstein & Gigerenzer's conditions are also met.

Example 1: Low validity for complete recognition. One way that less-is-more effects may be produced relates to how decisions are made when both items are recognized (in a 2-alternative forced choice task). LINDA is assumed to access limited and possibly inaccurate knowledge about the size of each recognized item, and use this knowledge to choose the item she believes to be larger. Suppose that choosing between two recognized items may, in some instances, be extremely difficult. An extreme version of this appears in Figure 1. When only one item is recognized, LINDA makes decisions on the basis of whether the item is judged above median (choose the recognized item) or below the median (choose the unrecognized item), as given in the appendix. Recognition-criterion correlations can be varied by varying the availability of the items in the subsets available to LINDA. For example, if all items in subset A

(top quartile of the criteria) are recalled before all items in subset C (below median) then the recognition-criterion correlation is obviously higher than when all items in subset C are recalled before all items in subset A . In this simulation, we manipulated the recognizability of individual items within the subsets to obtain pre-set correlations between recognition and criterion. For the current example, we also assume that LINDA does not have the capacity to make a decision when both items are recognized, and so is obliged to guess, that is $\alpha_{110}, \alpha_{101}, \alpha_{011}, \alpha_{200}, \alpha_{020}$ and α_{002} were not calculated but all set at 0.5, as would be the case with simulations of the RH. The situation resembles one outlined in Goldstein and Gigerenzer (2002, pp. 84-85) in which German participants were experimentally exposed to the names of US cities without being presented with any further information which might be of use, and is also comparable with Schooler and Hertwig's (2005) ACT-R implementation of the recognition heuristic, which also assumed chance level performance when both items were recognized (Schooler & Hertwig, 2005, p. 614).

Figure 1: Proportion correct for the LINDA model when discrimination between two recognized items is at chance

Figure 1 shows clear less-is-more effects for all values of the recognition-criterion correlation tested. As more items are recognized (beyond a mid-point of 50% recognition rate) the proportion of correct inferences drops.

Unlike the RH model, which requires quite large criterion-recognition correlations to allow recognition validity to exceed knowledge validity, LINDA shows less-is-more effects for all values of the criterion recognition correlation, ρ , although the largest less-is-more effects occur for the largest values of ρ . For comparison, Figure 2 shows the predicted performance of the RH when knowledge validity is at chance and recognition validity takes the values of ρ reported in Figure 1. The validity of recognition is determined to some extent by ρ , which is determined for LINDA by the orderings of subset availability, and she experiences less-is-more effects occur even with low and zero values of ρ .

Figure 2: Predictions for the RH when recognition validity (RV) takes the values of the recognition-criterion correlation reported for LINDA. In this example, the RH is followed despite below-chance levels of validity ($RV < 0.5$) which may not be realistic, but alternative strategies have yet to be suggested for these situations and, in particular, the point at which the RH is abandoned is not clearly outlined.

Example 1 relies upon the assumption that distinguishing between two recognized items is sufficiently difficult as to be effectively at chance. Both LINDA and RH are open to the criticism that, if knowledge validity for full recognition is chance, any non-random strategy able to operate when only one item is recognized will outperform knowledge and show less-is-more effects. This is a particular problem with the RH, where both knowledge validity and recognition validity are both set a priori for simulations such as this. Example 2 shows that low knowledge validity for full knowledge is not a necessary precondition for the appearance of less-is-more effects.

Example 2: Variation in subset availability. In order to formally compare LINDA with the RH model, we arranged that the models perform equally well when all items are recognized. Calculated probability of success when all items were recognized was 0.7525 for LINDA so knowledge validity was set at this level for the RH. The orderings of subsets in terms of recognition provide a potential rationale for variation in criterion-recognition correlation between individuals. Different orderings of subsets (and hence different recognition-criterion correlations) were simulated and the expected proportions correct using LINDA and the RH is given in Figure 2. We will use the notation *ABC* to denote subset availability, where *ABC* means that items from subset *A* are all more recognizable than the items from subset *B*, which in turn are all more recognizable than the items from subset *C*. A strict *ABC* recognition order obviously implies a high recognition-criterion correlation. Other recognition orderings (e.g., *ACB*) imply lower criterion-recognition correlations. *ABC* ordering is equivalent to a correlation between recognition and criterion of $\rho = .919$ and *ACB* ordering is equivalent to $\rho = .306$.

Figure 3. Performance of LINDA and the RH according to a recognition - criterion correlation determined by the recognizability of subsets. *ABC* ordering results in a high correlation and *ACB* a low (but still positive) correlation.

Figure 3 shows the performance of LINDA and the RH model for two different criterion-recognition orderings: *ABC* (items in the top quartile of the size distribution are most recognizable and items below median are least recognizable) and *ACB* (items in the top quartile are most recognizable, then items from below the median and finally items from the second quartile). *ABC* ordering corresponds to a strong criterion-recognition correlation ($\rho = .919$) and *ACB* ordering to a smaller, but still positive, correlation between criterion and recognition ($\rho = .306$).

The *ABC* ordering produces the expected effects from the literature. The RH model shows the less-is-more effect, while the knowledge-based LINDA model shows a monotonic relation between proportion correct and number of recognizable items. The situation is quite different for the *ACB* ordering: here, LINDA produces an inverted-U shaped function and a less-is-more effect. Less-is-more effects therefore do not imply use of the recognition heuristic – even given a positive criterion-recognition correlation – but may occur for other reasons. The inverted-U shaped functions that characterize the less-is-more effect indicate that a task becomes more difficult once the number of recognizable items passes a certain level. In the case of the RH model and the *ABC* ordering, this is because “easy” decisions (select the recognized item when only one item is recognized) are gradually outnumbered by “difficult” decisions (choose between items, both of which have been recognized) as the number of recognizable items increases. In the case of LINDA and the *ACB* ordering, moderate levels of recognition produce many easy decisions (discriminating a recognized item drawn from subset *A* from a recognized item drawn from subset *C*) but the decisions become more difficult when items of intermediate size, from subset *B*, begin to join the pool of recognizable items as the number of recognizable items increases.

Discussion

Whilst the two models give less-is-more effects in different circumstances, the effects are produced for essentially the same reasons. When few items are recognizable, the task is easier than when many items are recognizable. In the case of the RH model, for both Examples 1 and 2, when few items are recognizable the individual is more frequently confronted with the easy decision of selecting the one item recognized, rather than the problematic case of choosing between two recognized items, and this position is reversed when many items are recognizable. In Example 1 LINDA benefits from knowledge about the single item recognized which is not available to discriminate between two recognized items. For LINDA, performance in Example 2 for intermediate levels of recognition (up to 75 items) continues to improve as recognition rates rise because the discrimination required is still more likely to be between an item drawn from top quartile (subset A) and an item drawn from the bottom quartiles (subset C). Adding items from the second highest quartile (subset B), however makes the task more difficult this and leads to a drop in performance, and hence a less-is-more effect, at this point.

The fluency rule (discussed by Schooler & Hertwig, 2005) produces similar results and, once again, for similar reasons. Those items which are retrieved more quickly, dependent upon memory activation-level, are presumed to score more highly on the criterion (e.g., large cities are more quickly retrieved). For the fluency rule, intermediate rates of decay of activation allow for better discrimination between activated items than either fast or slow rates of decay. Over time, both slow and fast forgetting producing similar activation levels for dissimilar items (e.g., very large and very small cities). However, the fluency rule does not require or use any knowledge beyond the fact of fast retrieval. Thus, although it produces less-is-more effects of a kind, these are arguably recognition-driven based upon speed of access, rather than knowledge-driven, based upon some item-specific knowledge. The fluency rule is also reliant upon a fixed rate of decay from memory, an assumption which has recently been challenged (Berman, Jonides & Lewis, 2009; Lewandowsky & Oberauer, 2009; Lewandowsky, Oberauer & Brown, 2009; Nairne, 2002).

Testing LINDA.

LINDA demonstrates that less-is-more effects can occur for knowledge-based decisions and also that, when discrimination between two recognized items is sufficiently difficult, these effects can occur regardless of the recognition-criterion correlation. She therefore stands as an existence proof that less-is-more effects need not imply the use of recognition-driven inference but can be produced by strategies that invoke criterion knowledge. Any model that makes use of limited knowledge is likely to produce LINDA-like behavior.

Although LINDA reproduces the less-is-more effects observed with the RH, it is also worth noting that knowledge-based and recognition-based less-is-more effects

are, or should be, empirically distinguishable. LINDA produces less-is-more effects similar to the RH when full knowledge has validity only slightly higher than chance but, unlike the RH, LINDA produces such effects regardless of the size of the recognition-criterion correlation (Figure 1). She also shows less inclination to produce such effects when knowledge validity is not artificially constrained and the recognition-criterion correlation is particularly high. Indeed, LINDA is more likely to show less-is-more effects when the recognition-criterion correlation is rather more moderate (Figure 3). Thus, although LINDA provides a plausible alternative account of existing less-is-more effects, there are experimental manipulations not yet investigated which should provide data that favor either one account or the other.

Appendix

1. Derivation of the values of p_{ijk} in Equation (1):

Probability of recognizing no items:

$$p_{000} = [(N - a - b - c)/N] \times [(N - a - b - c - 1)/(N - 1)] \\ = (N - a - b - c)(N - a - b - c - 1)/[N(N - 1)]$$

Probabilities associated with the recognition of only one item:

$$p_{100} = [2a/N] \times [(N - a - b - c)/(N - 1)] \\ = 2a(N - a - b - c)/[N(N - 1)]$$

Probability of recognizing one item from the top quartile.

Similarly for second quartile and below median:

$$p_{010} = 2b(N - a - b - c)/[N(N - 1)] \\ p_{001} = 2c(N - a - b - c)/[N(N - 1)]$$

Probabilities associated with the recognition of both items:

$$p_{110} = 2ab/[N(N - 1)] \\ \text{(one item is in the top quartile and one item is in the second quartile)} \\ p_{101} = 2ac/[N(N - 1)] \\ p_{011} = 2bc/[N(N - 1)] \\ \text{(as above, substituting } v \text{ and } w \text{ where appropriate)} \\ p_{200} = a(a - 1)/[N(N - 1)] \\ \text{(both items are in the top quartile)} \\ p_{020} = b(b - 1)/[N(N - 1)] \\ p_{002} = c(c - 1)/[N(N - 1)] \\ \text{(as above, substituting } v \text{ and } w \text{ where appropriate)}$$

2. α_{ijk} parameters for the LINDA model demonstrated in Example 2.

$$\alpha_{000} = 0.5$$

No items are recognized, performance is chance.

$$\alpha_{100} = [0.5 \times (0.25N - a)/(N - a - b - c)] \\ + [(0.75N - b - c)/(N - a - b - c)]$$

Probability correct if one item from the top quartile is recognized.

$$\alpha_{010} = 0.5 \times (0.25N - b)/(N - a - b - c) \\ + (0.5N - c)/(N - a - b - c)$$

Probability correct if the recognized item is in the second quartile.

$$\alpha_{001} = (0.5N - a - b)/(N - a - b - c) \\ + 0.5 \times (0.5N - c)/(N - a - b - c)$$

Probability correct if the recognized item is below median.

$$\alpha_{110} = 0.5$$

Two items are recognized: one item is in the first quartile and the second item is in the second quartile, so with median knowledge, performance is chance.

$$\alpha_{101} = \alpha_{011} = 1$$

One recognized item is above median and one is below so success is certain.

$$\alpha_{200} = \alpha_{020} = \alpha_{002} = 0.5$$

Both recognized items are from the same quartile, and so cannot be distinguished.

3. α_{ijk} parameters for the Recognition Heuristic model demonstrated in Example 2.

$$\alpha_{000} = 0.5$$

$$\alpha_{100} = 0.5 \times (0.25N - a)/(N - a - b - c) \\ + (0.75N - b - c)/(N - a - b - c) \\ = (0.875N - 0.5a - b - c)/(N - a - b - c)$$

There is only one item recognized, it is in the top quartile.

$$\alpha_{010} = 0 \\ + 0.5 \times (0.25N - b)/(N - a - b - c) \\ + (0.5N - c)/(N - a - b - c) \\ = (0.625N - a - b - c)/(N - a - b - c)$$

The recognized item is in the second quartile.

$$\alpha_{001} = 0 \\ + 0.5 \times (0.5N - c)/(N - a - b - c) \\ = (0.25N - 0.5c)/(N - a - b - c)$$

The recognized item is below median.

$$\alpha_{110} = \alpha_{101} = \alpha_{011} = \alpha_{200} = \alpha_{020} = \alpha_{002}$$

All these cases involve recognition of both items, and it is assumed knowledge can be used with a certain probability of success. In the Example 2, this probability was chosen to ensure that the LINDA and RH models produced the same probability of success when all items were recognized.

What Makes a Good Reasoner?: Brain Potentials and Heuristic Bias Susceptibility

Abstract

Human reasoning is often biased by intuitive heuristics. A key question is why some people are less susceptible to this bias than others. It is debated whether the bias results from a failure to monitor one's intuitive conclusions for conflict with logical considerations or from a failure to inhibit the tempting intuitions. This results in different views on the role of individual differences in executive monitoring and inhibition capacity for sound reasoning. The present study presents a new approach to address this issue. After an initial reasoning screening a group of the most and least biased reasoners were invited for an EEG study in which neural markers of their executive monitoring (ERN amplitude) and inhibition (N2 amplitude) skills were recorded. Results indicated that biased reasoners were characterized by less developed inhibition but not monitoring capacity. Findings support the view that monitoring one's intuition for conflict during thinking is a flawless and undemanding process suggesting that even the poorest reasoners at least detect that they are biased.

Keywords: Decision-making; Reasoning; EEG

Introduction

Decades of reasoning and decision-making research showed that human thinking is often biased (Evans, 2008; Kahneman, 2002). In general, human reasoners seem to have a strong tendency to base their judgment on fast intuitive impressions rather than on more demanding, deliberative reasoning. Although this intuitive or so-called "heuristic" thinking can be very useful, it will sometimes cue responses that conflict with traditional normative logical or probabilistic considerations and bias our decision-making.

Whereas it is well established that human judgment is often biased, the nature of this bias is far less clear. Some influential authors have argued that the widespread heuristic bias can be attributed to a failure to monitor our intuition (e.g., Kahneman & Frederick, 2002). Because of lax monitoring, people would simply fail to detect that the intuitive response conflicts with normative considerations. However, others have argued that there is nothing wrong with the monitoring process (e.g., Epstein, 1994; Houdé, 2007; Sloman, 1996). According to these authors, people have little trouble in detecting that their intuitive response is

biased. The problem, according to this view, is that people's intuitive beliefs are so tempting that they fail to discard them. Thus, people "behave against their better judgment" (Epstein, 1994) when they give an unwarranted heuristic response: They detect that they are biased but simply fail to block the biased response. In sum, according to this flawless detection view, biased decisions are attributed to an inhibition failure rather than a conflict monitoring failure per se.

The debate on the nature of heuristic bias results in opposing views on the interpretation of individual differences in bias susceptibility. Although the vast majority of educated adults are typically biased when solving classic reasoning and decision-making tasks, some people do manage to reason correctly and refrain from giving the tempting but unwarranted heuristic response. Individual differences in executive control capacity (as measured with general working memory or intelligence test) are widely cited as the cause of this reasoning performance variability (e.g., De Neys, 2006; De Neys & Verschueren, 2006; Evans, 2008; Stanovich & West, 2000). However, conflict monitoring and inhibition are both considered key executive processes and the precise contribution of each component as possible mediator of reasoning performance has not been established. Bluntly put, it is not clear what makes a good reasoner: Having a superior monitoring capacity, having a superior inhibition capacity, or a combination of both.

The two views on heuristic bias make differential predictions here. According to the lax monitoring view, people are mainly biased because of inefficient monitoring. Hence, one can expect that good reasoners will be primarily characterized by superior executive monitoring skills. Good reasoners will be better at monitoring their intuitively cued conclusions for conflict with more normative considerations and will be more likely to detect that their initial response is biased. However, the flawless monitoring view conceives monitoring during thinking as a quite undemanding process by entailing that even the most biased reasoners are successful at it (De Neys, Moyens, & Vansteenwegen, 2010; Franssens & De Neys, 2009). Hence, given the postulated minimal demands of the monitoring process during thinking, one can predict that individual differences in

executive monitoring skills per se should have little impact on one's reasoning performance: Even people with the least developed monitoring skills should manage to detect the conflict during thinking. According to this view, it will be specifically one's inhibitory capacities that will determine the reasoning performance.

Clarifying the nature of heuristic bias and the individual bias differences is crucial for the study of human thinking. The issue has also far-reaching implications for our view of human rationality and the design of more optimal intervention programs to "debias" human thinking (De Neys & Glumicic, 2008; Evans, 2008). The problem, however, is that it is hard to decide between the alternative views based on traditional reasoning data (Evans, 2007, 2008). Although there have been some recent attempts to break the stalemate by developing processing measures of conflict detection and inhibition during reasoning (e.g., De Neys & Franssens, 2009), the rival views persist. The present study introduces a new approach to address this issue by focusing on neural markers of individual differences of conflict monitoring and response inhibition.

In the study we first invited a large number of participants for an initial screening session in which they were presented with reasoning problems based on two of the most-famous tasks from the judgment and decision-making field: Kahneman and Tversky's (1973) base-rate neglect and conjunction fallacy problems. In these tasks a stereotypical description cues a strong intuitive response that conflicts with more traditional probabilistic normative considerations (see Material for examples). Sound reasoning on these problems requires that people detect the conflict and inhibit the inappropriate heuristic response. Based on the screening, we invited a group of the least and most biased reasoners (i.e., participants with the highest and lowest normative reasoning scores) for a follow-up study in which they were presented with a Go/No-Go task while electroencephalography (EEG) was recorded. The Go/No-Go task is a classic task that is widely used to measure people's executive control abilities (e.g., Amodio et al., 2007; Nieuwenhuis et al., 2003). In the task participants must quickly respond to a frequently presented Go stimulus such that the 'Go' response becomes habitual. However, on a small proportion of trials, a No-Go stimulus appears, signaling that one's habitual response should be withheld.

The EEG recording allowed us to test for a possible neurological marker of the differential executive monitoring and/or inhibition capacities of the least and most biased thinkers. Available evidence suggests that the operation of the executive monitoring and inhibition components are reflected in two different event-related potentials (ERP). On one hand, erroneously solved No-Go trials on which participants give the inappropriate dominant 'Go' response are known to give rise to a specific ERP referred to as the Error-Related Negativity or ERN. The ERN is a sharp negative voltage deflection in the EEG that typically peaks about 50 ms after an erroneous response. The ERN is believed to reflect executive control activity associated with

the monitoring of conflict and error (Amodio et al., 2004, 2006; Compton et al., 2008; but see Burle et al., 2008). Available evidence suggests that the ERN amplitude is typically larger for people with better monitoring skills (Amodio et al., 2006; Inzlicht et al., 2009).

On the other hand, correctly solved No-Go trials on which participants manage to withhold the dominant 'Go' response are known to give rise to the so-called N2. The N2 is a negative voltage deflection in the EEG that typically peaks about 200 ms after the stimulus onset (i.e., before the response). The N2 is believed to reflect executive control activity associated with the successful inhibition of the prepotent Go response (Nieuwenhuis et al., 2003). Available evidence suggests that the few times that people with less developed inhibitory abilities do manage to withhold the Go response, the N2 amplitude is larger than for people with high abilities (e.g., Johnstone et al., 2007; Kaiser et al., 2003; Prox et al., 2007; Smith, Johnstone, & Barry, 2004; but see also Falkenstein, Hoormann, & Hohnsbein, 1999). This larger N2 amplitude has been interpreted as reflecting the fact that people who have fewer inhibitory control resources will need a much higher activation of the neural control structures for the response inhibition to be successful (Prox et al., 2007; Smith et al., 2004).

In sum, the EEG literature suggests that individual differences in executive inhibition abilities affect the N2 amplitude, whereas individual differences in executive monitoring abilities affect the ERN amplitude. Hence, contrasting these components in a group of biased and unbiased reasoners can help us to clarify the nature of individual differences in heuristic bias susceptibility. If the lax monitoring view is right and good reasoners are characterized by superior monitoring ability, the ERN should be more pronounced for the unbiased than for the biased reasoners. If the flawless monitoring view is right and good reasoners are characterized by superior inhibition rather than monitoring ability, biased and unbiased reasoners should not show a differential ERN and only the N2 should differ in the two groups.

Reasoning Bias Screening

Method

Participants. A total of 399 psychology undergraduates participated in return for course credit.

Material. To screen participants' bias susceptibility during reasoning we presented them with a booklet containing a total of three conjunction fallacy and three base-rate neglect problems. Problems were presented in a fixed, randomly determined order. In all problems a stereotypical description cued a heuristic response that conflicted with the normative response that is traditionally considered correct. Problem content was based on the work of De Neys, Vartanian, and Goel (2008). The exact problem format is illustrated below.

The average number of correct normative responses was taken as an index of people's reasoning performance.

Conjunction fallacy problems. In each problem participants first read a short personality description of a character. Next, they were given two statements about the character and were asked to indicate which one of the two was most probable. One statement always consisted of a conjunction of two characteristics (one characteristic that was likely given the description and one that was unlikely). The other statement contained only one of these characteristics (i.e., the unlikely one). Consider the following example:

Bill is 34. He is intelligent, punctual but unimaginative and somewhat lifeless. In school, he was strong in mathematics but weak in social studies and humanities.

Which one of the following statements is most likely?

- a. Bill plays in a rock band for a hobby
- b. Bill is an accountant and plays in a rock band for a hobby

Normative considerations based on the conjunction rule always cue selection of the non-conjunctive statement. However, intuitively, people will tend to select the statement that best fits with the stereotypical description (i.e., the most representative statement, see Tversky & Kahneman, 1983). Clearly, the fit will be higher for the conjunctive statement than for the unlikely non-conjunctive statement. Hence, people will be intuitively tempted to pick the erroneous conjunctive statement.

Base-rate neglect problems. In each problem participants first read information about the composition of a sample. People were also informed that short personality descriptions were made of all the individuals in the sample and they would get to see one description that was drawn randomly from the sample. They were asked to indicate to which one of the two groups the randomly drawn individual most likely belonged. Consider the following example:

A psychologist wrote thumbnail descriptions of a sample of 1000 participants consisting of 995 females and 5 males. The description below was chosen at random from the 1000 available descriptions.

Jo is 23 years old and is finishing a degree in engineering. On Friday nights, Jo likes to go out cruising with friends while listening to music and drinking beer.

Which one of the following two statements is most likely?

- a. Jo is a man
- b. Jo is a woman

Normative considerations based on the group size or base-rate information cue response (b). Given the size of the two groups in the sample, it will be more likely that a randomly drawn individual will belong to the largest group. However, people will be tempted to respond (a) on the basis of stereotypical beliefs cued by the description. Hence, just as in the conjunction problems, normative considerations will conflict with the cued heuristic response.

Descriptions were selected on the basis of an extensive pilot study (Franssens & De Neys, 2009). Selected descriptions moderately but consistently cued one of the two groups. This point is not trivial. We label responses that are in line with the base-rates as correct answers. However, if reasoners adopt a formal Bayesian approach (e.g., Gigerenzer, Hell, & Blank, 1988) and combine the base-rates with the diagnostic value of the description, this can lead to complications when the description is extremely diagnostic. Imagine that we have a sample of males and females and the description would state that the randomly drawn individual "gave birth to two children". Now, by definition, no matter what the base-rates in the sample are, one would always need to conclude that the person is a woman. We limited the impact of this problem by only selecting descriptions that were judged to have a moderate diagnostic value. By combining these with quite extreme base-rates (i.e., 995 and 5) one may generally conclude that the response that is cued by the base-rates should be selected if participants manage to refrain from giving too much weight to the intuitive answer cued by the description.

Results and Discussion

The reasoning performance of our screening sample replicated the typical results in previous studies. Overall, participants were typically biased and gave the cued heuristic responses. The average percentage of correct normative responses on the six problems was only 24% ($SD = 33\%$). This pattern was similar for the conjunction ($M = 21\%$, $SD = 32\%$) and base-rate problems ($M = 28\%$, $SD = 31\%$).

After the screening we invited a group of the most (i.e., participants who always gave the heuristic response) and least biased reasoners (i.e., participants who gave at least one normative response on both the conjunction and base-rate problems) for the EEG recording session. This cutoff value (at least one response correct) corresponded to the median accuracy for both types of reasoning problems.

EEG Recording

Method

Participants. After the bias screening seven of the least and seven of the most biased reasoners were recruited for the main Go/No-Go EEG study. We refer to these groups as the poor and good reasoners, respectively (see Table 1 for an overview of their reasoning screening performance). Participants were paid €25 for their participation.

Material. Go/No-Go task. The Go/No-Go task was based on the procedure introduced by Nieuwenhuis et al. (2003) and Amodio et al. (2007). On each trial, either the letter "M" or "W" was presented in the center of a computer screen. Approximately half of the participants in each group were instructed to make a "Go" response (mouse button press) when they saw "M" but to make no response when

they saw “W”; the remaining participants completed a version in which “W” was the Go stimulus and “M” the No-Go stimulus. Each trial began with a fixation point, presented for 500 ms. The target then appeared for 100 ms, followed by a blank screen. Participants were instructed to respond within 500 ms of target onset. A warning message appeared on the screen for 1 s after responses that exceeded this deadline and after erroneous responses. The inter trial interval was 1 s.

The task consisted of 600 trials: 80% Go trials and 20% No-Go trials. The high frequency of Go trials induced a prepotent “Go” response, enhancing the difficulty of successfully overriding a response on the critical No-Go trials. Participants received a short 2-min break after every 150 trials.

Procedure. EEG recording. Participants were fitted with a Quickcap, and EEG was collected from 128 equidistantly positioned scalp sites using Ag/AgCl electrodes. The active reference electrode was placed on the vertex between electrodes Cz and Cpz. A ground electrode was placed on the forehead close to AFz. Vertical and horizontal electro-oculogram (EOG) was collected to permit the reduction of the artifact due to eye movements. Impedances were below 5k Ω at each scalp site. EEG was recorded through a 0.15 – 30 Hz bandpass filter and digitized at 1000 Hz using a SynAmps2 amplifier. Data were referenced to the average earlobe. Offline, we used a computerized algorithm to remove eye-blink artifacts. EEG epochs with voltage exceeding ± 200 μ V were rejected as reflecting additional artefact.

ERP processing. N2. Our quantification of the N2 and ERN was based on Amodio et al. (2007). For N2 quantification a 1000 ms epoch of EEG signal, beginning 200 ms prior to stimulus onset, was selected for each artifact-free trial. Baseline correction procedures subtracted the average voltage during the 200 ms interval before stimulus onset within each epoch from the entire epoch. Epochs associated with correct responses on Go and No-Go trials were averaged within their respective trial types. The N2 was scored as the peak negative deflection occurring between 200 and 400 ms, relative to target onset, at the vertex site (Cz), where it is typically maximal. The critical N2 component refers to the average N2 amplitude associated with correct “No-Go” responses.

ERP processing. ERN. For quantification of the ERN an 800 ms response-locked epoch of EEG signal, centered on the time of response within each trial, was selected for each artifact-free trial. Baseline correction procedures subtracted the average voltage occurring from 400 ms to 50 ms prior to the response from the entire epoch. Epochs associated with incorrect responses on No-Go trials and correct responses on Go trials were averaged within their respective trial types. The ERN was scored as the peak negative deflection occurring between -50 and 150 ms, relative to response onset, at the frontocentral scalp site (Fcz). The critical ERN

component refers to the average amplitude associated with incorrect “Go” responses on “No-Go” trials.

Results and Discussion

Behavioral findings. The behavioral Go/No-Go performance of our two groups of reasoners (see Table 1) was as expected. Accuracy on the No-Go trials is considered an excellent marker of people’s executive control ability. Consistent with the well established finding that good reasoners have superior executive control capacities, we observed that our group of unbiased reasoners outscored the more biased group on the No-Go trials, $F(1, 12) = 11.26$, $p < .01$, $\eta^2p = .48$. As expected, accuracy on the Go trials, where correct responding did not require monitoring or overriding the intuitive response, was at ceiling and did not differ for the two groups of reasoners, $F(1, 12) < 1$.

Table 1: Average (SD) Reasoning and Go/No-Go Accuracy

	Reasoning			Go/No-Go	
	Base-rate	Con-junction	Total	No-Go	Go
Poor reasoners	0% (-)	0% (-)	0% (-)	67% (11)	99% (1)
Good reasoners	52% (26)	62% (30)	57% (21)	83% (5)	99% (1)

N2 findings. Our ERP data indicated that the average N2 amplitude differed in the group of good and poor reasoners, $F(1, 12) = 4.75$, $p < .05$, $\eta^2p = .28$. As Figure 1 shows, whenever the poor reasoners did manage to solve No-Go trials correctly this was accompanied by a more pronounced N2 amplitude (i.e., a more negative deflection). Next, we also calculated the correlation between each individuals’ actual reasoning performance on the base-rate and conjunction problems and their N2 amplitude. This analysis showed that in our restricted sample of good and poor reasoners, the N2 amplitude was a good predictor of the tendency to give the standard normative response on these classic reasoning problems, $r = .55$, $p < .05$. Hence, the better participant’s executive inhibition capacity, as indexed by their N2 amplitude, the more they managed to refrain from heuristic responding during reasoning.

ERN findings. As Figure 1 indicates, in contrast with the N2 findings, the average ERN amplitude did not differ for our group of good and poor reasoners, $F(1, 12) < 1$. A correlational analysis also established that the ERN amplitude was not predictive of participant’s reasoning performance, $r = .14$, $p = .63$. Consistent with the flawless monitoring view, this suggest that individual differences in bias susceptibility during reasoning are not driven by differences in executive monitoring skills as indexed by the ERN amplitude.

Figure 1. ERP waveforms corresponding to correct No-Go responses (N2 top panel, stimulus onset at 0 ms) and incorrect No-Go responses (ERN bottom panel, response onset at 0 ms), with the waveform for correct Go responses subtracted, for the most (poor) and least (good) biased reasoners.

General Discussion

In the present EEG study we contrasted neural markers of people's executive monitoring (ERN amplitude) and inhibition (N2 amplitude) capacity in two groups who showed differential susceptibility to heuristic bias during reasoning. Results indicated that less biased reasoners showed a smaller N2 amplitude than more biased reasoners while the ERN amplitude of biased and unbiased reasoners did not differ. Consistent with the flawless monitoring view, this suggests that good reasoners are specifically characterized by a superior executive inhibition capacity rather than by a superior monitoring capacity. Hence, what makes a good, unbiased reasoner is not a more developed ability to monitor one's intuitive conclusions for conflict with normative considerations but the ability to inhibit these tempting erroneous intuitions in case such a conflict occurs.

It should be stressed that the present results do not downplay the importance of conflict monitoring during reasoning per se. Both the lax and flawless monitoring views consider the monitoring of one's intuitive inferences as a cornerstone of the reasoning process. Obviously, if people would not monitor their intuitively cued problem solutions, they could simply not detect whether or not it is necessary to override them. Indeed, even the most gifted reasoners do not simply inhibit intuitive inferences throughout and tend to rely on heuristic computations in case it is appropriate (e.g., De Neys & Franssens, 2009; De Neys, Schaeken, & d'Ydewalle, 2005). As suggested previously (e.g., De Neys & Glumicic, 2008), the

monitoring process allows reasoners to take advantage of the computational benefits (e.g., speed) of heuristic thinking as long as it does not conflict with normative principles. The key point, however, is that this crucial monitoring process does not seem to be very demanding. According to the flawless monitoring view, monitoring one's intuitions during reasoning is an effortless process that requires only minimal executive monitoring resources. It is this postulated undemanding or automatic nature of the monitoring process during reasoning that can explain why individual differences in executive monitoring capacity do not affect the reasoning performance. The undemanding nature of the monitoring during thinking entails that even for people with minimal executive monitoring resources, the process will be successful.

Our individual differences findings fit with some recent studies that started examining the processing characteristics of the conflict monitoring process during thinking. For example, Franssens and De Neys (2009) tested the postulated effortless nature of the monitoring process in a dual task study. People were asked to solve base-rate problems while their executive resources were burdened with a secondary task. After the reasoning task participants were also presented with a surprise recall test that can be used to measure whether people were monitoring their intuitive inferences and detected the conflict between cued intuitive and normative responses (see De Neys & Glumicic, 2008). Results showed that reasoning accuracy decreased under load (i.e., people gave more heuristic responses). However, the crucial finding was that the conflict monitoring index was not affected by the load. People were equally accurate in detecting the presence of conflict whether or not they were reasoning under load. Combined with the present individual differences findings these studies lend credence to the idea that conflict monitoring during thinking is effortless and flawless.

The present study is the first one to introduce EEG methodology to examine the nature of individual differences in bias susceptibility. Clearly, this implies that our results need to be interpreted with some caution. Although our data fits with recent findings pointing to the effortless nature of the monitoring process during thinking, the results will need to be validated in future studies. Bearing this in mind, our initial findings do suggest that individual differences in executive monitoring are not playing a major role in people's bias susceptibility. A good, unbiased reasoner seems to be primarily characterized by superior inhibitory skills. Although most reasoners might be detecting that their intuitive answer is biased, only people with superior inhibitory capacity manage to discard the tempting intuitive response.

Keywords: embodied cognition; computation; concepts.

Overview and Motivation

Embodied cognition is a theoretical stance which postulates that sensory and motor experiences are key parts of the representation of our knowledge. This view has challenged the longstanding assumption that knowledge is represented abstractly in an amodal conceptual network.

There now exist a large number of interesting and intriguing demonstrations of embodied cognition. Examples include changes in perceptual experience or motor behaviour as a result of semantic processing. These demonstrations have received a great deal of attention in the literature, and have spurred many researchers to take an embodied approach in their own work.

There are also a number of theoretical accounts of how embodied cognition might work. One influential proposal is “perceptual symbols system” theory, according to which the retrieval of conceptual meaning involves a partial re-enactment of experiences during concept acquisition. However, to a large extent, embodied theories are still developing, particularly in terms of computational implementations, as well as specification with regard to moment-by-moment on-line processing.

Given the established empirical foundation, and the relatively underspecified theories to date, many researchers are extremely interested in embodied cognition but are clamouring for more mechanistic implementations. This symposium aims to address this specific need for more detailed explorations of the specific processing mechanisms involved in embodied cognition. Four speakers from varying backgrounds and approaches will describe how they think the human mind is embodied, and what they view as the critical current and next steps toward mechanistic theories of embodiment.

Toward Implementing Embodiment

Lawrence Barsalou (Emory University, Atlanta, Georgia, USA) and Ken McRae (University of Western Ontario, London, Canada) will address issues concerning the construction of embodied computational models. One general set of issues concerns the computational architecture, aside from whether it takes the form of neural networks, Bayesian approaches, production systems, classic AI architectures, or another form. To implement a truly

embodied system, multiple modalities are essential. In particular, intelligent action coupled with perception epitomizes embodied approaches, beyond basic response production. Other modalities are also essential from the embodied perspective, including affect and motivation, as well as abstract thought. Another architectural issue concerns the hierarchical structure of feature areas, the hierarchical structure of association areas, and the connectivity patterns among them (Simmons & Barsalou, 2003). Also important are the unique areas associated with bottom-up activation versus top-down simulation, along with shared areas. Finally, issues associated with the architecture’s development and plasticity are important, including genetic and experiential contributions, and how epigenesis is realized (Elman et al., 1996).

A second set of critical issues surrounds specific forms of functionality to implement in the architecture. Barsalou (2003) argues that selective attention and categorical memory integration are essential for creating a symbolic system. Once these functions are present, symbolic capabilities can be built upon them, including type-token propositions, predication, categorical inference, conceptual relations, argument binding, productivity, and conceptual combination. Another key aspect is the implementation of space and time. Perception, cognition, and action must be coupled in space and time, and simulations of non-present situations must be implemented in space and time, perhaps using overlapping systems.

Because situated action in the environment is fundamental for all organisms, implementing embodied cognition that supports intelligent activity in a few critical situations may be a good place to start (Robbins & Aydede, 2008). By focusing on a complete embodied approach to achieving goals in specific situations, modelers must not only implement specific capabilities, such as goal setting, planning, perception, action, cognition, affect, reward, and learning, but implement interfaces that allow all these processes to interact effectively.

These are lofty goals indeed, and the remaining talks will describe current projects that are working toward them.

Computational Explorations of Perceptual Symbol Systems Theory

The second speaker is **Giovanni Pezzulo** (National Research Council, Rome, Italy) who has worked extensively

on computational models of embodied cognition. He will present an overview of his computational work and describe the precise mechanisms and processes involved in the emergence of embodied cognitive performance.

Pezzulo will present a computational architecture that acquires a “perceptual symbol system” through its autonomous interaction with the environment, and assembles perceptual symbols to form simulators for perceptual and abstract categories.

He will discuss the design of the architecture, which includes a combination of schema-based and dynamical systems principles, with the aim of suggesting a few basic mechanistic principles from which embodied theories of cognition can be implemented and tested.

Pezzulo will also discuss more generally the functioning of the perceptual-symbol-system-based architecture in prediction, categorization, and abstraction tasks, with the aim to assess the possible roles of perceptual symbols systems in producing embodied cognitive processing.

It is worth noting that, in addition to their use as “proofs of concept” for an embodied theory of cognition such as perceptual symbol systems, the importance of computational models also lies in the possibility to investigate elements that are left unspecified in the initial theoretical formulations, or that are challenging to study by means of experimental methods only. Therefore, Pezzulo will discuss the specific predictions and implications of our computational architecture for the perceptual symbol systems theory, and in particular the (tentative) answers it gives to challenging questions such as: *How are simulators formed from perceptual symbols? Which features are stored in simulators, and which are not? How are the most relevant simulators selected depending on the organism’s goals and the current environmental context?*

Cognitive Modeling with the Open Source Humanoid Robot iCub

The third speaker is Angelo Cangelosi (University of Plymouth, UK) who leads a large-scale EU project on language and action learning (www.italkproject.org) and the Marie Curie doctoral network on developmental robotics (www.robotdoc.org). Approaching embodiment from an engineering and cognitive modeling perspective, his talk will describe the current state of development of efforts to implement human cognition in a physical agent with sensory and motor capabilities. He will describe in detail two current cognitive robotics models based on the humanoid robot iCub: one study on stimulus response compatibility effects and one on language acquisition. In addition, he will present the open source humanoid robotic platform iCub, and the associated computer simulator.

A Theoretical Framework for Embodied Cognition

The final speaker, Michael J. Spivey (University of California, Merced, USA), is a cognitive scientist who uses

eye-tracking, reach-tracking, and neural network simulations to explore the close-knit relationship between sensorimotor processes and high-level cognition (Spivey, 2007). In Spivey’s talk, he will discuss how the mountains of evidence for embodied cognition are now being acknowledged by classical cognitive scientists, albeit warily (Mahon & Caramazza, 2009). However, the next step, of how these many varied findings can impact traditional mainstream theories of cognition, is still not well articulated in the field. Rather than treating sensorimotor properties as “something extra” that gets facilitated after certain concepts become active, those sensorimotor properties may be part and parcel of the very conceptual representations themselves. What is needed at this stage is a push toward explicit computational models that implement sensorimotor grounding as intrinsic to cognitive processes. With such models, theoretical descriptions can be fleshed out as explicit mechanisms, idiosyncratic patterns across experiments may be explained, and quantitative predictions for new experiments can be put forward. Spivey will discuss some examples of such nascent modeling efforts.

On the Notion of Intended Meaning

Marco Cruciani (marco.cruciani@unitn.it)
Dept. of Information Engineering and Computer Science
University of Trento, Italy

Abstract

The issue of intended meaning is an open problem in the study of linguistic processes. The paper presents a notion of intended meaning based on the idea of speaker's preference for a state of affairs to which a sentence refers. Its argument has two components. The first is the conception of meaning developed by analytic philosophy of language; that is, the meaning of a sentence depends on the truth conditions of the sentence, and the meaning of an expression depends on contribution of that expression to the truth value of the sentence in which it appears. The second is the notion of agent's interest, as a state of affairs which implies a goal of agent, as developed by cognitive social theory. The paper maintains that a speaker's intended meaning establishes when the truth conditions of a sentence and the possibility conditions of the state of affairs preferred by the agent match. The last part of the paper illustrates three linguistic disputes to support its theoretical intuitions. The first dispute concerns syntactic ambiguity, while the other two disputes concern semantic ambiguity. The paper deals with the general problem of the semantic underdeterminacy of the conventional meaning of natural language sentences. Its specific contribution relates to the problem of intended meaning in communicative processes and to meaning negotiation processes in conflicting interactions.

Keywords: state of affairs; truth conditions; semantic underdeterminacy; intended meaning; interest; negotiation.

Introduction

The issue of intended meaning is an open problem in the study of linguistic processes (see Grice 1957, 1989; Kripke, 1979; Sperber & Wilson, 1986; Clark, 1996; Recanatì, 2001; Bach, 2004; Bianchi, 2006). In this paper I present a notion of intended meaning based on the notion of speaker's preference for a state of affairs to which a sentence refers. This notion derives from the analysis of negotiation processes and the determination of meaning in linguistic controversies provoked by ambiguous clauses in contracts. The paper's contribution to the notion of intended meaning is based on the following thesis: given a set of contextually plausible interpretations of a sentence, the agent's intended meaning is determined by his/her extra-semantic situational interests (Cruciani, 2009a). It uses the notion of interest viewed as a state of affairs preferred by an agent because it implies his/her goal (see Conte & Castelfranchi, 1995).

In my view, the notion of the intended meaning of declarative sentences is founded on the relation between the states of affairs in which a sentence is true and the speaker's preferences ordering in regard to the states of affairs in which the sentence is true. A sentence can be true with respect to different sets of truth conditions, which correspond to different states of affairs (more technically, they correspond to sets of states of affairs).

The state of affairs preferred by a speaker because it implies his/her goal provides the truth conditions which determine the intended meaning in the specific situation of use. From this perspective, the determination of intended meaning is viewed as a selection of a state of affairs which makes a sentence true (via truth conditions) and satisfies the agent's interest in situation.¹

However, the aim of the paper is not to argue in favour of this conception, since the author has done so elsewhere (Cruciani, 2009b), but rather to explain its ontology. The schema in figure 1 illustrates the notion of intended meaning as it is conceived here. At the bottom of the schema is a sentence which, given a context of use, has some plausible interpretations. Each interpretation refers to a state of affairs which makes the sentence true: that is, it refers to specific truth conditions. The correspondence between the state of affairs preferred by the speaker and one of the states of affairs which make the sentence true determines the intended meaning. In other words, when the possibility conditions of the state of affairs preferred by speaker match the truth conditions of a sentence, we have intended meaning.

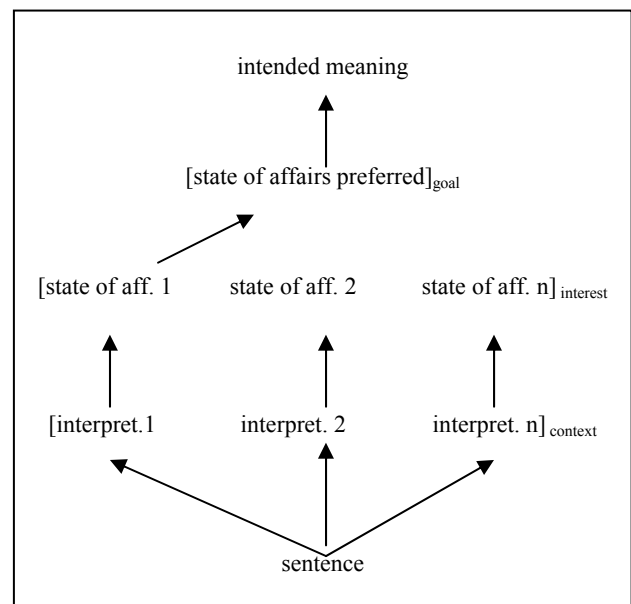

Figure 1

Meaning, Truth Conditions, States of Affairs and Context

In this section I illustrate the relation among meaning based on truth conditions, states of affairs, and context of use, and I outline some differences between semantics and pragmatics in regard to the phenomenon of semantic underdeterminacy. I base my view on the conception of

¹ Hence, the process of determining intended meaning can be explained in terms of preferences ordering.

meaning as developed by analytic philosophy of language (specifically by structural semantics). This maintains that the meaning of a sentence depends on its truth conditions, and that the meaning of an expression depends on the contribution of that expression to the truth value of sentence in which it appears (see Tarski, 1944). This notion entails that knowing the truth conditions of a sentence corresponds to knowing how the world would be if the sentence were true; but it does not correspond to knowing whether or not the sentence is actually true (see Wittgenstein, 1921). Hence, in cognitive terms, a speaker who knows the truth conditions of a sentence knows the meaning of the sentence even if s/he does not know how the world actually is, but only how it would be if the sentence were true.

The conception of meaning as (a set of) truth conditions is accepted by most philosophers and pragmatists of language. Any disagreement essentially concerns whether conventional meaning (obtained by linguistic conventions and rules) is sufficient to provide truth conditions or whether other items are required as well. In other words, is it sufficient to know semantic conventions and linguistic rules or do we need to know elements of the specific situation of use?

On a semantics view, conventional meaning and a small number of contextual parameters are sufficient to determine the truth conditions of a sentence (proposition expressed by the sentence). On a pragmatics of language view, conventional meaning is not sufficient to determine a unique set of truth conditions (semantic underdeterminacy): we need information on the context of use to complete the conventional meaning and to determine the truth conditions. Semantic underdeterminacy occurs when the conventional meaning of a sentence used by a speaker in a specific situation, coded by semantic conventions, underdetermines the proposition explicitly expressed by the utterance (see Travis, 1975, 1981; Searle, 1979, 1980).

In semantics, context is composed of some objective elements of the situation of utterance, and it is used to decode only some problematic kinds of expressions: indexical and demonstrative expressions such as “I”, “here”, “now” and “this”, “that” (see Kaplan, 1977)²; pronouns such as “she”, “he” (e.g. anaphoric use); cases of structural and lexical ambiguity (see Perry, 1997); and verbal tense.³ In semantics, truth conditions lie at the level of the objective context of utterance and conventional meaning (obtained by linguistic conventions and rules). Pragmatists do not agree, however, arguing that in order to fix truth conditions we need supplementary contextual information. This information consists of shared knowledge (encyclopaedic and local), the discourse or sentence in which an expression is used, and elements of the physical surroundings.⁴ A technical distinction between information on the semantic context and information on the pragmatic context is that the former is made accessible by and constrained to linguistic form of expression, while the latter is made accessible by

speaker’s communicative intentions and is not constrained to linguistic form.

I do not deal, in the paper, with the problem of whether there is a need for non-linguistic information to fix a unique set of truth conditions; there is a need (pragmatics/semantics distinction debate). I instead deal with the problem of intended meaning when a number of interpretations are all plausible in the same context (any context or combination of contexts).

I report a simple example to shed light on this point. The issue is the following: the conventional meaning of a sentence, even without indexical expressions, and structural and lexical ambiguity, actually underdetermines the proposition expressed by the sentence. And even with the additional pragmatic contribution of relevant contextual information, it is not always possible to fix a unique proposition. The sentence is as follows: (1) “there is water on Pluto”. I do not know whether there is water on Pluto, but I understand the sentence because I am able to imagine the ways in which there might be water on Pluto: for example, in the form of ice on the planet’s surface or in the form of gas in its atmosphere. Consequently, sentence (1) can have at least two interpretations (two different sets of truth conditions); that is, it can be true both if there is water in the form of ice on the surface and if there is water in the form of gas in the atmosphere. The two truth conditions correspond to different states of affairs:

- a. “there is ice on the surface of Pluto”;
- b. “there is water vapour in the atmosphere of Pluto”.

Hence, (1) can refer to both states of affairs. This is the case if we consider linguistic conventions, but also, in our propaedeutical example, if we consider the text of the sentence in which the word “water” appears and we use encyclopaedic knowledge (e.g. physical states of water). In general, then, how is it possible to determine the speaker’s intended meaning when a sentence admits to various meanings all plausible in a context of use (or any combination of contexts), that is, when the context seems not to be conclusive?

Intended Meaning and Speaker’s Meaning

In this section I illustrate the notion of speaker’s meaning proposed by Grice (1989) in regard to the notions of “what is said” (explicit level of communication) and “what is communicated” (implicit level of communication). Speaker’s meaning corresponds to “what is communicated” by a speaker with a sentence. “What is communicated” is understood by an interlocutor by means of an inference (i.e. conversational implicature) based on the conventional meaning of the sentence and contextual information concerning the situation in which the sentence is uttered. Relevant information is made accessible to the interlocutor by means of speaker’s communicative intentions. Essentially, Grice argues that conventional meaning, completed with treatment of ambiguity and indexical expressions (*latu senso*), determines a unique proposition (“what is said”), and he examines the implicit communicative process based on it.

Most philosophers, linguists, and relevant theorists agree on the notion that the speaker’s meaning is “what is

² Note that Kaplan (1989), when introducing the “directing intention”, admits a ‘cognitive turn’ for the reference of demonstrative pronouns (see Bianchi, 2006).

³ On possessive expressions see Clark (1992).

⁴ On background of meaning see Searle (1980).

communicated” by a speaker (implicit level of communication). But they do not agree on the role of conventional meaning in fixing “what is said” by a speaker (explicit level of communication) (see Sperber & Wilson, 1986; Carston, 1988, 2002; Recanati, 1989, 1993; Travis, 1997; Levinson, 2000; Bianchi, 2004). They consequently argue that we need some inferential (or associative) processes based on contextual information (e.g. free enrichment, transfer, saturation, bridging, narrowing, broadening, etc.). These processes fix a unique proposition (the one *explicitly* expressed by a sentence). In other words, these processes fix “what is said” by a speaker with a sentence in a specific situation. Consequently, conversational implicature determines, on the basis of “what is said” and further contextual information, “what is communicated” by a speaker. However, not all pragmatists agree on the temporal sequence of the above processes. Some of them maintain that implicature works in parallel with free enrichment, transfer, etc.⁵ However, according to (a weak version of) contextualism in pragmatics, my proposal in regard to intended meaning concerns the level of “what is said” (explicit level of communication).⁶

I consider that if pragmatic processes, based on non-linguistic contextual information made accessible by communicative intentions, are not sufficient to determine a unique set of truth conditions (proposition), then, in order to determine the explicit level of communication, we can take into account the speaker’s preferences for the states of affairs which make a sentence true.

State of Affairs and Preference

In this section I outline the notion of preference for a state of affairs based on the comparative notions: “better than” ($>$), “equal in value to” (\equiv) and “at least good as” (\geq) taken from decision theory (see Hansson, 1994). Using this language, it is possible to express the preferences of agents for states of affairs. For instance, on writing: $[(sa_1) > (sa_2)]_{Ag}$, we assert that an agent prefers the state of affairs 1 rather than the state of affairs 2.

Decisions theorists assume that a rational agent *correctly* chooses an option if the ordering of options realizes certain properties: ordering, continuity, independence (see Myerson, 1991). For my purposes here, it is sufficient to consider the property of ordering, which concerns completeness and transitivity. Completeness for weak preference is defined as follows:

the relation \geq is complete if and only if for any elements A and B of its domain, either $A \geq B$ or $B \geq A$.

Transitivity for weak preference is defined as follows:

the relation \geq is transitive if and only if it holds for all elements A, B and C of its domain, so that if $A \geq B$ and $B \geq C$, then $A \geq C$.

⁵ On the notion of explicature in Relevant Theory (see Carston, 1988); on implicature in linguistics (see Bach, 1994).

⁶ However, communication can succeed at the “what is said” level, for instance, in contracts and scientific texts. Note that when communication takes place at the implicit level a speaker can retract his/her statements; instead, when communication happens at the explicit level, s/he cannot freely retract.

These properties ensure that an agent is able to compare some options coherently with his/her own interest. However, it is possible that an agent is not always able to compare all options clearly, but this does not prevent him/her from choosing coherently with his/her own interest. In our case, we can consider an agent as preferring one state of affairs coherently with his/her own interest if s/he chooses in accordance with the rule which states:

an alternative is uniquely the best if and only if it is better than all the other alternatives. If there is uniquely a best alternative, choose it (see Hansson, 1994).

Hence, in order to consider an agent’s choice coherent with his/her interest, it is sufficient that s/he is able to determine the best state of affairs among others without necessarily ordering the other states of affairs. In this case, a partial ordering is sufficient to consider agents rational.

A Case of Syntactic Ambiguity

In this section I illustrate a case of structural ambiguity where support by the context is not sufficient to determine the state of affairs to which a sentence refers. I cite a case of linguistic controversy provoked by a labour agreement stipulated by a firm and a local trade union. The agreement stated the modes, schedules and procedures for the placement of redundant workers on a publicly-funded wages guarantee scheme and their job mobility.

The situation was as follows: the firm was attempting to turn around its economic-financial performance (economic reorganization) and had begun the procedures for the placement of redundant workers on the public wages guarantee scheme and for job mobility. To make the procedures lawful, the firm stipulated a collective company-level agreement with the local trade union to order to manage surplus workers. During the procedures, a controversy arose in regard to the one-off payment of a sum of money as an incentive for voluntary redundancy (as provided for the agreement). The controversy developed around two different interpretations of a specific clause in the agreement. The clause was the following:

“The firm shall pay a lump sum to workers accepting voluntary redundancy during the wage guarantee fund’s validity (...).”⁷

The linguistic controversy concerned whether the expression: “during the wage guarantee fund’s validity” referred to “the firm” or to “workers accepting voluntary redundancy”, and therefore, whether only redundant workers who resigned would receive the sum of money or whether all workers (both redundant and still employed) who resigned in that period would receive the lump sum payment as an incentive.

Which state of affairs made the clause true?

⁷ In Italian the clause is as follows: “L’azienda riconoscerà al personale dimissionario nel periodo di vigenza della Cassa Integrazione Guadagni straordinaria un importo forfetario *una tantum* (...)”.

States of Affairs and Goals

The state of affairs preferred by the firm corresponded to its interest that only workers covered by the wage guarantee fund resigned, so that the firm could use the fund (it was limited by the agreement) for other employed workers (who took place of workers who accepted voluntary redundancy) and thus avoid paying their wages. The goal of the firm was to reduce the total amount of one-off incentives, to reduce payment of wages and to complete its restructuring. The state of affairs which comprised the possibility conditions for achievement of the firm's goal can be expressed as follows: 'the firm pays a lump sum for voluntary redundancy to *only* workers on the wages guarantee fund'.

The state of affairs preferred by the trade union corresponded to its interest in extending to all workers the possibility of receiving the lump sum for voluntary dismissal during the period of the redundancy payment scheme. The goal of the trade union was to improve the economic circumstances of workers as much as possible. The state of affairs which comprised the possibility conditions for achievement of the trade union's goal can be expressed as follows: 'the firm pays a lump sum for voluntary redundancy to *all* workers (those on the wages guarantee fund and those in employment) during the period of the wage guarantee fund's validity'.

Intended Meaning and Negotiation

In short, the goal of the firm was to reduce total wages, reduce total incentives and complete its restructuring. The interest of the firm was to move employed workers from regular employment to placement on the public wages guarantee scheme. The goal of the trade union was to improve the economic circumstances of workers. The interest of the trade union was to enable all workers to receive the sum of money.

The state of affairs was negotiated as follows: the firm gave eligibility to incentive to all workers. It thus obtained stability of the company-level agreement avoiding the risk of halting the reorganization and having to return the money already furnished by the state for wage guarantee fund. The trade union gave stability to the agreement by confirming its validity and obtaining the voluntary redundancy incentive for all workers. The state of affairs fixed in the negotiation was compatible with the truth conditions which made one interpretation of the clause true and excluded the other interpretations.

Two Cases of Semantic Ambiguity

In this section I illustrate two cases which concern two linguistic disputes provoked by the same clause in a nation-wide collective agreement stipulated by a trade union and Confindustria (corresponding to the British CBI). I show that the two different negotiations of interests gave rise to two different intended meanings in two very similar contexts. The clause was the following:

"The parties agree on working hours, which apply also to groups of workers, with respect to flexibility regarding the seasonality of products [...]. The parties further agree that, at company level, the modes and schedules of

implementation will be agreed with the local trade union representatives".⁸

The dispute centered on the expression "seasonality of products". The two interpretations were:

- (a) 'seasons of the year';
- (b) 'peaks in the market',

respectively in both cases. The clause's meaning was important because of its impact on the criterion for implementing flexibility measures. In both cases the respective interpretations were the same: in the former case the company adopted interpretation (b), and the local trade union adopted interpretation (a). Analogously, in the latter case, another company adopted interpretation (b) and the same trade union adopted interpretation (a). In my view, it is very interesting that the same agent was involved in both situations and negotiated the same interpretations with different agents. In particular, I would stress that, in the two negotiations, different interests induced the same agent (the trade union) to select two different meanings in two very similar contexts.

Before I report the two cases I shall briefly present the notion of 'meaning negotiation'. According to Bouquet and Warglien, agents have a meaning negotiation problem whenever they have:

"the problem of reaching an agreement on the meaning of an expression when an agreement is valuable for all agents, but agents have conflicting preferences over which solution should be selected, so that every agreement implies that at least someone has to concede to some extent to other agent" (Bouquet & Warglien, 2002, p. 2).

In what follows, I shall show how agreement on situational extra-semantic interests selects which is the intended meaning in linguistic disputes.⁹

Case 1

In case 1, the term "flexibility" in the clause meant that the company, during some periods of the year, could require its employees to work a large amount of overtime. Overtime was required on Saturdays or in addition to the daily regular working hours. The company compensated overtime with paid rest days taken in other periods of the year. Essentially, the clause regulated the times and ways in which the company could require overtime and compensate it with paid rest days.

The company was interested in managing working hours with discretionary power in order to save money,

⁸ The clause in Italian is as follows: "Le parti convengono, a titolo di flessibilità sulla stagionalità dei prodotti e per le attività di installazione e montaggio, sull'orario plurisettimanale, da realizzarsi anche per gruppi di lavoratori". [...] "Le parti altresì concordano che, a livello aziendale, verranno convenute, tramite accordo, le modalità di attuazione oltre che i tempi di implementazione dell'orario settimanale di cui al presente punto con le rappresentanze sindacali unitarie e le organizzazioni sindacali territoriali".

⁹ As Clark puts it, "we cannot hope to understand language use without viewing it as joint action built on individual actions. The challenge is to explain how all these actions work" (Clark 1996, p. 4).

possibly on the basis of information unavailable to the local trade union (e.g. orders). In particular, the interest of the company was to be able to use overtime without paying the wage supplements due and to distribute the cost of paid rest days among periods according to its needs (its discretion). Moreover, the company was interested in being able to resort to overtime at any time of the year on the basis of market demand, and it was not interested in hiring new personnel or in paying overtime regularly. On the other hand, the trade union was interested in reducing (or avoiding) the use of overtime and particularly if it was not regularly paid, in favouring the right to rest and to plan free time. It was also interested in inducing the company to hire new personnel and/or pay overtime regularly.

The company argued that overtime should be regulated with respect to peaks in the market: specifically, the company could resort to unpaid overtime at any time of the year on the basis of market demand. The company could not know peaks in the market in advance and thus could not fix a specific period *a priori*. The trade union argued that overtime should be regulated with respect to the seasons of the year in which the company's products were most in demand, spring in particular.

The two interpretations were both plausible in the situation, where the relevant combination of contexts consisted of the linguistic context, i.e. the text of the clause; the encyclopaedic knowledge, i.e. the contract's rules (e.g. civil code); and local knowledge, i.e. the specific shared activity which the clause regulated. At this point the parties attempted to reach an agreement by negotiating their interests. And, in the end the company and the trade union fixed the intended meaning whereby "seasonality of products" stood for "season of year when products are particularly in demand"; in particular a 'positive season' was spring and a 'negative season' was autumn. They agreed that, in a positive season, the company could utilize non-regularly-paid overtime, while in the negative season overtime was recompensed with paid rest days. How did the agents determine the intended meaning? How did the negotiation of interests work?

The company obtained high discretionary power to utilize unpaid overtime in the positive season (from March to June) *de facto* independently of peaks in the market, and to arrange paid rest days in a period of year when it did not need labour, that is, during the negative season (from September to December). The company relinquished overtime throughout the year (except in the positive season) and discretionary power to distribute paid rest days during the negative season. The trade union obtained a reduction in unpaid overtime (except in the positive season) and the right of employees to choose which days to use for paid rest during the negative season. Moreover, the trade union induced the company to hire new personnel or to pay overtime regularly (except in the positive season). The trade union relinquished to check overtime in the positive season. Finally, the trade union relinquished the possibility of distributing paid rest days throughout year, in that they could only be taken in the negative season.

The agents' interests were mediated with respect to the specific situation: each party gave up something in favour of the other party, and meaning (a) (compatible with the agreement reached) was finally fixed.

Case 2

In case 2, the term "flexibility" meant that the company could hire temporary workers and manage working hours and shifts according its needs.

The company was interested in hiring temporary workers on the basis of increased orders in any period of the year. The company was also interested in managing temporary workers because of information unavailable to the trade union. The trade union was interested in reducing temporary work; in particular, it was interested in restricting the use of temporary labour to only limited periods of the year. Moreover, the trade union was interested in reducing the use of temporary workers and in changing temporary jobs into salaried ones (on both permanent and fixed-term contracts).

The company claimed that the use of temporary labour must be regulated in accordance with peaks in the market: that is, at any time of the year on the basis of market demand. The company could not know peaks in the market in advance and thus could not fix a specific period *a priori*. The trade union claimed that the use of temporary labour must be regulated according to the seasons of the year in which the company's products are most in demand, summer in particular.

The two interpretations were both plausible in the situation, where the relevant combination of contexts consisted of the linguistic context, i.e. the text of the clause; encyclopaedic knowledge, i.e. the rules of contracts (e.g. civil code); and local knowledge, i.e. the specific shared activity which the clause regulated. At this point the parties attempted to reach an agreement by negotiating their interests. And, in the end, the company and the trade union fixed the intended meaning whereby "seasonality of products" stood for "peaks in the market". How did the agents determine the intended meaning? How did the negotiation of interests work in this case?

The company and the trade union reached an agreement in which the employer could use, in the case of peaks in the market throughout the year, an amount of temporary labour representing only ten percent of salaried labour (employees). Hence the company obtained high discretionary power throughout year, but only for a limited number of workers. The trade union obtained a reduction in the use of temporary labour (ten percent of the workforce), but relinquished control over it. Finally, it lost bargaining power on new hirings.

The agents' interests were mediated with respect to the specific situation: each party gave up something in favour of the other party, and meaning (b) (compatible with the agreement reached) was finally fixed.

In the two negotiations, two different meanings were determined for the same expression on the basis of two different negotiations of interests; even the same agent determined two different intended meanings with regard to the two different interests. It is in this sense that situational interest drives the determination of intended meaning.

Conclusion

The paper has presented a notion of intended meaning for declarative sentences. Its argument has been based, on the one hand, on meaning as truth conditions and, on the other, on interest as a state of affairs preferred by a speaker because it implies his/her goal. The compatibility

of the two notions is centered on the notion of state of affairs.

The notion of intended meaning presented in the article is compatible with that of “what is said” in pragmatics: that is, it represents the explicit level of communication. It is compatible with “what is said” because it is fixed by means of pragmatic processes based on information not constrained to the linguistic form of the sentence. But it differs from “what is said” because of the kind of information used: essentially, the pragmatic context refers to items in the current situation or past situations (linguistic context, shared knowledge, physical surroundings). Instead, my approach also takes into account future states of affairs related to agents’ goals.

On this view, the truth conditions which make a sentence true can be fixed by means of the commitment of agents to realizing a certain state of affairs. However, agents do not fix meaning freely; rather, they are constrained by sets of truth conditions previously selected by a combination of relevant contexts in the specific situation.

We have seen three cases of structural and semantic ambiguity where semantics, which should be able to fix meaning in these kind of cases, failed. We have also seen that standard pragmatic information is not conclusive in fixing the intended meaning; as a consequence, the situational interests of agents have been taken into account. In conclusion, this notion seems to be adequate to express intended meaning, given a set of contextually plausible interpretations, both in cases of communicative processes to determine speaker’s intended meaning and in cases of negotiation to resolve linguistic disputes.

Predicative Metaphor Comprehension as Indirect Categorization

Abstract

In this paper, we address the problem of how people understand predicative metaphors such as “The rumor flew through the office,” and argue that predicative metaphors are understood as indirect categorizations. In the indirect categorization process, the verb (e.g., *fly*) of a predicative metaphor evokes an intermediate entity, which in turn evokes a metaphoric category of actions or states (e.g., “to spread rapidly and soon disappear”) to be attributed to the target noun (e.g., *rumor*), rather than directly creating a metaphoric category as argued by Glucksberg’s (2001) categorization theory. We test our argument using two experiments, offline comprehension and on-line priming. The two experiments provided convergent evidence for our argument. The psychological validity of indirect categorization as a process of predicative metaphor comprehension was confirmed.

Keywords: Metaphor comprehension; Predicative metaphor; Categorization; Priming; Verb

Introduction

Predicative metaphors are figurative expressions that involve the metaphorical use of a verb, such as “*The rumor flew through the office*” and “*His fame echoes throughout the world*.” Despite their frequent use in everyday communication, predicative metaphors have been paid little attention in metaphor research. Particularly, the cognitive mechanism underlying predicative metaphor comprehension has never been examined, although a considerable number of studies have been made on the comprehension mechanism of nominal metaphors such as “*My job is a jail*” (e.g., Bowdle & Gentner, 2005; Glucksberg, 2001; Jones & Estes, 2006; Utsumi, 2007). Given the differences in what is being processed metaphorically between predicative metaphors (i.e., actions, states) and nominal metaphors (i.e., objects), together with a recent neuroanatomical finding (Chen, Widick, & Chatterjee, 2008) that predicative and nominal metaphors may be processed differently, it is obviously crucial to explore the cognitive mechanism of predicative metaphor comprehension.

Cognitive linguists may argue that the cognitive linguistics research on metaphor (e.g., Kövecses, 2002; Lakoff & Johnson, 1980) has addressed predicative metaphors as manifestations of the conventionalized, conceptual metaphors. However, these studies do not explore how the conceptual metaphors are constructed, i.e., how a set of correspondences or mappings is made between the source domain and the target domain. This problem becomes more serious when we consider how people comprehend novel predicative metaphors.

Glucksberg (2001, 2003) argues that people comprehend predicative metaphors via a categorization process as they do for nominal metaphors. Just as nominal metaphors use the source concepts that epitomize certain categories of objects or situations, predicative metaphors use verbs that epitomize certain metaphoric categories of actions (e.g., the cat-

egory of *speedy travel* evoked by the verb “fly”). However, no clear empirical evidence has been provided for his argument. Although Torreano, Cacciari, and Glucksberg (2005) demonstrated that the level of abstraction of a verb’s referent was related to the metaphoricity of a predicative metaphor, this finding does not necessarily imply that the verb directly evokes a metaphoric category in metaphor comprehension.

In this paper, we propose *indirect categorization* as the comprehension process of predicative metaphors (Utsumi & Sakamoto, 2007b). Indirect categorization is a two-stage process of categorization in which evocation (or creation) of metaphoric categories is indirect and mediated by intermediary entities, rather than direct as predicted by the categorization theory. Utsumi and Sakamoto (2007b) suggested a possibility of indirect categorization using a computer simulation, but no clear empirical evidence has been provided. Therefore, in this paper we conducted two psychological experiments to obtain empirical evidence for our indirect categorization theory. In these experiments, we manipulated metaphor aptness and vehicle conventionality because recent metaphor studies (e.g., Bowdle & Gentner, 2005; Glucksberg & Haught, 2006; Jones & Estes, 2006) have demonstrated that these properties play an important role in comprehension of nominal metaphors.

In Experiment 1, we examined what proportion of interpretations of predicative metaphors were derived directly from the verb and what proportion of interpretations were indirectly associated with the verb. For this purpose, we assessed a concordance rate between words listed as metaphorical interpretation and those associated with the verb or associated with the verb associates. In Experiment 2, we used a priming paradigm to assess the online availability of direct and indirect categories for predicative metaphor comprehension. In this experiment, a metaphorical sentence was presented as a prime and its effect on the speed of lexical decision about a subsequent target word was measured. The target conditions were a word related to the metaphorical meaning, a word directly associated with the verb, a word indirectly associated with the verb, and a control word unrelated to the metaphor.

Direct versus Indirect Categorization

As we mentioned above, Glucksberg’s (2001, 2003) categorization theory argues that people understand predicative metaphors as direct categorizations. Just as nominal metaphors use vehicles (or source concepts) that epitomize certain superordinate categories of objects, which include a target concept as a member, predicative metaphors use verbs that epitomize certain categories of actions. According to this theory, for example, the predicative metaphor “The rumor flew through the office” is comprehended so that the verb *fly* evokes an ad hoc

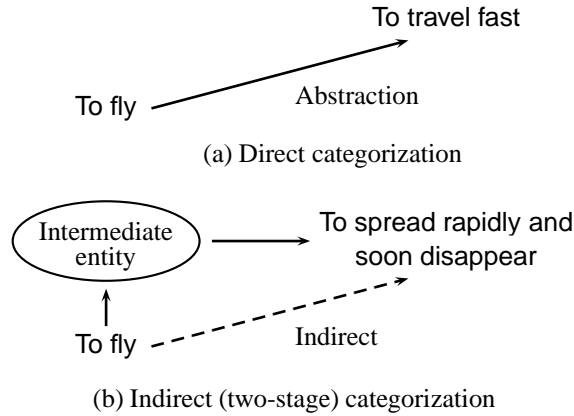

Figure 1: Direct and indirect categorization for the metaphor "The rumor flew through the office."

superordinate category of an action "to travel fast" and such the action is attributed to the target *rumor*, as illustrated in Figure 1 (a).

However, it is doubtful that predicative metaphors are processed in the same way as nominal metaphors. A primary reason for this doubt is that many empirical findings on semantic representation demonstrate that the semantic structure of verbs, which refer to events or actions, differs from that of nouns, which refer to objects, in many respects (Vigliocco & Vinson, 2007). For example, the hierarchical organization for objects and events is different; event categories are represented by fewer levels (generally two) and with fewer distinctions at the superordinate level than object categories. The role of hierarchical relations also differs between nouns and verbs. For nouns, the most important roles are played by the hierarchical relations including superordination and coordination, whereas the dominant relations for verbs are nonhierarchical ones such as entailment, causation, and antonymy. Some evidence compatible with the different role of hierarchical relations is provided by the analysis of semantic substitution errors; Garrett (1992) reported that for nouns the large majority of substitutions involve category coordinates (i.e., words in the same level of the hierarchical structure), while for verbs the preferred semantic relationship between target and intruding words is opposition (e.g., go/come). Furthermore, a neuroanatomical difference appears to exist between nouns and verbs (Shapiro & Caramazza, 2004; Vigliocco & Vinson, 2007) and between nominal metaphors and predicative metaphors (Chen et al., 2008). These findings indicate that hierarchical relations are less activated in the processing of verbs, and thus it is less likely that verbs directly evoke superordinate categories of events or actions; this contradicts Glucksberg's categorization theory.

Furthermore, the categorization theory does not address the richness of the metaphorical meanings expressed by predicative metaphors. For example, people can derive more meanings from the metaphor "The rumor flew through the office" than supposed in the categorization theory (e.g., *to travel fast*); the rumor spreads rapidly and suddenly, the rumor is dispersed or disseminated, the rumor disappears or is forgot-

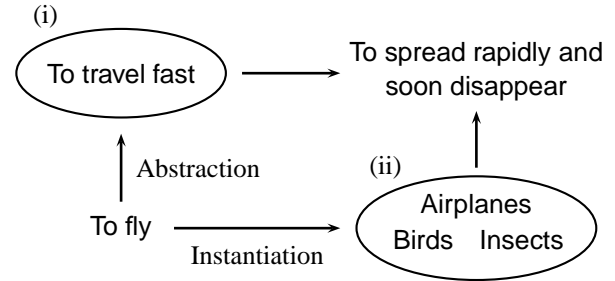

Figure 2: Two possibilities of an intermediate entity in indirect categorization.

ten very soon, and so on. These rich interpretations are unlikely to be derived directly from the verb *fly*, given that the semantic structure of verbs is hierarchically less rich.

To overcome the difficulties of the categorization theory of predicative metaphors, we propose an indirect categorization theory. The intuitive idea behind indirect categorization is that a correspondence between the actions or events literally expressed by the verb and the actions or events to be attributed to the target noun would be indirect, rather than direct as predicted by the categorization theory; constructing a correspondence is mediated by an intermediate entity. As illustrated in Figure 1 (b), in the case of "fly" metaphor, the verb *fly* first evokes some sort of an intermediate entity and the intermediate entity then evokes a final abstract category of "to spread rapidly and soon disappear," which is attributed to the target *rumor* being described.

One important question that arises here is what kind of entities are involved in the intermediate step. Two possible answers can be provided: (i) abstract actions or states produced by generalization from the verb, and (ii) objects produced by instantiation of the verb. In the case of "fly" metaphor, as illustrated in Figure 2, people may think of a very abstract action "to travel fast" by abstracting the verb *fly*, and this abstract intermediate entity is then specified to refer to *rumor*. A perhaps more likely explanation would be that people may consider a set of objects "things that fly" or "flying objects," which contains airplanes, birds, and insects, by instantiating the argument of the verb *fly*. Some actions or events that are relevant to both the "flying" objects and the target *rumor* are then extracted. These two types of intermediate entities may be activated simultaneously during comprehension, rather than selectively. The preference for instantiated objects (ii) may be determined depending on the difficulty in deriving an abstract category from a verb.

Experiment 1

In Experiment 1, we tested our indirect categorization theory by comparing people's interpretations of predicative metaphors (i.e., $I(M)$ in Figure 3), with words or phrases associated directly or indirectly with the verb of predicative metaphors (i.e., $A(w_v)$ or $A(S)$ in Figure 3). If a metaphoric category is evoked indirectly in predicative metaphor comprehension, the interpretation of predicative metaphors $I(M)$ would have greater overlap with indirectly associated words $A(S)$ than with directly associated words $A(w_v)$. If a metaphoric

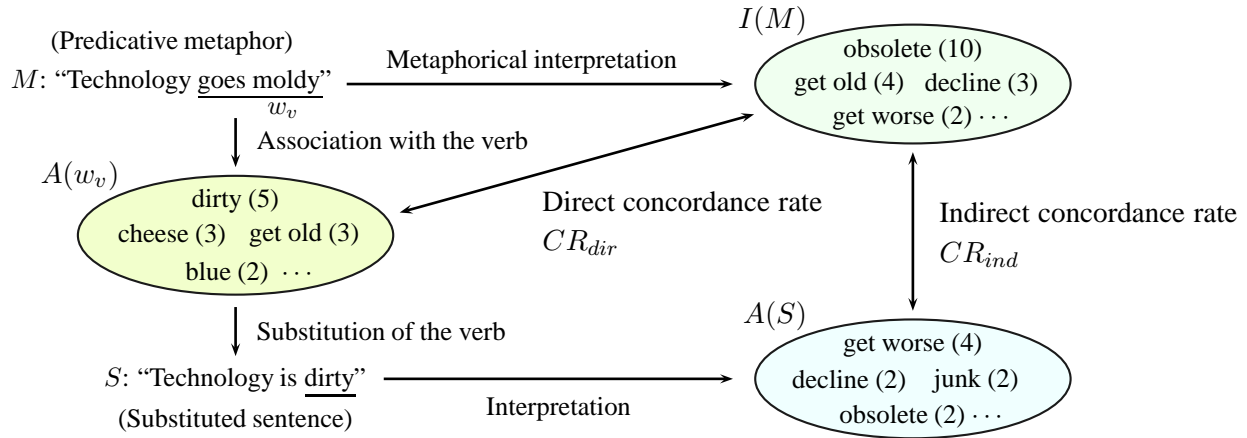

Figure 3: Direct concordance rate and indirect concordance rate as measures of the degree of overlap between the metaphorical interpretation and the direct or indirect associates.

category is evoked directly from the verb, the percentage of overlap between the metaphorical interpretation $I(M)$ and a set of directly associated words $A(w_v)$ would be greater than, or at least equal to, that between the interpretation and a set of indirectly associated words $A(S)$.

Our indirect categorization view therefore predicts that, regardless of metaphor aptness and vehicle conventionality, the interpretation of predicative metaphors has greater overlap with indirectly associated words $A(S)$. On the other hand, Glucksberg's categorization view predicts that, regardless of vehicle conventionality, the interpretation of predicative metaphors (in particular apt metaphors) has greater (or equal) overlap with directly associated words $A(w_v)$.

Method

Participants Eighty-eight people (78 undergraduate and graduate students and 10 working persons) participated as volunteers. All participants were native speakers of Japanese.

Materials Forty Japanese predicative metaphors were used for the experiment. These metaphors were selected from 80 metaphors in a pilot study.

Pilot study For a pilot study, we used 80 Japanese predicative metaphors. They included 20 intransitive verbs (e.g., "go moldy" ["*kabiru*" in Japanese]¹ or "echo" ["*hibiku*"]) and each verb was paired with four abstract nouns (e.g., "Technology goes moldy" ["*Gijutsu ga kabiru*"], "His fame echoes" ["*Meisei ga hibiku*"]). In order to eliminate the possibility that the generated sentences were interpreted as personification metaphors, in which the subject of the sentence, rather than the verb, was used metaphorically, we did not use verbs that literally refer to human actions or experiences.

In this pilot study, we collected the aptness and conventionality ratings to select 40 metaphors used in the main study. Because the conventionality rating task requires the salient meaning of predicative metaphors, the pilot study was conducted separately in two parts. In the first part of the pilot

study, 50 participants were assigned 40 metaphors such that each metaphor was assigned to 25 participants. They were asked to write down at least three interpretations of each metaphor and to rate the aptness of the metaphor on a 7-point scale (1 = *not at all apt*, 7 = *extremely apt*). A list of generated interpretations for each metaphor was used as a set $I(M)$. In the second part, 15 participants were given a list of 80 verbs used in the metaphors with the most salient meaning of the metaphors, i.e., the meaning listed by the largest number of participants in the first part of the pilot study. They were asked to rate how conventional each meaning was as an alternative sense of the verb on a 7-point scale of 1 (*very novel*) to 7 (*very conventional*).

After the pilot study, we chose 40 metaphors for the main study in the following way. First, we calculated the mean aptness rating and the mean conventionality rating for each metaphor. We then classified the 80 metaphors into four groups — conventional and high apt, conventional and low apt, novel and high apt, and novel and low apt — according to whether the mean aptness or conventionality was more than the mid-point 4. Finally, we chose 10 metaphors from each group such that metaphors in the same group had as different verbs as possible and their variance of aptness and conventionality was as low as possible.

Procedure In the experiment, we collected words or phrases associated directly or indirectly with the verb. The experiment was conducted separately in two parts because direct verb associates $A(w_v)$ were required for substituted sentences, from which indirect verb associates $A(S)$ were collected, as shown in Figure 3.

In the first part of the experiment, 12 participants were assigned all 16 verbs which were used in the 40 chosen metaphors, and asked to list at least two words or phrases that they associated with each verb. A list of generated words for each verb was used as a set $A(w_v)$ of direct verb associates.

The second part was performed by other 11 participants. They were assigned 40 substituted sentences and asked to list at least two words or phrases that they thought were involved in the interpretation of substituted sentences. A list

¹Note that the original Japanese verb "*kabiru*" is a verb, although its English translation "go moldy" is a verb phrase.

Table 1: Means (M) and standard deviations (SD) of concordance rates between metaphor interpretation and direct or indirect association.

Metaphor group	CR_{dir} (Direct)		CR_{ind} (Indirect)	
	M	SD	M	SD
Conventional, High-Apt	.256	.202	.391	.279
Conventional, Low-Apt	.172	.135	.408	.318
Novel, High-Apt	.201	.171	.354	.240
Novel, Low-Apt	.125	.103	.368	.167
All	.189	.159	.380	.248

of generated words for the substituted sentences was used as a set $A(S)$ of indirect verb associates. Substituted sentences were generated by substituting three words in $A(w_v)$ listed by the largest number of participants for the verb w_v of the metaphor. For example, when three words “dirty” [“*kitanai*”], “cheese” [“*chizu*”], and “get old” [“*furuku-naru*”] were listed by the largest number of participants for a verb “go moldy,” the substituted sentence of a predicative metaphor “Technology goes moldy” was “Technology is dirty,” “Technology is cheese,” and “Technology gets old.”

After the experiment, we generated three sets of words for each metaphor, namely $I(M)$, $A(w_v)$, and $A(S)$ in the following way. First, closely related words or phrases were accepted as the same word if they belonged to the same deeper category of a Japanese thesaurus. After that, any word that was mentioned by only one participant was eliminated from the set of words.

Results and Discussion

As shown in Figure 3, in order to assess the degree of overlap between the metaphorical interpretation and the direct or indirect verb associates, we calculated the direct concordance rate CR_{dir} and the indirect concordance rate CR_{ind} for each metaphor M :

$$CR_{dir} = \frac{\sum_{x \in I(M) \cap A(w_v)} n_I(x) + n_A(x)}{\sum_{x \in I(M)} n_I(x) + \sum_{x \in A(w_v)} n_A(x)} \quad (1)$$

$$CR_{ind} = \frac{\sum_{x \in I(M) \cap A(S)} n_I(x) + n_S(x)}{\sum_{x \in I(M)} n_I(x) + \sum_{x \in A(S)} n_S(x)} \quad (2)$$

where $n_I(x)$, $n_A(x)$ and $n_S(x)$ respectively denote the number of participants who listed a word x as a metaphorical interpretation, a verb associate, and an associate of the substituted sentences. (The numbers in parentheses in Figure 3 represent these values.) The direct concordance rate CR_{dir} defined by Equation 1 evaluates the degree of overlap between metaphorical interpretation and direct verb association, while the indirect concordance rate CR_{ind} defined by Equation 2 evaluates the degree of overlap between metaphorical interpretation and indirect association. For example, the direct concordance rate of the example shown in Figure 3 is calculated as $CR_{dir} = (4+3)/\{(10+4+3+2)+(5+3+3+2)\} =$

$7/32 = 0.219$, and the indirect concordance rate is calculated as $CR_{ind} = \{(10+2) + (3+2) + (2+4)\}/\{(10+4+3+2) + (4+2+2+2)\} = 23/29 = 0.793$.

Table 1 shows the mean concordance rates for direct and indirect categorization. Overall, as shown in the last row of Table 1, the mean indirect concordance rate CR_{ind} across the 40 metaphors was higher than the mean direct concordance rate CR_{dir} . This result is consistent with our indirect categorization theory and inconsistent with Glucksberg’s categorization theory.

To confirm this difference statistically, we conducted a three-way ANOVA of Categorization (direct or indirect) \times Conventionality (conventional or novel) \times Aptness (high or low). In the analysis, the data were analyzed only by items (F_i) because the concordance rates could not be calculated for each participant. The factor of Categorization was within items and other two factors were between items. The predicted difference between the direct and indirect concordance rate was confirmed; the main effect of Categorization was significant, $F_i(1, 36) = 22.19$, $p < .001$, and the effect size was also large, $\eta^2 = .18$. None of the other main effects and interactions were significant. Hence it is concluded that the result of Experiment 1 supports the indirect categorization theory.

Furthermore, in order to examine which kind of entities were involved in the intermediate step of indirect categorization, we roughly estimated the preference for abstract actions as an intermediate entity by calculating the percentage of verbs and adjectives (i.e., verb rate) that were involved in the set of direct verb associates $A(w_v)$ for each metaphor. The mean verb rate across 40 metaphors was 0.46 ($SD=0.17$), ranging from 0.20 to 0.77. The correlation between the verb rate and the indirect concordance rate CR_{ind} was far from significant, $r = .06$. This finding suggests that there may be no preferred process (generalization or instantiation) that leads to an intermediate entity; people understand predicative metaphors both by abstracting the verb and by enumerating entities typically expressed by the verb.

Experiment 2

In Experiment 2, we tested the indirect categorization view using a priming paradigm, in which a metaphorical sentence was presented first and the task was to make a lexical decision about a target word presented after the metaphorical sentence. The target conditions were a word related to the metaphorical meaning, metaphor target (MT); a word directly associated with the verb, direct associate target (DAT); a word associated with the substituted sentence, indirect associate target (IAT); and a control target (CNT) unrelated to the metaphor.

Faster lexical decisions in comparison with the CNT indicate on-line activation. If predicative metaphors are comprehended by the direct categorization process, the DAT would be faster to make a lexical decision than the CNT, but the IAT would not be faster. Hence, Glucksberg’s categorization theory predicts facilitation of the DAT and no facilitation of the IAT. On the other hand, if predicative metaphors are comprehended by the indirect categorization process, the IAT would be faster than the CNT. Hence, our indirect categorization theory predicts facilitation of the IAT. The DAT may also

Note. *DIF* = difference from control target.

be activated, but to a lesser degree than the IAT. Concerning the MT, both theories predict facilitation of the MT.

Method

Participants Forty-five undergraduate and graduate students participated as volunteers. All participants were native speakers of Japanese.

Materials The 40 predicative metaphors used in Experiment 1 were employed as prime sentences. The other 40 metaphors that were not selected in the pilot study of Experiment 1 were used as filler sentences for nonword targets.

For each prime metaphor, the MT, DAT, and IAT were selected from among the set of metaphorical interpretations $I(M)$, the set of direct verb associates $A(w_v)$, and the set of indirect verb associates $A(S)$ respectively. For an MT, we selected the word in $I(M)$ that was listed by the largest number of participants. For a DAT and an IAT, we selected the word that was listed by the largest number of participants in $A(w_v)$ or $A(S)$, excluding the MT word. The CNT was selected randomly from a dictionary such that it was not related to the metaphor. For example, the metaphor “Technology goes moldy” was combined with the MT “obsolete” [“*furukunaru*”], the DAT “dirty” [“*kitanai*”], the IAT “get worse” [“*waruku-naru*”], and the CNT “vanish” [“*toozakaru*”].

Procedure A within-participants design was used with each participant comprehending all the 80 metaphors under all conditions. Participants, who were run individually, were seated in front of a computer screen. They were first given an overall instruction of the experiment and then presented with six practice trials followed by the 80 experimental trials presented in a random order. On each trial, they were presented with a predicative metaphor on the screen for 3000 ms and asked to interpret the metaphor. A target word (MT, DAT, IAT, CNT, or nonword) was then presented 500 ms after the offset of the predicative metaphor. Participants were asked to decide whether the target word was a word or a nonword as quickly as possible; they indicated decision by pressing the appropriate key on the keyboard. Reaction times were measured from the onset of the target word until the appropriate key was pressed.

Results and Discussion

A total of seven participants were eliminated from the analysis because they did not reach the decision error criterion

of 90% correct. Only reaction times of correct decision were used in the analysis. Following metaphor priming research (Blasko & Connine, 1993), reaction times greater than 1750ms were eliminated from the analysis. This elimination caused the further elimination of two participants’ data because the data of some conditions were missing.

Table 2 shows mean lexical decision times and standard deviations for the correct “yes” responses. The time difference (*DIF*) from the CNT indicates the extent of the priming effect. Although the pattern of *DIF* differs depending on conventionality and aptness, the overall result was that the IAT produced the greatest priming effect (44.9ms faster than the CNT), but the DAT showed the smallest priming effect (only 13.8ms faster). The MT showed a moderate priming effect (22.4ms faster). This result is consistent with the indirect categorization theory and inconsistent with the direct categorization theory.

A three-way ANOVA of Target (MT, DAT, IAT, or CNT) \times Conventionality (conventional or novel) \times Aptness (high or low) was conducted on lexical decision times. In the analysis, the data were analyzed by participants (F_p) and by items (F_i). The factor of Target was within participants and within items, while other two factors were within participants and between items. The main effect of Target was significant by the participant analysis, $F_p(3, 105) = 3.21$, $p < .05$, although its effect size was small, $\eta^2 = .01$. The main effect of Target was not significant by the item analysis, $F_i(3, 108) = 1.55$, $p = .21$, but a small effect size was found, $\eta^2 = .03$. Post-hoc pairwise comparisons ($p < .05$) revealed that the IAT ($M=801.3$ ms) was significantly faster than the CNT ($M=846.3$ ms); this indicates a significant activation of indirectly associated meanings during metaphor comprehension. In addition, the difference between the IAT ($M=801.3$ ms) and the DAT ($M=832.4$ ms) was marginally significant ($p < .10$). Again, the result is consistent with the indirect categorization theory but inconsistent with the direct categorization theory; predicative metaphors are understood via the indirect categorization process, in which constructing the correspondence between the actions or events literally expressed by the verb and those expressed metaphorically is mediated by intermediate entities. A little surprisingly, the priming effect of the MT was not statistically significant.

In addition, the interaction between Conventionality and Aptness was significant by the participant analysis, $F_p(1, 35) = 4.32$, $p < .05$. The nature of this interaction

was that, when predicative metaphors were high apt, decision times to all targets were faster for conventional metaphors ($M=799.6\text{ms}$) than for novel metaphors ($M=848.8\text{ms}$), but such the difference disappeared when metaphors were low apt ($M=825.8\text{ms}$ for conventional metaphors; $M=829.6\text{ms}$ for novel metaphors). The main effect of conventionality was also significant, $F_p(1, 35) = 4.91$, $p < .05$; $F_i(1, 36) = 3.80$, $p = .06$. Mean decision times to all targets were shorter for conventional metaphor primes ($M=812.7\text{ms}$) than for novel metaphor primes ($M=839.2\text{ms}$). These results suggest that vehicle conventionality facilitates comprehension of predicative metaphors, in particular when they are highly apt, but the comprehension process remains unchanged.

General Discussion

The two experiments reported in this paper provided empirical evidence in favor of the proposed view that predicative metaphors are understood as indirect categorizations.

As we mentioned previously, the most important problem with the indirect categorization view is what entities are involved in the intermediate step of indirect categorization. We provide two possible answers, i.e., abstract actions obtained by abstracting the verb, and objects typically expressed by the verb. Experiment 1 suggested that there seemed to be no preference between two possibilities, but we point out that objects typically expressed by the verb are really involved in the comprehension process.

“Float like a butterfly, sting like a bee.”

These are the words of Muhammad Ali, a famous American boxer who won World Heavyweight Champion three times. This predicative metaphor expresses Ali’s boxing style by describing his swift footwork as “float” and lightning-quick punch as “sting.” At the same time, this metaphor clearly conveys a kind of gorgeousness and sharpness in his behavior, which cannot be derived solely from these verbs. It is more likely that such the interpretation would be derived when people call to mind “things that float” and “things that sting,” and in the case of this metaphor they are verbalized in “like a butterfly” and “like a bee.” In other words, these phrases suggest the psychological reality of the intermediate entities that are typically expressed by the verb for indirect categorization.

We have also argued that the indirect categorization view explains adjective metaphor comprehension (Utsumi & Sakamoto, 2007a). Because the semantic structure of adjectives is not at all hierarchical, intermediate entities only include objects with the property referred to by the adjective of a metaphor (i.e., “things that are red” in the case of the metaphor “red taste”). Some evidence for the predominance of intermediate objects is provided by Nakamura, Sakamoto, and Utsumi (2010).

At any rate, it would be vital for future research to explore in more detail the internal process of indirect categorization.

Abstract and Belief-Based Language Differentiate Joking, Pretending, and Literal Toddler-Directed Speech

Elena Hoicka (elena.hoicka@stir.ac.uk)

Ruth Campbell (rec00001@students.stir.ac.uk)

Psychology Department, University of Stirling, Stirling, FK9 4LA, UK

Abstract

Twenty-two parents read a book containing joking, pretense, and literal pages to their 15- to 21-month-old toddlers. Parents differentiated joking from pretense book pages by using (1) more disbelief statements and humor-specific words, (2) fewer belief statements, and pretense-specific words. Parents differentiated joking from literal book pages by using more (1) high-level abstract language, (2) disbelief statements, and (3) humor-specific words. This study extends findings that abstract language cues non-literal concepts in general (e.g., metaphor, irony). This is also the first study to discover differences in cues to joking and pretense.

Keywords: Humor, Pretense, Abstract language, Beliefs, Parent-child interaction

Introduction

Human life is permeated with social institutions with conventional and normative structures. In order to participate in collective activities, children must learn how to act within these settings. One interesting question is how children respond to violations of normative rules. Sometimes, the appropriate response may be to protest (e.g., Rakoczy, Warneken, & Tomasello, 2008), but sometimes the appropriate response may be to treat the violation as a joke (and laugh), or as pretend (and maybe join in). This involves not only understanding that people have intentions, but also that they have intentions to do the wrong thing. This is an important, yet difficult concept required to understand humor, pretense, lying, false belief, and metaphor (Hoicka, Jutsum, & Gattis, 2008, Leekam, 1991).

While some accounts suggest that children possess an innate capacity to understand others' pretense and false beliefs (e.g. Leslie, 1987), such accounts do not explain how children might distinguish when someone is pretending versus joking, or even doing the right thing. For example, how do we use a telephone? We could speak into it when someone is on the other end (literal). We could speak into it when no one is listening (pretending). We could put the receiver on our foot and speak (joking). To an adult, the act in and of itself may distinguish whether a person intends to joke, pretend, or be literal. However for a toddler still learning about new objects, it may not be clear which act follows which intention. If they have had little experience with telephones, any act could be seen as the literal act. Even with experience of telephones, the pretend act could be seen as a joke (it's silly to talk to no one) and the

humorous act could be seen as pretending (she's pretending that her foot is her ear). In order for toddlers to distinguish amongst various types of communicative intentions, it is thus plausible that parents give additional cues in order to help them in this task.

The goal of the current study was to determine whether parents differentiate joking, pretense, and literal speech with linguistic cues. Parents use more abstract language when reading humorous versus non-humorous book pages (Hoicka, et al., 2008). Similarly children use past and future tenses when pretending (e.g. Lodge, 1979; Musatti, 1993; Sawyer, 1997). Since references to past and future are forms of abstract language (Hoicka, et al., 2008), parents might also use abstract language to cue pretending. When irony and metaphor, two other concepts involving intentional wrongness, are couched in abstract language, adults are more likely to judge them as ironic or metaphorical respectively (Hoicka, 2010; Torrealano, Cacciari, & Glucksberg, 2005). Theoretically, infants and toddlers could use abstract language in the same way to determine that joking or pretense was intended.

Belief-based language may serve to highlight differences between joking and pretense. When parents read a humorous versus non-humorous book, they used more disbelief statements, i.e., statements that conveyed that they did not believe what they had said (Hoicka, et al., 2008). For example, when making the joke, "Ducks say moo", parents made statements such as, "What are ducks supposed to say?" Thus parents cued their toddlers to humorous intentions by contrasting the jokes to the parents' true knowledge and beliefs. In contrast, utterances referring to pretend play have "at best weak correspondence in the immediate situation" (Veneziano, 2001, p. 331), for example, saying "here is a drink" whilst referring to an empty cup. Parents refer to absent references when pretending (Lillard & Witherington, 2004). For example, when pretending to eat, versus really eating, parents utter more words referring to the act of eating, or the objects involved in eating. Parents may use disbelief statements when joking because they (1) have said something to express disbelief about, and (2) by highlighting wrongness, parents may help toddlers understand the punch line of the joke. Parents may create absent references, a.k.a., belief statements, when pretending because (1) parents must convey what their wrong action was meant to be, e.g., putting a cup to one's mouth is not actually drinking, and so

making statements such as “I’m drinking” could help toddlers understand what the action represents, and (2) the purpose of pretense, unlike joking, is to represent a wrong action as something right in a possible world (Nichols & Stich, 2003), thus belief statements could emphasize the truth-values of the representational state. However the Hoicka et al. (2008) study did not measure belief statements, nor did the Lillard and Witherington (2004) study measure disbelief statements. This study aimed to determine whether parents use belief-based language to differentiate joking and pretense.

A second way in which parents might differentiate joking from pretense is by using humor- and pretense-specific words. Parents used humor-specific words such as “funny” or “silly” more often when reading a humorous versus non-humorous book to their toddlers (Hoicka, et al., 2008). Similarly, parents used the word “pretend” more often when pretending versus being literal (Lillard, et al., 2007). Such words could assist children in linking past and present experiences, and determine whether they are acts of joking or pretense. Indeed, preschoolers are more likely to understand pretend intentions when words such as “pretend” are used (Rakoczy, Tomasello, & Striano, 2006).

In the current study, parents read a book to their toddler which contained two joking, two pretense, and two literal pages. We designed the book in this way so that we could compare (1) cues to joking versus pretending, and (2) cues to literal versus joking speech.

Method

Participants

Twenty-two parents (20 mothers, 2 fathers) and their toddlers (age $M = 18$ months, 19 days, $SD = 2$ months, 16 days, $range = 15$ months, 5 days to 21 months 26 days; 9 boys) participated. One additional participant was not included due to fussiness. Participants were recruited from playgroups, toddler classes, and a press release in the local news paper. Parents and children were primarily Scottish.

Materials

Four illustrated versions of a book, “James’ Big Day” were created. See Figure 1 for an example of pages. A Shure head-mounted microphone was fit into an Olympus MP3 recorder to record the parents’ speech. A Sony digital camcorder was used to record the visual aspects of the reading session, and as a backup for speech recordings.

Design

This was a within-subjects design. The independent variable was the type of utterance each page conveyed: joking, pretense, or literal. There were a total of six target sentences per book; two conveyed joking, two conveyed pretense, and two conveyed something literal. The books were designed such that the same target sentence conveyed either joking, pretense, or was literal, depending on the

sentences prior to the target sentence, as well as the accompanying images in the books. See Figure 1 for an example. Four different books matched different page types to eight target sentences, and this was counterbalanced. Parents read only one book each. The dependent variables included parents’ use of abstract language, belief-based language, and humor- and pretense-specific language.

Coding

Parents’ utterances were transcribed from the MP3 files. For parents’ use of abstract language, each extra-textual utterance (ETU) was coded for levels of abstraction following Hoicka, et al. (2008), and Van Kleeck, et al. (1997). These included:

Level 1 (perceptual identification, concrete): The utterance refers solely to one object in the event. This level includes object labelling either at the basic, subordinate, or superordinate levels. It also includes stating an intrinsic property of the object (e.g., color) or drawing attention to the object or one of its properties. Examples are “What’s that?” and “It’s a bowl.”

Level 2 (perceptual relationship, concrete): The utterance links two objects or events. The link may involve an intrinsic property (same color), spatial relation (left of, above), a common action (X and Y produce something, or X acts on Y), or a common feeling. Examples are “This car is like the other car.” and “The cake is in his hand.”

Level 3 (displaced reference, abstract): The utterance links an object or event with an object or event that is absent either in space (spatially displaced reference) or time (past talk), typically including subjective experiences with the object. Examples are “Do you remember seeing a duck in the pond?” and “You have a car at home.”

Level 4 (inference, abstract): The utterance conveys one of several inferences, including logical reasoning and imaginary description, or states some social knowledge. Examples are “If he eats that with his hands, he’ll make a mess”, and “It’s like the boy is flying through the air”.

Transcripts were separately coded for belief-based language, following Hoicka, et al. (2008) for disbelief statements. All ETUs which followed the target sentences were coded as either a belief statement, a disbelief statement, or neither.

To be coded as a belief statement, the ETU should suggest that the parent believed the assertion of the target sentence. This can be coded in three ways:

General belief statements: statements which express belief that can be applied to any statement, e.g., “That’s right”, or “It’s true”

Sentence-specific belief statements: statements which express belief specifically in relation to the target sentence. This could include a repetition or re-phrasing of the target sentence.

Build-on belief statements: statements which show belief through building on the target sentence. E.g., if the context is that a child is pretending that a basket is a pram, or the child is really sitting in a pram, and the target sentence is

“He’s sitting in the pram”, the parent might add to this by saying something like “There’s the wheel”

To be coded as a disbelief statement, the ETU should suggest that the parent does not believe the assertion of the target sentence. This can be coded in three ways:

General disbelief statements: statements or questions which express disbelief that can be applied to any statement, e.g., “That’s wrong”, or “That’s not true”.

Sentence-specific disbelief statements: statements and questions which express disbelief specifically in relation to the target sentence, e.g., for the target utterance, “He’s sitting in the pram”, the parent might say, “That’s not a pram”, or “Is that a pram?”

Build-on disbelief statements: statements which show disbelief through building on the target sentence. E.g., for the target sentence, “He’s sitting in the pram”, parents might say, “Prams should have wheels.” or, “What is he really sitting in?”

ETUs were coded for humor-specific words such as jok*, funn*, hilarious, and sill*, and for pretense-specific words such as preten*, imagin*, and make-believe.

Results

No effects of child age were found, so child age was dropped from final analyses. Linear mixed models were used with participant code and target sentence as random variables. Simple contrasts were used to compare Joking to both Pretense and Literal pages.

Abstract Language

Means for Page Type by Abstraction Level can be found in Figure 2. No effects of child gender were found, so child gender was not included in the final analyses. A 3 (Page Type: Pretense, Joking, Literal) X 4 (Level of Abstraction 1-4) mixed model found an effect of Level of Abstraction, $t(503) = 2.87, p = .0043$, and an interaction between Level of Abstraction and Page Type, $t(503) = 2.41, p = .0165$. Additional models were run to examine interactions.

3 (Page Type) mixed models on Levels 1, 2, and 3 Abstraction using simple contrasts found no effects (Level 1: Pretense $M = 0.70, SD = 1.19$; Joking $M = 0.75, SD = 1.45$; Literal $M = 0.93, SD = 1.53$; Level 2: Pretense $M = 0.34, SD = 0.71$; Joking $M = 0.55, SD = 1.09$; Literal $M = 0.23, SD = 0.60$; Level 3: Pretense $M = 0.18, SD = 0.50$; Joking $M = 0.32, SD = 0.83$; Literal $M = 0.23, SD = 0.60$). A 3 (Page Type) mixed model on Level 4 Abstraction using a simple contrast found that parents uttered significantly more Level 4 ETUs when reading Joking ($M = 1.34, SD = 1.58$) versus Literal pages ($M = 0.61, SD = 1.22$), $t(108) = 2.64, p = .0094$. There was no difference between Joking and Pretense ($M = 1.30, SD = 1.72$) pages.

Belief-Based Language

Means for Page Type by Belief-based Language can be found in Figure 3. A 3 (Page Type: Pretense, Joking, Literal) X 2 (Statement Type: Belief, Disbelief) X 2 (Child Gender) mixed model found effects of Page Type (Pretend

vs. Joking), $t(232) = 5.07, p < .0001$; Page Type (Joking vs. Literal), $t(232) = 2.17, p = .0309$; an interaction between Statement Type and Page Type (Pretend vs. Joking), $t(232) = 5.04, p < .0001$; an interaction between Statement Type and Page Type (Joking vs. Literal), $t(232) = 3.27, p = .0012$; and an interaction between Statement Type, Page Type (Joking vs. Literal), and Child Gender, $t(232) = 2.35, p = .0197$. Additional models were run to examine interactions.

No effects of child gender were found for disbelief statements, so were dropped from the following analysis. A 3 (Page Type: Pretense, Joking, Literal) mixed model for disbelief statements with a simple contrast found that parents used significantly more disbelief statements when expressing Joking ($M = 1.45, SD = 1.70$) versus Pretense ($M = 0.39, SD = 0.92$), $t(108) = 2.42, p = .0173$, and when expressing Joking versus Literal ($M = 0.18, SD = 0.45$) speech, $t(108) = 4.03, p < .0001$.

A 3 (Page Type: Pretense, Joking, Literal) X 2 (Child Gender) mixed model for belief statements with a simple contrast found that parents used significantly more belief statements when expressing Pretense ($M = 0.66, SD = 1.35$) versus Joking ($M = 0.36, SD = 0.75$), $t(108) = 2.70, p = .0080$. An interaction between Child Gender and Page Type (Pretense, Joking), was found, $t(108) = 2.90, p = .0045$, such that parents used more belief statements when expressing Pretense to boys versus girls, but more belief statements when expressing Joking to girls versus boys. There was no difference between Joking and Literal ($M = 0.68, SD = 0.88$) speech.

Humor- and Pretense-Specific Words

Means for Page Type by use of humor- and pretense-specific words can be found in Figure 4. No effects of child gender were found, so child gender was not included in the final analyses. A 3 (Page Type: Pretense, Joking, Literal) X 2 (Word Type: Humor, Pretense) mixed model found effects of Page Type (Pretense vs. Joking), $t(237) = 2.40, p = .0173$; Page Type (Joking vs. Literal), $t(237) = 2.40, p = .0173$; and an interaction between Word Type and Page Type (Pretense vs. Joking), $t(237) = 2.87, p = .0045$. Additional models were run to examine interactions.

A 3 (Page Type: Joking, Pretense, Literal) mixed model for humor-specific words using a simple contrast found that parents used significantly more humor-specific words when expressing Joking ($M = 0.32, SD = 0.64$) versus Pretense ($M = 0.02, SD = 0.15$), $t(108) = 2.12, p = .0366$, and when expressing Joking versus Literal speech ($M = 0.02, SD = 0.15$), $t(108) = 2.12, p = .0366$.

A 3 (Page Type: Pretense, Joking, Literal) mixed model for pretense-specific words using a simple contrast found that parents used significantly more pretense-specific words in the Pretense ($M = 0.11, SD = 0.44$) versus Joking ($M = 0.02, SD = 0.15$) conditions, $t(108) = 2.05, p = .0427$. There was no difference between the Joking and Literal ($M = 0, SD = 0$) conditions.

Discussion

The current study investigated whether parents use linguistic cues to differentiate (1) joking from pretense, and (2) joking from literal speech

Joking vs. Pretense

This research provides the first evidence that parents use belief-based language to differentially cue toddlers to joking and pretense. Parents used significantly more disbelief statements and significantly fewer belief statements when reading joking versus pretense pages. Parents also used significantly more humor-specific words when reading joking versus pretense pages, and significantly more pretense-specific words when reading pretense versus joking pages.

While intentionality research typically focuses on whether or not children understand intentions (e.g., Carpenter, Akhtar, & Tomasello, 1998; Gergely, Bekkering, & Király, 2002; Meltzoff, 1995) little research has examined how children come to understand intentions to do the wrong thing, and how children come to distinguish amongst various types of intentions. The current study demonstrates that parents offer toddlers linguistic cues to distinguish between joking and pretense. Thus it may be the case that children learn to distinguish amongst abstract, non-literal concepts such as jokes and pretense. In particular, hearing proportionally more disbelief statements and proportionally fewer belief statements when encountering joking could allow a child to identify the reference to the wrong act, and to identify that the act was meant only as a wrong act and nothing else. In contrast, by hearing a more even mixture of belief and disbelief statements when encountering pretense, children could identify the reference to the wrong act through disbelief statements, and could also identify the representation of the wrong act through belief statements. Additionally, humor-specific words could help toddlers link past and present humorous situations, while pretense-specific words could help toddler link past and present pretense situations.

Literal vs. Non-literal Speech

The current study found that parents used more high-level abstract language when reading joking versus literal pages. This replicates findings that parents use high-level abstract language to cue humor (Hoicka, et al., 2008). This also converges with findings that abstract language cues adults to both metaphor and irony (Hoicka, 2010; Torreano, et al., 2005), two other non-literal abstract concepts. Interestingly, there was no difference between the amount of high-level abstract language that parents used to cue joking versus pretense. Thus parents may use abstract language in order to cue their children to both joking and pretense. This may allow toddlers to think in an abstract way in order to resolve the joke, or understand the representation underlying the pretense.

The current study also found that parents used more disbelief statements when expressing joking versus literal concepts. Additionally, parents used significantly more

humor-specific words such as “funny” and “silly” when reading joking versus literal pages. This replicates and extends past research which found that parents use disbelief statements, as well as humor-specific words to cue humor (Hoicka, et al., 2008).

The present findings suggest that parents may bootstrap non-literal concepts, such as joking and pretending, by helping their toddlers to think in an abstract way, and by identifying that what was said is not literally true. These linguistic cues could also help toddlers identify what exactly made the situation false. Additionally, given that toddlers do not understand that others can intend to joke until they are 2 years old (Hoicka & Gattis, 2008), and do not understand that others can intend to pretend until they are 3 years old (Rakoczy, Tomasello, & Striano, 2004), abstract and belief-based language may help toddlers realize that others can intend to do or say the wrong thing in the first place.

Future Research

Future Research will examine whether mothers and fathers give the same or different types of linguistic cues to differentiate joking and pretense, and to differentiate literal from non-literal speech. Additionally, we will examine whether parents use the same types of linguistic cues when engaging in acts of joking and pretense with their toddlers, as compared to when they read about these concepts. Finally, future research should also consider whether toddlers can use these cues to adequately differentiate joking from pretense, and literal versus non-literal events.

Figures

Pretense:

James and his big sister Katie are playing make-believe. Katie crawls around and meows. Meow meow. Mummy asks, “What was that?” James knows...

It was a cat.

Joking:

James and his big sister Katie go in the yard. They hear some barking. Ruff ruff. Mummy says, “What was that?” James wants to make a funny joke...

It was a cat.

Literal:

James and his big sister Katie are really excited because Mummy brought home a new pet. They hear something go meow meow. What was the pet?

It was a cat.

Figure 1: Examples of Page Types for same target sentence. Original images were in color.

Figure 2: Mean number of ETUs for each Level of Abstraction

Figure 3: Mean number of ETUs expressing Belief and Disbelief.

Figure 4: Mean numbers of ETUs using humor- and pretense-specific words.

Acknowledgments

We would like to thank parents and toddlers for participating in our research. We would also like to thank Felicity Malla, Jennifer Dent, and Sarah McAllister for help with creating stimuli and data collection. This research was supported by a British Academy Small Research Grant SG-54221 and an ESRC Small Research Grant RES-000-22-3888, both awarded to Elena Hoicka.

Abstract

This paper examines the concept of wrongness as a violation of intention, convention, or fact. We demonstrate that wrongness is an underlying factor in mistakes, jokes, pretense, lying, metaphor, and irony. We argue that children's use and understanding of wrongness evolves in four steps through a developing understanding of representation. First, children understand that a wrong act can *refer* to a right act, through mistakes and basic jokes. Second, this leads to understanding that a wrong act can *represent* a right act, through pretense, puns and metaphor. Third, this leads to understanding mental representation, which in combination with understanding reference allows understanding of intentional jokes and lies. Finally, this leads to understanding mental representation in combination with representation, allowing an understanding of irony, and intentional pretense, metaphor, and puns.

Keywords: Wrongness; Representation; Mistakes; Jokes; Pretense; Lying; Metaphor; Irony

Wrongness and Representational Thought

Parents, educators, and even psychologists generally assume that an important goal of development is learning to do the right thing. In this paper, we consider the value of learning to do the wrong thing. We propose that learning about wrongness proceeds through four stages, each of which plays a critical role in the development of representational thought.

What is wrongness?

Most analyses of wrongness focus on the moral aspects of doing the wrong thing. For example, philosophers have argued that wrongness is something prohibited by morality (e.g. Calder, 2005), such as murder or cheating (e.g. Feezell, 1988; Marquis, 2001). The moral concept of wrongness is also examined in research on lying (e.g., Sorenson, 2007). Similarly, psychologists interested in wrongness have focused on deontic reasoning, that is, the speaker's attitude towards what she is saying, and in particular, how necessary a speaker deems some condition or act. This includes permission (*what one may do*), and obligation (*what one must do*), thus wrongness might violate what one is obliged or expected to do (Cummins, 1996; Tomasello, 2003).

Morality is not, however, the only basis for wrongness. Wrongness can be evaluated as a violation of fact, irrespective of moral issues. For example, if you eat the last cookie, and say that you did not, your statement, "I did not eat the last cookie" is wrong simply because it does not

reflect truth-values in the world (Carson, 2006). Similarly, metaphors, pretending, and joking all involve wrongness because they do not represent the true state of affairs (Amsel, et al., 1996; Kazmerski, Blasko, & Desalegn, 2003; Leekam, 1991).

Wrongness extends beyond truth values, and can also describe violations of convention. Conventions do not have absolute truth values. Nonetheless an action which breaks convention, such as moving 6 places on a board game after having rolled a 5, is also wrong. Conventions can apply to how we speak, use objects, eat, dress, play games, interact with others, and hence permeate many aspects of our daily lives. Searle (2005) posits that there are two types of conventions in regards to objects. One type includes causal usage functions, in which we have the convention of using an object in a certain way, supported by the physical features of the object (e.g., knives are sharp, and so are used to cut things). Status functions are more conventional and attach arbitrary functions to objects, for example, in the case of paper used as money. Thus while you could technically try to use a knife as a paper weight, or tissues to pay for your purchase, this would be wrong according to convention. Children as young as 2 years demonstrate sensitivity to the conventions associated with objects, displaying what is called functional fixedness, where they refuse to use objects in unconventional ways, after only one exposure to how an object should be used (Casler & Kelemen, 2005). Language itself is also a set of conventions where certain words happen to be paired with certain actions, objects, and so on (Searle, 1969). Furthermore, different languages have different conventions, and within a language one must adhere to the specific labels given to specific objects and actions. Infants and toddlers respect the conventionality of language, demonstrating hesitance to assign the same label to multiple objects (e.g. Markman & Wachtel, 1988). Thus using the wrong words can be wrong by violating convention.

Wrongness can also describe violations of intentions. For example, it is not more right to request chocolate versus vanilla ice cream. However if you intend to eat chocolate, and instead ask for vanilla, such an utterance would be wrong in terms of the current goal. Thus mistakes embody a form of wrongness that violates one's intentions.

Wrongness as Violation

We define wrongness as a violation of intention, convention, or fact, independent of the moral standing of the act. Several concepts involve understanding wrongness. In

the next section we review relevant empirical findings on mistakes, jokes, pretending, lies, irony, and metaphor, which all involve wrongness (e.g., Carpenter, Akhtar, & Tomasello, 1998; Hoicka, Jutsum, & Gattis, 2008; Kazmerski, et al., 2003; Leekam, 1991).

Mistakes

Mistakes by definition involve doing the wrong thing. This type of wrongness necessarily involves a violation of intention: you meant to perform one act, but performed another instead. This could be for one of two reasons: you could do something in an accidental fashion, such as fall over, which might be considered a true mistake. You could also truly believe that what you are doing is the right thing, even though it is not, and perform what might be better called an error, where you violate your intention because of lack of knowledge (e.g., Lee & Cameron, 2000). As an example of a mistake (or error), you may wish to turn on the television, but press the wrong button (either through an accidental physical movement or a false belief that it is the right button), such that it does not light up, and the goal of turning on the television is not achieved. Additionally, mistakes could involve a violation of convention (accidentally driving on the wrong side of the road, either because you falsely believed that that is the convention in that country, or perhaps because the road is poorly lit), as well as a violation of fact (e.g., Saying that Tony Blair is the Prime Minister of the United Kingdom either because you did not realize that Gordon Brown had taken his place, or because the wrong name came out). However mistakes need not require a violation of convention or fact, for example, when accidentally requesting the wrong object the request cannot be wrong, but it still violates an intention.

Mistakes may be the earliest understood form of wrongness. Meltzoff (1995) found that when adults performed incomplete actions with objects (i.e., failed attempts, which could be viewed as a mistake) 18-month-olds completed (or corrected) those actions. From 14 months, infants avoid actions accompanied by the expression “Whoops!” (Carpenter, et al., 1998) and by rising intonation (Sakkalou & Gattis, in press). Finally, infants as young as 9 months (but not 6 months) react differently to someone unwilling to give an object, versus unable, due to an accident or failed attempt, a.k.a., a mistake, through looking and reaching less (Behne, et al., 2005).

Jokes

Basic jokes, which involve saying or doing something wrong, violate convention or fact (Hoicka & Gattis, 2008; Hoicka, et al., 2008). For example, one could joke that ducks say, “moo” (violating fact) or one could point to a duck and call it a “moogy” (violating English language conventions). Jokes by definition cannot violate intention since joking involves intentionally doing or saying the wrong thing.

Basic jokes are another form of wrongness that is understood early in development. Three- to 5-year-olds primarily laugh at events that others, or they themselves, intend to be humorous, such as clowning or being silly (Bainum, Lounsbury, & Pollio, 1984). This suggests that they appreciate that others do the wrong thing in order to joke. As early as 30 months, children copy mislabelling behaviors when couched in a humorous context, but not in a non-humorous context (Hoicka & Akhtar, 2010). From 25 months children copy incorrect actions followed by laughter, but correct the same incorrect actions followed by the expression, “Whoops!” indicating that they interpret others’ wrong actions as humorous (Hoicka & Gattis, 2008). Finally, 15-month-olds match humorous cues to humorous actions, and from around 10 months, infants laugh when their mothers perform incongruous actions, such as putting socks in their mouths (Hoicka & Wang, 2010; Sroufe & Wunsch, 1972). Finally, observational evidence suggests that infants may not only appreciate others’ jokes, but may create jokes as well. From 15 months, infants have been observed to create jokes such as putting sponges in their mouths, and from 8 months, repeat incongruous actions, such as screwing up their faces, in order to re- elicit laughter (Loizou, 2005; Reddy, 2001).

More complex joking, such as puns, involves saying something that initially appears to violate fact or convention, but upon further reflection is consistent with fact or convention (e.g., Shultz, 1974). By initially appearing to be unrelated, puns appear to be wrong answers to questions as they violate conventions of communication, specifically Grice’s Maxim of relation, and by being ambiguous (having two meanings), puns also violate Grice’s maxim of Manner (e.g., Grice, 1975). These types of jokes are not normally understood until later. From 8 years, children choose joke endings with double meanings as more humorous than non-sequitor joke endings. However 6-year-olds judge both joke endings to be equally humorous, demonstrating that they only find a violation of the Maxim of relation humorous, or put another way, saying something wrong in the context of the previous utterance (Shultz, 1974). However using cartoons instead of words, even 4-year-olds appreciate jokes involving double meanings (Pien & Rothbart, 1976).

Pretense

Pretense involves understanding that someone has done the wrong thing, but has represented this action as right in a possible world (Nichols & Stich, 2003). In particular, pretense violates conventions and facts. For example, one might pretend that a block is a bar of soap, and violate convention by rubbing the block on one’s body. One might also make statements which violate fact, for example, if a child says, “I can fly”, which is not technically true. Like joking, pretense cannot violate intention, since pretense involves intentionally doing the wrong thing by its very nature (Hoicka & Gattis, 2008; Hoicka, et al., 2008).

Lillard (1998) found that 4- and 5-year-olds did not understand intentions to pretend. However the task involved hearing stories illustrated by pictures or dolls, and verbal responses were required. In experiments using an action-based task, 36-month-olds, but not 26-month-olds, differentiated intentions to pretend from trying (Rakoczy, Tomasello & Striano, 2004). Additionally, children can tell whether someone else is pretending or doing the real thing from 2.5 years (Ma & Lillard, 2007). Finally, using a looking-time paradigm, infants as young as 15 months detected violations in a pretense scheme (Onishi, Baillargeon, & Leslie, 2007). Children themselves pretend from around 18 months (e.g., Elder & Pederson, 1978; Ungerer, et al., 1981).

Lies

Lying involves understanding that someone has said the wrong thing for the purpose of deceiving someone (e.g., Leekam, 1991). Lying can be a violation of fact (e.g., saying one has not eaten cake when one has) and could also be a violation of convention (e.g., telling someone that they should drive on the left side of the road whilst in Spain). Lee and Cameron (2000) argue that a lie need not actually violate a fact as long as the liar thinks that the lie violates fact. Thus one could argue that lying either involves violating fact or convention, or having false (or wrong) beliefs about facts and conventions.

In order to truly understand that someone is lying, it is necessary to understand their intention to lie. While joking, pretending, and metaphor can be detected without understanding the intention behind an action or utterance, for example, by finding the joke funny, or noticing a similarity between a pretend act or metaphor and its representation, this is not the case for lying. If one simply notices that someone has said the wrong thing, this could be due to their lying, or it could be due to them having made a mistake. What is crucial is thus whether the liar intended to deceive.

Depending on how studies are performed, children start to understand lies between 3 and 5 years. Lee, et al., (2002) conducted an experiment in which young children were told lies that violated a reality-fantasy distinction. Five- and 6-year-olds identified the lies, and hence did not believe them, while 3- and 4-year-olds accepted the lies. Wimmer, Gruber, and Perner (1985) used a story-based method to assess what young children understood about lying. When asked whether the character should be punished, children as young as 4.5 years assigned punishment to liars, but not to people who were mistaken. However when asked whether the person had lied, children did not reliably distinguish the liar from the mistaken person. Thus 4.5-year-olds have a moralistic understanding of lies, without necessarily understanding the lexical term relating to lies. Using a picture-based method, 4-year-olds differentiated lies from promises (Maas, 2008). Finally, children as young as 3 years distinguished lies from mistakes, (Siegal & Peterson, 1996, 1998). Considering when children begin to lie, from around 3 or 4 years children lie in order to hide a

transgression of peeking when they were not supposed to, and tell white lies when receiving an unwanted gift (Talwar, et al., 2002; Talwar, Murphy, & Lee, 2007).

Metaphor

Metaphor involves intentionally saying the wrong thing, (e.g., Harris, Friel, & Mickelson, 2006) for purposes such as to provoke thought, compare similarities, and add interest, describe, and clarify (e.g., Gardner & Winner, 1986; Roberts & Kreuz, 1994; Sperber, 1984). Metaphor can violate fact, for example, saying, "Your room is a pig sty" when in fact it's just a room (e.g., Andrews, et al., 1986).

It is not until school age that children understand that people can intend to create metaphors. Eight-year-olds, but not 6-year-olds, differentiate metaphors from mistakes (Andrews et al., 1986). When one does not consider intentions, younger children appear to understand metaphors. In one task, 3-, 4-, and 5-year-olds were told stories that used time-based metaphors, and were then asked comprehension questions based on the metaphors. From 4 years, children correctly answered questions relating to metaphors (Ozcaliskan, 2005). In another task, 3- and 4-year-olds produced significantly more errors when repeating anomalous versus metaphorical utterances, and made the same number of errors when producing metaphorical and literal utterances, suggesting that the children understood the metaphors (Pearson, 1990). Finally, in terms of metaphor production, from 3 years children can produce appropriate metaphorical compounds. For example, if a stick-shaped bug is called a "leaf-bug" children might make a more appropriate metaphor by calling it a "stick-bug" (Gottfried, 1997).

Irony

Like metaphor, irony involves intentionally saying the wrong thing. Irony can violate fact, for example, saying, "That bungalow is the tallest building in the world" (e.g., Andrews, et al., 1986). Irony can also violate convention, for example, saying, "Driving on the right side of the road in London was a great idea." Again, irony cannot involve a violation of intention as irony is intentional in nature. Indeed, like lying, intention is the most important part of irony. An utterance is only ironic if the person meant it to be (e.g., Andrews, et al., 1986; Winner & Leekam, 1991).

Irony, like metaphor, is notoriously difficult for children to understand. It is not until school age that children understand intentions to be ironic. Eight-year-olds, but not 6-year-olds, differentiated irony from lies (Andrews et al., 1986). Winner and Leekam (1991) tested 7-year-olds on their ability to distinguish irony from deception. They found that children's ability to do so was contingent on their ability to distinguish second order intentions, that is, that the liar intended for the audience to believe the falsehood, whereas the ironist did not.

Wrongness, Reference, and Representation

Understanding the various types of wrongness involves understanding representation at different levels, and this understanding develops in stages (see Figure 1). The first stage involves understanding that a wrong act refers to a right act. While representation makes one think *of a wrong act as* a right act, reference only makes one think *of* a right act. Reference should be easier to understand since it can be accomplished by considering two different acts sequentially rather than simultaneously. Without being able to make a reference between a wrong act and a right act, it would be difficult to determine that an act was wrong in the first place: reference allows comparison between two acts. The ability to compare two acts appears to be present by 9 months, as children are first able to detect mistakes at 9 months (Behne, et al., 2005), and jokes at 10 months (Sroufe & Wunsch, 1972).

The second stage in understanding wrongness involves understanding representation, such that a wrong act can represent a right act (e.g., Nichols & Stich, 2003). Thus one act can have two meanings at the same time: the literal, and the imagined. This should be more difficult to understand than reference as representation requires simultaneous, rather than sequential processing. Understanding representation is essential for understanding pretense, metaphor, and pun-type jokes (e.g., Leslie, 1987; Shultz, 1974). Pretense is likely the first instance of understanding that a wrong act represents a right act. As metaphors and verbal puns require advanced linguistic skills as compared to pretense, understanding of metaphor and verbal puns should be delayed compared to pretense, but should involve the same underlying representational skills. Since children generally understand pretense from around 18 months (e.g., Ungerer, et al., 1981) this should mark when children understand the representation of wrong acts as right acts. Once children understand that a wrong act can represent a right act, then they have the possibility to distinguish mistakes and jokes from pretense. Thus a wrong act for which children cannot determine how it represents a right act could be thought of as a mistake or joke, and a wrong act for which children could determine how it represents a right act could be thought of as a general “as-if” for pretending (perhaps if action based). Later, when children’s language abilities develop, they should also be able to distinguish metaphors from puns as well. At this point, lies and irony, if the verbal content were to be understood, might still be thought of as mistakes or jokes, since they (at least appear) to refer to right acts, instead of representing them.

The third stage involves a basic understanding of mental representation. This involves processing a mental representation and its reference sequentially: understanding that an *intended* wrong act refers to a right act. The earliest instance of this may be when children understand that others can intentionally do the wrong thing through joking from 25 months (Hoicka & Gattis, 2008), since both the actor’s intention, and the reference between right and wrong acts are detected.

For the fourth stage, children must understand mental representation in terms of representations themselves. This requires understanding a representation in relation to mental representation, or in other words, understanding that an *intended* wrong act represents a right act. This may first be understood when children understand that others’ can intend to pretend, at 36 months (Rakoczy, et al., 2004), when both the actor’s intention, and the corresponding representation are detected.

Irony is more complex still. Like metaphor, it involves saying something wrong which represents something right. However, in metaphor, the similarity between concepts can lead a child to infer that a metaphor was made, without reference to the speaker’s mental state. In contrast, like lying, irony is about the attitude of the speaker, and cannot be inferred without understanding intention and belief (e.g., Andrews, et al., 1986; Winner & Leekam, 1991). Thus irony involves understanding two mental representations simultaneously: the wrong act (what the ironist intended to say) and the right act (what the ironist believed). At this point, when children can simultaneously process two mental representations: the intention to perform a wrong act, and the belief of a right act, children should be able to distinguish all types of wrong acts from each other.

We propose that these four stages of representation are linked. First, understanding the reference point between right and wrong, through mistakes and basic jokes, could help children later understand the representation of a wrong act as a right act, through pretense. By processing two acts sequentially when detecting jokes or mistakes, children may get used to considering two ideas in relation to each other. This may bootstrap an understanding of representation as it involves a shift from considering two ideas sequentially to considering two ideas simultaneously. This should be easier than making a bigger shift of never processing two ideas in relation to each other, to processing two ideas simultaneously.

Second, we propose that understanding that a wrong act can represent a right act (e.g., through pretense) is a precursor to mental representation (following, Leslie, 1987), since understanding mental representations, such as intentions, involves understanding something that is inferred, and not concretely perceivable. At this point, children should already understand reference, and should thus bootstrap their understanding that a wrong act refers to a right act, to understanding that an *intended* wrong act refers to a right act. This would be a simpler cognitive leap versus having no understanding or reference, and then suddenly having an understanding of reference in terms of mental representations. Finally, once children can process an intentional wrong act, and a (belief-based) right act, sequentially, this should create a smoother transition for processing an intentional wrong act, and a (belief-based) right act, simultaneously.

Spatial Position in Language and Visual Memory: A Cross-Linguistic Comparison

Solveig Bosse (solveig@udel.edu)

Anna Papafragou (annap@udel.edu)

Department of Psychology, 109 Wolf Hall
Newark, DE 19716 USA

Abstract

German and English speakers employ different strategies to encode static spatial scenes involving the axial position (standing vs. lying) of an inanimate figure object with respect to a ground object. In a series of three experiments, we show that this linguistic difference is not reflected in native speakers' ability to detect changes in axial position in non-linguistic memory tasks. Furthermore, even when participants are required to use language to encode a spatial scene, they do not rely on language during a recognition memory task. These results have implications for the relationship between language and visual memory.

Keywords: Positional verbs, visual memory, space, language and thought

Introduction

It has often been observed that languages make available different strategies to encode spatial relations (Ameka & Levinson, 2007). A question of central interest within the cognitive sciences is how these cross-linguistic differences interact with underlying spatial representations recruited in spatial memory and other cognitive processes. According to an influential position, language exerts a strong influence on cognitive processes (Levinson, Kita, Haun & Rasch, 2002). Based on several cross-linguistic experiments involving spatial tasks, Levinson et al. proposed that spatial frames of reference provided by people's native language affect how people remember spatial arrays. Crucially, such linguistic effects are argued to emerge even when no overt linguistic labels accompany encoding of the spatial scene. The idea is that obligatory spatial distinctions made within one's native language direct attention to those aspects of spatial representation - thereby affecting spatial memory.

According to a different position, effects of native language on mental representation and memory are more limited. For instance, studies have shown that, despite differences in encoding motion events between English and Greek, memory for aspects of motion does not differ across speakers of these languages (Papafragou, Massey & Gleitman, 2002; cf. Gennari, Sloman, Malt & Fitch, 2002 for related results on English vs. Spanish). Other work has also suggested an independence of memory from cross-linguistic differences in spatial encoding (see Munich,

Landau & Doshier, 2001; cf. reviews in Gentner & Goldin-Meadow, 2003).

The question of whether (and how) cross-linguistic differences might affect memory for spatial scenes is related to the question of whether (and how) the explicit presence of linguistic labels during spatial encoding might affect memory. Effects of overt labeling, even though not as deep and pervasive as the effects proposed by Levinson et al. (2002), are still important for understanding how language interfaces with other cognitive faculties. Several studies have shown that explicit spatial language can affect spatial memory – even though the scope and mechanisms responsible for such effects are still not well understood. For instance, there is evidence that memory for motion events can be biased depending on whether path (*exit*) or manner (*skip*) verbs accompany the events, regardless of whether the verbs are provided by the experimenter (Billman & Krych, 1998) or generated by participants (Billman, Swilley & Krych, 2000). Relatedly, Feist and Gentner (2007) showed that providing participants with spatial language can influence their behavior in a recognition task. Specifically, viewing ambiguous spatial representations paired with spatial prepositions (e.g., *on*) resulted in a false memory bias towards typical portrayals of the relation encoded by the prepositions. In another demonstration, Archambault, O'Donnell and Schyns (1999) showed that the level at which an object is categorized (general, e.g. “a mug”, or specific, e.g. “Steve’s mug”) influences the time it takes people to detect a change in a picture containing the object. If objects are known at a specific (individual) level, then the changes are detected faster than if the objects are known on a general level. Crucially, in this study, the level of categorization was provided through linguistic labels prior to the main testing phase.

In this paper, we explored the extent of the influence that language can have on spatial memory (including contexts with and without overt linguistic encoding). We focused on an area of spatial encoding that has only recently begun to receive attention in the literature – namely, positional systems (see Ameka & Levinson, 2007) – and compared two languages, English and German, that differ in a specific aspect of spatial-positional encoding. Specifically, German naturally uses positional verbs that specify the axial orientation of the figure object: an object that is perceived to

be upright (whose vertical height exceeds its width) is described with the verb *stehen* ‘stand’, while an object whose horizontal width exceeds its vertical height is described with the verb *liegen* ‘lie’. Although English has equivalent verbs and uses them for humans and other animates, the positions of inanimate objects are typically and canonically described with the English copula *be* (Kutscher & Schultze-Berndt, 2007). Consider, for example, the two scenes in Figure 1. In German, the two scenes would be canonically described with two different sentences:

- 1) Das Buch **steht** auf dem Stuhl. (Fig.1a)
the book stands on the chair
- 2) Das Buch **liegt** auf dem Stuhl. (Fig.1b)
the book lies on the chair

In English, however, both scenes can canonically be described with the same sentence:

- 3) The book **is** on the chair.

Figure 1a: *stehen* ‘stand’

Figure 1b: *liegen* ‘lie’

Since this aspect of linguistic encoding represents an obligatory way of encoding spatial position in German but is absent from the corresponding English sentences, we considered it a particularly appropriate test case for the hypothesis that linguistic distinctions influence non-linguistic memory. In a series of experiments (Exp. 1, 2 and 3), we investigated whether this difference in linguistic encoding is mirrored in performance in a (nonverbal) memory task. If language influences memory, then German speakers should perform better than English speakers on a recognition memory task involving changes of posture such as those between Figure 1a and 1b, *even when no language is overtly present as spatial scenes are committed to memory*. If language does not influence memory, native speakers of German and English should perform similarly on the recognition task.

Our studies also addressed the question whether the overt presence of linguistic labels during the encoding of spatial scenes affects memory performance (Exp. 3). Again if overt language affects memory for spatial scenes, German speakers should have an advantage in recognition memory

targeting axial position of a figure object compared to English speakers. If recognition memory is independent of overt labeling, no difference in memory for positionals should exist between English and German speakers.

Experiment 1

Experiment 1 was conducted to collect linguistic data to confirm the difference in the use of positional verbs between English and German. The experiment also tested memory performance for the corresponding positions after participants had freely inspected a set of spatial scenes.

Participants

Twenty-six native speakers of German and 28 native speakers of English participated. The German speakers were recruited at Ruprecht-Karls-Universität Heidelberg in Germany, and the English speakers at the University of Delaware in the U.S. None of the German speakers spoke English natively, although almost all had studied it in school, usually alongside other languages. Similarly, none of the native English speakers had native speaker proficiency in German. Equal numbers of men and women were included.

Stimuli

The stimuli consisted of 40 pairs of pictures, taken in color with a digital camera. Each picture depicted two everyday household objects arranged in a particular way. The objects were placed in mostly unconventional pairings (e.g., a boot with a frying pan, a teabag with a wine glass) so that the participants would not focus on the position of the objects but rather on their unpredictable combinations of the objects. Each object appeared in one and only one pair of pictures.

Sixteen of the 40 pairs were test items, which always displayed a figure object on top of a ground object. One picture in each pair depicted the figure object in a standing, vertical position, consistent with the German verb *stehen*, while the other picture depicted the figure object in a lying, horizontal position, consistent with the German verb *liegen*. The position of the ground object was the same in both pictures (see Figure 1 for an actual example drawn from our stimuli). The figure objects had to be medium-sized items that balanced well, could be placed in either a standing or lying position, and would look acceptable in both. We avoided objects that resembled animate beings (e.g., dolls) because English uses *stand* and *lie* for human beings in the upright or horizontal position. In fact, most everyday objects have an inherent orientation — they either stand up or lie flat in their natural state. Therefore, we supplemented our small number of orientation-free figure objects (e.g., lipstick, a roll of paper towels) with an equal number of figures that either naturally “stand” (e.g., a wicker basket) or naturally “lie” (e.g., a wallet), in order to avoid any bias created by unusual positioning.

Another 8 of the 40 pairs of pictures were changing control items (i.e., they involved changes that were

unrelated to the stand-lie distinction). In the changing control pictures, the two objects were placed in a non-support relationship in at least one of the two pictures. Such relationships involved attachment (e.g., a paper clip on a pen), containment (e.g., a banana in a bowl), or piercing (e.g., a knife in an apple). The difference between the two arrays in each pair were either changes of state (e.g., a banana becomes a peeled banana) or non-axial changes in position (e.g., a paper clip originally attached to the cap of the pen becomes attached to the body of the pen).

Finally, 16 of the 40 pairs of pictures were non-changing control items. The two members of each pair were identical to each other and depicted relationships of support (with one object resting on top of another), attachment, or containment.

These pairs of pictures were arranged for display in two lists of 40 pictures each. One picture of each pair became part of List 1 and the second picture of each pair became part of List 2. Within each List, half of the test items depicted a standing relation and half a lying relation. Lists 1 and 2 displayed pictures in two different random orders. We also created two more lists (Lists 3 and 4) by reversing the presentation order of Lists 1 and 2. For the memory task, we arranged these lists into four different working orders that varied in terms of which list was used during the initial (encoding) phase vs. the second (memory) phase (List 1 vs. 2, 2 vs. 1, 3 vs. 4, or 4 vs. 3 respectively).

For the language task, we selected a subset of these stimuli for presentation. Specifically, we only used List 1 and List 2 but omitted the non-changing control items such that each list contained 16 test and 8 changing control items only.

Procedure

Language Task For the language task, we tested 10 German speakers and 12 English speakers. Participants viewed either the (shortened) List 1 or the (shortened) List 2. They were told that each picture would depict two household objects paired together, and were asked to describe each arrangement with a single complete sentence. Participants recorded their responses on a lined answer sheet and controlled the pace of the task by advancing the display themselves.

Memory Task For the memory task, we tested 16 German speakers and 16 English speakers. None of these had participated in the language task. Each participant was assigned to one of the four stimuli orders. The participants were simply told that they would see a set of pictures and their task was to look at the pictures carefully. During this encoding phase, each picture appeared for two seconds before the display automatically advanced to the next picture. Then participants were told that they would view a second set of pictures and were instructed to verbally provide fast judgments of whether each picture was the “same” or “different” (i.e., whether the exact same picture had appeared in the first round, or the picture was similar to a picture that had appeared before but was also recognizably

changed). The pictures in the memory phase were also displayed for two seconds each. If a participant did not provide an answer within those two seconds, his or her response was discarded.

Results and Discussion

Language Task As the dependent variable, we calculated the percentage of answers that included a positional term for each language group. All positional information was encoded in verbs, namely German *stehen* and *liegen* and their English equivalents *stand* and *lie*. German speakers encoded position 90% of the time while English speakers encoded position only 32.3% of the time. This difference is significant (two-tailed t-test, $p < .001$). Thus, as expected, native speakers of German are more likely to encode the detailed spatial position of a figure object than English speakers.

Memory Task The results for this task are displayed in Figure 2. (All error bars in this paper indicate standard error.) For this and the following memory experiments, the dependent variable is the percentage of correctly identified pictures. An ANOVA with Language (German, English) and Trial (Test, Changing Control, Non-Changing Control) as factors returned only a main effect of Trial ($F(2,29)=22.04$, $p < .0001$). The effect is due to a significant difference between Test items ($M = 69.73$) and Changing Control items ($M = 88.49$; $p < .0001$), as well as a difference between Test items and Non-Changing Controls ($M = 91.51$; $p < .0001$). Thus, despite differences between English and German in the labeling of spatial position, English speakers did not perform differently from German speakers in memory for spatial position.

Figure 2: Accuracy in Memory Task of Experiment 1

Experiment 2

One possible explanation for the lack of native language influence in the memory task of Experiment 1 is that participants were not warned that memory for pictures would be tested. It is possible that prior knowledge of the nature of the task would make people more likely to recruit linguistic resources to encode the objects and relations in the pictures in anticipation of later testing. In Experiment 2, we

tested this hypothesis. Specifically, we replicated Experiment 1 but made participants aware of the fact that they would have to remember the pictures. To further bolster the opportunity to use linguistic labels (and store both the labels and the visual scene in memory) we introduced a temporal gap between pictures during the encoding phase. We reasoned that this lag of time would allow participants to encode stimuli verbally even if they were not specifically instructed to do so.

Participants

Sixteen native speakers of German were recruited at the Carl-von-Ossietzky Universität Oldenburg in Germany, and 16 English speakers were recruited at the University of Delaware in the U.S. None of the German speakers spoke English natively, although almost all had studied it in school. Similarly, none of the native English speakers had near-native speaker proficiency in German. Approximately equal numbers of men and women were included. None of these people had participated in Experiment 1.

Stimuli

The same materials as in Experiment 2 were used.

Procedure

The same procedure as for the memory task in Experiment 1 was used but with two modifications. First, participants were told that this would be a memory experiment and that they needed to remember the pictures they would see for a later recognition test. Second, 3 seconds of blank screen were inserted between pictures in the encoding phase.

Results and Discussion

The results are displayed in Figure 3. An ANOVA with Language and Trial as factors returned only a main effect of Trial ($F(2,29)=26.42$, $p<.0001$). This effect is driven by lower performance on Test items ($M = 71.29$) compared to the Changing Controls ($M = 90.23$; $p<.0001$) and the Non-Changing controls ($M = 93.16$; $p<.0001$). Thus even when participants know that they are participating in a memory experiment and are given the opportunity to encode the stimuli linguistically, linguistic encoding does not appear to affect the outcome of recognition memory.

Figure 3: Accuracy in Memory Task of Experiment 2

Experiment 3

Participants in Experiment 2, even though given the opportunity to encode the visual scenes linguistically, did not necessarily do so. It is an open question whether, under different conditions (e.g., a more difficult task), participants might spontaneously recruit labels implicitly as an additional encoding strategy (which would lead to English-German differences in memory accuracy here). Experiment 3 followed the basic method of Experiment 2 but introduced a novel manipulation to address this question.

Specifically, we included a Non-Linguistic Shadowing condition in which participants engaged in a secondary task (shadowing a rhythm by tapping) while inspecting the scenes: crucially, this shadowing task did not engage the language faculty. We hypothesized that, because of the high cognitive load imposed by the secondary task, participants would be likely to recruit language as an additional means of encoding the scenes in preparation for the memory test. If so there could be language-specific patterns in memory performance. For comparison purposes, we also included a Linguistic Shadowing condition in which participants engaged in a comparable secondary task that blocked the language code (verbally shadowing a rhythm). This task was not expected to lead to recruitment of labels during encoding (or to cross-linguistic differences in spatial memory). Hermer-Vazquez et al. (1999) showed that these two types of shadowing tasks impose the same cognitive load but employ different cognitive resources. Thus, labeling could be possible with Non-Linguistic Shadowing but not in Linguistic Shadowing.

Experiment 3 also tested the hypothesis that, when forced to provide linguistic labels explicitly, participants would use such labels later during the recognition phase (thus triggering language-specific effects on memory performance). In a Linguistic Completion condition, participants were asked to fill out a sentence after each scene describing the scene they saw; critically, they had to provide the spatial verb describing the relationship between the figure and ground object. German speakers were expected to produce more positional verbs than English speakers. Importantly, if labels can affect visual memory, we should expect an advantage for German speakers compared to English speakers in later recognition of standing vs. lying object positions. This manipulation provides a powerful test for the hypothesis that labels affect memory performance by virtually guaranteeing the presence of labels (hence of cross-linguistic labeling differences) during the initial inspection of visual scenes.

Participants

Thirty-six native speakers of German were recruited from either the Carl-von-Ossietzky Universität Oldenburg or the Gymnasium Nordenham in Germany. All had learned English but none of them spoke it natively. Thirty-six native speakers of English were recruited at the University of Delaware. No native speaker of English was fluent in

German. None of these participants had participated in Experiment 1 or 2. Approximately equal numbers of men and women participated.

Stimuli

The same materials as in Experiment 2 were used.

Procedure

Participants were randomly assigned to one of three conditions:

Non-Linguistic Shadowing Procedure was as in Experiment 2 but participants wore headphones during the encoding phase and listened to an irregular rhythm. Their task was to repeat the rhythm by tapping it with their fingers on the table.

Linguistic Shadowing Participants followed the same procedure as those in the Non-Linguistic Shadowing condition except that they had to repeat the rhythm constantly using the syllable “na” (they had to say the syllable loud enough for the experimenter to hear it).

Linguistic Completion Procedure was as in Experiment 2 with some modifications. After each picture in the encoding phase, instead of a blank screen, participants saw a screen displaying a sentence. The sentence was presented for 3 seconds and appeared in the native language of each participant. The sentence described the preceding spatial scene but was missing the verb and the ground object. For instance, for Figure 1a above, English speakers saw “The book ____ on the ____.” Participants were instructed to read the sentence out loud during the time it was displayed adding in the missing words (the ground object was omitted so that English speakers would not simply have to provide the copula *is* throughout). Sentences were recorded and later transcribed for coding.

Results and Discussion

Non-Linguistic and Linguistic Shadowing Conditions

The results from the memory task for these two conditions are presented in Figures 4a-b. For the Non-Linguistic Shadowing condition, an ANOVA with Language and Trial as factors returned only a main effect of Trial ($F(2,21) = 10.5$, $p < .001$). The effect is driven by lower performance on Test items ($M = 62.6$) compared to Changing Controls ($M = 83.9$) and to Non-Changing Controls ($M = 80.2$, $p < .05$). A similar ANOVA for the Linguistic Shadowing condition gave similar results (main effect of Trial, $F(2,21) = 13.47$, $p < .0001$, with lower performance on Test items ($M = 61.1$) compared to Changing and Non-Changing Controls ($M = 79.7$ and 78.6 respectively, $p < .05$). No difference was observed between performance in the two shadowing conditions ($p > .05$). Thus even in a task with higher cognitive demands that allows for the use of the linguistic code, language does not seem to have an effect on scene representations recovered from memory.

Linguistic Completion As expected, participants’ linguistic productions confirmed the asymmetry between English and German: German speakers offered verbs

encoding the (correct) position of the figure object for 73.3% of the Test items; English speakers did so for only 2.8% of these items. This difference is significant (two-tailed t-test, $p < .05$).

Figure 4a: Accuracy in Memory Task (Non-Linguistic Shadowing Condition) of Experiment 3

Figure 4b: Accuracy in Memory Task (Linguistic Shadowing Condition) of Experiment 3

Figure 4c: Accuracy in Memory Task (Linguistic Completion Condition) of Experiment 3

For the memory data (Figure 4c), an ANOVA with Language and Trial returned only a main effect of Trial ($F(2,21)=47.29$, $p < .0001$). This effect is driven by lower performance on Test items ($M = 66.3$) than Changing Controls ($M = 92.1$) and Non-Changing Controls ($M = 93.7$). German speakers – unlike English speakers – overwhelmingly mentioned the axial position of the object

in filling out the target sentences but this linguistic encoding did not lead to an advantage in remembering axial position.

General Discussion

In this study, we asked whether differences in the way English and German encode the axial position of a figure object affect recognition memory for axial position. Our results suggest that cross-linguistic differences in positional encoding have no influence on memory for spatial scenes. Specifically, in a variety of contexts allowing or encouraging the choice to encode the scenes linguistically, participants did not appear to make this choice. These results argue against theoretical positions according to which obligatory lexical or grammatical distinctions in a language create cognitive biases in speakers even in situations where no language is overtly present (e.g., Levinson et al., 2002). Our data are consistent with prior finding showing that spatial memory is independent from cross-linguistic differences in spatial vocabulary (Papafragou et al., 2002; Gennari et al., 2002).

A particularly noteworthy aspect of our data is that native language distinctions failed to affect recognition memory even when participants explicitly provided linguistic encoding of the spatial scenes (Linguistic Completion condition of Exp. 3). This finding differs from previous reports which found effects of explicit labeling on visual memory in speakers of a single language (see Introduction). To reconcile these divergent findings, one possibility is that language effects are more likely to surface when labels occur before (as in Feist & Gentner, 2007; Archambault et al., 1999; Billman et al., 2000) or during (as in Billman & Krych, 1998) the encoding of visual scenes rather than after visual encoding has occurred (as in our Exp. 3). In support of this possibility, work by McCloskey and Zaragoza (1985) showed that verbally presented misinformation about an object *after* an object had been viewed (e.g., referring to a hammer as a screwdriver) did not impair participants' ability to later recognize the object, as opposed to a new, previously unmentioned, object. Nevertheless, this explanation cannot account for other work showing that, even when linguistic labels are generated as spatial scenes or events are viewed, they do not necessarily alter visual memory (Papafragou et al., 2002; Gennari et al., 2002).

Another possibility is that language effects are more likely to emerge when the visual scenes to be remembered are ambiguous (Feist & Gentner, 2007) or can be categorized on several levels (Archambault et al., 1999), and thus allow language to play a disambiguating role. Regardless of the specific explanation that will turn out to be correct, the fact that linguistic labels in the Linguistic Completion condition degraded faster than the visual memory of the scenes provides evidence that linguistic and visual representation of spatial position belong to different levels of representation and are potentially independent of each other. Further work is needed to specify the precise factors that affect language intrusions into non-linguistic cognitive processes. Nevertheless, results from the

Linguistic Completion task suggest that such intrusions depend on subtle features of the task at hand and do not generalize across all contexts in which language is used to label spatial scenes.

Acknowledgments

We would like to thank the members of the Language and Cognition Lab and the participants at the University of Delaware and in Germany. This research was partly supported by NIH grant 5R01HD55498-2 to A.P.

Abstract

Online language comprehension is guided by knowledge regarding real-world events. However, it remains unclear whether activation of event knowledge during language comprehension is constrained by the linguistic context or is generalized, including a wide variety of information associated with the event even if that information has not been mentioned previously and does not satisfy constraints imposed by the local linguistic context. The present study addresses this issue by analyzing event-related brain potentials recorded as participants read brief scenarios describing typical real-world events. The amplitude of the N400 elicited by a contextually anomalous word was reduced if that word was related to the event described. This result suggests that online language comprehension involves construction of rich event representations that include information beyond that which is relevant to the processing of the current linguistic input.

Keywords: event knowledge; online language comprehension; event-related potentials; ERP; N400

Background

Online language comprehension is a rapid and incremental process guided by a wide variety of information sources. Some researchers characterize this process as the incremental mapping of linguistic structure onto real-world event structure, mediated in part by the comprehender's prior knowledge associated with the described event (e.g., Altmann & Mirković, 2009). Recent research has highlighted the importance of event knowledge to online

language comprehension. At the lexical level, priming studies have shown, for example, that verbs activate agents, patients, and instruments typically associated with the specific actions denoted by the verbs (Ferretti, McRae, & Hatherell, 2001), that agent, patient, instrument, and location nouns activate verbs denoting the events in which they typically participate (McRae, Hare, Elman, & Ferretti, 2005), and that word triplet priming with lexically unassociated primes and targets reveals rapid activation of script information (Chwilla & Kolk, 2005). Such findings suggest that processing words in isolation activates event knowledge, resulting in subsequent activation of other entities and/or actions associated with the event.

At the sentential level, self-paced reading (Bicknell, Elman, Hare, McRae, & Kutas, 2008) and eye-tracking (Kamide, Altmann, & Haywood, 2003) studies have demonstrated that comprehenders can rapidly integrate information provided by a verb in combination with its preceding agent in order to predict likely upcoming patients. For example, Kamide et al. monitored participants' eye movements around a visual scene as the participants listened to sentences such as *The [man/girl] will ride the [motorbike/carousel]*. They found more anticipatory looks to the picture of the motorbike when the agent of *ride* was *man* than when the agent was *girl* (and similarly more looks to the carousel for *girl will ride* than for *man will ride*), even though both a motorbike and carousel are equally plausible patients of the verb *ride*. This result demonstrates that thematic role assignment is not guided by the verb alone,

but crucially by knowledge associated with the event denoted by the agent-verb combination. Online language comprehension thus makes rapid use of event knowledge.

While event knowledge is clearly important to linguistic processing, the specificity of the event knowledge activated during comprehension remains an open question. Is the activated event knowledge general, containing a wide variety of salient features associated with the event? Or is activation restricted to only what is relevant to the current linguistic context? Consider the passage in (1):

- (1) A huge blizzard swept through town last night.
My kids ended up getting the day off from school. They spent the whole day outside building a big snowman in the front yard.

Given the previously discussed findings, it is likely the case that at the point of reading *building a*, a comprehender's knowledge regarding "playing in the snow" events allows for *snowman* to become activated as a likely patient (as opposed to *house*, for example). Is activation of event knowledge at this point limited to this feature of the "playing in the snow" event? If this were the case, it would indicate that event knowledge activation is constrained by the linguistic context, limiting activation to those event features that are relevant to the processing of the current linguistic input. However, it is also possible that an entire body of "playing in the snow" knowledge is activated in reading this passage. This knowledge might include, for example, the fact that the children are probably wearing jackets, hats, and mittens, even though this has not been explicitly mentioned and is not directly relevant to comprehending the passage. This study seeks to determine whether event knowledge activation during comprehension involves rich, generalized representations such as this, or if it is limited to what is currently relevant given the linguistic context.

In the present study, participants read brief passages describing typical real-world events. The final sentence of each passage contained either a highly expected target word (in the above example, *building a snowman*) or one of two contextually anomalous target words: one related to the event described (e.g., *building a jacket*) and one unrelated to the event described (e.g., *building a towel*). Participants' EEG was recorded as they read the passages, and the event-related brain potentials (ERPs) elicited by these three target types were contrasted. The analysis focuses on the N400, an ERP component whose amplitude is inversely proportional to the degree to which a word is expected given the preceding context (Kutas & Hillyard, 1984). It was predicted that if language comprehension involves generalized event knowledge activation, then the event-related anomalous target should become activated during the reading of the passage, while the event-unrelated anomalous target should not. This should then result in a graded N400 effect: the smallest N400 to the expected target, the largest N400 to the event-unrelated target, and an intermediate N400 to the event-related target. Such a result would indicate that although both the event-related and event-

unrelated targets violate local linguistic constraints, the event-related target becomes activated by virtue of its association with the event described. More generally, this result would support the notion that language comprehension involves generalized event knowledge activation.

Stimuli

Seventy-two experimental items (scenarios) were constructed. Each scenario consisted of three sentences and described a common real-world event. The first two sentences established the event (e.g., playing in the snow). The final sentence contained one of three sentence-medial target words: a highly expected word, a contextually anomalous word that was related to the established event (event-related anomalous target; ERA), or an equally anomalous word that was unrelated to the established event (event-unrelated anomalous target; EuRA). Each experimental item thus had three possible target words, giving the experiment three conditions.

Expected Targets

The expected targets were obtained via a cloze task in which participants read each scenario up to the word preceding the target and were asked to provide the single word most likely to come next. Participants completed the cloze task through an online form. Scenarios were presented one at a time, with all three sentences presented in paragraph format. The third sentence left off at the word preceding the target, and participants provided the most likely upcoming word in a blank text field before moving onto the next scenario. Responses could not be modified once entered.

Thirty undergraduates (twenty-three women) at the University of California, San Diego participated for course credit. All were native English speakers. Cloze probability was calculated as the percentage of participants who provided a particular response for the given scenario. The response with the highest cloze probability was chosen as the expected target word. Across the seventy-two items, mean cloze probability of the expected target was 0.81, with a standard deviation of 0.17.

Event-Related Anomalous Targets

To obtain the event-related anomalous targets (ERAs), a new group of participants completed a norming task in which they provided a list of people or things most likely to be present at each event. Participants completed this task through an online form. Scenarios were presented one at a time in paragraph format, with the expected target word obtained in the previous cloze task now filled in. Participants were instructed to read each item and to paint a mental picture of the event described. They were told that their picture would likely include prominent people or things that would participate in the event, but were not explicitly mentioned in the text. They were asked to provide up to five responses for each scenario. Responses could not be modified once entered.

Table 1: Norming results for the three rotation groups and the stimuli set overall¹

		Group 1	Group 2	Group 3	Overall
Expected targets	Cloze probability	0.81	0.80	0.80	0.81
	Log frequency	6.95	7.01	6.88	6.95
	Orthographic length	5.58	5.71	5.75	5.68
Event-related targets	Cloze probability	0.00	0.00	0.00	0.00
	Log frequency	6.89	6.91	6.76	6.86
	Orthographic length	5.96	5.96	5.71	5.87
	Event-relatedness score	88.1	86.5	92.5	89.1
Event-unrelated targets	Cloze probability	0.00	0.00	0.00	0.00
	Event-relatedness score	0.00	0.13	0.04	0.06

Forty-five undergraduates (twenty-six women) at the University of California, San Diego participated for course credit. All were native English speakers, and none had participated in the cloze task. Each participant's responses for a particular scenario were given weighted scores based on response order (i.e., 5 for the first response, 4 for the second response, 3 for the third response, etc.). The highest scoring response that was not provided as a response in the previous cloze task (i.e., had a cloze probability of zero) was chosen as the ERA for the item. In a small number of instances, the highest scoring zero-cloze response was deemed to be a contextually sensible continuation of the scenario, despite having not been provided as a response in the cloze task. In these cases, the next highest scoring zero-cloze response was chosen. Across the seventy-two scenarios, the mean event-relatedness score of the ERA was 89.1, with a standard deviation of 34.4.

Event-Unrelated Anomalous Targets

Event-unrelated anomalous targets (EuRAs) were obtained by shuffling the ERAs across scenarios. Before this was done, the seventy-two experimental items were split into three rotation groups of twenty-four items each, allowing for three experimental lists to be constructed by rotating each group through the three conditions across the three lists. To minimize variability across the experimental lists, the rotation groups were matched on the following factors: mean cloze probability, log frequency, and orthographic length of the expected target; mean event-relatedness score, log frequency, and orthographic length of the ERA.

ERAs were shuffled across the items within each rotation group to obtain the EuRAs, thereby matching the ERAs and EuRAs for lexical factors within each group. EuRAs were

chosen such that they were all zero-cloze, and in all but two of the seventy-two scenarios, EuRAs had event-relatedness scores of zero. (The two exceptions had extremely low event-relatedness scores of 1 and 3.) In addition, the shuffling was done in such a way as to match the ERAs and EuRAs within each scenario for animacy and concreteness. This was done so that if the ERA constituted an animacy or concreteness violation with respect to preceding context, the EuRA constituted the same violation. The norming results for each rotation group and the stimuli set overall are presented in Table 1.

Lexical Associations

One concern in constructing the stimuli was that the ERAs might be significantly more likely than the EuRAs to be lexically associated with the expected word. Such a confound might undermine the experiment, as the predicted graded N400 effect could then be accounted for by priming of the ERA by the expected word, as opposed to the activation of event knowledge. The University of South Florida Free Association Norms (Nelson, McEvoy, & Schreiber, 1998) were consulted to ensure that the ERAs and EuRAs were on average associated to equal degrees with their corresponding expected targets. Sixty-five of the seventy-two scenarios' expected targets appeared in the Nelson norms; mean association scores for the ERAs and EuRAs were calculated across these sixty-five items. The mean association score for the ERAs was 0.0005, and for the EuRAs was 0.0001.² These extremely low mean association scores and the small difference between them were deemed acceptable for the purposes of the study.

¹ Recall that the event-unrelated and event-unrelated targets consist of the same lexical items. Mean log frequency and orthographic length of the EuRAs is therefore equal to that of the ERAs and is not reported in the Table 1.

² The association score for a given word is calculated simply as the proportion of participants that provided the word (ERA or EuRA) in response to the cue word (expected target). The mean scores for ERAs and EuRAs thus correspond to one response per two thousand participants and one response per ten thousand participants, respectively.

Experiment

To examine the specificity of the event knowledge activated during online language comprehension, participants' EEG was recorded as they read the carefully constructed scenarios described in the previous section. To review, each scenario consisted of three sentences. The first two sentences established a typical real-world event. The third sentence contained one of three possible target words: a highly expected word, an anomalous but event-related word (ERA), or an anomalous and event-unrelated word (EuRA). It was hypothesized that the expected word would elicit the smallest N400, the EuRA would elicit the largest N400, and the ERA would elicit an intermediate N400. Such a finding would indicate that although both the ERA and EuRA violated local linguistic constraints, the ERA was activated through the activation of generalized event knowledge by the preceding context.

Methodology

Materials The materials consisted of seventy-two scenarios constructed according to the previously discussed criteria. Three experimental lists were created based on the grouping of the seventy-two items into the three rotation groups, such that each experimental item occurred exactly once in each

condition across the three lists and exactly once in each list. In addition to the seventy-two scenarios, twenty-four fillers were included. Like the experimental items, these were three-sentence scenarios describing real-world events. None contained any anomalous words. Presentation order of experimental items and fillers was fully randomized for each participant.

Participants Thirty undergraduates (twenty-two women) at the University of California, San Diego participated for course credit. All were right-handed native monolingual English speakers with normal or corrected-to-normal vision. None reported any history of learning or reading disabilities or neurological or psychiatric disorders.

Procedure Participants sat in an electromagnetically shielded chamber and read each scenario from a computer monitor. The first two sentences of each scenario were presented in paragraph format. Once participants understood the two sentences, they pushed a button to advance to the final sentence. The final sentence was presented via rapid serial visual presentation (RSVP) with a stimulus onset asynchrony (SOA) of 350ms and a stimulus duration of 200ms. After the offset of the final word, participants answered a yes-no comprehension question before advancing to the next trial. Response hand was

Figure 1: Grand average ERPs at all electrode sites

counterbalanced across participants.

EEG was recorded from twenty-six electrodes distributed evenly over the scalp, referenced online to the left mastoid and re-referenced offline to the average of the left and right mastoids. Electrodes were placed on the outer canthus and infraorbital ridge of each eye to monitor eye movements and blinks. All electrode impedances were kept below 5K Ω . EEG was amplified with Nicolet amplifiers with a bandpass of 0.016 to 100 Hz and digitized at a rate of 250 samples per second.

Results

Before analysis, all epochs containing artifacts caused by blinks, eye movements, muscle tension, channel drift, or amplifier blocking were rejected offline. Participants' responses to the comprehension questions were analyzed to ensure that each participant was reading the scenarios for comprehension. Only one participant scored below 90% correct (88.9%), indicating that participants were comprehending the scenarios.

EEG was time-locked to the onset of the target words and was first averaged within participants to obtain individual participant averages for each condition. These individual participant averages were then averaged together to obtain a grand average ERP waveform for each condition. Figure 1 contains the grand average ERPs at each electrode site, arranged according to the distribution of electrodes over the scalp (i.e., frontal electrodes at the top, posterior electrodes at the bottom; midline electrodes in the middle, lateral electrodes to the side); Figure 2 presents a close-up of the grand average ERPs at the midline parietal recording site (Pz). To conduct an analysis of N400 amplitude, mean amplitudes from 200 to 500ms post-stimulus onset (relative to a 500ms pre-stimulus baseline) at each electrode for each participant were entered into a repeated measures ANOVA. A main effect of Condition was obtained [$F(2,58)=38.33$, $p<0.0001$], as was a Condition X Electrode interaction [$F(50,1450)=7.26$, $p<0.0001$]. Planned comparisons revealed the event-unrelated condition to be significantly more negative than the event-related condition [$F(1,29)=13.00$, $p<0.01$], which in turn was more negative than the expected condition [$F(1,29)=35.44$, $p<0.0001$]. This result confirms the predicted graded N400 effect: expected targets elicited the smallest N400, event-unrelated anomalous targets the largest N400, and event-related anomalous targets an intermediate N400. Analysis of the distribution of the N400 effect revealed a significant Condition X Hemisphere interaction [$F(2,58)=9.69$, $p<0.001$], a significant Condition X Laterality interaction [$F(2,58)=15.14$, $p<0.0001$], and a significant Condition X Anteriority interaction [$F(6,174)=4.96$, $p<0.01$], indicating that the N400 effect exhibited a posterior, slightly right-lateralized distribution across the scalp.

Discussion

Previous research has demonstrated the important role that event knowledge plays in online language comprehension.

However, the specificity of event knowledge activation has remained an open question. The results of the present study suggest that activated event knowledge is general, containing elements beyond what is relevant to the processing of the current linguistic input. This conclusion is supported by a reduction in N400 amplitude to a contextually anomalous word when that word is related to the event being described (and is crucially unrelated to the most expected word, as determined by consulting the South Florida Free Association Norms). This result shows that a wide range of event-relevant information is activated during online language comprehension, as opposed to only event-relevant information that meets local linguistic constraints.

It is important to note that while an event-related anomalous word elicits a reduced N400, it still elicits a larger N400 than a highly expected word. In the present study, the expected targets were more plausible patients of the preceding verbs than were the event-related targets. It is thus possible that event-related elements are activated in a gradient fashion, with those that satisfy the constraints imposed by the local linguistic context receiving greater activation. As the aforementioned study by Ferretti et al. (2001) suggests, verbs encode thematic roles in an event-specific fashion. According to this view, expected targets were closely related to the specific event denoted by the verb itself, whereas the event-related targets were related to the event described by the scenario as a whole but unrelated to the specific event denoted by the verb. This suggests that a word related to the event conveyed by the global linguistic context will receive even greater activation if it is also compatible with the event denoted by the verb.

While it is argued here that the N400 reduction for event-related targets results from activation of event knowledge, it might be argued that such a finding could arise if the event-related targets were lexically associated with the words in the preceding contexts to a greater degree than the event-unrelated targets. Associations between targets and their contexts were quantified using Latent Semantic Analysis (Landauer, Foltz, & Laham, 1998; <http://lsa.colorado.edu/>), a method for assessing word associations through analysis of the distribution of words in large-scale corpora. Each target received an association score between 0 and 1, with expected targets receiving a mean score of 0.276, event-related targets a mean score of 0.268, and event-unrelated targets a mean score of 0.220. A paired t-test confirmed the difference between event-related and event-unrelated targets ($p=0.002$). While this result suggests that the event-related targets were more strongly associated with the words in the preceding contexts than were the event-unrelated targets, this is in fact compatible the event knowledge account. Language describing real-world events will undoubtedly exhibit statistical regularities mirroring the structure of the real-world events themselves, and thus lexical co-occurrence measures calculated over large corpora should reflect the event structures encoded in event knowledge. In addition, event knowledge presumably can be derived from experience both in the real world and with language

Figure 2: Grand average ERPs at Pz

describing that world, meaning that co-occurrence patterns in language likely result in part from the structure of real world events and contribute to knowledge regarding those events. Lexical co-occurrence, event structure, and event knowledge are thus tightly linked, and it is unlikely that the reported results stem from lexical co-occurrence independent of event knowledge activation. This reasoning raises interesting questions regarding the interplay between knowledge of linguistic regularities and event knowledge during online language comprehension, which is an area worthy of future research.

The finding that event-related anomalous words elicit a reduced N400 stands in contrast with a previous study by Traxler, Foss, Seely, Kaup, and Morris (2000). In their study, the authors examined whether facilitated word processing during sentence comprehension might be captured by a schema-based account in which linguistic input activates a precompiled knowledge structure pertaining to the event being described. In Experiment 1, participants' eye movements were monitored as they read sentences such as *The [lumberjack/young man] chopped the axe early in the morning*. First fixation and gaze durations for the target word (*axe*) did not vary with the target's compatibility with the event denoted by the combination of the agent and verb (i.e., *axe* was read equally fast following *The young man chopped* as it was following *The lumberjack chopped*), suggesting that reading *The lumberjack chopped* did not activate a "lumberjacking" schema that contains an axe as a prototypical instrument.

Given the present finding, the result reported by Traxler et al. is quite surprising. According to the account put forth here, reading *the lumberjack chopped* should activate generalized "lumberjacking" knowledge that would likely include an axe. The source of this apparent discrepancy is unclear, although it is possible that the stimuli used here activated event knowledge more strongly than the stimuli used by Traxler et al. It is also possible that Traxler et al.'s stimuli included target words that were on average less strongly associated with the event being described, or it may simply be the case that such eye movement measures are not sensitive to the effect in question. Further examination is necessary to determine whether the findings reported by

Traxler et al. do in fact stand in contrast with those reported here, or if they are due to methodological differences.

Conclusion

Event knowledge plays an important role in online language comprehension. The present study demonstrates that activation of event knowledge is not constrained by the linguistic context, but instead is highly general, including a variety of information that is not necessarily relevant to the processing of the current linguistic input. This finding provides further support for the intimate link between language comprehension and real-world experience.

Abstract

While English speakers generally rely on a viewer-centered frame of reference when interpreting table-top space, they will also adopt an object-centered frame in certain situations—prompting the question: *What factors determine which frame?* The current research investigates two possible contributors: the intrinsic “frontedness” of a reference object involved in the scene and the syntactic structure of the sentence used to describe the scene. If an object possesses an “intrinsic front side,” then this side should highlight the properties necessary for the object to be capable of having its own distinguishable perspective. Also, certain linguistic constructions may further increase the salience of the reference object’s inherent geometrical properties, leading to greater use of an object-centered frame.

Keywords: Frame of reference; spatial language.

Introduction

English spatial terms can be ambiguous as to which area of space they refer if a frame of reference is not established before analyzing any spatial relation between two or more objects. When interpreting descriptions of table-top space, English speakers have been shown to rely primarily on a viewer-centered (VC) frame of reference (Majid, Bowerman, Kita, Haun, & Levinson, 2004); however, interpretation may alternatively depend upon an object-centered (OC) frame (Carlson-Radvansky & Irwin, 1993; 1994) when applicable.

The VC frame – also referred to by Levinson (1996, 2003) as the relative frame and by Miller and Johnson-Laird (1976), Retz-Schmidt (1988), and Carlson-Radvansky and Irwin (1993, 1994) as the deictic frame – assigns spatial terms according to the properties of an observer located externally to the scene. For example, a viewer attempting to determine the location of a teacup with respect to a nearby teapot will transfer his or her own left and right sides onto the scene and judge that the teacup is to the left/right of the teapot if the space occupied by the teacup corresponds with the viewer’s own left/right side. Because the VC frame is relative to an external observer, it can be based on different

perspectives: one whose origin is grounded on “ego” (a speaker) and another whose origin has been transferred from “ego” to a third party (an addressee) (Retz-Schmidt, 1988; Levinson, 1996; 2003). If the speaker and the addressee share vantage points, locating one object with respect to another is relatively straightforward; however, if not, their viewpoints may conflict, with the result that spatial term use relying on the VC frame may be ambiguous.

Unlike the VC frame, an OC frame of reference – also referred to as the intrinsic frame by Miller and Johnson-Laird (1976), Retz-Schmidt (1988), and Levinson (1996, 2003) – assigns spatial terms according to the ground object’s inherent properties. With this frame, a viewer attempting to locate the teacup would first determine whether or not the teapot has its own left and right sides and then judge that the teacup is to the left/right of the teapot if the teacup’s occupied space corresponds with the teapot’s left/right. Unlike the VC frame, the OC frame is not affected by the locations of any external observers; regardless of the viewpoints of the speaker and the addressee, the teacup will remain intrinsically to the teapot’s left as long as neither object is moved. However, use of the OC frame will require mental rotation if the vantage points of the viewer and ground object are not aligned, and knowledge of the ground’s orientation (Levelt, 1996). In addition, because many objects may lack inherent left and right sides, the assignment of *left* and *right* in this frame is ambiguous and is influenced by functional properties of the object (Levelt, 1996) as well as the vantage point from which the object is considered (Retz-Schmidt, 1988). Contrary to the findings of Majid et al. (2004), Miller and Johnson-Laird (1976) have argued that interpretations based on the OC/intrinsic frame actually dominate those based on the VC/deictic frame, with VC/deictic interpretations requiring specific qualifications from the speaker, such as “the teacup is to the left of the teapot *from my point of view*.”

In order to better understand the semantics of projective terms, many of which can be used with either a VC or an OC frame of reference, we ask in this paper what factors

in a spatial scene determine which frame will be selected for use.

Possible Contributing Factors to Frame of Reference Selection

Vandeloise (1991) and Levinson (1996, 2003) suggest that one way to resolve the ambiguity of spatial terms may lie in the structure of the utterance used to describe the scene (see also Levelt, 1996). They argue that rephrasing “the teacup to the left of the teapot” as “the teacup to the teapot’s left” should encourage use of an OC frame because the possessive construction points out that the teapot has its own “left side” that may be separate from the “left side” that a viewer assigns to the scene. Moreover, because this construction is specifically possessive, it may suggest that “the teapot’s left side” is the correct interpretation.

In addition, because use of an OC frame makes more sense when the ground object possesses distinguishable sides (Levelt [1996] argues that the OC frame is only possible if this holds), this frame should be more salient when the object possesses a high degree of “frontedness.” Landau and Jackendoff (1993) argue that the ground object’s inherent axial structure is its most important property, and the more an object can be thought of as possessing a front side, the more viewers should notice that its two horizontal axes are different: one assigns an object’s front and back while the other assigns its left and right. For example, a ground object like a teapot, which has an obvious front side, should encourage greater use of the OC frame because its front side calls attention to its possession of a perspective and orientation governed by its intrinsic front, back, left, and right sides. A ball, on the other hand, should not encourage use of an OC frame because it lacks an inherent front, and therefore lacks distinguishable sides; any sides assigned to it should be more strongly based on a VC perspective.

In the current study, we ask whether these two factors – the syntactic form of the spatial description and the inherent frontedness of the ground object – facilitate use of an OC frame of reference for English speakers’ descriptions of spatial relations in tabletop space.

Method

Participants

Twenty-five students from the University of Louisiana at Lafayette who were enrolled in an introductory psychology course received extra credit in return for their participation.

Stimuli

The task took place on a computer using the E-Prime software package. The stimuli used in the experiment included photographs of a figure and ground taken at a “3/4” angle (halfway between head-on and bird’s-eye). Each scene was presented with a sentence including a locative expression (see Figure 1 for an example).

The black dot is to the left of the jack o' lantern.

Figure 1. Example of fronted object stimulus.

For the sentences, we considered the two locative terms *left* and *right*, which could be aligned with one of the horizontal axes. There were two levels of Sentence Structure: *non-possessive* and *possessive*. Participants either saw sentences of the form “The F is to the left/right of the G,” (non-possessive) or the form “The F is to the G’s left/right” (possessive). These two structures were presented between-participants to forestall a strategy of pairing each structure with a different reference frame.

The pictures each showed one figure – a black dot (a black-painted wooden circle) – paired with one of 6 different ground objects that varied on two dimensions of Frontedness, *fronted* and *non-fronted*. Stimuli in the *fronted* group included a camera, a flower, and a jack o’ lantern; stimuli in the *non-fronted* group included a balloon, a glass, and a watermelon¹.

The final two variables were Figure Position (FP) and Ground Rotation (GR), which were manipulated to vary the frame of reference with which the picture-sentence pairs were consistent (VC, OC, VC and OC, or none (cf., Carlson-Radvansky & Irwin 1993; 1994). The design included 4 degrees of ground rotation (facing 0, 90, 180, or 270 degrees), and four figure positions (at a 0, 90, 180, or 270 degree arc). VC-consistent arrangements always included FP 270 for *left* and FP 90 for *right*, regardless of Ground Rotation; OC-consistent arrangements depend upon both figure position and ground rotation for their interpretation. Figure 2 shows VC-consistent and OC-consistent FP-GR pairings for *left* and *right* (with stimuli at GR 180 being consistent with both frames) illustrated

¹ Assignment to the fronted or non-fronted group was based on two norming studies. In the first, viewers rated the extent to which different objects were said to have an intrinsic “front side;” objects with low ratings were considered non-fronted, while objects with high ratings were considered fronted. In the second, viewers attempted to select the “front side” of the two types of objects. A chi-square analysis revealed that viewers chose the intended front side significantly more often than the other sides for the objects in the fronted group only.

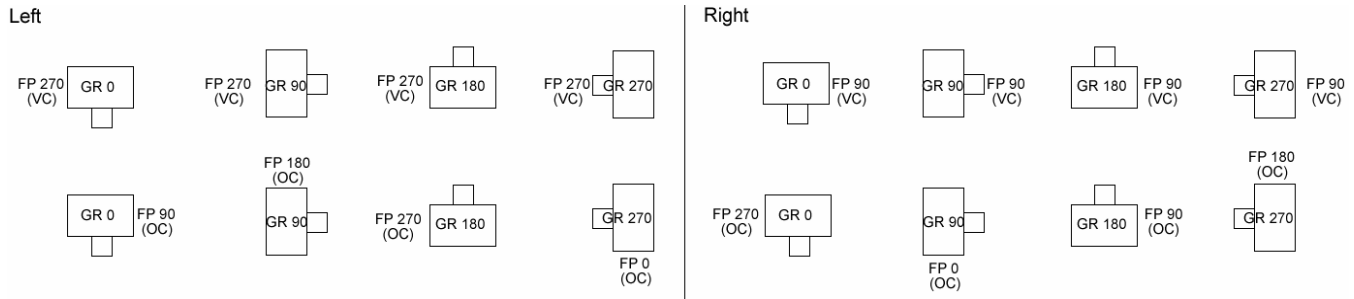

Figure 2. Viewer-centered (VC) and object-centered (OC) assignments of *left* and *right* for fronted objects. Non-fronted objects were assigned similarly to facilitate comparisons between object types.

for clarity with fronted ground objects. Each Figure Position-Ground Rotation combination was created for each of the Ground objects, for a total of 96 pictures.

However, because non-fronted objects cannot truly be said to face in a specific direction in a way that allows the different Ground Rotations—and ultimately, the OC frame of reference—to apply to them, attempting to compare the non-fronted objects to fronted objects becomes problematic. We resolved this issue by including non-fronted objects that possessed a pattern that allowed for their different sides to be discernable upon their rotation, and an arbitrary side was designated as the “front” side so that the objects could be said to “face” in the different directions of Ground Rotation. This designation also allowed for the object to possess “left” and “right” sides. Then, in order to make comparisons between non-fronted and fronted objects, we simply compared ratings at the same Figure Positions and Ground Rotations across object type.

The design of the experiment was 2 (Sentence Structure: *non-possessive* and *possessive*) X 2 (Spatial Term: *left* and *right*) X 2 (Frontedness: *non-fronted* and *fronted*) X 4 (Figure Position: 0, 90, 180, 270) X 4 (Ground Rotation: 0, 90, 180, 270). Spatial Term, Frontedness, Figure Position and Ground Rotation varied within participants, while Sentence Structure varied between participants.

Procedure

Participants were divided into two groups. One group saw arrangements with corresponding sentences in the *non-possessive* construction, while the other group saw arrangements with corresponding sentences in the *possessive* construction. For the first part of the experiment, participants looked at pictures of the ground objects (one picture per object) in order to introduce each object before the rating task began.

For the rating task, each of the 96 pictures was presented twice, once with a “left”-sentence and once with a “right”-sentence, in random order on a computer screen, for a total of 192 trials. In each case, the participant was asked to rate the acceptability of the sentence as a description of the picture, on a scale from 1

(not acceptable at all) to 5 (very acceptable). The variables for each trial were completely randomized.

Predictions

Acceptability of OC assignments should be higher when the spatial description is in the possessive structure (“the fork is to the knife’s left”) than when it is non-possessive (“the fork is to the left of the knife”), if awareness of the OC frame is made explicit by the possessive structure. Also, the inclusion of a fronted ground object should lead to higher acceptability of OC assignments than inclusion of a non-fronted object.

Alternatively, implicit awareness of the OC frame may lead to lower ratings of the VC assignments with a possessive structure or fronted object—which would suggest that viewers may at least recognize the possibility of using a different reference frame, even if they are not completely comfortable with it. Such a result might further suggest that the two frames share conceptual space and are simultaneously acceptable in a way that is similar to the predictions of the multiple frame activation hypothesis (Carlson-Radvansky & Irwin, 1994).

Furthermore, object frontedness and the structure of the spatial description should cooperate; when the possessive structure is combined with a fronted ground object, the structure of the description should call attention to the inherent frontedness of that object, maximally increasing acceptability of the OC frame. In this case, we would expect to see a situation in which acceptability of the OC frame surpasses that of the VC frame.

Results and Discussion

Because our interest is in how Sentence Structure and Frontedness might influence spatial term acceptability across the 16 figure position-ground rotation combinations, we will focus our discussion on higher-order interactions with the variables of figure position and ground rotation.

Sentence Structure

Figures 3a and 3b show that Sentence Structure influenced the pattern of acceptability across the figure position-ground rotation combinations, $F(9, 207)$, =

Figures 3a – 3b. Mean sentence acceptability ratings for the 16 figure position/ground rotation arrangements broken down by Sentence Structure and collapsed across Term and Frontedness.

3.107, $p < .05$. At the two ground rotations where the VC frame was out of alignment with the OC frame, the average rating of all VC-consistent arrangements (FP 90-GR 90, FP 270-GR 90, FP 90-GR 270, FP 270-GR 270) ($M = 2.922$) was significantly higher than the average rating of all OC-consistent arrangements (FP 0-GR 90, FP 180-GR 90, FP 0-GR 270, FP 180-GR 270) ($M = 2.314$) for the non-possessive sentence structure, $t(14) = 3.183$, $p < .05$. However, these average ratings did not differ within the possessive condition (VC assignments, $M = 2.593$, vs OC assignments, $M = 2.737$, $t(10) = -.641$, ns). This effect is in line with the prediction that the possessive sentence structure may facilitate consideration of an OC frame of reference by increasing ratings of OC assignments and/or decreasing ratings of VC assignments to the point at which the two frames are equally acceptable.

Frontedness

Figures 4a and 4b show that Frontedness influenced the pattern of acceptability across the figure position-ground

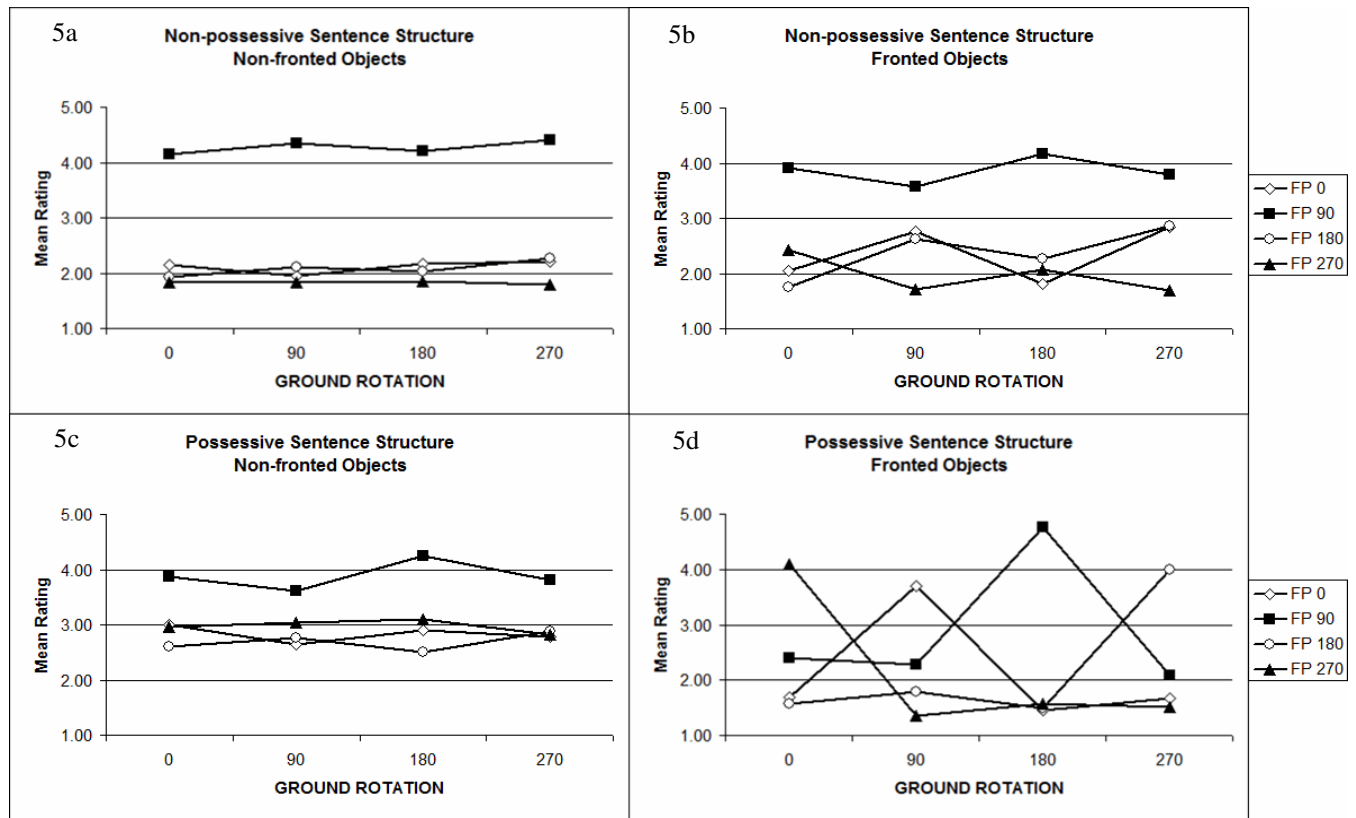

rotation combinations, $F(9, 207) = 13.555$, $p < .05$, much as Sentence Structure did. For non-fronted objects, the average rating of all VC-consistent arrangements at the two ground rotations where the VC frame was out of alignment with the OC frame was significantly higher ($M = 3.218$) than the average rating of all OC-consistent arrangements ($M = 2.342$), $t(24) = 5.054$, $p < .05$; however, for the fronted objects, no difference was found (VC assignments, $M = 2.336$, vs OC assignments, $M = 2.659$, $t(24) = -1.353$, ns). As was the case for the possessive sentence structure, the inclusion of a fronted ground object appears to equalize the acceptability of a VC interpretation and the acceptability of an OC interpretation.

Sentence Structure and Frontedness

The combination of the influence of Sentence Structure and Frontedness is evident in the five-way interaction of Term, Sentence Structure, Frontedness, Figure Position and Ground Rotation; $F(9, 207) = 5.444$, $p < .05$. For the sake of brevity, and because results for the terms *left* and

Figures 4a – 4b. Mean sentence acceptability ratings for the 16 figure position/ground rotation arrangements broken down by Frontedness and collapsed across Term and Sentence Structure.

Figures 5a – 5d. Mean sentence acceptability ratings for the 16 figure position/ground rotation arrangements broken down by Sentence Structure and Frontedness for the term *right*.

right were similar, here we only describe the analysis of *right* (see Figures 5a – 5d).

The Viewer-centered frame. In order to further understand the way in which the variables of Sentence Structure and Frontedness influenced the acceptability of *right* for arrangements consistent with a VC frame of reference (FP 90), we examined changes in acceptability ratings across the different levels of Sentence Structure and Frontedness². Looking at the acceptability ratings for these points across the 4 conditions (Figures 5a – 5d), we observe that VC points are rated as most acceptable for the non-possessive, non-fronted condition (5a) and for the possessive, non-fronted condition (5c), with lower acceptability in the non-possessive, fronted condition (5b), and with lowest acceptability in the possessive, fronted condition (5d). These differences in acceptability are significant (non-possessive, non-fronted vs. possessive, non-fronted, $M = 3.767$, $t(23) = 1.326$, ns ; non-possessive, non-fronted, $M = 4.301$, vs. non-possessive, fronted, $M = 3.754$, $t(13) = 2.508$, $p < .05$ one-tailed; non-possessive, non-fronted vs. possessive, fronted, $M = 2.252$, $t(23) = 4.463$, $p < .05$; non-

possessive, fronted vs. possessive, fronted, $t(23) = 3.040$, $p < .05$).

The Object-centered frame. In order to further understand how the variables of Sentence Structure and Frontedness influenced the acceptability of *right* for arrangements consistent with an OC frame of reference (FP 270-GR 0, FP 0-GR 90, FP 180-GR 270) (see Figure 2 for representations of these arrangements), we examined changes in acceptability ratings across the different levels of Sentence Structure and Frontedness for these arrangements. Looking at acceptability ratings across the different conditions reveals that OC points received the highest ratings in the possessive, fronted condition (Figure 5d). Ratings were lower in the non-possessive, fronted (5b) and possessive, non-fronted conditions (5c) and lowest in the non-possessive, non-fronted condition (5a). These differences in acceptability are significant (possessive, fronted vs. non-possessive, fronted, $M = 2.683$, $t(23) = -2.421$, $p < .05$; possessive, fronted, $M = 3.930$ vs. possessive, non-fronted, $M = 2.828$, $t(10) = -2.366$, $p < .05$; non-possessive, fronted vs. possessive, non-fronted, $t(23) = -.296$, ns ; possessive, non-fronted, vs. non-possessive, non-fronted, $M = 2.015$, $t(23) = -2.184$, $p < .05$).

² For this and following analyses, we excluded data for GR 180, as at this ground rotation the VC and OC frames are in alignment.

Comparing the two types of reference frame. To test our prediction that the combination of a possessive sentence structure and fronted object would create a situation in which OC assignments would be rated as more acceptable than VC assignments—and that this effect would be unique to this combination—we compared ratings of OC assignments to ratings of VC assignments in each condition. For the non-possessive, non-fronted condition, the average rating of VC arrangements ($M = 4.301$) was higher than the average rating of OC arrangements ($M = 2.015$), $F(1, 13) = 22.718$, $p < .05$. For the possessive, fronted condition, the average rating of the OC arrangements ($M = 3.930$) was significantly higher than the average rating of the VC arrangements ($M = 2.252$), $F(1, 10) = 6.698$, $p < .05$. Average ratings of the VC arrangements and the OC arrangements did not differ for either of the remaining conditions.

Considered individually, both the possessive sentence structure and the fronted objects appear to raise the salience of the OC frame of reference as evidenced by an increase in acceptability ratings for OC-consistent arrangements and/or a decrease in acceptability ratings for competing VC-consistent arrangements. Figures 3 and 4 show this effect. However, the lack of difference between average ratings of the VC and OC assignments suggest that the simple act of incorporating a possessive sentence structure or a fronted object may only cause the OC frame to be as acceptable as the VC frame. In contrast, the combination of a possessive sentence structure and fronted ground object both decreases acceptability of VC assignments and increases acceptability of OC assignments to the point in which English speakers prefer an OC assignment to a VC assignment (at least when these assignments are in competition).

Conclusions

In this paper, we examined two factors that may influence how a reference frame is selected for a spatial description. Taken together, the results from this study provide more insight into the nature of viewers' consideration of the VC and OC frames of reference. When the non-possessive sentence structure is used to describe a scene in which a non-fronted object serves as the ground, viewers prefer a VC assignment over an OC assignment. When either a possessive structure or a fronted object is introduced, VC and OC assignments appear equally appropriate. Finally, when both a possessive structure and a fronted object are introduced, a preference for OC assignments over VC assignments arises. These results support our predictions that, as Levinson (1996, 2003) argues, VC assignments are the default for English speakers, but consideration of other assignments may increase when certain elements of the situation are changed in order to call attention to the ground object's inherent features (Carlson-Radvansky & Irwin, 1993, 1994). The inclusion of a possessive sentence structure and/or a fronted object appears to do

just that. When a fronted object serves as the point of reference, the asymmetries associated with this type of object's axial structure (Landau & Jackendoff, 1993) may point out to the viewer that this object might have its own perspective, different from that of the viewer, which can also be used to assign space. Additionally, in support of Vandeloise's (1996), Levinson's (1996), and Levelt's (1996) claims, the use of a possessive sentence structure to describe the scene may also highlight any asymmetries associated with the ground object and similarly cause viewers to notice potentially competing perspectives. However, neither of these factors alone leads to a preference for one type of reference frame over the other. Rather, the inclusion of either factor on its own only seems to equalize the acceptability of the two reference frames, while preference for an OC assignment appears when there is a combination of a fronted ground object and possessive sentence structure.

Sentence Production in Naturalistic Scenes with Referential Ambiguity

Abstract

Language production often happens in a visual context, for example when a speaker describes a picture. This raises the question whether visual factors interact with conceptual factors during linguistic encoding. To address this question, we present an eye-tracking experiment that manipulates visual clutter (density of objects in the scene) and animacy in a sentence production task using naturalistic, referentially ambiguous scenes. We found that clutter leads to more fixations on target objects before they are mentioned, contrary to results for visual search, and that this effect is modulated by animacy. We also tested the eye-voice span hypothesis (objects are fixated before they are mentioned), and found that a significantly more complex pattern obtains in naturalistic, referentially ambiguous scenes.

Keywords: language production; eye-tracking; naturalistic scenes; eye-voice span; referential ambiguity.

Introduction

Language production often happens in a visual context, for example when the speaker describes a picture, gives directions on a map, or explains the function of an artifact. In these situations, the speaker needs to select which objects to talk about, and in which order. He/she also needs to disambiguate the utterance referentially. For instance, if there are multiple clipboards in the visual context, then the speaker has to encode additional visual information to pick out one of them uniquely (e.g., *the brown clipboard* or *the clipboard on the table*).

Most work in psycholinguistics has dealt with isolated sentences, but there is some existing research investigating how language is processed in a visual context. A prominent line of research employs the visual world paradigm (VWP; Tanenhaus et al. 1995; Altmann and Kamide 1999) for this purpose. In a typical VWP study, participants' eye-movements are recorded while they view a visual scene and listen to a sentence at the same time. Some VWP experiments have investigated language production; the most well-known example is Griffin and Bock's (2000) study, in which participants were asked to describe line drawings depicting two objects (e.g., a turtle and a kangaroo) performing a transitive event (e.g., splashing). The key finding of this study was that speakers fixate visual referents in the order in which they are mentioned, and they begin fixating an object about 900 ms before naming it. The span between fixating and naming a referent is known as the **eye-voice span**; other studies (e.g., Qu and Chai 2008) have reported eye-voice spans consistent with those found by Griffin and Bock (2000).

The aim of the present paper is to establish whether the simple relationship between language production and eye-movements implied by the eye-voice span extends to more realistic situations. We investigate language production in a

visual context that consists of naturalistic scenes (rather than line drawings) and in which multiple objects can correspond to a given linguistic referent (in contrast to Griffin and Bock 2000). This enables us to study how scene complexity and referential ambiguity affect the eye-voice span. Furthermore, we are interested in the interaction of visual and conceptual factors during linguistic encoding. The visual factor we focus on is clutter (density of objects in the scene); **clutter** has been investigated in the visual processing literature and found to affect visual search (Henderson et al., 2009). The conceptual factor we investigate is the **animacy** of the referent; animacy has been manipulated in the psycholinguistic literature and found to affect sentence production (Branigan et al., 2008). Here, we address the question whether these two factors representing different modalities contribute independently to the formation of reference in sentence production, or whether they interact.

Background

The recent visual cognition literature has emphasized the importance of contextual information for visual processing. For example, prior information about object categories facilitates visual search (Malcolm and Henderson, 2009; Schmidt and Zelinsky, 2009). This effect occurs if participants are asked to look for an object embedded in a scene or an object array (Brockmole and Henderson, 2006), or if categorical templates are provided which the visual system can use to determine where the target object is located (Vo and Henderson, 2010). It seems likely that similar contextual guidance effects (Torralba et al., 2006) also occur if the context is provided by another modality, e.g., by the linguistic material involved in a language production task.

In such task, speakers will often be faced with referential ambiguity, which they resolve by including disambiguating material in a sentence. For example, spatial prepositions can be used to locate an object in relation to the surrounding space, e.g., *the clipboard on the table* or adjectives can be used to contrast the intended referent with a competitor, e.g., *the brown clipboard*. Before any linguistic encoding can take place, however, the disambiguation has to happen at the visual level. When a target object is selected as a referent (because it will be mentioned in a sentence), the visual system has to retrieve scene and object information that can be used to refer to the object unambiguously. One can therefore hypothesize that if participants are faced with a linguistic task (e.g., scene description), then contextual guidance is afforded not only by visual information, but also driven by linguistic processing and the need to disambiguate.

Experiment

In this experiment, we investigated how visual attention is influenced by contextual factors during sentence production. Participants had to describe a visual scene after being prompted with a cue word. This cue word was ambiguous, i.e., two objects in the scene could be referred to by the cue. We manipulated the animacy of the cue (e.g., *man* vs. *clipboard*), expecting an effect on both linguistic encoding and visual attention. Animate objects are associated with a larger number of conceptual structures in encoding (Branigan et al., 2008); we should therefore observe more sentences containing action information in this case (e.g., *the man is reading a letter*). At the same time, we expect visual attention to be localized on animate targets, an effect that has already been demonstrated in visual search (Fletcher-Watson et al., 2008).

The second experimental manipulation concerned a visual factor, viz., clutter, defined as the density of visual information (Rosenholtz et al., 2007). Again, this is a factor that has shown effects on the performance and accuracy of visual search: the more cluttered the scene is, the less efficient the identification of target object (Henderson et al., 2009). In a language production task, however, the effect of clutter can be expected to change, due to the disambiguation strategies required. Clutter could have a beneficial effect: the more visual information there is, the more disambiguating material can be retrieved; clutter could therefore facilitate language production.

Finally, this experiment makes it possible to investigate the effect of referential ambiguity on the eye-voice span. In previous work, the relationship between linguistic and visual referents was unambiguous: looks to the visual referent always preceded naming (Griffin and Bock, 2000) and this trend exponentially increases towards the mention (Qu and Chai, 2008). In our setting, we expect a more complex gaze-to-name relationship caused by a process of visual disambiguation that arises both before and after the intended referent is mentioned.

Method

We used a factorial design that crossed the two factors *Clutter* (Minimal/Cluttered) and *Cue* (Animate/Inanimate). Participants' eye-movements were recorded while they described photo-realistic scenes after being prompted with a cue word, which ambiguously corresponded to two visual referents in the scene (see Figure 1).

We created 24 experimental items using photo-realistic scenes drawn from six indoor scenarios (e.g., Bathroom, Bedroom; four scenes per scenario). In each scene, we inserted two animate and two inanimate objects using Photoshop, which correspond to the two *Cue* conditions; *Clutter* was either added or removed.

Twenty-four native speakers of English, all students of the University of Edinburgh, were each paid five pounds for taking part in the experiment. They each saw 24 items randomized and distributed in a Latin square design that made sure that each participant only saw one condition per scene.

Figure 1: Example of an experimental trial, with visual region of interest considered for analysis. PRIMARY indicates that the ANIMATE and INANIMATE visual objects are spatially close and semantically connected (e.g., the MAN is doing an action using the CLIPBOARD). SECONDARY is used to indicate the remaining referent of the ambiguous pair. BACKGROUND and CLUTTER are defined in opposition: BACKGROUND is everything other than CLUTTER.

An EyeLink II head-mounted eye-tracker was used to monitor participants' eye-movements with a sampling rate of 500 Hz. Images were presented on a 21" multiscan monitor at a resolution of 1024 x 768 pixels; participants' speech was recorded with a lapel microphone. Only the dominant eye was tracked. A cue word appeared for 750 ms at the center of the screen, after which the scene followed and sound recording was activated. Drift correction was performed at the beginning and between each trial. There was no time limit for the trial duration and to pass to the next trial participants pressed a button on the response pad. The experimental task was explained using written instructions and took approximately 30 minutes to complete.

Data Analysis

We defined regions of interest (ROIs) both for the visual and the linguistic data. The visual data was aggregated into six different regions: PRIMARY and SECONDARY ANIMATE, PRIMARY and SECONDARY INANIMATE, BACKGROUND, and CLUTTER (see Figure 1).

For the linguistic data, we made a general division between time windows *Before* and *During* production. This allows us to capture the overall trend of the two main phases of a trial. For the analysis of eye-voice span, we consider a window of 2000 ms before the referent was mentioned, similar to Qu and Chai 2008. The resolution of visual ambiguity is analyzed using a window of 1600 ms (divided into 40 time slices 40 ms each): 800 ms before and after the mention of *Cue*. This makes it possible to explore how the linguistic referent is visually located before being mentioned and just after.

In order to unambiguously analyze fixated and named referents, we aggregate eye-movements responses in four blocks (Primary, Secondary, Ambiguous and Both) by manually

checking which referent was mentioned in each sentence.¹ We introduced referential ambiguity as predictor in the inferential model described below to investigate how looks to the mentioned object differ from those to its competitor. For reason of space, we only present the analysis for the *Primary* objects mentioned. The effect of mention on eye-movements' pattern is evaluated by comparing Primary with Secondary objects.

As an initial exploration of our data, we investigate the overall trend of fixations *Before* and *During* production. Production is a task with large between-participant variability, e.g., one participant will spend 2000 ms *Before* and 1000 ms *During* production, whereas another one will show the opposite pattern. Normalizing the production data is therefore crucial, in particular as we want to interpret eye-movements in relation to phases of linguistic processing. We normalize each sequence S_{old}^i of eye-movements by mapping it onto a normalized time-course of fixed length S_{new}^i . The length of S_{new}^i is set on the basis of the shortest eye-movement sequence $\min_i[\text{length}(S_{old}^i)]$ found between *Before* and *During* production, across all participants.² For each sequence S_{old}^i , we obtain the number of old time-points k^i corresponding to a new time-unit u , as $k^i = \text{length}(S_{old}^i) / \text{length}(S_{new}^i)$. Proportions are then calculated over k^i old time-points and subsequently mapped into the corresponding unit u of the normalized time-course. In the Results section, we show plots of normalized proportions for *Primary* and *Secondary* (Animate and Inanimate) across conditions, *Before* and *During* production.

To explore the eye-voice span hypothesis, we compute the number of fixations to the mentioned object compared to the competitor. We also look at latencies, i.e., the onset of the last fixation to the referent or competitor before the mention, and gaze duration as a function of latencies, i.e., the time spent looking at the referent or competitor for the different latencies.

We also report inferential statistics for the referent region (for the time windows previously described). The dependent measure is the empirical logit (Barr, 2008), calculated as $\text{emplog} = \ln \frac{0.5+\phi}{0.5+(1-\phi)}$, where ϕ is the number of fixations on the region of interest. The analysis is performed using the framework of linear-mixed effect (LME) models as implemented by the R-package lme4 (Baayen et al., 2008). The predictors included were *Animacy*, *Clutter*, *Time* and *Object*. The random factors were *Participant* and *Item*. To reduce collinearity, factors were centered.

The model selection followed a conservative stepwise forward procedure that tests model fit based on a log-likelihood

¹PRIMARY means that the Primary Animate or Inanimate is mentioned (e.g., *The man is writing on the clipboard*). SECONDARY is used when the Secondary Animate or Inanimate is mentioned (e.g., *The man is reading a letter*). AMBIGUOUS is used when it is unclear which one is referred to (e.g., *the man is sitting on the couch*). BOTH indicates that both referents are mentioned (e.g., *the man is writing on a clipboard while the other man reads a newspaper*).

²We remove outliers that are two standard deviation away from the mean, after having log-transformed our data. The data are not normally distributed, due to right skewness. The log-transformation helps us to reduce the skew.

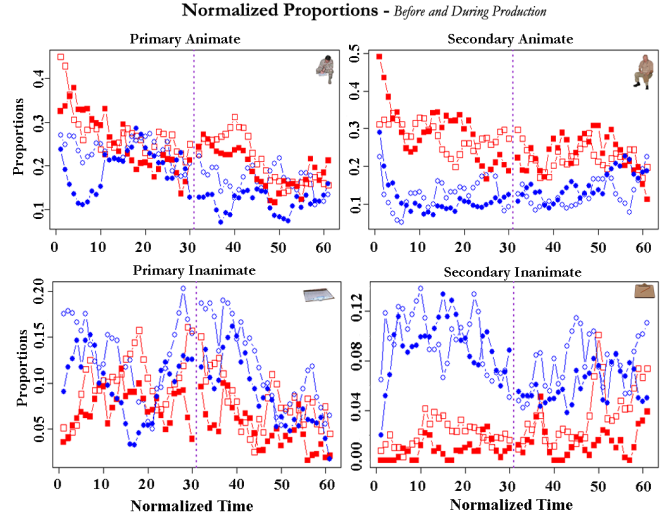

Figure 2: Normalized proportions of looks (60 bins) across the four conditions, *Before* and *During* production, for the different visual ROIs. The purple dashed vertical line indicates *Before* (to the left) and *During* (to the right) production. The four conditions are coded as following: *Animate/Cluttered*: red, full-square; *Animate/Minimal*: red, empty square; *Inanimate/Cluttered*: blue, full circle; *Inanimate/Minimal*: blue, empty circle

test comparing models each time a new parameter is included. If the fit improves, we accept the new model, otherwise we keep the old one. We include predictors, random intercepts and slopes ordered by their log-likelihood impact on model fit. We iterate until there is no more improvement on the fit; leaving us with the best model. In the result section, we show plots of the values predicted by the model for each condition.

Results and Discussion

Before and During Production We first look at how fixations are distributed when we collapse the two main phases of the experiment: *Before* and *During* production. This analysis does not distinguish whether the *Primary* or *Secondary* referent was mentioned. Figure 2 shows normalized proportions of looks on the competitor visual objects corresponding to the *Cue* (Animate/Inanimate).

The first thing to note is that for the visual ROI corresponding to the *Primary* referent, the pattern of fixations is more complex than for the ROI of the *Secondary* referent. The spatial proximity and semantic relatedness of the two *Primary* referents result in a more complex pattern of interaction. The clearest effect is found in relation with the animacy of *Cue*; we observe more fixations to the animate referent when the cue is also animate. When looking at the *Primary* ROI, the effect is seen at the beginning of both the *Before* and the *During* region. At the beginning of the trial, the visual system retrieves information about the cued objects; when production starts, the referents are fixated again, probably before being mentioned. For the *Secondary* ROIs, the relation with the *Cue* is stronger, probably reinforced by the referential competition. Moreover, the pattern of looks is much clearer than for the *Primary* ROI. This confirms that spatial proximity and

Table 1: Eye-voice span statistics. *Excluding* indicates that the percentage is calculated considering only those cases in which either the referent or competitor have been fixated, *Including* takes into account also cases where both have been fixated.

Measure		Referent	Competitor
Percentage of looks	Including	71.65	43.30
	Excluding	36.44	8.09
Mean Latency	Including	1032 ms	1203 ms
	Excluding	1012 ms	1325 ms
Gaze Duration	Including	489 ms	432 ms
	Excluding	568 ms	623 ms

semantic relatedness increase the interaction between visual referents. *Clutter* does not have a strong effect, though there is a small increase of looks when the scene is minimal and the animacy of the target matches that of the cue.

Eye-Voice Span We analyzed eye-voice span to investigate the gaze-to-name relation for the mentioned referent and its competitor. Table 1 shows percentages of looks to referent or competitor with mean latencies and gaze durations.³

There is a preference for looks to the referent over looks to the competitor, with a latency of about one second, confirming previous findings (Griffin and Bock, 2000). In a minority of cases, participants only look at the referent (36.44%); competition between the two ambiguous visual referents is the norm (71.65%). Moreover, we notice that the competitor is fixated earlier than the referent and the duration is shorter for the Including condition (which includes trials in which both referents have been fixated). This may indicate that the final decision on which referent is mentioned is made after discarding the competitor.

Figure 3(a) shows frequencies of *Latencies* at different temporal blocks (200 ms each) within a total window of two seconds. We find that latency frequency decreases towards the mention for both the referent and the competitor. This finding contrasts with Qu and Chai (2008) who found the opposite trend, i.e., the closer to the mention, the more gazes are associated with the referent object. Note also that this effect cannot only be due to the presence of a competitor, e.g., comparative looks before mention, as these present a similar decreasing trend.

In Figure 3(b) we show mean gaze duration as a function of the different latencies. Again, a decreasing trend is clearly visible: the closer the latency to the mention, the shorter the gaze duration. Interestingly there is a peak of gaze duration at 1600/1400 ms. The higher duration found at this latency might be an indicator of referential selection (gaze-to-name binding). We also find evidence of competition at 600/400 ms, where the competitor receives longer gazes compared to referent. A last visual check on the competitor is probably performed before referentiality is encoded linguistically.

³The measures are calculated only when the Primary and Secondary referent are mentioned; thus, we exclude the Both and Ambiguous cases, for which it was not possible to establish unambiguous eye-voice span relation.

(a) Frequencies of latencies at different temporal blocks (from two seconds to mention): red is the referent, blue the competitor. The latency measures the time elapsed from the beginning of the last fixation to the object (referent or competitor) until is mentioned.

(b) Mean gaze duration as a function of latency. The mean of gaze duration is calculated for the different blocks of latencies. We analyze only cases where gaze duration is shorter than latency, thus avoiding cases where fixations spill over into the region after mention.

Figure 3: Eye Voice Span statistics.

Inferential Analysis We now analyze the pattern of eye-movements before and after the mention of the cue word. To save space, we focus on the case where the Primary visual object is mentioned. Based on the eye-voice span analysis, we expect to find a decreasing trend of looks before the referent is mentioned, and the presence of competition should weaken the gaze-to-name relationship.

Recall that our experiment had two factors (Cue: animate/inanimate; Clutter: minimal/cluttered); we also include the object fixated (Object: primary/secondary) and Time (in 40 ms slices, see Data Analysis above) in the analysis. Figure 4 plots LME predicted values for the four conditions, Before and After mention.⁴

Beginning with the animate visual objects in Figure 4, we expect the *Primary Animate* to receive more looks than the *Secondary Animate*, and the number of looks should increase. We observe a preference for looks to Primary Animate,

⁴The intercepts for Before and During are different because they are calculated over distinct time intervals.

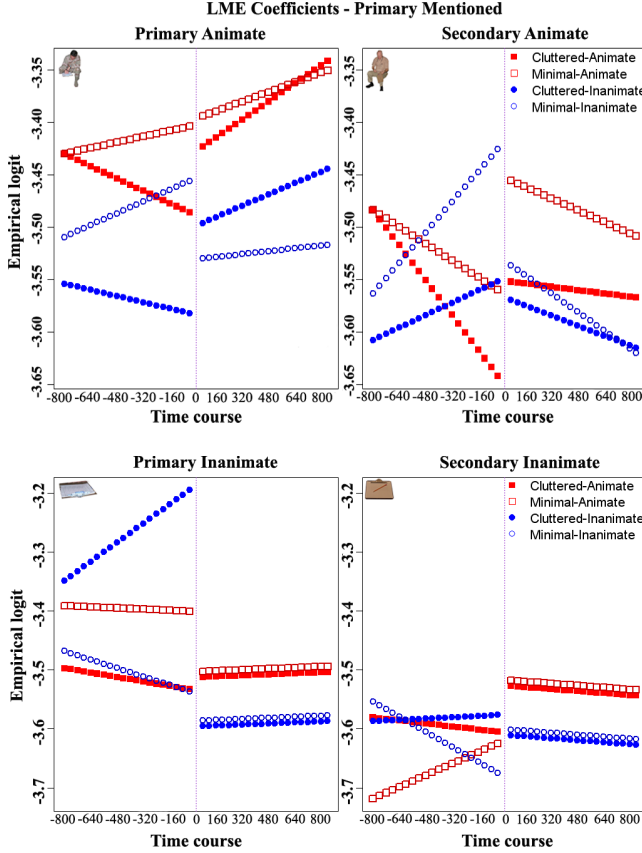

Figure 4: Linear mixed effect model: plot of predicted values (40 windows of 40 ms each) across the four conditions, Before and After referent, on the different visual ROIs. The *First* referent is mentioned and the dashed line indicates when.

but the difference is not statistically significant ($\beta_{Primary} = 0.0255; p > 0.1$). However, we find a main effect of *Cue* ($\beta_{Animate} = 0.0543; p < 0.01$): an animate cue facilitates looks to Animate visual objects. When looking at the time course, we find a general decreasing trend ($\beta_{Primary:Time} = -0.022; p < 0.01$), partly compensated by a three-way interaction of *Animacy*, *Object*, and *Time* ($\beta_{Animate:Primary:Time} = 0.049; p < 0.001$). Moreover, we observe a two-way interaction of *Clutter* and *Time* ($\beta_{Minimal:Time} = 0.024; p < 0.01$): a minimal scene makes it difficult to retrieve disambiguating information for the animate referent, forcing the visual system to look for this information on the referent itself. It is also conceivable that the minimality of the scene makes visual responses similar to those found for line drawings (Griffin and Bock, 2000); thereby explaining the increasing trend. In a cluttered environment, instead, there are more ways to relate the referent to the surrounding context, hence helping language production to disambiguate. This explains the decreasing trend of fixations on the referent in the cluttered condition.

After mention, we observe interactions of *Cue* with *Clutter* ($\beta_{Animate:Minimal} = 0.0165; p < 0.001$) and *Object* ($\beta_{Animate:Primary} = 0.017; p < 0.01$), confirming both the facilitation of the cued referent and the preference for refer-

ent information when scenes are minimal. In contrast with previous findings, we observe increasing looks to the referent after mention ($\beta_{Primary:Time} = 0.0530; p < 0.001$). This effect could be due to referential ambiguity: the visual system is connecting disambiguating material retrieved before mention to the referent just uttered. For the *Secondary Animate*, we find an increasing trend of looks when *Cue* is Inanimate and especially for minimal scenes ($\beta_{Inanimate:Time} = 0.056, p < 0.001; \beta_{Minimal:Time} = 0.041, p < 0.01$). The minimality of the scene gives prominence to animate referents; probably the spatial and semantic proximity of one of Primary Inanimate and the Primary Animate also trigger comparative looks to Secondary Animate, i.e., participants check whether it can also be contextually related to the cue.

After the referent is mentioned (*Primary* in this case), looks to the *Secondary Animate* decrease over time in all conditions. Competition is triggered by visual ambiguity, but once the association of the visual with the linguistic referent has been established (i.e., after the mention), participants look back to the referent mentioned, presumably finalizing the choice made.

Looking at inanimate referents in Figure 4, we observe a statistically significant preference for looks to the Primary Inanimate ($\beta_{Primary} = 0.0621; p < 0.05$). This preference could be due to the spatial proximity and the semantic relation with the primary animate, which makes the primary inanimate more likely to be encoded either as a direct object or as subject of the description. As a consequence, we find an interaction with the animacy of the *Cue* ($\beta_{Animate:Primary} = 0.0155; p < 0.05$) but not a main effect ($\beta_{Inanimate} = 0.017; p > 0.1$). In contrast with standard visual search task, where performance degrades as a function of clutter, here we observe instead a positive interaction of *Clutter* and *Cue* on the target ($\beta_{Inanimate:Cluttered:Primary} = 0.028, p < 0.001$), which increase over time ($\beta_{Cluttered:Time} = 0.054, p < 0.01$). The visual system is not performing a search task, rather it is sourcing information to ground language processing. In a cluttered scene, an inanimate referent could be spatially related to many other different objects, whereas a minimal scene has fewer points to anchor the referent. The visual system therefore needs to select among the different spatial relations to find one that optimally situates the object within the contextual information.

For the secondary inanimate, there is a negative relationship between the animacy of *Cue* and the minimality of *Clutter* ($\beta_{Animate:Minimal:Secondary} = -0.0719; p < 0.001$); the proximity and relatedness of the primary inanimate and the primary animate is highlighted when visual information is minimal, which results in the secondary inanimate being fixated less.

General Discussion

Referential ambiguity is a common phenomenon in everyday experience. In a naturalistic scene, the same object (e.g., a clipboard) can occur multiple times (e.g., on a desk or on a counter). This fact turns into linguistic ambiguity when a referent has to be selected from the set of visual competi-

tors. Typically, referential ambiguity is resolved by encoding sufficient contextual information to discriminate the intended referent from competitors (e.g., *the clipboard on the desk*). However, this process of ambiguity resolution cannot be explained by linguistic factors alone, especially given that the disambiguating material needs to be selected by the visual system prior to any encoding. We therefore hypothesized that visual factors interact with well-established conceptual factors active during language production.

We reported the results of an eye-tracking language scene description experiment that support this hypothesis. We explored how the conceptual properties of the target referent (factor *Cue*: animate/inanimate) and the density of visual information (factor *Clutter*: minimal/cluttered) interact during the resolution of referential ambiguity. The results showed that the animacy of the cue facilitates looks to animate objects, especially at the beginning of two main phases of linguistic production: before and during the mention of the referent. The data indicate that a visual search is performed to localize the objects matching the cue word (Malcolm and Henderson, 2009). Our results also contrasted interestingly with findings for visual search, where clutter decreases search performance (Henderson et al., 2009). In cases in which an animate referent is mentioned, we found that there were fewer fixations to the target object in the cluttered condition compared to the uncluttered one. In other words, clutter makes language production easier, not harder: the visual system is not just searching for the target object, but it is also retrieving visual information that can be used to linguistically anchor it (e.g., for disambiguation). The more clutter there is, the easier this process becomes, explaining the reduced number of fixations in the cluttered condition.

Turning at the relation between fixating and naming an object (the eye-voice span), previous work found that referents are fixed shortly before being mentioned (Griffin and Bock, 2000). It has also been observed that fixation probability increases with decreasing distance to the mention (Qu and Chai, 2008). In our data, we found a numerical preference for looks to the mentioned referent over looks to the competitor, but this preference was not confirmed in the inferential analysis (see Figure 4). Only if the primary inanimate was mentioned, it was fixated significantly more than the secondary inanimate. This preference is likely due to the proximity, spatial and semantic, between the primary animate and inanimate. Moreover, we found that fixation probability decreased with decreasing distance to the mention, contrary to previous results, in particular when the scene was cluttered. The competition between visual referents seems to override the standard eye-voice span effect. Interestingly, we also observed an increasing trend of fixation to the referent object *after* its mention. Once production has started, the visual system needs to retrieve contextual information to produce disambiguating linguistic material, resulting in an increase in the number of looks after mention.

Taken together, our results indicate that visual factors such as clutter interact with conceptual factors such as animacy in language production. The simple view according to which

referents are fixated in the order in which they are mentioned, with a fixed eye-voice span between fixation and mention, does not seem to generalize to more realistic settings in which speakers describe naturalistic scenes that involve referential ambiguity.

Abstract

Since causal evidence is often ambiguous, models of causal learning should be able to represent uncertainty over causal hypotheses. Uncertainty is especially important in *retrospective revaluation* (the re-evaluation of ambiguous evidence in light of subsequent learning). We examine how a Bayesian model and an associative model (the modified SOP model of Dickinson & Burke, 1996) deal with this uncertainty. We tested the predictions of the models in an experiment with retrospective revaluation of preventive causes. Results were consistent with the predictions of the Bayesian model, but inconsistent with the predictions of the modified SOP model.

Introduction

Causal evidence is often ambiguous and causal inference uncertain. When examining an isolated case of food poisoning, it is difficult to identify the meal – never mind the food item – that caused the illness. Uncertainty is especially salient in *retrospective revaluation* (when established but ambiguous evidence is re-evaluated after subsequent learning). We examine how Bayesian and associative models of causal learning represent and deal with ambiguous evidence in retrospective revaluation. Although Bayesian models naturally represent the uncertainty of causal inference from ambiguous evidence, associative models do not.

Examples of retrospective revaluation include *reduced overshadowing* and *backward blocking*. In both of these phenomena, there is one effect whose presence we denote as + and absence we denote as - and two cues that we will call cue A and cue B. In both reduced overshadowing and backward blocking, the initial evidence shows that the effect occurs after the presentation of both cues (AB+). This evidence is ambiguous because it could be that cue A alone causes the effect, cue B alone causes the effect, or that both cues A and B independently cause the effect. Of course, it is also possible that cues A and B interact to cause the effect, but we will not consider this possibility further. We assume that, due to parsimony, this explanation is only considered when the others are ruled out.

In reduced overshadowing, participants later learn that the effect does not occur after cue A is presented on its own (i.e., A- trials follow the AB+ trials). This new evidence suggests that cue A does not cause the effect. By conditional contrast or the process of elimination, this implies that cue

B caused the effect on the AB+ trials. In backward blocking, the new evidence shows that the effect occurs when cue A is presented alone (i.e., A+ trials follow the AB+ trials). Since the knowledge that cue A causes the effect explains the AB+ trials, this new evidence should make it less likely that cue B causes the effect. However, it is still possible that cue B also causes the effect. Intuitively then, reduced overshadowing – which implies that cue B must cause the effect – should offer stronger evidence for re-evaluation than backward blocking.

This intuition is reflected in studies that have compared reduced overshadowing and backward blocking to a control condition (just AB+ trials). These studies have shown that reduced overshadowing is stronger and more robust than backward blocking (Corlett et al., 2004; Larkin, Aitken, & Dickinson, 1998; see also Beckers, De Houwer, Pineno, & Miller, 2005; Lovibond, Been, Mitchel, Bouton, & Frohardt, 2003; but see Wasserman & Berglan, 1998; Wasserman & Castro, 2005).

In this paper, we consider how different models of causal reasoning explain reduced overshadowing and backward blocking. Our goals are two-fold. Firstly, we seek to provide a principled explanation of reduced overshadowing and backward blocking by representing uncertainty. In service of this goal, we formalize our intuitions in a Bayesian model of causal inference.

Secondly, we consider how associative models deal with retrospective revaluation. We focus on the modified SOP model (Dickinson & Burke, 1996) because it explains the observed asymmetry between reduced overshadowing and backward blocking. However, we will argue that the modified SOP model predicts this asymmetry for arbitrary reasons. Therefore, we tested the modified SOP and Bayesian models in a situation where they make competing predictions: the preventive analogs of reduced overshadowing (A+, ABC-, AB+) and backward blocking (A+, ABC-, AB-).

A Bayesian model of retrospective revaluation

Bayesian models have been applied to retrospective revaluation in order to explain trial-order effects (e.g., Daw, Courville, & Dayan, 2008; Kruschke, 2008; Lu, Rojas, Beckers, & Yuille, 2008) and the influence of prior knowledge (e.g., Sobel, Tenenbaum, & Gopnik, 2004). These models, however, have not been contrasted with

associative models that were designed to explain retrospective revaluation. For this comparison, we adapt Griffiths & Tenenbaum's (2005) model of causal inference.

The model represents each possible causal explanation as a *causal graph* (e.g., Figure 1). In the causal graphs that we consider, a causal link can be generative, preventive, or non-existent. Since we assume that there are multiple cues and a single effect, a causal graph can be represented as a vector of causal links \vec{l} , letting $l_i = 1$ denote a generative causal relationship between cue i and the effect, $l_i = 0$ denote the absence of a causal relationship, and $l_i = -1$ denote a preventive causal relationship. We provide each causal link with a weight that represents the strength of the causal relationship, and we represent these weights as a vector \vec{w} where $0 \leq w_i \leq 1$ for each w_i .

Figure 1: A causal graph where cue A causes the effect (as indicated by an arrow) and cue B prevents the effect (as indicated by a modified arrow terminating in a circle)

To represent a trial, we let the vector \vec{c} denote the presence ($c_i = 1$) or absence ($c_i = 0$) of the cues and let e denote the presence ($e = +$) or absence ($e = -$) of the effect.

To specify the probability of the effect, we need to define a generating function that describes how causes combine to produce the effect. We adopt the noisy-or and noisy-and-not generating functions, which can be derived from the assumptions of causal power (Cheng, 1997) for generative and preventive causation, respectively. Given the vectors \vec{c} , \vec{l} , and \vec{w} , let G be the set of indexes such that $l_i = 1$ (i.e., generative causes of e), and let P be the set of indexes such that $l_i = -1$ (preventers of e). Using the noisy-or and noisy-and-not function, the probability of the effect is:

$$P(e+ | \vec{c}, \vec{l}, \vec{w}) = \left[1 - \prod_{g \in G} (1 - w_g c_g) \right] \prod_{p \in P} (1 - w_p c_p) \quad (1)$$

Then, given data D that provides a frequency count $N(e, \vec{c})$ for each combination of the presence/absence of the effect and the cues, the probability of the data as a function of the causal graph and its weights is:

$$P(D | \vec{w}, \vec{l}) = \prod_{(e, \vec{c})} P(e | \vec{c}, \vec{l}, \vec{w})^{N(e, \vec{c})} \quad (2)$$

We assume a uniform prior distribution on \vec{w} and define a prior distribution on \vec{l} as shown in equation 3. For each causal link, we make the link generative with probability α , preventive with probability β , and nonexistent with probability $1 - \alpha - \beta$. We use α and β as model parameters.

For a causal graph with k generative causes, j preventive causes, and n cues, the priors are:

$$\begin{aligned} P(\vec{w}, \vec{l}) &= P(\vec{w} | \vec{l}) P(\vec{l}) \\ P(\vec{l}) &= \alpha^k \beta^j (1 - \alpha - \beta)^{(n-k-j)} \\ P(\vec{w} | \vec{l}) &\sim \text{unif} \end{aligned} \quad (3)$$

From Bayes' theorem and our assumptions about the priors, we have

$$P(\vec{w}, \vec{l} | D) = \frac{1}{Z} P(D | \vec{w}, \vec{l}) P(\vec{w} | \vec{l}) P(\vec{l}) \quad (4)$$

The variable Z represents a normalizing constant. The model can be used to answer questions about the strength of a causal link or about its existence and direction. To find the posterior probability of a set of causal weights (i.e., causal strengths), we can integrate equation 4 over the other causal weights and sum over the causal graphs.

The experiment in this paper, however, asks about the existence and direction of a causal link – not its strength. Therefore, we are more interested in the probability that a causal graph generated the data. This can be found by integrating over the causal weights.

$$P(\vec{l} | D) = \int P(\vec{w}, \vec{l} | D) d\vec{w} \quad (5)$$

To calculate the probability that a cue is causal, preventive, or noncausal, we sum the probabilities of each causal graph that contains the desired relationship. If we let L be the set of causal graphs such that $l_i = x$ (where $x \in \{-1, 0, 1\}$ represents the existence and direction of the causal relationship), then:

$$P(l_i = x | D) = \sum_{\vec{l} \in L} P(\vec{l} | D) \quad (6)$$

Finally, to model causal judgments, we take the logit of this probability to obtain a measure of causal support, which is often viewed as a psychologically realistic measure of causal judgment (Griffiths & Tenenbaum, 2005):

$$\text{causal support} = \log\left(\frac{P(l_i = x | D)}{1 - P(l_i = x | D)}\right) \quad (7)$$

Retrospective revaluation

To explain reduced overshadowing and backward blocking, we consider the causal graphs with two cues and one effect. Since we only allow causal relationships between cue A and the effect and cue B and the effect, this gives us 9 (i.e., 3^2) causal graphs. We set the parameters such that the priors across the graphs are uniform (i.e., $\alpha = \beta = 1/3$). When the model is given data where there are 4 trials of each type (e.g., 4xAB+ 4xA+ in the backward blocking condition), it can be used to generate a support measure for the hypothesis that cue B causes the effect. The model predicts that the difference between reduced overshadowing and a control (AB+) is larger than the difference between backward blocking and the control (see Table 1).

To understand these predictions, it is useful to consider the posterior distribution of the weights. First, we consider the joint posterior of cues A and B after the AB+ trials conditional on both links being generative (see Figure 2). This posterior suggests that there is considerable uncertainty over the weights of cues A and B. However, it also suggests a dependency between the weights of the cues: at least one

of the cues must be causal. If w_a is small, then w_b must be large. However, if w_a is large, then there is still uncertainty over w_b . This dependency explains reduced overshadowing and backward blocking. If subsequent evidence indicates that cue A does not cause the effect (as is the case for reduced overshadowing), then cue B must. However, if subsequent evidence indicates that cue A causes the effect (as is the case for backward blocking), then the influence of cue B cannot be conclusively known.

Table 1: The causal support measure for the causal link between cue B and the effect for reduced overshadowing, control, and backward blocking

Condition	support
reduced overshadowing (AB+, A-)	5.02
backward blocking (AB+, A+)	0.09
control (AB+)	1.05

Figure 2: The joint posterior distribution of w_a and w_b .

These predictions are reflected in the posterior weights of cue B alone in the different retrospective revaluation conditions (see Figure 3). In the reduced overshadowing condition, it is clear that cue B must cause the effect: there is almost no possibility that the weight from cue B to the effect is zero. On the other hand, there is considerable uncertainty about the weight of cue B in both the blocking and control conditions: neither excludes the possibilities that B is noncausal or that B is causal.

Figure 3: The posterior of the weights of cue B when cue B is a generative cause.

Associative models

Retrospective revaluation is notoriously problematic for associative models, but two associative models have been developed to explain it: Van Hamme & Wasserman's (1994) modified RW (Rescorla-Wagner) model and the Dickinson & Burke's (1996) modified SOP model. The problem for standard associative models is that they only learn about present cues. This precludes an explanation of reduced overshadowing and backward blocking, where learning about cue A leads participants to revise their beliefs about the absent cue B. To surmount this difficulty, the modified RW model and the modified SOP model utilize *within-compound associations*: associations formed between simultaneously-presented cues. On the initial AB+ trials, these models learn an association between cues A and B. Later, the within-compound associations are used to recall associated cues that are absent on the trial, allowing the model to learn about them. If an A+ trial followed, the models would identify the absent cue B as an expected cue and would use this identification to support re-evaluation.

Although within-compound associations allow the models to learn about absent cues, it is not clear whether they offer a genuine representation of uncertainty.

Since the modified RW model incorrectly predicts that backward blocking will be at least as strong as reduced overshadowing (see Larkin et al., 1998 for a detailed explanation), we focus on the modified SOP model.

The modified SOP model

In the modified SOP model, there are three activation states: the A1 (observed), A2 (expected), and I (inactive) states. Each cue is represented by a node that is made up of many elements, so a node can be in more than one activation state. For example, if a cue were presented on a trial and it was expected on the basis of within-compound associations, there might be 40% of its elements in the A1 state, 40% in the A2 state, and 20% inactive. Excitatory learning occurs between two nodes to the extent that they are both in the A1 state or both in the A2 state. Inhibitory learning occurs between two nodes to the extent that one is in the A1 state and the other is in the A2 state. No learning occurs otherwise.

On AB+ trials, the modified SOP model learns that each cue is associated with the effect and that there is a within-compound association between cues A and B. When cue A is presented alone, the within-compound association between cues A and B leads cue B to enter the A2 activation state (see Table 2). The state of the effect depends on the type of retrospective revaluation. For reduced overshadowing, the effect is expected but absent, so it will enter state A2. This puts the effect in the same state as cue B, so learning will be exclusively excitatory. For backward blocking, the effect is both expected and present, so it will enter states A1 and A2. Since this means that cue B and the effect will be partly in the same state and partly in a different state, there will be conflicted learning that is both excitatory and inhibitory. Therefore, the modified SOP model predicts the off-

observed asymmetry between reduced overshadowing and backward blocking. When compared to a control condition, the modified SOP model predicts that reduced overshadowing will be a stronger and more robust effect than backward blocking.

Table 2: Activation states and learning during retrospective reevaluation. The \uparrow symbol indicates excitatory learning (an increase in associative strength) and the \downarrow symbol indicates inhibitory learning (a decrease in associative strength).

condition	Cue B	Effect	B-effect learning
r. overshadowing (A-)	A2	A2	\uparrow
b. blocking (A+)	A2	A1 and A2	$\uparrow\downarrow$
control	-	-	none

However, these predictions seem arbitrary: the modified SOP model predicts both excitatory and inhibitory learning whenever the effect is both present and expected, but it is not clear why this should be the case. To test the modified SOP model, we designed an experiment where its predictions diverged from those of the Bayesian model.

Method

To test the predictions of the modified SOP model, we examined the preventive analogs of reduced overshadowing (i.e., A+, ABC-, AB+) and backward blocking (i.e., A+, ABC-, AB-). Until the final AB+ or AB- trials, the evidence suggests that cue A causes the effect and that either cue B alone prevents the effect, cue C alone prevents the effect, or that cues B and C prevent the effect. Like its generative analog, preventive reduced overshadowing eliminates two of these explanations by showing that cue B does not prevent the effect. By the process of elimination, one would infer that cue C must have been responsible for preventing the effect on the ABC- trials. The AB- trials in backward blocking show that cue B prevents the effect, but these trials do not fully clarify the influence of cue C: it is still possible that C prevents the effect, and it is still possible that it does not. Preventive reduced overshadowing should be a stronger and more robust effect than preventive backward blocking.

The modified SOP model predicts the opposite. It predicts that learning is conflicted whenever the effect is both present and expected (as it is during reduced overshadowing AB+ trials), but that learning is clear whenever the effect is expected but absent (as it is during backward blocking AB- trials). According to the modified SOP model, preventive reduced overshadowing should be weaker and less robust than preventive backward blocking (see Table 3).

For our experimental task, we used a cover story where participants were asked to discover which foods cause and prevent allergic reactions in medical patients. We manipulated the retrospective reevaluation condition (preventive reduced overshadowing, preventive backward

blocking, reduced overshadowing control, and blocking control) within-subjects. We also manipulated expectations about the probability that a randomly selected fruit would prevent an allergic reaction. Bayesian models have a mechanism for integrating prior knowledge and evidence from observations, and we manipulated expectations to assess whether prior knowledge influenced the participants.

Table 3: Predicted changes in associative strength according to the modified SOP model for the preventive analogs of reduced overshadowing and backward blocking.

Preventive analog	Cue C	Effect	C-effect learning
r. overshadowing (AB+)	A2	A1 and A2	$\uparrow\downarrow$
b. blocking (AB-)	A2	A2	\uparrow
control	-	-	none

Participants

Twenty-four undergraduates at the University of California, Los Angeles participated for course credit. The participants were randomly assigned to a infrequent ($n = 7$), occasional ($n = 9$), or frequent ($n = 8$) prevention condition.

Materials

We selected icons that pictorially represented 21 different fruits.

Procedure

At the beginning of the experiment, participants were asked to take the perspective of allergists specializing in patients who have fruit allergies. They were informed that fruit allergies can be both caused and prevented in these patients. That is, some fruits might cause an allergic reaction in a patient, but other fruits might prevent an allergic reaction.

Participants were told that they would read through the “fruit journals” of patients. They were informed that a fruit journal lists the fruits that a patient ate on a given day, and also records whether the patient had an allergic reaction.

Each experimental trial corresponded to the record for one day in the fruit journal. A trial began by displaying the icons and names of whichever fruits the patient ate on that day. These icons were displayed alone for 1.5 seconds, at which point a cartoon face appeared. The cartoon face signified whether the patient had an allergic reaction on that day: a smiley face with the text “ok” meant that the patient did not have a reaction and a frowning face with the text “allergic reaction” meant that the patient had a reaction. The fruits and cartoon face were displayed together for 2.0 seconds before the trial ended.

Participants read the fruit journals of five different patients. The journal of the first patient was used to manipulate the priors. The other four journals represented the four retrospective reevaluation conditions. The fruits

were randomly mapped to the different fruit journals, and each fruit appeared in exactly one fruit journal.

When the first patient was introduced, participants were told the approximate probability that a fruit prevents allergic reactions (the bracketed phrases were selected according to the infrequent, occasional, or frequent priors conditions):

As is often the case with fruit allergies, a small number of fruits caused the patient's allergic reaction, [very few / some / many] prevented it, and [many / some / very few] did nothing.

The first fruit journal provided evidence for this claim. The patient experienced an allergic reaction after consuming one of the fruits alone, but the other four fruits in the journal did not cause the patient to experience an allergic reaction. Zero, two, or four of the other fruits prevented the allergic reaction (in the infrequent, occasional, and frequent priors conditions, respectively). This was demonstrated by showing, for each of the other fruits, whether the patient had an allergic reaction after consuming that fruit and the causal fruit at the same time.

To familiarize the participants with the causal questions, the participants were then asked whether each fruit in the first journal caused, prevented, or did nothing to influence the patient's allergic reactions. Participants responded on a sliding scale running from -6 to 6 where -6 was labeled “definitely prevents”, -3 was labeled “maybe prevents”, 0 was labeled “neither”, 3 was labeled “maybe causes”, and 6 was labeled “definitely causes.”

After answering questions about the influence of fruits on the first patient, participants viewed, in random order, a fruit journal for each retrospective revaluation condition. In each journal, the trials were divided into three stages, and the data for each stage are shown in Table 4. Each of the listed patterns was shown four times (e.g., fruit A caused an allergic reaction four times in stage 1). Within each stage, the trials were presented in a random order.

Table 4: The data (by retrospective revaluation condition)

condition	stage 1	stage 2	stage 3
reduced overshadowing	A+ B- C- D-	A+ ABC-	A+ AB+
backward blocking	A+ B- C- D-	A+ ABC-	A+ AB-
control (rOS)	A+ B- C- D-	A+ ABC-	A+ AD+
control (BB)	A+ B- C- D-	A+ ABC-	A+ AD-

Following the presentation of the data for each retrospective revaluation condition, participants were asked to report whether each fruit caused, prevented, or did nothing to influence the patient's allergic reactions. The response scale was identical to the scale that was used in the first fruit journal.

Results

The ratings for cue C are shown in Figure 4. The predicted asymmetry between reduced overshadowing and backward blocking was found. Compared to its control, reduced overshadowing had a substantial influence: it led participants to be much more certain that cue C prevented allergic reactions. Ratings for cue C did not differ substantially between the backward blocking and control conditions. The priors manipulation did not seem to substantially influence the causal ratings.

An ANOVA confirmed that the retrospective revaluation condition influenced causal ratings, $F(3, 63) = 23.84$, $p < .001$, and that there was no effect of the priors manipulation, $F(2, 21) = 0.29$, $p = .75$, or interaction between the priors condition and retrospective revaluation condition, $F(6, 63) = 0.57$, $p = .75$. Planned comparisons indicated that the effect of retrospective revaluation condition was driven by the difference between reduced overshadowing and its control, $t(23) = 6.30$, $p < .001$, and not by the difference between blocking and its control, $t(23) = 0.94$, $p = .36$.

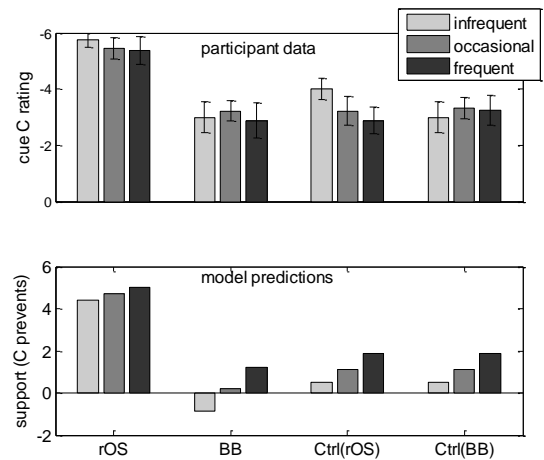

Figure 4: Causal ratings and Bayesian model predictions for cue C by retrospective revaluation condition and the prior likelihood of prevention. On both graphs, higher points on the y-axis correspond to greater certainty that cue C prevents allergic reactions. (rOS = reduced overshadowing, BB = backward blocking, Ctrl = control)

To derive the predictions of the model, we set $\alpha = .2$ and then set β depending on the priors condition ($\beta = .2$ for infrequent, $\beta = .4$ for occasional, and $\beta = .6$ for frequent). The predictions of the model are shown for each condition in Figure 4. The model offered a good quantitative fit to the data, $r = -.87$.

Discussion

The results clearly contradict the predictions of the modified SOP model. Preventive reduced overshadowing was a much stronger effect than preventive backward blocking. The Bayesian model predicts this finding, and also offers a principled justification for its prediction.

The priors manipulation did not influence the participants' causal ratings, but the interpretation of this finding is unclear. The Bayesian model predicts a limited effect of the priors manipulation, and the small number of participants per condition limited the experiment's statistical power. Furthermore, since the prior frequencies were merely manipulated verbally, the manipulation may have been too weak. Other research has shown that priors can influence causal judgment (e.g., Sobel, Tenenbaum, & Gopnik, 2004).

A final possibility is that the participants only represented approximate probabilities. Participants may have categorized the probability of causation by tracking whether a causal link *definitely*, *maybe*, or *definitely does not* exist. Consistent with this possibility, participants did not seem to differentiate between different degrees of *maybe* (e.g., see Figure 4).¹

The modified SOP model predicts the relative size of reduced overshadowing and backward blocking, but the preventive analogs of these findings illustrate that it does so for the wrong reasons. In both the modified RW model and modified SOP models, within-compound associations make a poor substitute for a genuine representation of uncertainty. Other associative models that use within-compound associations may be capable of explaining these results (e.g., Denniston, Savastano, & Miller, 2001), so further experimentation is necessary. However, the results of this experiment raise serious questions about whether within-compound associations offer a genuine representation of uncertainty. As instantiated by the modified SOP model, they clearly do not.

¹ Interestingly, causal support does something similar. Rather than using the untransformed probability of a causal link (equation 6), causal support transforms this probability with the logit function. The logit function deemphasizes differences in moderate probabilities (i.e., those near .5) and emphasizes differences in extreme probabilities.

It is worth noting, however, that the logit transformation would not save the modified RW and the modified SOP models. Even when augmented with a logit transformation, these models fail to explain the results. The modified RW model learns that cue C is non-causal in preventive backward blocking more quickly than it learns that cue C is preventive in preventive reduced overshadowing. If anything, the logit transformation would highlight this failing. The modified SOP model makes predictions in the wrong direction. As a monotonic transformation, the logit function preserves the direction of these incorrect predictions.

Abstract

Inductive reasoning allows us to go beyond the target hypothesis and capitalize on prior knowledge. Past research has shown that both the similarity of categories and specific knowledge about causal relations affect inductive plausibility. We go one step further and focus on the role of abstract causal schemas about main effects and interactions. Two experiments show that both prior assumptions about abstract causal schemas and the similarity of the corresponding causal effects affect inductive judgments. Reasoners have different prior beliefs about the likelihood of main-effect versus interactive schemas, and rationally combine these prior beliefs with new evidence in a way that can be modeled as Bayesian belief updating.

Keywords: inductive reasoning; causal schemas; causal interactions; Bayesian inference

Introduction

Inductive reasoning occurs in various contexts. In associative learning we infer a general regularity from a set of learning trials. In causal learning we use a sample of observations and go beyond the information given to induce general causal laws. Inductions not only occur at the level of learning exemplars but can also relate prior knowledge about hypotheses to new hypotheses. For example, knowing that cats have hearts allows us to give an informed guess about the probable validity of the hypothesis that wolves have hearts, as well. The interconnectedness of our knowledge is a powerful tool to form informed guesses about new hypotheses.

Although inductive inferences based on exemplars have for a long time been studied in learning, inductions between hypotheses is a fairly recent research goal (see Feeney & Heit, 2007, for an overview). Many early studies have focused on the similarity of categories as the basis for inductive inference.

However, similarity between categories is not the only factor influencing inductive inferences. Based on a variant of causal-model theory, Rehder (2007) has proposed a theory which treats inductive generalizations as causal reasoning. According to this theory we assess the likelihood that a novel feature applies to a new category on the basis of our beliefs about the causal relations that connect that feature to the category. For example, subjects tend to infer that a category has a novel feature if they believe that this feature is caused by or is the cause of a characteristic feature of the category.

Whereas previous research on inductive reasoning has focused on the similarity of categories (i.e., feature overlap) or the causal relation connecting a novel feature to the categories, our current research explores the role of more abstract and complex causal schemas in inductive reasoning about hypotheses.

Causal Schemas in Learning

Thus far, causal schemas have mainly been studied in the context of learning, not inductive reasoning. We will briefly review this research to derive hypotheses for inductive reasoning. Within the causal learning literature it has typically been assumed that the default assumption about multiple causes is that they combine additively. For example, Cheng (1997) has postulated a noisy-OR schema as the default for generative causes according to which multiple causes independently generate an effect.

Although additive integration of multiple causes may be the default, causes may also interact (Kelley, 1972; Novick & Cheng, 2004). The majority of research about additive integration and interactions has been conducted within the associative learning literature. Popular examples of an interaction are positive and negative patterning, in which the effect cannot be predicted on the basis of an additive integration of the individual causes. Positive patterning (PP) refers to learning a situation in which two cues (e.g. A and B), when presented individually, are not paired with the outcome (A- and B- trials), but when presented together they are paired with the outcome (AB+ trials). For example, two drugs may individually not cause a side effect but only in combination. The corresponding additive cue combination (A-, B- => AB-) we henceforth call negative main effect (ME-). In contrast, negative patterning (NP) refers to a situation in which cues A and B, when presented alone, are paired with the outcome (A+ and B+ trials), but when presented together are not paired with the outcome (AB- trials). An example of this interaction are two drugs which each cause a side effect, but cancel out each other's effect when presented together. The complimentary main effect (A+, B+ => AB+) we will call positive main effect (ME+).

Shanks and Darby (1998) found that people can learn both of these interactions (PP and NP) concurrently, and can form the appropriate abstract schematic representations. Moreover, Shanks and Darby demonstrated that people transfer these schemas to new cues which have not previously been shown together. For example, participants

that underwent NP training with cues A and B, and were then shown C+ and D+ trials, could infer that the novel compound CD would not be followed by the outcome (see also Lucas & Griffiths, 2010).

Kemp et al. (2007) have proposed a Bayesian model which explains Shanks and Darby's (1998) data. The model learns causal schemas by monitoring the co-occurrences of cues and outcomes, and groups together cues that behave in a similar fashion. In the NP case this model groups together cues that co-occur with the outcome in isolation, but do not co-occur with the outcome when paired with another cue of the same kind. Importantly, the model can use these cue groupings to generate predictions about novel cue-combinations at test, and thus solve the [C+, D+, CD?] test cases.

Causal schemas differ in learning difficulty in a way consistent with the assumptions in the causal literature. Studies of patterning have shown that learning about patterning schemas is a difficult task and proceeds much slower than when organisms are confronted with main effects (Kehoe, 1988).

Causal Schemas in Inductive Reasoning

Previous research has shown that people are capable of abstracting causal schemas from learning data and transferring them to new situations. However, very little is known about how causal schemas affect inductive plausibility when knowledge is presented as a set of individual facts and hypotheses. Based on the findings in the learning literature and our predecessor study (O. Griffiths et al., 2009), we expect that reasoners bring to bear different priors about causal schemas. We expect them to consider main-effect relations more likely than interactions, especially disordinal ones as in the NP case. Different priors for schema knowledge should therefore constitute one important, hitherto neglected factor influencing inductive plausibility between facts and hypotheses. In particular, a simple application of Bayes' rule predicts that a new instance of an unlikely interaction should have a larger impact on inductive beliefs than a new instance of a schema that is already considered common (e.g., main effects).

A second factor we will explore in the present research concerns the question whether the similarity of the schemas influences induction. Since causal schema hypotheses are abstract not only with respect to the involved cues but also with respect to other properties of the underlying causal relation, similarity between patterning or main effect instances is obviously determined by at least two factors: the similarity of the involved cues in corresponding roles (thus the similarity between the pair of cues A and B and the pair of cues C and D) as well as the similarity of the effects which are generated by A and B on the one hand and C and D on the other hand. In the present experiments we will keep the similarity between cues constant across conditions but we will manipulate the similarity of the effect, a factor that has been neglected in previous research. Moreover, similarity will be investigated in the context of both

confirming and disconfirming evidence. Our main hypothesis is that both confirming and disconfirming evidence should more strongly increase or decrease the prior belief, respectively, if the similarity between the effects mentioned in the facts and the hypotheses is high rather than low.

Schema-based Priors and Belief Updating

O. Griffiths et al. (2009) proposed a simple Bayesian account of schema-based belief updating which models how people update their belief in some schema hypothesis H_i (i.e., H_{PP} , H_{NP} , H_{ME+} or H_{ME-} , respectively) given a confirming instance D via Bayes' rule:

$$P(H_i|D_i) = \frac{P(D_i|H_i)P(H_i)}{P(D_i)}$$

The posterior belief in H_i depends upon the likelihood of the confirming instance D_i given H_i being true, and the participants' prior belief in H_i . An example would be an inference about the hypothesis $(A+, B+) \Rightarrow (AB-)$ when it is already known that the conclusion $(C+, D+) \Rightarrow (CD-)$ is true for novel cues C and D from the same domain as A and B.

Assuming that people consider patterning schemas to be less plausible than main-effect schemas, Griffiths et al. (2009) used this Bayesian belief updating to derive the following predictions: Beliefs regarding patterning schemas will be change more profoundly in response to the observation of a confirming instance than beliefs regarding main-effect schemas. After updating, however, plausibility ratings for patterning schemas should still not exceed those for main-effects.

In an experiment Griffiths et al. (2009) tested these predictions. 32 participants were presented with a series of eight fictitious scenarios describing causal relationships between a number of cues and an effect in several different content domains (e.g., physics or biology). Each of the eight trials consisted of two subscenarios (see Table 1). Subscenario 1 contained three statements: The first two statements, the premises, were labeled as facts (*Fact A* and *Fact B*), and the participants were instructed to treat them as true facts. Each of these premises described one of two cues (A or B) that either did or did not cause an outcome. The third statement, labeled *Conclusion*, was a causal statement about the compound AB that again either did or did not cause the same effect. The distribution of presence or absence of the effect in the three statements determined the cue interaction type of the trial (see Table 1). Participants were then requested to indicate to what extent they believed the conclusion statement to be true as well. Given that the cues and their combinations were novel, these responses were taken as indicators of prior beliefs in the plausibility of the corresponding schema. Afterwards, subjects were presented with the second subscenario, in which they received confirming evidence in the form of three further premises (*Facts 1–3*). These premises described two different cues from the same domain (C and D) and their

compound CD causing or not causing the same effect as in the first subscenario. Moreover, the presented schema was the same. Then the participants were once more asked to indicate the extent to which they believed the conclusion statement about the compound AB to be true, this time in consideration of the additional evidence they had received about C and D.

Table 1: Design of the Experiment by Griffiths et al. (2009)

Subsc.	Statement	Cue Interaction			
		PP	ME-	NP	ME+
1	Fact A	A-	A-	A+	A+
	Fact B	B-	B-	B+	B+
	Conclusion	AB+	AB-	AB-	AB+
2	Fact 1	C-	C-	C+	C+
	Fact 2	D-	D-	D+	D+
	Fact 3	CD+	CD-	CD-	CD+
	Fact A	A-	A-	A+	A+
	Fact B	B-	B-	B+	B+
	Conclusion	AB+	AB-	AB-	AB+

Note. Letters A – D represent causes. Symbols + and – indicate statements in which the cause either produced the effect or did not, respectively. The dashed line separates premises from conclusions. Subsc. = Subscenario. Adapted from Griffiths et al. (2009).

The results of this study were in line with the predictions of Bayesian updating. The baseline ratings in subscenario 1 indicated that participants assigned a higher prior probability to main effects than to patterning interactions. The increase in the ratings between subscenarios 1 and 2 was higher for patterning interactions than for main effects, while the mean ratings in subscenario 2 remained higher for main effects than for patterning interactions even after updating.

Bayesian Belief Updating and Similarity

For the sake of simplicity, Griffiths et al. (2009) assumed that the likelihood $P(D_i|H_i)$ of a confirming instance D_i is represented by some fixed number larger than 0.5 (i.e., the instance is informative) but less than 1 (i.e., the inference from the instance to the hypothesis, which is formulated with respect to another pair of cues, is tainted with uncertainty), and that the likelihood is a function of the similarity between the confirming instance D_i and the instance addressed by the hypothesis H_i .

Since the similarity of instances was not manipulated by Griffiths et al. (2009), it remained open whether this factor influences judgments. Making the similarity component explicit and extending the model to disconfirming instances the proposal of Griffiths et al. (2009) can be revised as:

$$P(D_i|H_i) = \begin{cases} \frac{S(D_i, H_i)}{2} & D_i \text{ confirms } H_i \\ 1 - \frac{S(D_i, H_i)}{2} & D_i \text{ disconfirms } H_i, \end{cases}$$

with $S(D_i, H_i) \in [0,1]$ representing some monotone similarity measure expressing the subjective similarity between the instance D_i and the instance addressed by H_i . Thus, the more similar D_i and H_i are, the stronger the predicted belief update should be (either in the positive direction in the confirming case, or in negative direction in the disconfirming case). Disconfirming evidence is defined as evidence that confirms the contrast hypothesis. For example, $(C+, D+) \Rightarrow (CD-)$ confirms the negative-patterning hypothesis and disconfirms the positive main-effect hypothesis.

Experiment 1

This experiment aims at replicating and extending the results from the experiment by Griffiths et al. (2009). We make a first attempt to manipulate the similarity between the different hypotheses from the same domain. As laid out above, a decrease in similarity between the confirming instance and the instance about which the hypothesis is formulated should decrease the tendency to generalize from the confirmatory evidence to the conclusion statement in question. In the present experiment we will use identical cues in the two subscenarios (i.e., $A=C$, $B=D$) but vary the similarity of the effects. Thus, Bayesian belief updating predicts a stronger increase of inductive confidence from subscenario 1 to subscenario 2 in the high similarity condition as opposed to the low similarity condition.

Method

Participants 48 University of Göttingen undergraduates participated in a series of various unrelated computer-based experiments in our lab either for course credit or for €7/h.

Design The design was closely matched to the experiment by Griffiths et al. (2009). We manipulated two independent variables in the scenarios presented to participants. The first factor was the type of causal schema and had four levels: ME-, ME+, NP, and PP. The second factor was the similarity between the to-be-judged conclusion and the confirmatory evidence. We manipulated whether the two scenarios used the same causal effect or different effects from the same domain.

Each participant responded to a total of 16 scenarios. The scenarios were randomly assigned to the experimental conditions separately for each participant. We used a complete 4 (Cue Interaction: ME-, ME+, NP, PP) \times 2 (Similarity: same effect vs. different effect) repeated-measurement ANOVA design. Each subject thus received two trials in each experimental condition. The trial order was randomly determined for each individual participant.

Materials and Procedure Participants completed the experiment individually on desktop computers. The experiment began with an instruction section which informed participants about the course of their task and briefly tested whether they thoroughly understood it.

Afterwards, participants were presented with 16 fictitious scenarios from different content domains (physics, chemistry, biology, medicine) that were constructed to cover

a broad range of settings. Fictitious cues and effects were used to make sure that participants could not rely on specific prior causal knowledge when making their inferences. Each scenario again consisted of two subscenarios. Subscenario 1 was set up exactly as in Griffiths et al. (2009) (see upper part of Table 1). After having read the two premises (*Facts A—B*) and the *Conclusion*, participants indicated the extent to which they believed the conclusion statement to be true (this rating will be labeled *Rating 1* from now on). For this task participants were provided with an 11-point scale, ranging from “definitely false” at the left-hand end (0) to “definitely true” at the right-hand end (10).

After having provided this rating, participants proceeded to subscenario 2. Its set-up was similar to that in Griffiths et al. (2009) in that three additional facts from the same domain were introduced (*Facts 1—3*; see lower part of Table 1). These facts always constituted confirming evidence for the hypothesis that the conclusion is true. The three statements from subscenario 1 were repeated below the three new statements. Apart from that, we made two important changes in the present experiment regarding the materials of subscenario 2 in order to manipulate the similarity between the to-be-judged conclusion and the confirmatory evidence. First, the confirming evidence consisted of statements about the *same* cues as in the statements in subscenario 1 (i.e., A & B), so that overall similarity was increased compared to the material in Griffiths et al. (2009). Second, we manipulated the similarity between the effect caused by these cues in subscenario 1 and in the new statements of subscenario 2. In half of the trials, cues A and B caused (or did not cause) the same effect in both the to-be-judged conclusion and the provided confirmatory evidence. In the other half, the effect differed between both sets of statements. This means that in all same-effect conditions, in subscenario 2 *Facts 1—2* were identical to *Facts A—B*, and *Fact 3* was identical to the to-be-judged conclusion. Logically, all participants should have indicated certainty about the truth of the conclusion in this condition, since it was already stated as true in the premises. Table 2 shows the material of subscenario 2 in a sample trial.

Table 2. Sample of Subsc. in an NP/Different Effect trial

<i>Fact 1:</i>	Aering Heptosulfin with methane causes the Heptosulfin to become crystalline.
<i>Fact 2:</i>	Aering Heptosulfin with butane causes the Heptosulfin to become crystalline.
<i>Fact 3:</i>	Aering Heptosulfin with a mixture of methane and butane does not cause the Heptosulfin to become crystalline.
<i>Fact A:</i>	Aering Heptosulfin with methane causes the Heptosulfin to become isomorph.
<i>Fact B:</i>	Aering Heptosulfin with butane causes the Heptosulfin to become isomorph.
<i>Conclusion:</i>	Aering Heptosulfin with a mixture of methane and butane does not cause the Heptosulfin to become isomorph.

Following the presentation of the statements, participants were asked once again to rate the *Conclusion*, using the same scale as in subscenario 1. This rating, which was given after confirming evidence had been presented, is from here on referred to as *Rating 2*. Participants then proceeded directly to the next scenario. This process was repeated until all 16 scenarios were complete. The computer program ensured that participants were not able to return to any previous questions.

Results

The results of Experiment 1 are summarized in Figure 1. First, different assumptions about the prior probability of main effects vs. patterning interactions are evident in the much higher mean ratings in *Rating 1* in ME- and ME+ trials compared to NP and PP trials ($F_{3,141}=177.3$, $p<.001$, $\eta_p^2=.79$). Thus, again main-effect schemas were assumed to be more likely than interaction schemas. Second, belief change (increase from *Rating 1* to *Rating 2* within conditions) was influenced by the Cue Interaction factor ($F_{3,141}=28.18$, $p<.001$, $\eta_p^2=.37$), by the Similarity factor ($F_{3,47}=82.39$, $p<.001$, $\eta_p^2=.64$), and by the interaction between both factors ($F_{3,141}=15.18$, $p<.001$, $\eta_p^2=.24$). That is, after receiving positive evidence, participants tended to increase their confidence in the conclusion more in the cases exhibiting patterning-interactions than in the cases exhibiting main-effects. The dependence of belief updates on prior knowledge is predicted by basic Bayesian belief updating and replicates the findings of Griffiths et al. (2009). The belief change is also larger when the cues cause the same effect in both instances rather than a different effect. Furthermore, the interaction indicates that the difference in belief change between same-effect and different-effect conditions was much more pronounced in patterning-interactions than in main-effect trials (planned contrast¹: $F_{1,47}=22.05$, $p<.001$).

Experiment 2

The main goal of Experiment 2 was to investigate how effect similarity and type of evidence (i.e., confirming vs. disconfirming evidence) interact with the type of causal schemas. In Experiment 1 we have already shown that the more similar the instances are, the more confident the participants are in the truth of the hypothesis. Bayesian belief updating predicts that the opposite is expected if disconfirming evidence is presented. To test this prediction, we included disconfirming evidence in half of the trials. In contrast to Experiment 1, we increased the dissimilarity of the cues between the subscenarios to test whether the similarity of the effect event also influences inductive ratings when the cues are more dissimilar.

¹ $(M_{Same/PP\&NP} - M_{Diff/PP\&NP}) - (M_{Same/ME} - M_{Diff/ME}) = 4.15$

Figure 1: Means of belief ratings of conclusions, and standard errors for pattering-interaction and main-effect schemas (ME-, ME+, NP, PP) plotted against effect similarity (E: same effect, F: different effect). Light grey bars (left hand side) indicate ratings before the confirming instance was shown (*Rating 1*), dark grey bars (right hand side) show ratings after the confirming instance was presented (*Rating 2*).

Figure 2: Mean belief ratings in conclusion statements, and standard errors for pattering-interaction and main-effect schemas (ME-, ME+, NP, PP) plotted against effect similarity (E: same effect, F: different effect) and evidence type ("−": disconfirming evidence, "+": confirming evidence). Light grey bars (left hand side) indicate ratings before the (dis)confirming instance was shown (*Rating 1*), dark grey bars (right hand side) show ratings after the (dis)confirming instance was presented (*Rating 2*).

Method

Participants A different sample of 48 University of Göttingen undergraduates participated.

Design We manipulated the same two independent variables as in Experiment 1. Additionally, we varied whether subscenario 2 contained confirming vs. disconfirming evidence for the to-be-judged conclusion statement. This

yielded a complete 4 (Cue Interaction: ME-, ME+, NP, PP) \times 2 (Similarity: same effect vs. different effect) \times 2 (Evidence: confirming vs. disconfirming) repeated-measurement ANOVA design. Each participant again responded to 16 trials, one from each condition.

Materials and Procedure The procedure and materials corresponded to Experiment 1, apart from two changes. First, we manipulated an Evidence factor. In half of the trials, the additional evidence in subscenario 2 was disconfirming rather than confirming evidence. That is, *Facts 1–3* did not instantiate the same causal schema presented in subscenario 1, but rather its complement. If the statements in subscenario 1 formed a positive (negative) main effect, the additional evidence in subscenario 2 was confirming for negative (positive) patterning, and vice versa. The second change was that *Facts 1–3* were no longer about the same cues as *Facts A–B* and *Conclusion* (i.e., A and B), but about different cues from the same domain (C and D). That is, in all same-effect conditions, both instances differed with regards to the cues, whereas they differed with regard to both the cues and the effect in the different-effect conditions. We thus introduced a constant level of dissimilarity in all conditions on the cue level so that in none of the cases the to-be-judged

conclusion was identical to one of the premises.

Results

The results are summarized in Figure 2. First, different assumptions about the prior probability of main effects vs. patterning interactions are evident in the much higher mean ratings in *Rating 1* in ME- and ME+ trials compared to NP

and PP trials ($F_{3,141}=251.6$, $p<.001$, $\eta_p^2=.84$). Thus, main effects were again assumed to be more likely than interactions.

Second, belief change (difference between *Rating 1* and *Rating 2* within conditions) was influenced by Cue Interaction ($F_{3,141}=14.10$, $p<.001$, $\eta_p^2=.23$) and type of additional evidence ($F_{3,47}=124.42$, $p<.001$). Planned contrasts revealed that in the case of confirming evidence, the increase in belief was stronger for patterning interactions than for main effects ($F_{1,47}=11.04$; $p<.01$); in the case of disconfirming evidence, the decrease in belief was stronger for main effects than for patterning interactions ($F_{1,47}=40.06$; $p<.001$), as predicted in (ii).

Finally, there was no main effect of the similarity factor on belief change ($F_{3,47}<1$, $p=.45$). This, however, was to be expected: While the confidence in the hypothesis should increase more after confirming evidence about the same effect than about a different effect, it should also *decrease* more after disconfirming evidence about the same effect than about a different effect (thus, on the level of the similarity factor both effects cancel out each other). This prediction, in turn, is reflected in the significant Evidence \times Similarity interaction ($F_{3,47}=82.39$, $p<.05$, $\eta_p^2=0.09$) which is driven by the predicted specific differences (planned contrast²: $F_{1,47}=4.43$, $p<.05$). These results confirm prediction (iii).

General Discussion

We have presented two experiments which replicate and extend a previous study testing a rational model of belief updating (Griffiths et al., 2009). We showed again that people lacking specific causal knowledge may use knowledge about abstract causal schemas in inductive reasoning. Moreover, we found again that people find interactions less plausible than main effects, while, in line with Bayesian updating, evidence about a case of an interaction increases confidence more than evidence about main effects, which stays at a relatively high level. In the present study we elaborated our model to accommodate variations of similarity and cases of confirming versus disconfirming evidence.

The present research suggests a number of directions for future research. In the present experiments we have shown that the similarity of effect events influences inductive reasoning with both confirmatory and disconfirmatory evidence. It would be interesting to additionally explore the role of the similarity of the cues (A-D), which was only varied across experiments in the present paper. We expect that both the similarity of the cues and of the effect will equally contribute to similarity-related effects.

The present research used extremely abstract materials and a subset of possible interaction types. It might be interesting to look at differences between different causal schemas when more domain knowledge is allowed (see Waldmann, 2007, for other domain related schemas).

Finally, in the Introduction we have separated learning tasks from inductive reasoning tasks, but combinations are conceivable. Previous knowledge need not be stated as facts but can be presented in the form of statistical evidence (e.g., learning trials). It would certainly be interesting to develop a model of inductive reasoning that integrates prior beliefs about abstract and specific causal relations, similarity, and different types of evidence.

Abstract

We hypothesized that causal conditional reasoning reflects judgment of the conditional likelihood of causes and effects based on a probabilistic causal model of the scenario being judged. Although this proposal has much in common with Cummins' (1995) theory based on the number of disabling conditions and alternative causes, it takes more variables into account and therefore makes some differing predictions. To test this idea we collected judgments of the causal parameters of the conditionals and used them to derive predictions from a model with zero free parameters. We compared these predictions to Cummins' acceptability ratings and to analogous likelihood judgments that we also collected. The hypothesis was borne out for Affirming the Consequent and the analogous diagnostic likelihood judgments, where the model obtained close fits to both data sets. However, we found a surprising dissociation between Modus Ponens and judgments of predictive likelihood leading to a relatively poor fit to the Modus Ponens acceptability ratings. We propose an explanation for this in the discussion.

Key Words: Causal Conditional Reasoning, Conditional Probability, Reaction Time, Probabilistic Model, Modus Ponens, Affirming the Consequent

Causal Conditional Reasoning

When reasoning about deductive arguments people are biased to accept conclusions that are consistent with their beliefs and reject those that are inconsistent, regardless of argument validity (Evans, 2007). In a set of seminal papers, Cummins (1995; Cummins et al., 1991) showed that these belief biases follow systematic principles when people reason about conditional arguments with causal content. People judged the validity of four argument schemata: Modus Ponens (MP), Modus Tollens (MT), Denying the Antecedent (DA) and Affirming the Consequent (AC), though we focus on just MP and AC in this paper.

Despite MP being deductively valid and AC invalid regardless of content, Cummins predicted that for arguments where the antecedent is a cause of the consequent, acceptance rates for MP would be affected by the number of disabling conditions while AC would be affected by the number of alternative causes for the effect.

In the case of MP, thinking of a disabling condition provides a counterexample to the argument and hence may lead people to reject it. An example is given below. Cummins' predicted that (a) would be judged more acceptable than (b) because the conditional in (a) has fewer disablers; reasons why one could put fertilizer on plants and not have them grow quickly are more available than reasons why one could jump into a pool and not get wet.

(a) If Mary jumped into the swimming pool then she got wet.
Mary jumped into the swimming pool.
Therefore she got wet.

(b) If fertilizer was put on the plants then they grew quickly.
Fertilizer was put on the plants.
Therefore they grew quickly.

In the case of AC, alternative causes provide an alternative explanation for the effect and hence make the antecedent seem less necessary. For example Cummins predicted that (c) would be judged more acceptable than (d). It is hard to think of alternative causes for a gun firing besides the trigger being pulled but it is relatively easy to think of causes of wetness besides jumping into a swimming pool.

(c) If the trigger was pulled then the gun fired.
The gun fired.
Therefore the trigger was pulled.

(d) If Mary jumped into the swimming pool then she got wet.
Mary got wet
Therefore she had jumped into the swimming pool.

To test these ideas Cummins' asked one group of participants to spontaneously generate alternative causes and disabling conditions for a host of conditionals and then divided the conditionals into four groups of four conditionals each based on the number of alternatives and disablers (many alternatives, many disablers; many alternatives, few disablers; few alternatives, many disablers; few alternatives, few disablers). A different group was given the arguments based on the 16 conditionals and asked to judge the extent to which the conclusion could be drawn from the premise. Responses were on a 6 point scale from "very sure that the conclusion cannot be drawn" (-3) to "very sure that the conclusion can be drawn" (3). The results provided good support for both predictions.

A Causal Model Theory

Following Oaksford, Chater and Larkin (2000), if the conditional schemata are interpreted in terms of conditional probability, the acceptability of MP maps onto $P(\text{Effect}|\text{Cause})$ and AC to $P(\text{Cause}|\text{Effect})$. Throughout the paper, we refer to $P(\text{Effect}|\text{Cause})$ as a *predictive* likelihood judgment and to $P(\text{Cause}|\text{Effect})$ as a *diagnostic* judgment.

By assuming the conditional scenarios approximate a noisy-or common effect model (Cheng, 1997) the expressions in (1) and (2) can be derived for MP and AC respectively (Fernbach & Darlow, 2009; Waldmann et al., 2008). The noisy-or model assumes that there are multiple independent causes for a given effect, each of which may or may not be effective on a given trial.

$$MP \approx P(\text{Effect} | \text{Cause}) = W_c + W_a - W_c W_a \quad (1)$$

$$AC \approx P(\text{Cause} | \text{Effect}) = 1 - (1 - P_c) \frac{W_a}{P_c W_c + W_a - P_c W_c W_a} \quad (2)$$

W_c is the causal power of the cause, the probability that the cause successfully brings about the effect (e.g. the probability that pulling the trigger causes the gun to fire), W_a is the combined strength of all alternative causes, equivalent to the probability of the effect in the absence of the cause (e.g. the probability of the gun firing given the trigger wasn't pulled) and P_c is the prior probability of the cause (e.g. the probability of the trigger being pulled).

According to the full probabilistic model MP increases with both the causal power of the cause and the strength of alternatives (because alternative causes raise the probability of the effect). However, in previous work, we have found that people are not sensitive to the strength of alternative causes when judging predictive likelihood despite its relevance (Fernbach, Darlow & Sloman, 2010). Thus, like Cummins we predicted no effect of W_a and our model for MP is given in (3).

$$MP \approx P(\text{Effect} | \text{Cause}, \sim \text{Alternatives}) = W_c \quad (3)$$

AC is a function of all three parameters. It increases with P_c and W_c and decreases with W_a .

Relation Between Cummins' Analysis and Model

According to the causal model the determinants of causal inferences, and hence MP and AC acceptability, are causal power, strength of alternatives and prior probability of the cause. The number of disablers and number of alternatives are factors in the first two parameters, respectively. Causal power is inversely related to the number of disablers. All else being equal, as the number of disablers increases, the probability that the cause fails to bring about the effect increases, corresponding to a decrease in causal power. Thus the model is consistent with the decrease in MP as number of disablers increases, as predicted and found by Cummins. However, not all disablers are equally likely or equally effective in preventing the effect. A single strong disabler could lead to a lower causal power than several weaker disablers, making number of disablers an imperfect predictor of causal power.

Similarly, the number of alternatives is a factor in strength of alternatives. All else being equal, as the number of alternatives increases so does the probability that they will bring about the effect. Therefore, the model predicts that AC will decrease with number of alternatives. As with disablers though, number of alternatives is only a partial predictor of strength of alternatives.

Despite these similarities, the model suggests that Cummins' analysis is incomplete because it only takes a single parameter into account for each judgment. The implication for MP is that its acceptability should increase with the strength of alternative causes but as discussed above we predicted no effect of alternative causes on MP. Our prediction for MP only differs from Cummins in that

we expected W_c to provide a better fit than number of disablers.

The model identifies three factors relevant to the acceptability of AC arguments. First, according to the model the prior probability of the cause plays an important role in diagnostic strength. For instance, a cause that is very improbable is unlikely to have occurred relative to other more likely causes and is therefore not as good an explanation for the effect. The second factor is the overall strength of alternatives. This differs from the number of alternatives because not all alternative causes are created equal. In the causal model the strength of alternatives reflects the probability of the effect in the absence of the cause and thus is a joint function of the prior probabilities and causal powers of alternatives. For instance, even a large number of highly improbable or weak alternatives should have less effect on the judgment than a single probable, strong cause. Finally, causal power -- and hence disablers -- should have some influence on AC. All else being equal, if the causal power of the cause is higher, the cause is more likely responsible for the effect. Table 1 summarizes how our predictions differ from Cummins' theory.

Table 1: Best Predictors for MP and AC judgments and Predictive and Diagnostic Likelihood Judgments According to Cummins (1995) and According to our Model

	MP	AC
Cummins' Theory	No. of Disablers	No. of Alternatives
Causal Model	Causal Power (W_c)	Full Diagnostic Model
	<i>Predictive Likelihood</i>	<i>Diagnostic Likelihood</i>
Cummins' Theory	No Prediction	No Prediction
Causal Model	Causal Power (W_c)	Full Diagnostic Model

Qualitative Support for Causal model

Some trends appear in Cummins' (1995) data that are not predicted by her theory. One is that acceptability ratings of AC for conditionals with many alternative and few disablers were lower than those with many alternatives and many disablers. Both groups had many alternatives and thus should have yielded similar AC judgments according to Cummins. The difference was replicated by De Neys, Schaeken and D'yevalle (2002) who found lower AC ratings for all few disabler items compared to many disabler items.

De Neys et al. (2002) proposed that when there are many disablers, they interfere with searching memory for alternatives, leading to the observed difference. A perusal of the individual conditionals suggests an alternative explanation based on the causal model. The two groups appear to vary not just in number of disablers but also in some of the factors that the probabilistic analysis says should affect diagnostic judgments. Specifically, the items that obtain low acceptability scores share the property that the cause is weak or improbable relative to the strength of alternatives (see Table 2). For instance, jumping into a swimming pool is improbable relative to other causes of wetness. Likewise, pouring water onto a fire is not the most

common cause of a campfire going out. On the contrary, the high ratings obtain for arguments in which the cause is strong and probable relative to alternatives. There may be many alternatives for a car slowing, but braking is likely the dominant cause. Likewise, studying hard is probably the strongest cause of doing well on a test. Thus, number of alternatives may be equated across groups, but diagnostic strength is not.

Table 2: Mean Acceptability of AC arguments for Two Groups of Conditionals from Cummins' (1995) Exp.1

Conditional	Acceptability (-3 to 3)
<i>Many Alternatives, Many Disablers</i>	
If fertilizer was put on the plants, then they grew quickly	1.00
If the brake was depressed, then the car slowed down	1.00
If John studied hard, then he did well on the test	1.50
If Jenny turned on the air conditioner, then she felt cool	1.08
<i>Many Alternatives, Few Disablers</i>	
If Alvin read without his glasses, then he got a headache	0.75
If Mary jumped into the swimming pool, then she got wet	0.25
If the apples were ripe, then they fell from the tree	1.00
If water was poured on the campfire, then the fire went out	-0.08

Another trend unexplained by her analysis is that few alternative conditionals obtained slightly higher MP judgments than many alternative conditionals despite being equated across number of disablers. Again, the probabilistic analysis suggests why this may be so. Several of the many alternative items have somewhat low causal powers (e.g. 'if the apples were ripe then they fell from the tree') while virtually all of the few alternative items have very high causal powers (e.g. 'if the gong was struck then it sounded.'). Thus, while number of disablers was equated across groups, causal power may have varied leading to differing MP judgments.

Experiment

To test whether the causal model accounts for the causal conditional acceptability ratings we collected judgments of the relevant parameters: the prior probability of the cause (P_c), the causal power of the cause (W_c) and the strength of alternatives (W_a) for Cummins' (1995) conditionals. Using these judgments we derived predictions with zero free parameters to which we compared Cummins' acceptability ratings.

Another implication of our argument is that judgments of the conditional probability of effects and causes should be similar to Cummins' acceptability ratings and should also be accounted for by the causal model. Thus, we collected predictive and diagnostic conditional probability judgments from a second group of participants. We also collected reaction times for these judgments. De Neys et al. (2002) showed that reaction times for causal conditionals basically supported Cummins' analysis. Collecting reaction times with materials phrased in conditional likelihood language allowed us to verify and extend these findings.

Method

Participants 133 Brown University students were approached on campus and participated voluntarily or participated through the psychology research pool in return for class credit.

Design, materials and procedure All experimental conditions used questions based on the 16 conditionals from Cummins' (1995) experiment 1. We therefore adopted Cummins' 2 (number of alternatives; few/many) X 2 (number of disablers; few/many) design with four conditionals in each condition. Judgments were on a 0 ('impossible') to 100 ('definite') scale.

17 Participants provided judgments of the prior probabilities (P_c) and strength of alternatives (W_a) for the 16 conditionals. The questions were split onto two pages with all of the P_c questions on the first page and all of the W_a questions on the second page. The order of questions was randomized on each page. For each question we first stated the conditional and then asked the relevant likelihood question. Examples of P_c and W_a questions are given in (e) and (f) respectively.

(e) If John studied hard then he did well on the test.
How likely is it that John studied hard?

(f) If John studied hard then he did well on the test.
John did not study hard. How likely is it he did well on the test?

A minority of participants interpreted the conditional statement in the P_c questions as indicating that the cause was present and therefore gave ratings of 100 for all of the P_c questions. We removed these responses from the dataset for all subsequent analyses.

An additional 21 participants judged causal power (W_c). Methods were identical except that there was just one page of questions. An example of a W_c question is given in (g).

(g) How likely is it that John studying hard for the test causes him to do well?

95 participants provided predictive and diagnostic likelihood judgments, fully within-participant. Each of these participants therefore answered 32 questions, one predictive and one diagnostic for each conditional. In order to avoid any reaction time differences due to reading time, the wordings of the questions were modified such that each had between 13 and 15 words and between 65 and 75 characters and such that the mean number of words and characters was equated across the four groups of conditionals. Examples of predictive and diagnostic questions are given in (h) and (i):

(h) John studied hard. How likely is it that he did well on the test?

(i) John did well on the test. How likely is it that he studied hard?

This part of the experiment was administered on a computer in the lab. For each question, participants input their answer using the number keys and hit 'return' to move to the next question. Reaction times were measured from the moment the question appeared on the screen to when the participant

hit 'return'. Order of questions was randomly determined for each participant.

Parameter Judgments and Modeling Results

For the following tests we collapsed over conditionals and compared participant means, using Bonferroni correction to control family-wise error rate. As expected, W_a was judged higher for many alternative items compared to few alternative items ($t(16)=13.4$, $p<0.001$) and didn't vary across few and many disablers ($t(16)=1.4$, ns).

W_c also varied across the number of alternatives manipulation; W_c was judged higher for few alternative items ($M=83.4$) compared to many alternative items ($M=73.9$), $t(20)=4.8$, $p<0.001$). This was not intended by Cummins, but confirmed our intuitions about the unexplained trend in MP; weak alternative items seemed to have lower causal powers despite being equated across number of disablers. Surprisingly, W_c did not vary across the many/few disablers manipulation ($t(20)=1.2$, ns) suggesting that number of disablers and causal power were not as closely linked as we expected. The low correlation between number of disablers and W_c ($r=-0.11$, ns) also supported this conclusion. P_c did not vary across either manipulation.

Applying the Model Simply computing Equations 2 and 3 using item means would have been inappropriate because the parameter judgments were collected between participants. We therefore used a sampling procedure to generate model predictions. For each conditional we took 10,000 samples each of W_a , P_c and W_c uniformly and randomly from participant responses, and calculated Equations 2 and 3 for each set of samples. We therefore generated 10,000 samples of each probability for each conditional and then took the mean over samples for each conditional as the output of the model. Reruns of the model yielded only negligible differences.

Fits to AC and Diagnostic Judgments Figure 1a depicts Cummins' acceptability ratings for AC on the X-axis plotted against model fits (Equation 2) on the Y-Axis for each of the 16 conditionals, along with the least squares regression line. Figure 1b shows diagnostic judgments plotted against model fits. The model predictions were highly correlated with both Cummins' acceptability ratings (AC) ($r=0.87$, $p<0.001$) and the diagnostic judgments (D) ($r=0.93$, $p<0.001$). To test whether the model is a better predictor of AC and D than the number of alternatives, we performed hierarchical multiple regression analyses of AC and D responses using the model predictions and the number of alternatives as predictors. The model accounted for a significant amount of unique variance beyond what number of alternatives accounted for, both for AC ($F(1,14)=10.7$, $p<0.01$) and for D ($F(1,14)=38.4$, $p<0.001$). Number of alternatives did not account for any unique variance for AC ($F(1,14)=0.24$, ns) or for D ($F(1,14)=0.46$, ns).

Fits to MP and Predictive Judgments Figure 1c depicts Cummins' acceptability ratings for MP plotted against

model fits (equal to W_c according to Equation 3). Figure 1d shows predictive judgments plotted against model fits. Surprisingly, MP ratings and predictive judgments were not highly correlated ($r=0.30$, ns), and each was correlated with a different independent variable. MP ratings were significantly correlated with number of disablers ($r=0.53$, $p=0.035$) but not with the model ($r=0.39$, ns). Conversely, predictive judgments were highly correlated with the model ($r=0.81$, $p<0.001$) but not with number of disablers ($r=0.04$, ns). As predicted, alternative strength did not add any explanatory power; the full model was poorer than W_c at accounting for both MP and predictive judgments.

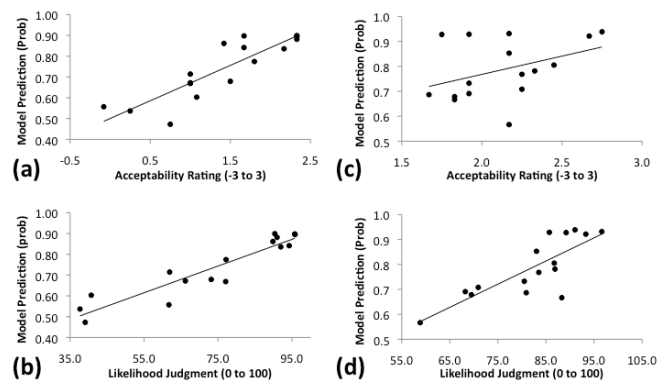

Figure 1: (a) Model fits against Cummins' AC acceptability ratings. (b) Model fits against diagnostic likelihood judgments. (c) Model fits against Cummins' MP acceptability ratings. (d) Model fits against predictive likelihood judgments.

Reaction Time Results

For the sake of concision, the analyses of the predictive and diagnostic judgments are described in the appendix and only the reaction times results are presented in this section. All statistical tests on reaction times used a log transform to normalize the data. Outliers were removed by eliminating all trials that fell more than four standard deviations above or below the participant's mean reaction time. Additionally any trial faster than 1 second was removed.

The reaction time results are depicted in Figure 2. The cleaned data were subjected to a 2 (direction of inference) X 2 (number of alternatives) X 2 (number of disablers) repeated measures ANOVA. There was a main effect of direction of inference; prediction ($M=5.88$ s) was faster than diagnosis ($M=6.21$ s), $F(1,95)=25.1$, $p<0.001$. There was also a significant interaction between number of alternatives and direction of inference, $F(1,95)=4.0$, $p<0.05$. No other main effects or interactions were significant.

The interaction between strength of alternatives and direction of inference was driven by diagnostic judgments being faster for items with few alternatives ($M = 6.09$ s) than for items with many alternatives ($M=6.32$ s), $t(94)=1.95$, $p=0.05$. Predictive judgments showed no difference in reaction time across the number of alternatives manipulation, $t(94)=0.61$, ns .

Number of disablers had no effect on reaction times for predictive judgments ($t(94)=1.2$, ns). Since W_c accounted for the predictive judgments better than number of alternatives, we suspected it might also yield reaction time differences. To test this we split the conditionals at the median based on W_c and compared reaction times. Confirming the prediction, predictive judgments were faster for items with high W_c ($M=5.71$ s) than for items with low W_c ($M=6.05$ s), $t(94)=4.19$, $p<0.0001$.

General Discussion

Summary and Interpretation of Results

Model Fits The diagnostic model achieved very good fits to both Cummins' AC data and our diagnostic likelihood judgments with zero free parameters. It also explained more variance than the single parameter number of alternatives. This confirmed the qualitative analysis indicating that AC judgments were sensitive not just to number of alternatives, but also to the other factors in the causal model in approximately the right way. The model also accounted for the previously unexplained trend in Cummins' AC data for higher AC ratings with more disablers. Altogether, it seems that when judging AC for causal conditionals, people are actually judging the likelihood of the cause (premise) given the effect (conclusion).

The model also matched the predictive judgments closely and differences in W_c explained the previously unexplained trend in Cummins' MP judgments for higher MP judgments with fewer alternatives, a pattern that also showed up in the predictive likelihood judgments (see appendix). But the model didn't match the MP data that well and in fact was slightly worse than the number of disablers at accounting for the variance. Additionally, number of disablers was a remarkably poor predictor of W_c judgments. This was surprising because we expected causal power to vary inversely with number of disablers.

Reaction Times The reaction time data yielded three noteworthy findings: First, predictive judgments were faster than diagnostic ones. This corroborates De Neys et al. (2002) who found that MP was faster than AC and it supports the claim that reasoning from cause to effect is easier in general than reasoning from effect to cause (Tversky & Kahneman, 1982). This difference likely reflects the time it takes to consider alternative causes and prior probability in diagnostic judgment.

Second, diagnostic judgments were faster with few alternatives. This also corroborates De Neys et al. (2002). It

implies that searching for alternative causes takes time. It could also reflect the fact that when alternative causes are very weak the judgment is very high and may not require as much thought to calculate. Predictive judgments showed no reaction time differences across number of alternatives. This is more evidence that people don't think of alternatives when making predictions (Fernbach, Darlow & Sloman, 2010).

Finally, we found no reaction time differences for many versus few disablers. This failed to corroborate De Neys et al. (2002) who found that MP was faster for few versus many disablers. We did however find an effect of W_c on reaction times. Prediction was faster for high versus low W_c .

Explaining MP

Both the model fitting and reaction times imply dissociation between how people judged MP and how they judged predictive likelihood. Predictive likelihood judgments and reaction times were explained by differences in W_c but were uncorrelated with number of disablers. Conversely, number of disablers was slightly better at accounting for Cummins' (1995) MP acceptability ratings than W_c and also yielded reaction time differences for MP in De Neys et al.'s (2002) study. This leaves three open questions: First, why is number of disablers such a poor predictor of W_c ? Second, why is W_c better at accounting for predictive likelihood judgments and reaction times? Third, why is it worse at accounting for MP?

A speculative answer to the first two questions comes from the possibility that when making predictive likelihood judgments people represent causal systems in terms of their normal, common or prototypical components. If asked to list disablers they may be able to come up with a relatively large number, some of them being very uncommon or atypical. But when asked to judge causal power or make a prediction they think only of the most important disablers. The 'depressed brake' provides a good example. It is not too hard to come up with disablers for why brakes would fail to slow a car (e.g. cut brake lines) but none of them is common. Thus, while number of disablers is relatively high, many of those disablers make a small impact on actual causal power and may have no effect on people's estimates of causal power. On this account, low causal power might still correlate with slower reaction time on the assumption that examples with a greater number of typical or high probability disablers yield lower W_c judgments, lower predictive judgments, and take longer to reason about.

This leaves the question of why W_c fails to account for MP judgments and reaction times, while number of disablers is somewhat better. We don't have a conclusive answer to this question, but we suspect it may be due to people using a mixture of strategies when judging MP. In a deductive context, people reason about MP more naturally than other conditional schemata (Johnson-Laird & Byrne, 2002). This suggests that some participants may be engaging in a different kind of thinking when judging MP in comparison to the other schemata. Perhaps more abstract

thinking leads to rejection of MP based on the ability to think of specific counterexamples without regard to their probability, in which case the number of disablers may be more important than W_c . This is consistent with work by Verschueren, Schaeken and d'Ydewalle (2005) showing two processes in causal conditional reasoning: A relatively quicker intuitive process that arrives at judgments that are highly correlated with conditional probability and a relatively slower, analytic process that correlates with number of alternatives or disablers. Of course, it's important not to jump to firm conclusions on the basis of so few examples (the poor fit to MP was primarily driven by 4 data points). Future work should aim to corroborate the differences in ratings and reaction times for MP versus predictive likelihood with a larger number of well-controlled items.

Conclusions

Our work provides some evidence in favor of the conditional probability approach to conditional reasoning (Oaksford & Chater, 2001, 2003; Over et al., 2007). One caveat to this is that the causal model we propose is incorrect in some important senses. People tend to neglect the strength of alternatives when making predictions, and while aggregate data are fit really well by the diagnostic model, individual data are less consistent. This suggests that people are not actually computing probabilities. It is more natural to think of the model as a computational solution that people only approximate. The literature on probabilistic causal reasoning tends to focus primarily on computational models like this to the detriment of process level implementations. The focus on semantic memory models in the causal conditional reasoning literature is admirable, but the downside of these models is that, as our work shows, people are sophisticated causal reasoners. Simple memory models based on the number of alternatives or disablers won't suffice. A complete model requires mechanisms for judging prior probability, for integrating over the strengths and probabilities of alternative causes, for judging causal power and for combining these various pieces of information in a reasonable way. These processes undoubtedly rely on retrieval from semantic memory – our reaction time data is strong evidence of that – but no current memory model can accommodate the balance of empirical evidence. Exploring how people construct their causal models from remembered alternatives, disablers and other parameters thus offers a promising avenue for future research.

Appendix

The predictive and diagnostic judgments were subjected to a 2 (direction of inference) X 2 (number of alternatives) X 2 (number of disablers) repeated measures ANOVA. All of the main effects and two-way interactions were significant ($p < 0.01$).

Further post hoc tests were performed on predictive and diagnostic judgments separately. Diagnostic judgments were sensitive to number of alternatives with higher judgments for the items with few alternatives ($M = 90.7$) than for the items with many alternatives ($M = 57.3$), $t(94) = 27.9$, $p < 0.001$. Diagnostic judgments also varied across number of disablers, with higher judgments for many disablers ($M = 78.1$) than few disablers ($M = 70.1$), $t(94) = 8.9$, $p < 0.001$.

As suggested by the differing W_c judgments, predictive judgments also varied across the number of alternatives; Few alternative items ($M = 87.8$) yielded higher diagnostic judgments than those with many alternatives ($M = 76.3$), $t(94) = 6.0$, $p < 0.001$. Predictive judgments did not vary with the number of disablers ($t < 1$, *ns*). We also tested whether predictive judgments varied with the strength of W_c by dividing the 16 conditionals into two equal groups based on W_c and comparing predictive judgments. As expected, conditionals with high W_c obtained higher predictive judgments ($M = 89.1$) than those with low W_c ($M = 75.2$), $t(94) = 7.0$, $p < 0.001$.

Causal Models Interact with Structure Mapping to Guide Analogical Inference

Hee Seung Lee (heeseung@ucla.edu)

Keith J. Holyoak (holyoak@lifesci.ucla.edu)

Department of Psychology, University of California, Los Angeles
Los Angeles, CA 90095 USA

Abstract

We recently proposed a theoretical integration of analogical transfer with causal learning and inference (Lee & Holyoak, 2008). A Bayesian theory of learning and inference based on causal models (Lee, Holyoak & Lu, 2009) accounts for the fact that judgments of confidence in analogical inferences are partially dissociable from measures of the quality of the mapping between source and target analogs. The integrated theory postulates a dual role for causal relations, which can guide both analogical mapping and also subsequent inferences about the target. It follows that depending on whether or not a mapping is structurally ambiguous, dropping a preventive cause from the target can either decrease or increase confidence in the same analogical inference. We report an experiment that yielded data in close agreement with predictions of the Bayesian theory. These results provide further support for the importance of integrating analogical transfer with the broader framework of causal models.

Keywords: analogical inference; causal models; mapping; Bayesian modeling.

Introduction

Analogical transfer plays a key role in scientific reasoning (Dunbar & Fugelsang, 2005). Indeed, in some areas of science in which experimental research is impossible, such as historical ethnography, analogy may provide the only viable mechanism for evaluating hypotheses. Talalay (1987) gives the example of interpreting the function of strange clay fragments discovered in Neolithic Greek sites: individual female legs, apparently never attached to torsos, that had been manufactured in pairs and later broken apart. The best clues to their function have come from other cultures in which similar tokens are known to have served to seal contracts and provide special evidence of the identity of the bearer (in feudal China, for example, a valuable piece of jade would be broken in two to mark a contract between a master and his vassal, with each keeping one piece so they could later be matched). Here the known function in a source domain has a *causal* connection to the form of relevant artifacts, and the ethnographer makes the analogical inference that a similar cause may have operated in the target domain (see Bartha, 2010).

The general question faced by a reasoner using analogy to make inferences is: Given prior knowledge at various levels of abstraction, including one or more examples that serve as source analogs, what is the probability that any potential inference about a target analog is true? For analogical inferences that involve empirical claims about the world (e.g., scientific hypotheses), answering this question depends on at least two basic subprocesses: deciding how

the causally-relevant elements of the source analog(s) relate to elements of the target (structure mapping), and using the corresponding causal relations suggested for the target to estimate the probabilities of potential inferences about the target (causal inference). In the above ethnography example, mapping is required to relate the two pieces of a broken jade object to the two parts of a broken piece of pottery; causal inference is required to evaluate the probability that the clay fragments could achieve a function analogous to that achieved by a divided jade object.

Both structure mapping and causal inference have received considerable attention within cognitive science. Mapping has been the central focus of many models of analogical reasoning (e.g., Falkenhainer, Forbus & Gentner, 1989; Holyoak & Thagard, 1989; Hummel & Holyoak, 1997). Causal learning and inference have also been studied extensively, with theoretical work largely based on the framework of *causal models* (Pearl, 1988; Waldmann & Holyoak, 1992; Waldmann, Holyoak & Fratianne, 1995). The power PC theory (Cheng, 1997) provides a quantitative explanation of how the strengths of probabilistic causal relations can be learned from contingency data. More recently, this theory has been extended based on a Bayesian formulation (Griffiths & Tenenbaum, 2005; Lu et al., 2008). Theories of category-based induction have also been enriched by adopting the framework of causal models (e.g., Ahn, 1999; Kemp, Goodman & Tenenbaum, 2007; Sloman, 1994; Rehder, 2009).

Integrating analogical inference with causal models

We have proposed that a more complete understanding of analogical transfer requires specifying the role played by causal models (Lee & Holyoak, 2008; Lee, Holyoak & Lu, 2009). Figure 1 schematizes causal models for a source (left) and target analog (right). The nodes represent variable causes (C) and effects (E). The superscripts (S , T) indicate the source and the target, respectively. The links represent the causal structure (only linked nodes have direct causal connections). The vectors w_i represent the causal polarity (generative or preventive) and the causal strength for links. A key assumption is that analogical transfer involves using causal knowledge of the source to develop a causal model of the target, which can in turn be used to derive a variety of inferences about the values of variables in the target. Causal relations in Bayesian causal models can carry information about existence of causal links (e.g., causal structure) and distributions of causal strength, as well as about the generating function by which multiple causes combine to influence effects.

Figure 1: Framework for analogical transfer based on integrating mapping with causal models. Dotted lines indicate knowledge transferred from source to target (see text).

In our theory, the first step in analogical inference is to learn a causal model of the source. The source model is then mapped to the initial (typically impoverished) representation of the target. Based on the mapping, the causal structure and strengths associated with the source are transferred to the target, creating or extending the causal model of the latter. The model of the target can then be “run”, using causal reasoning to derive inferences about the values of endogenous variables in the target. Accordingly, as summarized in Figure 1, the four basic components in analogical inference are: learning of a causal model for a source (step 1); assessment of the analogical mapping between the source and a target (step 2); transfer of causal knowledge from the source to the target based upon the analogical mapping to construct the causal model of the target (step 3); and inference based on the causal model of the target (step 4).

To generate predictive inferences (from causes to their effect), let C^S denotes the information that the source has a background generative cause, B^S , plus additional generative and preventive causal factors. (In this paper, vectors are indicated by bold font.) C^T provides analogous information about possible causes in the target. In predictive inference, the model estimates the probability of an effect occurring in the target, $E^T = 1$, based on initial information about the source, (C^S, E^S) , and the target, C^T . The unknown causal strength of the target is represented by w^T . The basic equation for predictive inference is

$$\begin{aligned}
 & P(E^T | C^T, E^S, C^S) \\
 &= \sum_{w^T} P(E^T, w^T | C^T, E^S, C^S) \\
 &= \sum_{w^T} P(E^T | w^T, C^T) \sum_{w^S} [P(w^T | w^S, E^S, C^S, C^T) P(w^S | C^S, E^S)]
 \end{aligned}
 \tag{Equation 1}$$

where the rightmost term on the right side of the equation, $P(w^S | C^S, E^S)$, captures the learning of a source model from observed contingency data (step 1 in Figure 1). Recent computational studies have developed detailed models that estimate distributions of causal strength by combining priors and observations (Griffiths & Tenenbaum, 2005; Lu et al.,

2008). The middle term, $P(w^T | w^S, C^S, C^T)$, quantifies knowledge transfer based upon analogical mapping (steps 2 and 3 in Figure 1). We model the probability of transfer as

$$\begin{cases} P(w_i^T = w_i^S) = 1, & \text{if } C_i^T \text{ matches } C_i^S \\ P(w_i^T = w_i^S) = 0, & \text{otherwise} \end{cases}
 \tag{Equation 2}$$

where C_i^S and C_i^T represent the i th cause variables in the source and target, respectively. If the mapping of C_i^T to an element in the source is ambiguous (as will be the case for the materials we use in the experiment reported here), then Eq. 2 will simply sum over the transfer result obtained when C_i^T matches each of the alternative source elements, weighted by the probabilities of each of these possible matches.

The leftmost term, $P(E^T | w^T, C^T)$, uses knowledge from analogical transfer and observations about the presence of causal factors in the target to estimate the probability of the effect in the target (step 4 in Figure 1). For binary variables, this probability can be directly computed using the Bayesian extension of the power PC theory (Cheng, 1997; Griffiths & Tenenbaum, 2005; Lu et al., 2008).

Mapping and Causal Inference

Although causal relations have sometimes been assumed to have special importance in guiding mapping (Holyoak, 1985; Hummel & Holyoak, 1997; Winston, 1980), models of analogical transfer have generally treated inference as a direct extension of mapping. In contrast, our causal-model approach postulates a deeper role for causal knowledge in transfer (Lee & Holyoak, 2008).

The present study sought to demonstrate a direct interaction between mapping and causal inference, which is predicted by our Bayesian theory. According to the integrated theory, a causal relation in the target potentially plays a dual role: it first may guide structure mapping between the source and target; then if mapping succeeds, it will also guide causal inference based on the resulting causal model of the target. In the present study we investigated analogical transfer when the mapping between the source and target was in some cases structurally ambiguous (cf. Spellman & Holyoak, 1996).

More specifically, we examined how presence or absence of a certain causal relation (preventive cause in this study) in the target might increase or decrease inductive strength depending on whether the structural mapping is clear or ambiguous. The source analog included a preventive cause, which might or might not be also included in the target. When the mapping is clear, the expected effect of inclusion of the preventive cause is evident in that presence of a preventive cause will decrease inductive strength in target, as shown in previous studies (e.g., Lee & Holyoak, 2008). However, when the mapping is ambiguous, and if the preventive cause is able to resolve the mapping ambiguity, the expected result will be reversed. The materials were designed so that when the mapping was ambiguous, the

inclusion of the preventive cause in the target provided sufficient structural information to resolve the ambiguity, and hence allow transfer of causal structure from source to target. Conversely, if the preventive cause were omitted from the target, the mapping ambiguity would be left unresolved, thereby impairing transfer of a causal model from source to target. In such situations our Bayesian model predicts that including the preventive cause in the target will actually *increase* inductive support for the occurrence of the effect that it actually tends to prevent. No previous analogy model predicts this type of interactive impact of causal and structural constraints on analogical transfer.

Experiment: Can a Preventive Cause Either Decrease or Increase the Judged Strength of the Same Analogical Inference?

Method

Participants Forty-five undergraduate students at the University of California, Los Angeles participated in the experiment to fulfill a course requirement. Each participant was randomly assigned to one of eight different sets of materials generated for counterbalancing purposes.

Design and materials The source story described a biochemist's findings about an imaginary liver disease called "tibulosis", found in rats. The disease had two different subtypes, "Type A" and "Type B", described as being caused by different factors and exhibiting quite different symptoms. The scientist had identified several factors that determine whether or not rats might develop either Type A or Type B tibulosis. For each type, certain hormones, enzymes, and antibodies were involved. Participants were asked to carefully study the biochemist's findings using a verbal description and diagram presented in the booklet in order to determine what characteristics are likely to produce or prevent the development of each type of the disease. Participants were then given descriptions of human patients with a liver disease, and asked to apply what they had learned about tibulosis in rats to judge the probability that the human patients had tibulosis Type A or Type B.

In the source, the two disease subtypes were designed to create a potential mapping ambiguity. The two types had identical causal structures except for the names of causal elements, but with one critical structural difference involving a preventive cause. Each source included two generative causes, one preventive cause, and an effect (consistent with a common effect model; Waldmann & Holyoak, 1992). The two generative causes were certain types of hormones and enzymes and the preventive cause was a certain type of antibody. In each case the preventive cause was narrow in scope (Carroll & Cheng, 2009), in that it served to stop the causal impact of one of the two generative causes but not the other. The description of the causal structure for Type A tibulosis was as follows:

Factors influencing development of Type A tibulosis

Hormone A tends to stimulate the production of enzyme A, and vice versa.

Hormone A tends to PRODUCE Type A tibulosis.

Enzyme A also tends to PRODUCE Type A tibulosis.

The immune system sometimes PRODUCES antibody A in response to enzyme A, but never in response to hormone A.

Antibody A tends to PREVENT enzyme A from producing Type A tibulosis. However, antibody A provides no protection against the direct effect of hormone A on Type A tibulosis.

To aid comprehension of the causal structure, a schematic diagram was provided right below the description. Figure 2 depicts the causal structure for Type A, described above. Hormone A and enzyme A are two generative causes that both tend to produce the effect, type A tibulosis. Antibody A is a preventive cause with narrow scope, which prevents enzyme A (but not Hormone A) from producing the effect. The B subtype was very similar to the A subtype described above, except that the effect was "type B tibulosis" (rather than type A), and the names of the hormone, enzyme and antibody were also B. The critical structural difference between the two sources was that in the B version, the immune system was described as producing antibody B in response to hormone B, but never in response to enzyme B (opposite to the situation in the A version); furthermore, antibody B tended to prevent the effect of hormone B (not enzyme B).

In the target story, participants read reports about human patients who might have a human form of Type A or Type B tibulosis. Examination reports for seven patients were constructed. Each examination report included information about a hormone, an enzyme, and (in some versions) an antibody found in each patient. A 2 x 2 within-subjects design was employed, resulting in four basic versions of the target descriptions. The first independent variable was whether the target description was *specific* or *generic*. In the specific condition, specific names of the hormone, enzyme, and antibody (e.g., hormone A, enzyme A, antibody A) were explicitly stated in the description of the patient report provided in the target. Given that these names matched those for one of the two subtypes described in the source,

Figure 2: An example of a causal structure for one of two disease subtypes included in the source analog used in the experiment.

the mapping of the human case to Type A (or B) tibulosis as described in the source was accordingly transparent.

In contrast, in the generic condition, specific names of the hormone, enzyme, and antibody were not provided. Instead, each was simply described by its general categorical description (i.e., hormone, enzyme, and antibody). Thus in the absence of additional structural information, there was no basis for preferentially mapping the description of the factors observed in the human patient onto those related to Type A versus Type B tibulosis in rats.

The above manipulation of the target description was crossed with a second independent variable, *presence* or *absence* of the preventive cause (antibody) in the description of the human patient. Recall that the critical structural difference between Type A and Type B tibulosis as described in the source was that for Type A, the *enzyme* produced the antibody, which then acted to block the *enzyme's* impact; whereas for Type B, it was the *hormone* that produced the antibody, which then acted to block the *hormone's* impact. In the P-present condition, the target description included analogous information about the human case. For example, in the specific, P-present condition, the description might state:

Hormone A and enzyme A are present, and each stimulates production of the other.

The immune system produced antibody A in response to the enzyme (but not the hormone).

More critically, in the generic, P-present condition, the description stated:

A hormone and an enzyme are present, and each stimulates production of the other.

The immune system produced an antibody in response to the enzyme (but not the hormone).

Note that even though no specific names are provided, the above generic, P-present description (based on the second statement in the description) provides structural information sufficient to disambiguate the mapping between the human case in the target and the disease descriptions for rats as stated in the source. That is, only Type A tibulosis involves an antibody produced in response to an enzyme, which then blocked the enzyme's effect. Any of the major models of structure mapping (e.g., Falkenhainer et al., 1989; Hummel & Holyoak, 1997) would be able to use the structural information provided in the generic, P-present condition to resolve the potential ambiguity and identify a determinate mapping between the disease described in the target and one of the two subtypes described in the source. Accordingly, this condition would be essentially identical to the specific, P-present condition if participants could resolve mapping ambiguity using the preventive cause.

In the P-absent versions (both specific and generic), the second statement in the relevant description was simply replaced with "no antibody is present". Critically, in the generic, P-absent condition, no information was provided that could possibly serve to resolve the structural ambiguity inherent in the mapping; hence the target case could be mapped to either Type A or Type B in the source. If a

preventive cause plays a dual role in analogical transfer, as the integrated theory postulates, then in this experiment its inclusion will have a paradoxical influence on the judged probability of an effect in the target. Specifically, given a specific description of the target, inclusion of the preventive cause will *decrease* the judged probability of the effect (by acting as a preventer within the causal model of the target); but given a generic description of the target, its presence will *increase* the judged probability of the same effect (by serving to disambiguate the mapping so that a causal model of the target can in fact be constructed).

For each condition except the generic, P-absent condition, two patient reports were constructed, resulting in seven patient reports in total. For each of the first three conditions, one of the two patient reports supported mapping to type A, and the other supported mapping to type B. Because the generic, P-absent condition did not support mapping to one type over the other, only one version of this patient report could be constructed. Two different sets of materials were constructed by counterbalancing whether the hormone or the enzyme produced an antibody in type A and in type B. Within each set, four different orders of targets were constructed, resulting in eight versions of materials in total.

Procedure Participants were given a booklet that included the source story, the target story, and a series of inference tasks. First, participants read the source story about a biochemist's findings about a new liver disease found in rats, and studied what factors were likely to produce or prevent the development of two types of the disease based on the verbal descriptions and diagrams.

In the generic conditions (but not in the specific conditions), a mapping task was included before the inference task to check if the potential mapping ambiguity was resolved or not. This task required identifying the generic hormone as "hormone A", "hormone B", or "can't tell". The analogous question was also asked about the generic enzyme. For the analogical inference task, participants were given the examination reports for seven different patients. For each, participants were asked to judge how likely it was that the patient had each disease type. To answer each question, they were to imagine there were 100 cases with the same known characteristics as for the specific case, and judge how many of these 100 cases would be expected to have each type of the disease.

Results and Discussion

On the mapping task, 33 of the 45 participants reported the structurally-justified mappings for the hormone and enzyme in the generic, P-present condition. The other 12 participants gave a variety of responses in this critical condition. We analyzed the results both including and excluding data from those participants who made mapping errors. As the basic pattern was the same in both sets of analyses, we will report the analysis including all participants.

For each patient case, participants estimated both the probability that the patient had Type A of the disease and the probability that the patient had Type B. The format

encouraged participants to treat the two types as mutually exclusive, and assignments of Type A versus Type B were fully counterbalanced across conditions. To code the responses on the inference task, we defined the “correct” disease type as that supported by the preferred mapping in the three unambiguous conditions (specific, P-present; specific, P-absent; and generic, P-present). This same disease type (either A or B) was defined as “correct” in the matched generic, P-absent condition (in which neither answer was inherently preferred).

The mean rated probability of the correct effect for each of the four conditions is shown in Figure 3 (left). These data were analyzed using a 2x2 analysis of variance in which both target description (specific vs. generic) and presence of the preventive cause (P-present vs. P-absent) were within-subjects variables. A significant main effect of specificity of the target description was obtained, $F(1, 44) = 123.09$, $MSE = 302.52$, $p < .001$, in that inference strength was significantly higher when the description was specific ($M = 83.03$, $SD = 16.09$) than when it was generic ($M = 54.26$, $SD = 17.70$). The main effect of presence of the preventive cause was not significant, $F < 1$. Most importantly, a significant interaction was obtained between target specificity and presence of preventive cause, $F(1, 44) = 79.66$, $MSE = 281.49$, $p < .001$, implying that the presence of a preventive cause had a different impact on analogical inference depending on the ambiguity of the mapping. When the description of the target was specific so that the mapping to one of the disease types in the source was transparent, participants gave significantly higher estimates of the probability of the correct effect in the P-absent condition ($M = 92.42$, $SD = 13.99$) than in the P-present condition ($M = 73.63$, $SD = 28.52$), $t(44) = 4.02$, $p = .001$. This result replicates previous findings (Lee & Holyoak, 2008; Lee et al., 2009), in that dropping a preventive cause from the target increased the strength of a predictive inference. In contrast, when the target description was generic, the effect of including the preventive cause was reversed. The estimated probability of the correct effect was now higher in the P-present condition ($M = 67.19$, $SD = 29.63$), where the preventive cause served to disambiguate the mapping, than in the P-absent condition, ($M = 41.33$, $SD = 23.89$), where the mapping was structurally indeterminate, $t(44) = 4.28$, $p < .001$.

Comparison of Bayesian Model to Human Data

We used our Bayesian model to provide a more quantitative account of our findings. The basic model was identical to that outlined by Lee et al. (2009), as summarized earlier. To fit the specific causal structures used in the present experiment, people were assumed to have no prior knowledge about causal structure or strength of the source; hence the stated causal relations were assigned a uniform strength distribution ranging between 0 and 1. Because no further information about the causal strengths was provided in the source, these distributions remained uniform (no updating based on examples), so that in effect only causal

structure, not strength, was available to be transferred to the target. Based on Equation 2, causal links with uniform strength distributions were directly transferred from the source to the target analog when the mapping was determinate. Thus in the three unambiguous conditions (specific, P-present; specific, P-absent; and generic, P-present), the causal model for the correct effect was transferred to the target. In the ambiguous condition (generic, P-absent), the model summed over predictions made for each of the potential mappings to the two alternative sources, weighting them equally.

Given the general assumptions of the Bayesian version of the power PC theory (Lu et al., 2008), the predicted probability of the correct effect in the target, given the source, can be derived analytically without estimating any free parameters. To do so, the functional form of the preventive cause (a noisy-AND-NOT function) was applied in a manner that reflected the appropriate narrow scope of the preventer (Carroll & Cheng, 2009). The influences of the causes were integrated sequentially. After applying a noisy-AND-NOT function to integrate the influence of the preventer with that of its related generative cause, a noisy-OR function was applied to combine this intermediate result with the influence of the other generative cause and an assumed background cause. Figure 3 (right) depicts the parameter-free predictions of the Bayesian model. The quantitative fit was good, $r(2) = .93$. When data from just those participants who solved the mapping task correctly were modeled, the fit increased slightly, $r(2) = .94$. The model captures the trade-off that arises in the generic, P-present condition, where the presence of the preventer exerts a positive influence on analogical transfer by guiding the mapping, but then reduces transfer somewhat by acting to prevent the effect within the causal model created for the target. Also, the model makes identical predictions for the specific, P-present and generic, P-present conditions. This pattern is consistent with human response patterns in that most participants gave the same ratings for these two conditions. In the generic, P-absent condition, due to the unresolved mapping ambiguity, the probability that the effect occurs in the target is predicted by the sum of its

Figure 3: Mean probability of the correct effect in each condition. Left: human data; right: predictions derived from Bayesian model. Error bars represent 1 standard error of the mean.

probabilities based on each possible source, weighted by the probability of the mapping between the target and each source (equally weighted with probability of .5). Again, this prediction appears to be consistent with human response patterns, which primarily consisted of giving equal probability ratings for the two alternatives (i.e., 50/50) in this condition.

Conclusion

Our experiment demonstrated that the inclusion of a preventive cause in the target had an opposite impact on the judged probability of an effect in target, depending on whether or not the source-target mapping was ambiguous in the absence of the preventer. When the mapping was transparent (because objects in the target were described in the same specific terms as the corresponding objects in the source), inclusion of the preventive cause in the target decreased inference strength, as observed previously (Lee & Holyoak, 2008). However, when the mapping was potentially ambiguous (because objects in the target were described in generic terms), and the preventive cause provided structural information sufficient to disambiguate the mapping, then inclusion of the preventive cause in the target increased inference strength.

This pattern of interaction was predicted by our Bayesian theory (Lee et al., 2009), adding to the empirical and theoretical evidence supporting the importance of integrating theories of structure mapping with the framework provided by causal models (Waldmann & Holyoak, 1992). This type of integrated theory may provide deeper insight into many aspects of analogical inference, including its role in both the generation and evaluation of scientific hypotheses.

Abstract

We present a model of symbol manipulation implemented using spiking neurons and closely tied to the anatomy of the cortex, basal ganglia, and thalamus. The model is a general-purpose neural controller which plays a role analogous to a production system. Information stored in cortex is used by the basal ganglia as the basis for selecting between a set of inferences. When an inference rule is selected, it commands the thalamus to modify and transmit information between areas of the cortex. The system supports special-case and general-purpose inferences, including the ability to remember complex statements and answer questions about them. The resulting model suggests modifications to the standard structure of production system rules, and offers a neurological explanation for the 50 millisecond cognitive cycle time.

Keywords: decision making; neural production system; neural engineering; cognitive architectures

Introduction

The primary goal of our ongoing research is the creation of a biologically realistic neural cognitive architecture. Such an architecture would provide an explicit and quantitative connection between cognitive science and neuroscience. Bridging these fields leads to benefits in both directions; aspects of a cognitive theory can predict and be constrained by neurological details, and the neurological details can in turn identify important modifications to cognitive theory.

In this paper, we present a model of sequential symbolic reasoning implemented using 373,000 simulated spiking neurons. The connectivity of these neurons, their neural parameters, and their associated neurotransmitters are fixed based on neurological evidence from the basal ganglia, thalamus, and cortex. By adjusting the synaptic connections of neurons at the inputs and outputs of the basal ganglia, we can define the inferences that the system will follow. Since these rules can be adjusted for a wide variety of IF-THEN symbol manipulation tasks, we believe that our model is the first biologically realistic general-purpose neural controller that can play a role analogous to a production system.

The model involves the basal ganglia, the thalamus, and various cortical areas. The cortex holds a variety of information about the current situation, such as visual input and the contents of working memory. The basal ganglia performs action selection, taking information from the cortex to determine which of the rules is most appropriate to use in the current situation. This choice is sent to the thalamus, which acts as a routing system, implementing the effects of those rules by transferring information between

cortical areas. As the information stored in the cortical areas changes, different actions will be selected in turn, allowing for controlled and organized sequences of actions.

To present this model, we first provide a brief description of the Neural Engineering Framework (NEF; Eliasmith and Anderson, 2003), a general method for organizing realistic spiking neuron models so as to represent and transform information. This is used to derive the optimal synaptic connections (under neurological constraints) for creating our model. Next, we introduce Vector Symbolic Architectures (VSAs; Gayler, 2003), a method for efficiently encoding symbolic structures as high-dimensional fixed-length vectors. This is used to encode structured information in the cortex and to represent the IF-THEN rules themselves.

Given these tools, we then define the three anatomical components of our model (cortex, basal ganglia, and thalamus). This includes specifying the neurological parameters of the neurons involved, such as the neurotransmitters used. This is important for providing accurate timing predictions from our model, since various neurotransmitters have varying characteristic time constants.

We demonstrate our model performing three separate tasks: repeating the alphabet, repeating the alphabet starting from a particular letter, and answering questions using working memory. For each of these tasks we use exactly the same neural model; the only differences are the sensory inputs to the system.

Finally, we provide two conclusions that connect cognitive theory and neuroscience. First, we show that particular types of IF-THEN rules are more efficient to implement in spiking neurons, leading to a possible modification of standard production system-based theories. Second, we show that the time needed to select an action is determined primarily by the re-uptake rate of the neurotransmitter GABA in the basal ganglia, thus providing a neurological explanation for the 50-millisecond cognitive cycle time commonly found in behavioural results.

Neural Engineering Framework

To build a complex neural model, we need a method for determining how neurons can represent and transform information. We use the Neural Engineering Framework (NEF; Eliasmith and Anderson, 2003), which generalizes established findings on how sensory and motor neurons represent multidimensional information. This allows us to treat a group of neurons as representing a single vector of arbitrary length. By adjusting the connectivity between

groups of neurons, we can indicate how these representations should be changed over time.

The basic assumption of the NEF is that within a neural group, each neuron has a preferred value \mathbf{e} (for *encoding*) to which it responds most strongly (i.e. fires most quickly). As the difference between the actual value and the preferred value increases, this firing rate will decrease. If the value to be represented by the neurons is \mathbf{x} , this behaviour can be captured in terms of the amount of ionic current J flowing into the neuron given by Equation 1. Adjusting the neuron gain α , the background input current J_{bias} , and the preferred direction vector \mathbf{e} allows us to capture a wide range of known neural tuning curves.

$$J = \alpha \mathbf{e} \cdot \mathbf{x} + J_{bias} \quad (1)$$

In the simplest case, 100 neurons could represent a 100 dimensional vector \mathbf{x} by having each \mathbf{e} be a different unit vector in each of the 100 dimensions. This would provide a completely local representation of each value in the vector. More realistically, 100 neurons could represent one or two dimensions by having \mathbf{e} values chosen randomly (i.e. uniformly distributed around the unit hypersphere in that many dimensions). This approach has been observed in numerous areas of visual and motor cortex (e.g. Georgopoulos et al., 1986). The advantage of having more neurons than there are dimensions is that the amount of representational error can be controlled. Neurons are highly stochastic devices, but we have previously shown that the overall error is inversely proportional to the number of neurons per dimension (Eliasmith & Anderson, 2003).

Using Equation 1 to set the amount of input current to a particular neuron to represent a particular value, we can use existing models of neuron behaviour to determine the resulting spike times. There are an extremely wide variety of suitable neuron models, from Hodgkin-Huxley-type models up to extremely detailed compartmental models. For this model, we use a standard Leaky Integrate-and-Fire model, where input current causes voltage inside the neuron to gradually build up until it reaches a threshold, at which point it fires, producing a spike. Thus, given a particular vector, we can determine the resulting sequence of spikes.

We can also perform the opposite operation: given a sequence of spikes we can estimate the original vector. As shown elsewhere (Eliasmith & Anderson, 2003), this can be done by deriving the decoding vectors \mathbf{d} as per Equation 2, where a_i is the average firing rate for neuron i with a given vector \mathbf{x} , and the integration is over all values of \mathbf{x} .

$$\mathbf{d} = \Gamma^{-1} \mathbf{Y} \quad \Gamma_{ij} = \int a_i a_j d\mathbf{x} \quad \mathbf{Y}_j = \int a_j \mathbf{x} d\mathbf{x} \quad (2)$$

The resulting vectors \mathbf{d} can be used to determine an estimate of the represented value using Equation 3, where $h(t)$ is the current produced in a post-synaptic neuron by the pre-synaptic neuron firing at time $t=0$, and $t_{i,n}$ is the time that the i^{th} neuron fired for the n^{th} time.

$$\hat{\mathbf{x}}(t) = \sum_{i,n} \delta(t - t_{i,n}) * h_i(t) \mathbf{d}_i = \sum_{i,n} h(t - t_{i,n}) \mathbf{d}_i \quad (3)$$

This is an estimate that varies over time based on the individual spikes. Importantly, it is the *optimal* estimate

when under the constraint that the estimate must be built by linearly adding the effects of the post-synaptic currents caused by each spike. This is the constraint for other neurons receiving these spikes, so Equation 3 gives the optimal reconstruction of the vector by another neuron.

As a consequence of this, the decoding vectors \mathbf{d} provide an extremely important tool that is at the heart of the Neural Engineering Framework. We can use \mathbf{d} and \mathbf{e} to derive *optimal synaptic connection weights* to perform particular mathematical manipulations on the encoded information. If one group of neurons represents \mathbf{x} and we want another group to represent some particular linear transformation of this value (i.e. $\mathbf{y} = \mathbf{M}\mathbf{x}$), then we simply set the synaptic connection weights \mathbf{w} as per Equation 4.

$$\mathbf{w}_{ij} = \alpha_j \mathbf{e}_j \mathbf{M} \mathbf{d}_i \quad (4)$$

For nonlinear functions, we can modify Equation 2 to produce decoding vectors $\mathbf{d}^{f(\mathbf{x})}$ that optimally approximate any nonlinear function $f(\mathbf{x})$, as shown in Equation 5.

$$\mathbf{d}^{f(\mathbf{x})} = \Gamma^{-1} \mathbf{Y} \quad \Gamma_{ij} = \int a_i a_j d\mathbf{x} \quad \mathbf{Y}_j = \int a_j f(\mathbf{x}) d\mathbf{x} \quad (5)$$

This approach allows us to create complex neural models where we directly derive the necessary synaptic connection weights, rather than relying on a particular learning rule.

Vector Symbolic Architectures

While the NEF provides a method for representing vectors, in order to implement a cognitive model we need to represent complex symbol-like structures. That is, while we might be able to say that one particular vector represents the concept of a square, another vector represents a triangle, and another represents a particular colour, this does not address the question of how we can represent “a blue circle and a red square”.

A general approach to this problem is to use a Vector Symbolic Architecture (VSA; Gayler, 2003). There are three core ideas for all VSAs. First, each symbol is represented by a particular high-dimensional vector. For our purposes, we randomly choose these vectors, but they could also be selected based on semantic and sensory knowledge. Second, two vectors can be combined by superposition (+) to produce a new vector that is *similar* to both of the original vectors. Third, two vectors can be combined by binding (\otimes) to produce a new vector that is *dissimilar* to both of the original vectors.

This binding operation can be reversed by binding with the inverse of a vector ($\hat{\cdot}$), such that $\mathbf{A} \otimes \mathbf{B} \otimes \hat{\mathbf{B}} \approx \mathbf{A}$. These operations are similar to standard addition and multiplication in terms of being associative, commutative, and distributive.

For our model, we chose a particular VSA known as Holographic Reduced Representations (HRRs; Plate, 2003). For this, superposition is performed by vector addition and the binding operation is circular convolution. These operations can be efficiently implemented in spiking neurons using synaptic connections calculated using the NEF (Eliasmith, 2005) and Equations 4 and 5, above.

With such a system we can represent symbol trees by combining superposition and binding. For example, we can find a vector to represent “a blue circle and a red square” by performing the following calculation:

$$\text{blue} \otimes \text{circle} + \text{red} \otimes \text{square}$$

The result is a single vector of the same dimensionality as the vectors for the basic symbols (**blue**, **red**, **square**, etc.). This one vector can be interpreted as a representation of the entire structure because it is possible to extract the original components. For example, to determine which object is red, we take the whole vector and bind it with the inverse of **red**.

$$\begin{aligned} & (\text{blue} \otimes \text{circle} + \text{red} \otimes \text{square}) \otimes \text{red}^* \\ &= \text{blue} \otimes \text{circle} \otimes \text{red}^* + \text{red} \otimes \text{square} \otimes \text{red}^* \\ &\approx \text{blue} \otimes \text{circle} \otimes \text{red}^* + \text{square} \end{aligned}$$

The result is a vector that is similar to **square**, but is not exactly the same since it has an additional term superposed on it. Due to the properties of the binding operation, however, **blue** \otimes **circle** \otimes **red**^{*} will be a vector that is highly dissimilar to all of the original symbols, and can be treated as randomly distributed noise. We have previously shown how spiking neuron models can remove this noise (Stewart, Tang, & Eliasmith, 2009).

The Model

Basal Ganglia

The basal ganglia is generally believed by both neuroscientists (e.g. Redgrave et al., 1999) and cognitive scientists (e.g. Anderson et al., 2004) to be responsible for action selection. That is, given a wide variety of possible options as to what to do next, a single one must be chosen. This can be thought of as a winner-take-all mechanism: each option will have a numerical value indicating how relevant (or how beneficial) each action is in the current context, and the best of these should be chosen. Although winner-take-all mechanisms are common in neural models, there are few that adhere to the biological constraints of the basal ganglia, and none we are aware of that use realistic spiking neurons.

Figure 1: Basal ganglia model with three possible actions. Light lines are excitatory connections. Dark lines are inhibitory (based on Gurney et al., 2001, Figure 5).

While we have previously investigated simple mutual inhibition approaches for winner-take-all (Stewart & Eliasmith, 2009), for our current model we adapt work by Gurney, Prescott, and Redgrave (2001). As shown in Figure 1, the D1 cells in the striatum inhibit corresponding cells in the globus pallidus internal (GPI) and substantia nigra reticulata (SNr), while the subthalamic nucleus (STN) sends a broad excitatory signal to the GPI/SNr and globus pallidus external (GPe). The GPe and the D2 cells in the striatum act as a control signal on the excitation from the STN, adjusting it so that the correct amount of excitation is provided to select a single action. Each of these connections is well-documented anatomically, and the model's behaviour matches neurological results in rats and monkeys both with and without particular lesions (Gurney et al., 2001).

However, the Gurney et al. model uses idealized piecewise-linear non-spiking neurons that respond instantly without any random variation to changes in their inputs. We thus adapt their model, replacing individual idealized neurons with groups of realistic leaky-integrate-and-fire (LIF) spiking neurons. For our neurons, the membrane time constant (τ_{RC} ; controlling the amount of current leaking out of the neuron) was fixed at 20ms, and the α and J_{bias} values were randomly chosen constrained by the reported response properties given by Gurney et al., including background firing rates of 60-80Hz and maximum firing rates of 400Hz. All synaptic connections were derived using Equation 4. We use 20 neurons to replace one ideal neuron (circle in Figure 1), so 100 neurons are needed per possible action.

The behaviour of this model is shown in Figure 2. The inputs to the model (top) are the desirability of three different actions. The firing response of the output of the basal ganglia (bottom) is shown as these inputs change over time. As in the actual basal ganglia, the output is inhibitory, so an action is selected by *turning off* the appropriate output neurons, stopping them from performing their inhibition. It should be noted that this output lags behind the input due to the time constants of the post-synaptic current caused by different neurotransmitters. In this case, the excitatory connections use glutamate with AMPA receptors (2ms; Spruston et al., 1995), and the inhibitory connections use GABA (10ms; Gupta et al., 2000).

Figure 2: Inputs and outputs (GPI) of our basal ganglia model. The largest valued input consistently causes the corresponding output neurons to stop spiking.

Cortex

For the tasks under consideration in this paper, we need a visual area (for representing the current visual scene), a motor area (for producing outputs from the model), and a working memory (for storing a statement and questions to be answered). Each of these is implemented as 10,000 spiking neurons, storing a 250 dimensional VSA vector as per the NEF. We present stimuli to our model by injecting current into the visual area (**V** in Figure 3) using Equation 1. We can examine the contents of any area of the cortex by decoding the activation (Equation 3) and measuring the similarity (dot product) between the resulting vector and an ideal calculated vector. The closer this value is to 1.0, the more accurate the representation.

To perform general purpose tasks (such as question answering), our model contains two working memory areas: **A** and **B**. In order to maintain information over time, these areas contain connections back to themselves as per Equation 4 where **M** is the identity matrix. This forms the basis of an integrator model of memory, which has previously been used to model somatosensory working memory (Singh & Eliasmith, 2006). Areas **A** and **B** are also connected to two other neural groups **C** and **D** such that $\mathbf{C} = \mathbf{A} \otimes \mathbf{B}$ and $\mathbf{D} = \mathbf{A} \otimes \mathbf{B}'$. These connection weights are defined using Equation 5, where $f(\mathbf{x})$ is the circular convolution (see Eliasmith, 2005 for details). This allows the system to compute the VSA operations that are needed to perform symbol manipulation.

Thalamus

The only mechanism in our model for modifying the contents of the working memory areas and the motor areas is the thalamus. If the thalamic areas are all zero then no information is transferred between cortical areas. If the thalamic area corresponding to working memory **A** is set to some value (via the basal ganglia), then this value will be sent to cortical area **A**, using synaptic connections from Equation 4 with **M** as the identity matrix. Crucially for information transfer, if the thalamic area controlling the connection between **V** and **A** is set to **X**, then the value $\mathbf{V} \otimes \mathbf{X}$ will be sent to **A**.

Figure 3: Thalamus and cortex model. Circles are 10,000 neurons representing 250 dimensional vectors (**V**=vision; **M**=motor; **A**,**B**,**C**,**D**=working memory). \otimes are 40,000 neurons computing the binding operation.

Modelled Tasks

Fixed Sequences of Actions

The simplest task to perform with this model is sequentially going through a list of items, such the alphabet. We implement this by defining 25 rules of the following form:

IF working memory contains **letter+A**

THEN set working memory to **letter+B**

We create the IF portion of a rule by setting the synaptic connections between the working memory area of cortex and the striatum and sub-thalamic nucleus. Each component of the basal ganglia has a group of neurons corresponding to each rule (the dark circles in Figure 1). We set the input synaptic weights using Equation 4, where **M** is the vector corresponding to the IF portion of the rule (**letter+A**).

To implement the THEN portion of the rule, we set the synaptic connections at the output of the basal ganglia. In this case, we create a group of neurons that connect to the thalamic neurons that feed to working memory. We again use Equation 4 to set these weights, with **M** set to be the vector corresponding to **letter+B**. We then connect the group of neurons in the GPi that correspond to this rule to these new neurons. Because GPi is inhibitory, this connection will cause the new neurons to not fire at all, except in the case that the action selection system in the basal ganglia chooses this particular action. In that case, the inhibition will be turned off (as those GPi neurons will stop spiking), allowing **letter+B** to be sent to working memory. This in turn will cause the next rule to be selected, and so on. It should be noted that our model does not yet include the phonological loop, so any timing influence it may have on producing this sequence is not taken into account.

To test the model, we initialize it by forcing current into the working memory neurons as per Equation 1 such that they will represent **letter+A**. After this, all subsequent activity is due to the interconnections between neurons. Figure 4 shows the model correctly following the alphabet sequence. From the spiking pattern we see that the correct action for each condition is successfully chosen by turning off the appropriate inhibitory neurons in the GPi.

Figure 4: Contents of working memory (top) and spiking output from GPi indicating the action to perform (bottom).

Variables and Generic Rules

The previous section demonstrated that our model is capable of implementing rules where a specific pattern is sent to a specific part of cortex. While these sorts of rules may account for some kinds of highly specialized behaviour, most symbolic cognitive architectures assume that it is possible to have *general-purpose* rules. That is, these rules can contain variables, such as the following, where **?X** represents an unknown variable:

IF visual cortex contains **letter+?X**

THEN set working memory to **letter+?X**

The presence of this sort of rule in addition to the ones in the previous section would allow the model to start going through the alphabet starting from any letter. We would simply present the particular letter we wanted it to start from to the visual cortex (**letter+F**) and it would copy this value to working memory and continue from there.

While the above method is the standard approach for expressing this sort of rule, in order to implement it in our model, we need to slightly reformulate it as the following:

IF visual cortex contains **letter+?X**

THEN copy visual cortex to working memory

This rule has exactly the same effect as the first one. To implement it, we use the same approach as in the previous section. The synaptic connection weights for the inputs to the basal ganglia are set using Equation 4 with **M** as the vector for **letter**. For the output, instead of connecting to the parts of the thalamus which send information directly to cortical areas, we connect to the neural group which gates connections between these cortical areas. If we set this to the identity vector **I**, then working memory will now contain **V⊗I=V**. This has the effect of routing information between cortical areas.

The result of this model when **letter+F** is placed in the visual cortex is shown in Figure 5. The model correctly starts repeating the alphabet from F. Changing the visual stimulus to some other letter will start from there, demonstrating that the rule can apply to multiple situations.

Figure 5: Contents of working memory (top) and spiking output from GPi indicating the action to perform (bottom). The *look* action takes information from visual cortex (in this case, **letter+F**) and routes it to working memory.

Question Answering

For the final task, we consider question answering. We perform this by first presenting the model with a symbolic statement such as the following:

statement + blue⊗circle + red⊗square

This would indicate a blue triangle and a red square are all in the visual field. The statement is presented to visual cortex for 50ms, and it will use the following rule to move it into working memory, as in the previous section:

IF visual cortex contains **statement+?X**

THEN copy visual cortex to working memory

After the statement is shown for 50ms, we stop stimulating visual cortex for another 50ms. This means that the system must successfully keep the statement in working memory over this time. After this time, we present a question to the visual cortex, such as the following:

question + red

A separate rule is defined for dealing with this situation:

IF visual cortex contains **question+?X**

THEN copy visual cortex to working memory B and also copy from working memory D to motor cortex

This rule copies the question to a separate area of working memory (B). As described previously (see Figure 3), this area allows a vector to be combined with the current contents of working memory. Furthermore, this rule also copies information from a third area of working memory (D) to the motor cortex. Since area D is connected to A and B so as to store the result of convolving area A (the statement) with the inverse of area B (the question), it should contain the answer to the question.

The results of this model answering two different questions from the same remembered statement are given in Figure 6. These two generic rules can answer any question provided in this format. Previous work on the capabilities of neural implementations of VSAs (Stewart, Tang, & Eliasmith, 2009) indicates that this system will scale well to 8 or more terms in a statement, out of a total vocabulary of 100,000 possible terms.

Figure 6: Answering two different questions starting from the same statement. The similarity between the contents of motor cortex and 7 possible answers is shown. The correct answer is chosen in both cases.

Implications

The model presented here helps to bridge the gap between cognitive science and neuroscience. It allows us to transform symbolic rules (the basis of much of cognitive theory) into specifications for the synaptic connectivity between neurons in cortex, basal ganglia, and thalamus. The resulting models give detailed predictions about the timing of events and the spiking behaviour of the neurons involved. With such models, we can also predict performance accuracy and the effects of various types of neurological damage.

The model also addresses a long-standing concern in cognitive science as to how neurons can possibly support the rich cognitive capabilities that seem clearly based on symbols and symbol manipulation. Specifically, we suggest that a VSA approach to representing symbols can be implemented in spiking neurons, and that these representations can be manipulated in a controlled and generic manner. We are aware of no other neural model with this flexibility, scalability, and connection to the underlying neurophysiology.

Rule types

Bridging cognitive science and neuroscience provides more than a mere neural implementation of cognitive theory. For our model, it has also suggested possible modifications to cognitive theory. When implementing the rules, we changed them from including explicit variables into commands to transform and copy the information currently represented in various parts of visual and working memory. If our future applications of this model continue to find this approach to rule definition sufficient for a wide variety of cognitive tasks, then we would argue this may be a more suitable framework for expressing cognitive rules than the standard variable-binding approach.

Timing

Our model is also highly constrained by known neurological data; the characteristics of the neurons involved and their connectivity are based on empirical results. As such, we can predict results that were previously derived purely by parameter fitting. For example, in most production system models of cognition (Soar, GOMS, EPIC, ACT-R, etc.), a certain amount of time is needed to select and apply an action. Based on empirical evidence, this is normally fixed to be 50 milliseconds (e.g. Anderson et al., 1995).

As can be seen in Figure 4 and Figure 5, our model requires just under 50 milliseconds to select and apply an action. While the median time needed is 44 milliseconds, the mean time for our current model is 48 milliseconds, due to the model occasionally repeating a step. These times are not affected by the size of our model, but can be changed by adjusting the time constant for the inhibitory neurotransmitter GABA in the basal ganglia. We currently use a value of 10ms (Gupta et al., 2000), and are seeking more detailed results from this area of the basal ganglia.

Conclusion

We presented a large-scale (373,000 spiking neuron) model capable of exhibiting rule-like behaviours such as question answering. By representing the conditions for applying inference rules as VSA vectors, and by representing the effects of those rules as vector transformations between cortical areas, we have shown a generic method for controlling neurally realistic cognitive systems.

Our ongoing work explores the broader capabilities of this model, including scaling up the number of rules (only 100 neurons need to be added per rule), and exploring the accuracy of the question answering as the vocabulary size increases. Other neural areas can also be added, including full vision and motor systems, as well as long-term memory.

Abstract

Hubel Weisel models of the cortex describe visual processing as a hierarchy of increasingly sophisticated representations. While several models exist for image processing, little work has been done with Hubel Weisel models out of the domain of object recognition. In this paper, we describe how such models can be extended to the representation of concepts, resulting in a model that shares several properties with the PDP model of semantic cognition. The model that we propose is also capable of incremental learning, in which the knowledge is stored in the strength of the neuron connections. Degradation of old knowledge occurs as new knowledge is introduced to the system in a fashion that simulates decay theory in short term memory. The simulation model therefore captures several properties of cognitive conceptual memory, including generalization patterns, the role of rehearsal and, hierarchical representation.

Introduction

There exist several bottom-up approaches to hierarchical models of object recognition that are based on the visual cortex. They make use of Mountcastle's (1978) theory of uniformity and hierarchy in the cortical column and the model of simple to complex cells of Hubel and Weisel (1965), modeling how simple cells from neighboring receptive fields feed into the same complex cell, meaning that the complex cell has phase invariant response.

In this paper, we consider the following question. If the structure of the cortical column is uniform and hierarchical in nature and if the model of simple to complex cells can be used to model the visual cortex as discussed in prior works, then can such a model also be used to represent other modalities of information such as the concepts derived from text? We are therefore aiming to design a bottom up hierarchical memory for the representation of concepts, much the same way as it is designed for the representation of images. In this paper, we will define a concept as being a keyword in a document.

To deal with the dynamic nature of concept inputs, we look at incremental learning of concepts from two aspects relevant to concept representation from text – (a) with respect to new incoming features and (b) training of hierarchies. To perform this, we apply a set of geometric approximations to the incremental inputs and

the existing memory, such that the new memory can be acquired without damage to the old ones.

Related work

Mountcastle (1978) showed that parts of the cortical system are organized in a hierarchy and that some regions are hierarchically above others. In general, neurons in the higher levels of the visual cortex represent more complex features with neurons in the IT representing objects or object parts (Hubel and Weisel, 1965). Hubel Weisel models have therefore been developed for object recognition (Cadieu et al., 2007; Fukushima, 2003) proposing a hierarchy of feature extracting simple (S) and complex (C) cells that allow for positional invariance. The combination of S-cells and C-cells, whose signals propagate up the hierarchy allows for scale and position invariant object recognition.

The idea of feature based concept acquisition has been well studied in psychological literature. Sloutsky (2003) discusses how children group concepts based on, not just one, but multiple similarities, which tap the fact that those basic level categories have correlated structures (or features). This correlation of features is also discussed in McClelland and Rogers (2003) who argue that information should be stored at the individual concept level rather than at the super ordinate category level allowing properties to be shared by many items.

Our model is related to Hubel Weisel approaches in that it implements a hierarchical modular architecture for bottom-up propagation of conceptual information. To our knowledge, however, this is the first implementation of a Hubel Weisel approach to non-natural medium such as text, and has attempted to model hierarchical representation of keywords to form concepts.

System architecture

The system that we describe here is organized in a bottom up hierarchy. This means that the component features are represented before the representation of concept objects. Our learning algorithm exploits the property of this hierarchical structure. Each level in the

hierarchy has several modules. These modules model cortical regions of concept memory. The modules are arranged in a tree structure, having several children and one parent. In our paper, we call the bottom most level of the hierarchy level 1, and the level increases as one moves up the hierarchy. The keywords from a document form the inputs to the system. These are directly fed to level 1. Level 1 modules resemble simple cells of the cortex, in that they receive their inputs from a small patch of the input space. Several level 1 modules tile the input space, possibly with overlap. A module at level 2 covers more of the input space when compared to a level 1 module. It represents the union of the input space of all its children level 1 modules. However, a level 2 module obtains its inputs only through its level 1 children. This pattern is repeated in the hierarchy. Thus, the module at the tree root (the top most level) covers the entire input space, but it does so by pooling the inputs from its child modules. In the visual cortex, the level 1 can be considered analogous to the area V1 of the cortex, level 2 to area V2 and so on.

Learning the first batch of information

To understand how the model learns, let us consider the inputs and outputs of a single module $m_{k,i}$ in level k of the system as shown in Figure 1a. Let \mathbf{x} , representing connections $\{x_j\}$ be the input pattern to the module $m_{k,i}$. \mathbf{x} is the output of the child modules of $m_{k,i}$ from the level $k-1$, and \mathbf{a} represent the weights of the competitive network. The vector \mathbf{a} is used to represent the connections $\{a_j\}$ between \mathbf{x} and the cells in the module $m_{k,i}$. The output of a neuron in the module $m_{k,i}$ is given by $u = \sum_j a_j x_j$.

Figure 1a. Inputs and outputs to a single module $m_{k,i}$. b. The concatenation of information from the child modules of the hierarchy to generate inputs for the parent module

During learning, each neuron in $m_{k,i}$ competes with other neurons in the vicinity. Of the large number of inputs to a given module, a neuron is activated by a subset of them. The neuron then becomes the spatial center of these patterns. To ensure that there are no garbage neurons, we adopt in our creation of the module, a model of Growing SOM (GSOM) (Alahakoon et al., 2000).

When all the modules at level k finish training, the second stage of learning occurs. This comprises the

process by which the parent modules learn from the outputs of the child modules. Here, consider the case shown in Figure 1b where the module 3 is the parent of modules 1 and 2. Let $\mathbf{x}(1)$ be the output vector of module 1 and $\mathbf{x}(2)$ be the output vector of module 2. $\mathbf{x}(i)$ represents the Euclidean distance from the input pattern to the each output neuron i of the child modules. The input to module 3, $\mathbf{I}(3) = \mathbf{x}(1) || \mathbf{x}(2)$, is the concatenation of the outputs of modules 1 and 2. A particular concatenation represents a simultaneous occurrence of a combination of concepts in the child module. Depending on the statistics of the input data, some combinations will occur more frequently, while others will not. During the second stage of learning, the parent module learns the most frequent combinations of concepts in the levels below it. A GSOM is again used in the clustering of such combinations. The learning process thus defined can be repeated in a hierarchical manner.

Incremental learning

In this and the subsequent sections of the paper, we will use the terms *batch 0* to represent the first batch of documents. *Batch 1* refers to the subsequent set of documents. Once the system learns the documents in *batch i*, only the hierarchical structure and the neuron architecture are retained. All other information regarding the documents presented is discarded.

Incremental learning poses a challenge in Hubel Weisel based computational models due to three reasons. (1) Damage to the knowledge represented by old neurons which is fundamental in competitive learning. (2) Propagation of information in the hierarchical architecture. The number of output neurons of each child node increases with the introduction of the incremental batch. The input dimensions of the parent node are therefore changed and incompatible with the dimensions of the previous batch. (3) The irregularity in the input data dimensions. Where keywords are defined as concepts to be processed by the system, the keywords in an incremental batch will not be a subset of those in the previous batch. The architecture therefore has to provide rules for the generation and growth of new modules with respect to incoming incremental data.

Preventing Damage to Old Memories: This problem is tackled using a sampling method using pseudo data inspired from Liu et al (2008). The algorithm implemented summarizes data distribution in a cluster map. Given neuron \mathbf{a} in a GSOM of N neurons, consider the closest neuron \mathbf{b} , $\mathbf{a}, \mathbf{b} \in N$, their midpoint is given by $\mathbf{a} + \mathbf{b}/2$. We generate a random set of vectors around neuron \mathbf{a} , bounded on both sides by $\mathbf{a} + \mathbf{b}/2$. These pseudo vectors generated during the

training of batch k implicitly reconstruct the data used to train batches 0 to $k-1$.

Incremental learning in a hierarchy Let us consider Figure 2, where the modules α and β are child modules of γ . At batch 0, the training sets \mathbf{x}_α and \mathbf{x}_β , consisting of p_0 patterns each are used to generate the neurons \mathbf{y}_α and \mathbf{y}_β .

$$\forall i \in p_0, \mathbf{x}_{\gamma,i} = [|\mathbf{x}_{\alpha,i} - \mathbf{y}_\alpha| || |\mathbf{x}_{\beta,i} - \mathbf{y}_\beta|] \quad (1)$$

is passed to node γ . The vectors \mathbf{x}_α , \mathbf{x}_β and \mathbf{x}_γ are then discarded.

Figure 2. (a) Incremental learning stages. At batch 0, the training patterns at level 1, \mathbf{x}_α and \mathbf{x}_β cluster to form the neurons \mathbf{y}_α and \mathbf{y}_β . For simplicity, we consider that only one neuron is generated after training batch 0. (b) Batch 1 and the approximation of the pseudo vectors $\hat{\mathbf{x}}_\alpha$, $\hat{\mathbf{x}}_\beta$ and $\hat{\mathbf{x}}_\gamma$

When batch 1, consisting of p_1 vectors is now introduced, $\hat{\mathbf{x}}_\alpha$ and $\hat{\mathbf{x}}_\beta$ are approximated from \mathbf{y}_α and \mathbf{y}_β respectively and used along with the new batch to train the GSOM modules α and β . After training, the neurons of the level 1 nodes \mathbf{y}_α and \mathbf{y}_β adapt to \mathbf{y}'_α and \mathbf{y}'_β . A set of pseudo data $\hat{\mathbf{x}}_\gamma$ are approximated from the neuron \mathbf{y}_γ .

From equation 2, $\hat{\mathbf{x}}_\gamma$ represents the Euclidean of $\hat{\mathbf{x}}_\alpha$ and $\hat{\mathbf{x}}_\beta$ from \mathbf{y}_α and \mathbf{y}_β respectively, i.e, for a set of p_0' pseudo data,

$$\forall i \in p_0', \hat{\mathbf{x}}_{\gamma,i} = [|\hat{\mathbf{x}}_{\alpha,i} - \mathbf{y}_\alpha| || |\hat{\mathbf{x}}_{\beta,i} - \mathbf{y}_\beta|] \quad (2)$$

However, during the training of batch 1, the measure for $\hat{\mathbf{x}}_\gamma$ should be the distance to \mathbf{y}'_α and \mathbf{y}'_β , the updated neuron vectors. A set of adapted pseudo vectors $\hat{\mathbf{x}}_\gamma'$ should therefore be approximated.

In Euclidean space, we can visualize the problem as shown in Figure 3,

Figure 3. Approximation of incremented pseudo vector for levels 2 and above in the hierarchy

We consider two cases, (a) \mathbf{y}' is not the winning neuron for the pattern \mathbf{x} . (b) \mathbf{y}' is the winning neuron.

Case (a). \mathbf{y}'_α is not the winning neuron, i.e, $R < d$

For ease of analysis, assume that $d=1$

$$D \cong \frac{1}{\pi} \int_0^\pi |\mathbf{y}'(\theta) - \mathbf{x}| d\theta$$

$$D \cong \frac{1}{\pi} \int_0^{\frac{\pi}{2}} |\mathbf{y}'(\theta) - \mathbf{x}| + |\mathbf{y}'(\pi - \theta) - \mathbf{x}| d\theta$$

Where $f(\theta) = |\mathbf{y}'(\theta) - \mathbf{x}| + |\mathbf{y}'(\pi - \theta) - \mathbf{x}|$,

$$D \cong \frac{1}{\pi} \int_0^{\frac{\pi}{2}} f(\theta) d\theta \quad (3)$$

$$f(\theta) = \sqrt{(1 - \cos\theta R)^2 + (\sin\theta R)^2} + \sqrt{(1 + \cos\theta R)^2 + (\sin\theta R)^2}$$

Let $a = |\mathbf{y}'(\theta) - \mathbf{x}|$ and $b = |\mathbf{y}'(\pi - \theta) - \mathbf{x}|$

We obtain

$$f(\theta) = \sqrt{2}\sqrt{1 + R^2 + ab} \quad (4)$$

Where $E_0 = ab$,

$$E_0 = \frac{\sqrt{(1 - \cos\theta R)^2 + (\sin\theta R)^4 + \sin^2(\theta R)[2 + 2\cos^2\theta]}}{(11)}$$

$$\cong 1 - \frac{\cos^2(\theta R)}{2} + \frac{3\sin^2(\theta R)}{2} \quad (5)$$

Substituting (5) into (4), we obtain

$$f(\theta) = 2 \left(1 - \frac{R^2}{8} + \frac{1}{2} \sin^2(\theta R) \right) \quad (6)$$

Substituting (6) into (3), we obtain

$$D = 1 + \frac{R^2}{8} + \frac{R^2}{\pi} \int_0^{\frac{\pi}{2}} \sin^2 \theta d\theta \quad (7)$$

Solving (7), we have

$$D = 1 + \frac{3R^2}{8} \quad (8)$$

Based on Figure 3, if we approximate a $\theta = \pi/2$, we obtain $D = 1 + \frac{R^2}{2}$. In implementation, to satisfy (8) we use the inequality (9) to assign the value of θ .

$$\frac{4\pi}{9} < \theta < \pi/2 \quad (9)$$

We can therefore conclude that, a θ value specified by inequality (9) can be used to re-generate the dataset $\hat{\mathbf{x}}_{\gamma,1}[0,1, \dots, j, \dots, k_\alpha]$, where $\hat{\mathbf{x}}_{\gamma,1}[j] \equiv |\hat{\mathbf{x}}_{\alpha,1} - \mathbf{y}'_\alpha|$ and \mathbf{y}'_α is not the winning neuron.

Case (b): \mathbf{y}'_α is the winning neuron

If \mathbf{y}' is the winning neuron, a random value of θ , $0 < \theta < \pi$ can be used to regenerate $\hat{\mathbf{x}}_{\gamma,1}[j] \equiv |\hat{\mathbf{x}}_{\alpha,1} - \mathbf{y}'_\alpha|$, where \mathbf{y}'_α is the winning neuron.

Dealing with the problem of new input dimensions:

A rule based approach of creating a new module to process the new keywords is preliminarily proposed to deal with the dynamically increasing input dimensions. A module is trained and connected to parents only if the number of concepts that it represents increases above a predefined threshold. In order to avoid overcrowding, heuristic rules have been put into place such that a parent has atmost three children.

Experimental results

To illustrate the cognitive properties of the training model, we train the system using 21 concepts from 200 documents. The concepts included ideas such as “birds”, “animals”, “flowers”, “trees” etc, same as the ones used by McClelland and Rogers (2003). The following preprocessing was performed to the documents. First, the contents were analyzed and the stopwords removed. The concept terms were stemmed and grouped using Wordnet (Fellbaum, 1998) before a tf.idf weighing scheme was used to select the most relevant concepts to the batch. For visualization purposes,

Hierarchical identification of concepts from wiki documents

Figure 4. The number of concept neurons at the top of the hierarchy vs. the number of features per bottom level module

In this section we observe how our hierarchical model captures the properties of semantic cognition outlined by McClelland and Rogers (2003, 2008). The training data used by McClelland and Rogers is intuitively designed based on common sense knowledge. Our system, on the other hand is trained using information from 200 text descriptors of the concepts from wikipedia. The snippets varied in length from 50 word descriptions to 500 word descriptions. Figure 4 illustrates the number of concept neurons at the top level as a function of the ratio of the number of features to each level 1 module and the total number of features. When there are only two layers in the hierarchy, a larger number of concept neurons (16) are generated. The number of concept neurons converges to between 6 and 8 for all other architectures. Typically, for a six

concept cluster, the concept of penguin is separate from that of other clusters. This is shown in Figure 6.

Figure 5. Euclidean distance between various concepts vs. the number of training epochs

In Figure 5, we observe the evolution of the Euclidean distance between concepts. The training shows empirical properties of convergence. The distances between the various concepts are stable after 500 epochs of training. We can also observe promising results from the concept representation point of view. For instance, the Euclidean distance between “pine” and “oak”, for instance, is larger than the Euclidean distance between “birch” and “oak”, which belong to the same family.

Figure 6.a shows the top two levels of a five level hierarchy of hierarchy of concepts obtained (10 concepts per GSOM module and 160 concepts used in training). We observe, as is the result in McClelland and Rogers that similar concepts tend to be near each other in space. For instance, “canary” and “sparrow” tend to be closer to each other, but far from “penguin”. In some cases, super ordinate terms, such as “bird”, “tree” etc are mined as part of the hierarchy. There are some interesting observations that can be made here. We can see that the highest level (level 5) shows general concepts while level 4 shows the concepts one level lower. i.e., while the neuron 1 refers to “animals”, the neuron box “2” refers to more detailed differentiation of neuron 1. Further to this, the system also shows some intermediate level categorization characteristics that taps item frequency effects. In McClelland and Rogers’ paper, they describe it as the process by which certain descriptive terms such as “tree”, “bird” and “dog” tend to be acquired earlier than the super ordinate terms such as “plant” or “animal” or more specific terms such as canary, pine or poodle. The general consensus for this is that parents use certain intermediate level words more frequently when speaking to children. As such, intermediate concepts, based on their frequency of usage, are also clustered more tightly into intermediate groups within super ordinate concepts.

In the experimental data, some concepts were used more frequently than others of the same sub category. These include birch (12 instances) vs. 10 instances of pine and maple, 16 instances of rose vs. 3 instances of

daisy and 7 instances of sunflower. It is seem that the more frequent concepts are tied together with the super ordinate concept neuron (dog is tied with animal, rose with flower, sparrow with bird) and so on.

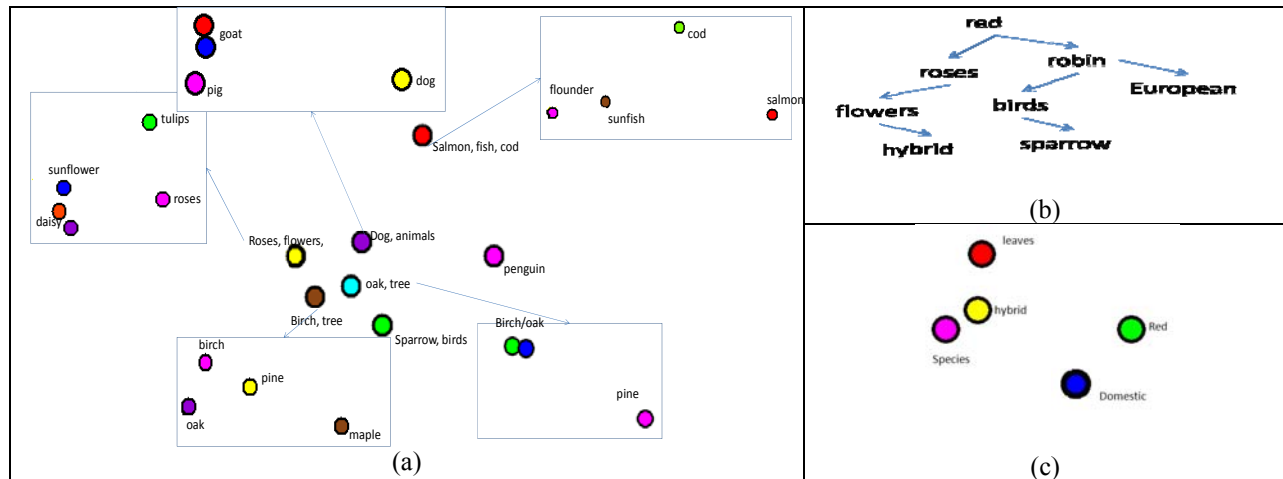

Figure 6 (a) Hierarchical representation of the 21 concepts in the memory system. (b) Grouping due to secondary characteristics – “leaves” groups all trees, “red” for rose, salmon etc. (c) Associative retrieval of concepts based on activation of high correlation neurons in the hierarchy.

At the lower level, we can also observe alternate similarity grouping which are based on individual features. For instance, at level 1 module, one might observe neurons denoting concepts such as “leaves” grouping birch, maple and oak. The concept “grow” groups objects of all categories. “Red” indicates objects that are red – rose, cod, salmon. One such lower layer representation is shown in Figure 6.c.

From these results, one can expect this model to perform a sort of associative retrieval of the kind that humans perform. For instance, if one sees the concept “gold”, one would think of perhaps “ring” and subsequently “marriage” and then “family”, “children” and so forth. In the same way, firing of the neuron “red” at level 1 will lead to firing of corresponding nodes at various levels. This will lead to other concepts being fired, both sequentially and parallelly. For instance, probing the model with “red” leads to the sequential firing as described in Figure 6.b.

Each concept can, in turn, be used as a probe to activate relevant neurons. In this sense, the model describes the human chain of thought process. Work is in progress to study how this process can be modeled and how the firing can be controlled by the wiring strength between modules.

Incremental learning performance

Overview of incremental learning with 5 concepts and 3 batches: In this section, instead of introducing all the concepts are one go, concepts are learnt in batches. The figure below shows the evolution of the incremental concept network at the top level for the first three batches (a) tulips and sunflowers only (b) sparrow and sunfish (c) salmon. In batch 1, the top level

generalizes, creating concept representation of flower and animal. Lower layers now portray the differentiated concepts. In batch 2, the concept of salmon was introduced. At this juncture, the old information from sunfish is sub grouped under fish and sparrow is considered a separate entity. These experiments suggest merit in the approximations that we have described earlier in the paper.

Figure 7. The top-level evolution of incremental concept representation. (a) Batch 0: tulip and sunflower. (b) Batch 1: sparrow and sunfish. (c) Batch 2: salmon

Hierarchical representation in incremental learning

In this experiment, concepts were introduced one by one, beginning with “birch” and “cod”. At some juncture concepts are reintroduced to investigate the effect of new data and rehearsal on old data. Some of the results obtained are discussed in this section.

Figure 8a shows the evolution of how the concepts “birch” and “betula” are represented (“Betula” is the scientific name for “birch”). Birch is the first concept that was introduced to the system. At batch 0, the distinction between the concepts “birch” and “betula” appears in level 3 of the hierarchy. To the system, “betula” and “birch” are two distinct concepts, though with a low Euclidean distance of 39.81. When batch 2 is introduced, the distinction between the two concepts moves one level lower to level 2 and eventually to level 1. However, as more concepts are introduced to the system, the presence of the new information makes the system lose the distinction between the concepts “birch”

and “betula”, and the Euclidean distance between the concepts reduces to 0 at batch 7. However, at batch 10, when the concept of birch is reintroduced, the Euclidean distance between the two terms increases

before gradually decreasing to 0 once again. A similar result is also observed in the relationship between terms “canary” and “islands”.

Figure 8. Evolution of the hierarchical and Euclidean relationship between the concepts (a) “birch” and “betula” vs “canary” and “islands” (b) “Birch” and “cod” vs. “birch” and “dog” (c) “dog” and “flounder” vs. “goat” and “dog”

Figure 8b shows the representation of the concept “birch” with respect to the concepts “dog” and “cod”. “Birch” is introduced to the system at batch 0, “cod” at batch 1 and “dog” at batch 4. The differentiation between the concepts “birch” and “cod” is at level 4 and converges to level 3. By batch 8, the concepts of “dog” and “cod” are of the same distance from “birch”. At this juncture, the system at level 3 no longer distinguishes between “birch”, “cod” and “dog”, but makes a distinction between “plant” and “animal”. Figure 8c shows a similar relationship of concepts “dog” with the concepts “flounder” and “goat”. The flounder-dog distinction converges to level 2 (from Figure 8b, we can see that the plant-animal distinction occurred at level 3) while the dog-goat distinction converges to level 1. The Euclidean distance between the concept terms “dog” and “goat” converges to approximately 700 which is close to the value that is obtained through batch learning (from Figure 5).

Conclusions and further work

In summary, our model attempts to propose a hierarchical Hubel Weisel model for the acquisition of concepts from text such that the concepts are represented in a hierarchical connectionist network. The result is a new framework that we have applied in two scenarios. The first is concept acquisition where we have shown that the system is able to represent everyday concepts in a hierarchical fashion, in a manner similar to the PDP model. The system was interestingly also able to perform chain retrieval, in that when “red” was given as a probe to the system, it was able to retrieve “robin” and by association “sparrow”. Secondly, we have modeled information approximation and incremental learning, which models some properties of short term memory.

There are several directions for further work in this area. In addition to the pertinent issues of improving computation time and processing algorithms to make the system able to handle large sets of data, one important direction is the incorporation of semantic information into the hierarchical architecture. As of

now, this information is ignored and only the statistical properties of keywords are taken into consideration in the generation of the concept hierarchy. Work is under process to integrate semantic information into the model. Work is also under progress to include common sense knowledge in the model. We expect that these additions will make the model more cognitively accurate. In addition to this, we are also incorporating other aspects of cognition such as attention; interest etc to study the generation and behavior of the cognitive map.

Abstract

Semantic priming involves a combination of automatic processes like spreading activation (SA) and controlled processes like expectancy and semantic matching. An alternative account for automatic priming has been suggested using attractor neural networks. Such networks offer a more biologically plausible model of real neuronal dynamics but fall short in explaining several important effects such as mediated and asymmetrical priming, as well as controlled effects. We describe a new attractor network which incorporates synaptic adaptation mechanisms and performs latching dynamics. We show that this model can implement spreading activation in a statistical manner and therefore exhibit all priming effects previously attributed to automatic priming. In addition, we show how controlled processes are implemented in the same network, explaining many other semantic priming results.

Keywords: Semantic priming; Attractor networks; Latching dynamics

Introduction

Semantic priming is one of the most important phenomena in the study of word perception and semantic memory. In a typical priming experiment (Neely, 1991), subjects are visually exposed to two words in succession, the prime and the target, and are required to silently read the prime and either name the target (pronunciation task), or decide whether it is a real word or not (lexical decision task). The target could either be semantically related or unrelated to the prime (or a nonword, in case of the lexical decision task). The priming effect is expressed as shorter average reaction times (RT) and reduced error rates in the related relative to unrelated condition. Sometimes, a neutral prime is used (e.g. a row of X's) to allow the differentiation between response facilitation (in the related condition) and inhibition (in the unrelated condition).

Computational accounts for semantic priming are divided between models based on automatic processes and those based on controlled processes. The most famous among the automatic accounts for priming is the spreading activation (SA) theory of Collins & Loftus (1975). This model suggests that concepts in semantic memory are represented by

nodes that are connected to each other according to their semantic relatedness. When a concept is activated (by external or internal input) the activity spreads to related concepts (see figure 1). In priming experiments, activation of the prime concept (e.g. *table*) leads to activation of its related concepts (e.g. *chair*). This pre-activation facilitates the recognition of subsequent related targets. If an unrelated or a neutral target appears, no such head-start is available. Hence spreading activation may account for the facilitation component of semantic priming. Automatic priming can also be conceived in attractor networks with distributed representations of concepts (e.g. Mason, 1995). In such models concepts are represented by activity patterns of neurons' assemblies and semantic relationship is implemented as correlation between these representations. When the prime appears, the network converges on its corresponding activity pattern. When the target is then presented, the network changes its activity pattern from that of the prime to the one corresponding to the target. If the target is related to the prime, fewer changes need to take place due to the correlations; therefore, the convergence takes less time and a priming effect emerges.

Attractor networks are probably more true to the biological nature of real neuronal dynamics which include content-addressable memories, distributed representations and attractor states. However, they fall short in explaining several important priming results. Mediated priming is one example (e.g. McNamara, 1992): It was found that word pairs which are indirectly related to each other (i.e., related only through a mediating word, like *lion* and *stripes*, related through *tiger*) can nevertheless prime each other. Allowing activation to spread to more than one step, SA theories could easily account for such effects. Attractor networks, on the other hand, cannot explain mediated priming since the activation patterns of indirectly related pairs are not correlated. Similarly, whereas SA models allow asymmetric connections between nodes and therefore allow asymmetric priming (in which the magnitude of priming varies according to which word in a given pair is designated prime and which is the target; e.g. *pay-check* vs. *check-pay*), such an effect cannot

be obtained by attractor network models because they rely on correlation, a symmetric trait by definition.

Here we present an attractor neural network which implements SA in a statistical manner. By doing so, we bridge between SA and attractor models and show how attractor networks can exhibit results like mediated and asymmetric priming. In addition, we discuss some controlled mechanisms like expectancy (Becker, 1980) and semantic matching (Neely, Keefe & Ross, 1989) and suggest how they may be interpreted within the same network.

Figure 1: The spreading activation theory. (A) Related concepts connected in semantic memory. (B) Activation spreads through the network

Computational Model

Following the traditional separation between stages of processing (e.g. Smith et al., 2001), our model consists of 2 computational layers, lexical and semantic (Figure 2). We assume that after a string of letters is analyzed for orthographic composition, the result is fed to the lexical network where word identification occurs. If the letters form a real word, this word is ‘recognized’ by the lexical network and its activity is fed forward to the semantic network where the word’s meaning is stored. However, the semantic network can influence lexical processing on line via feedback. Such a top-down effect contributes to semantic priming: when the semantic network is a priori ‘tuned’ to a concept with some relatedness to the newly arrived word, the lexical network recognizes this word quicker because both bottom-up and top-down pathways contribute to the recognition process (as opposed to the unrelated case, where the top-down pathway does not contribute). In the case of a neutral stimulus, none of the networks is activated and no transfer of information occurs.

The lexical and semantic networks are modeled as Hopfield-type attractor neural networks, with sparse representations and continuous-time dynamics (see Tsodyks, 1990). In our simulations, both the lexical and the semantic networks are fully connected recurrent networks, each composed of 500 neurons. Memory patterns (concepts) encoded by each network are binary vectors of size 500, with ‘1’ indicating a maximally active neuron, and ‘0’ an inactive one. The representations are sparse (i.e., a small number of neurons are active in each pattern) with p being the ratio of active neurons ($p \ll 1$). The connectivity between neurons assures stability of these patterns. External inputs to and from the network are always excitatory.

The neurons themselves are analog with activity in the range $[0,1]$ and obey a logistic transfer function of their local input $h(t)$. The local input itself obeys a linear differential equation (following Herrmann, Ruppel & Usher, 1993) of the form:

$$(1) \tau_n \dot{h}_i(t) = -h_i(t) + \sum_{j=1}^N J_{ij} x_j(t) - \lambda \cdot (\bar{x}(t) - p) - \theta + [I_i^{ext}(t) - \theta^{ext}]_+ + \eta_i$$

In (1), τ_n is the time constant of the neuron, $x_j(t)$ the activity at time t of the j -th neuron (with \bar{x} indicating average over all neurons), J_{ij} is the connectivity weight, N is the number of neurons (500 in our case), p is the sparseness of the representations, λ a regulation parameter which maintains stability of mean activation, and θ is a constant neuronal threshold (See Herrmann et al. for details). The $[\dots]_+$ symbol indicates a threshold linear function, such that $[x]_+ = 0$ for $x < 0$, and $[x]_+ = x$ otherwise. This leads the external input to the neuron, $I_i^{ext}(t)$, to be consequential only if it surpasses the constant external threshold θ^{ext} . Finally, η_i is a noise term drawn from a Gaussian distribution with some temporal correlations. Relatedness between concepts is implemented in the model as correlations between memory patterns (reflecting the degree of overlap between them). The stronger two concepts are related, the higher is their correlation. The correlation of unrelated patterns is negligible ($|c| < 0.05$ with c being the correlation)

Two major differences distinguish the lexical from the semantic network. First, while the semantic network includes correlated memory patterns representing semantic relations between concepts, there are no correlations in the memory patterns of the lexical network. This is not to indicate there are no lexical relations (such relations obviously exist), but merely to ensure that they would not influence the simulations. Indeed, typical semantic priming experiments do control for such confounds by selecting prime-target pairs that bare no lexical/phonological relations.

The second difference is, perhaps, the basic premise of our model: Unlike the lexical network (and the majority of previous attractor network models), our semantic network is associative in nature. Neuronal adaptation mechanisms at the synaptic level preclude the network from maintaining stability for long; therefore, the network, after converging to one attractor, leaves it quickly and jumps to another one. This process is stochastic in nature and can continue forever as long as no new input interferes. These jumps cannot be accurately predicted, but they tend to happen (although not necessarily) between correlated patterns. Such network behavior was termed ‘latching dynamics’ by Treves (2005). Specifically, short-term synaptic plasticity was modeled according to Loebel & Tsodyks (2002), with each synaptic weight of a neuron decreasing linearly with its activity:

$$(2) \dot{J}_{ij}(t) = \frac{J_{ij}^{max} - J_{ij}(t)}{\tau_r} - U x_{max} x_i(t) J_{ij}(t)$$

In (2), J_{ij}^{max} is the common Hopfield connectivity weight for sparse networks, τ_r is the time constant of recovery of the synaptic efficacy, and U is the utilization of synaptic

resources. The term x_{max} is a hypothetical maximum firing rate of a neuron (for example 100 pulses/sec) which adjusts the equation to fit a neural firing rate bounded by 1.

Links between the lexical and semantic networks are based on connections between active neurons in corresponding patterns (See figure 2): An active neuron in a certain word pattern in the lexical network sends excitatory connections to all active neurons in the corresponding concept-pattern of the semantic network, and vice-versa. Since correlations between patterns exist in the semantic network, one neuron in that layer could concurrently influence and receive input from different neurons activated in different patterns in the lexical layer. The lexical network also receives bottom-up input, representing the visual letter-string, which follows the same logic: Neurons belonging to the pattern presented to the lexical network receive excitatory inputs, while others receive no input.

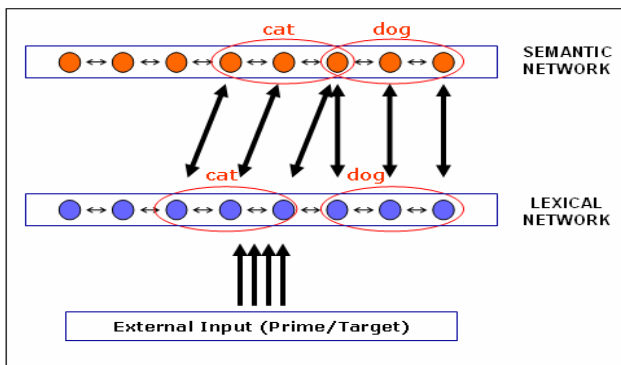

Figure 2: Architecture of the model. Two recurrent networks connected to each other with excitatory links. The semantic network contains correlated representations

Simulations

The simulations were run on an Intel Core 2 Quad CPU Q6600 with 2.4 Ghz and 2 GB of RAM. Simulations were written in Matlab 8a. In all the simulations, one numeric step represents 0.66ms.

Encoded Patterns

We encoded 17 memory patterns in each network. All patterns were binary vectors with equal mean activity and very sparse representations. In the semantic network, the following basic correlations between patterns were set: four groups, each containing four patterns, formed ‘semantic neighborhoods’ (patterns 1-4, 5-6, 9-12 and 13-16): Each pattern in a group was correlated with the other patterns in its group, but, with few exceptions (see below), no correlations existed between the groups. Correlations within a group had one of two values, representing two levels of direct relatedness. In addition, we also added some correlations between patterns of different neighborhoods to allow indirect priming investigations. For example, we added some correlation between pattern 2 and pattern 9, which

resulted in patterns 1 and 9 being indirectly related. The 17th memory pattern was a ‘baseline’ pattern which the network was initialized to at the beginning of each trial, and was not correlated to any of the other patterns. In the lexical network, all 17 patterns were unrelated to each other. The 17th pattern was, again, the initial state for the network, and was not linked through top-down or bottom up lexical-semantic connections to the baseline pattern in the semantic network (thus forming a ‘neutral’ pattern).

Experimental Procedure and Data Analysis

Each trial began with the presentation of a binary vector to the lexical network, corresponding to one of its patterns (1’s in the to-be activated neurons, 0’s in the rest). This vector served as “prime”. In neutral trials, pattern 17 (the neutral pattern) was presented. Two experiments were conducted. The first tested the general performance of the semantic network. The prime was presented for 100ms and it was always pattern no. 1. The network was allowed to advance according to the dynamic equations without further interference, for a total period of 3000ms. The procedure was repeated for 100 trials. Correlation of the momentary network state with each pattern, for each time point in the simulation, was averaged offline. The second experiment tested whether the performance of the model, when semantic priming occurs, corresponds with predictions based on human studies. The prime was presented for 100ms and followed by a target after 150 ms, hence creating a 250 ms SOA. The time interval from target onset until convergence of the lexical network indexed the reaction time, providing the network converged to the correct attractor. Primes and targets were either directly related (i.e., two patterns from the same neighborhood), indirectly related (two patterns from different neighborhoods but linked through a mediating pattern as explained earlier), unrelated (two patterns from different neighborhoods with no indirect connections), or neutral (in which the prime was the neutral pattern and the target any of the ‘real’ patterns). 100 trials were simulated for each relatedness condition, with prime-target pairs chosen randomly. Mean reaction times and standard errors were computed for each condition.

Results

Figure 3 presents the typical performance of the two networks (for presentation purposes, here we used a 1000ms SOA). Correlation of the state of each network with each of its stored patterns (including the memories and the neutral pattern) during a trial is presented in different colors, with convergence to a specific pattern indicated by its number appearing on top. The lexical network followed the external input, by converging to the corresponding memory pattern and keeping stability until a new input arrived. In contrast, the semantic network converged to the appropriate memory pattern, only to jump to other attractors in a serial manner, hence presenting latching dynamics. When a new external input arrived, the semantic network stopped its transitions and quickly converged to the corresponding memory pattern

shortly after the lexical network has done so. As evident in Figure 3, most jumps were within the neighborhood, while jumps to different neighborhoods occurred less frequently.

Figure 3: Typical behavior of the two networks

In the first experiment, trials always included pattern 1 as the prime. The mean correlation between the state of the semantic network and all its memory patterns was computed for each time point over trials. Figure 4A presents the correlations for five different time points after the prime onset. The x-axis represents different patterns according to their relatedness to pattern 1, with pattern 1 itself in the middle. Evidently, the mean correlations followed the principle of spreading activation: Initially, the concept represented by the external input has the strongest activation (correlation), its directly related concepts are activated to a smaller degree, and concepts not related to it are not activated at all. With time, as semantic transitions occur, the mean activation of the initial concept is decreasing, while activation in its related concepts increases. Indirectly related concepts also show some activation, with a delayed peak. Unrelated concepts receive no activation at all. After enough time, the mean correlation with each of the network's patterns is divided more or less equally, corresponding to a nearly deactivated state of the whole network (the mean activity would have reached near zero values in case more than 16 patterns were used).

In the second experiment, the mean RTs of the lexical network were computed and are presented in figure 4B. As can be seen, priming occurs for both directly and indirectly related pairs, although the effect is stronger in the direct case. In addition, weak relations produced smaller priming than strong relations. All these effects were significant at $p < 0.001$. There was no significant difference between the unrelated and neutral conditions, confirming that only facilitation occurred.

Discussion

The results of these simulations demonstrated that an attractor neural network with latching dynamics can implement spreading activation in a statistical manner. In a way, one could see the activity of nodes in the original spreading activation model as an average manifestation of the correlation in our attractor model. There is, however, an important distinction between our model and SA models: In our network, spreading is mixed with relaxation periods which

correspond to the network reaching an attractor. In other words, activation does not spread in a monotonic manner like in the original SA model, but rather in jumps which fit the dynamical jumps from one attractor to another.

Figure 4: Simulations results. (A) Statistical spreading activation portrayed by the network as mean correlation over trials. (B) Mean convergence times of the lexical network for the different relatedness conditions

The results of the second simulation demonstrate how the dynamics in the semantic network affects the convergence time of the lexical network such that priming effects are produced. When the semantic network state is correlated with the target pattern at the moment the target word appears, its top-down influence shortens the lexical network's convergence times. Due to semantic transitions, such correlations may occasionally appear in indirectly related trials and produce the mediated priming effect. Although not explicitly simulated, these jumps can also produce asymmetry in priming: Transition probabilities from pattern A to pattern B are not necessarily equal to those from B to A since network transitions, in general, are uniquely influenced by the other memory patterns A and B are correlated with (which can be very different for A and for B). This asymmetry allows making a distinction between semantic relatedness (as indicated by correlation) and associative relatedness (as indicated by the probability of one pattern leading to another pattern). Former attractor models relied solely on correlations between prime and target and therefore could not produce either mediated priming or asymmetry in priming.

Controlled Processes

When the SOA between prime and target is sufficiently long, subjects may decide to engage in specific strategies while responding. The general aim of such strategies is to shorten reaction times to the target. In contrast to the automatic nature of SA, strategies are considered to be under the subject's cognitive control.

A well known example of such strategies is expectancy (Becker, 1980). It is assumed that subjects may be able to realize that in part of the trials, the target is semantically and/or associatively related to the prime and develop a set of expected targets from the prime's semantic "neighborhood". When the target appears, this "expected set" is searched first, while the general lexicon is searched only if the target is not included in the expected set. Obviously, when the target is found in the expected set, its recognition time is accelerated. If it is not found there, however, its recognition is delayed by this initial screening procedure. Hence, the application of an expectancy strategy may account for both facilitation and inhibition of the priming effect. Two types of this strategy were identified (Becker, 1980): A 'prediction' strategy is used when the upcoming target is highly predictable. Only one item (or very few) is included in the expected set and, consequently, facilitation is robust while inhibition is negligible. A 'general expectation' strategy is used when more than a few items could potentially be targets and the expected set includes them all. Both facilitation and inhibition should result. However, subsequent studies have shown that not all conditions yield inhibition (for example, pronunciation tasks), which put this later strategy into question (Keefe & Neely, 1990). In either case, the requirements for this controlled process to be initiated are sufficiently long SOA and a sufficiently salient proportion of related pairs in the stimulus set (called the 'relatedness proportion') which makes such expectancies reasonable. Indeed, it was found that the relatedness proportion is positively correlated with priming, but only at long SOAs (Neely, 1991).

Controlled Processes in the Model

So far, we implicitly assumed that semantic transitions in the network happen automatically. We now turn to a different hypothesis: Semantic transitions may be controlled to some degree; therefore, while SA is the default behavior of the network when no interventions occur, other patterns emerge as soon as subjects attempt to control these transitions.

Controlling transitions can allow our model to implement the 'prediction strategy' of expectancy, if we consider the transition of the semantic network's state from a given prime pattern to another pattern as an 'expected' word for that prime. By default, such expected word is determined according to semantic relatedness principles. However, this conceptualization of expectancy makes it no different than our implementation of SA. What, then, makes expectancy a distinct mechanism? The answer is that expectancy can be modeled as the controlled operation of manipulating transition probabilities according to any information acquired by the subject up to that point, as to induce certain transitions and avoid others. For instance, expectancy can be realized by maintaining just one single transition in the semantic network (as opposed to many transitions in the default case). Another realization can be by controlling the variability of the semantic network's transitions, such that transitions will

almost always occur from the prime to its most correlated pattern (as opposed to the more stochastic nature of transitions in the default state). The first suggestion can be implemented by allowing the network to make a single jump, as usual, but then stop any further transitions by lowering the background noise. This means, of course, that noise amplitude must be susceptible to cognitive control. We suggest that this is the equivalence of 'focusing attention' on the prediction. The second suggestion can be implemented by lowering the amplitude of the temporal correlations of the noise, which may be seen as focusing attention on the most probable prediction. Each of these two manipulations, as well as their combination, may have beneficial results: In case they succeed (i.e., the target indeed turns out to be the equivalent of the pattern the network has jumped to), an increase in priming is to be expected compared to the default case since all of the activated neurons of the semantic network would participate in accelerating the response. Without such intervention, the network is much less likely to be converged on the 'right' pattern when the target arrives, which implies that on average, only a minor set of the activated neurons will participate in the acceleration of response. Naturally, if the prediction is wrong, the response might be delayed compared to the default case. Hence this mechanism should be used only when there are good reasons to assume the target is predictable, that is, when the relatedness proportion is high. Moreover, the effect of these manipulations is expected to be most conspicuous on long SOAs, since on short SOAs there is usually not enough time for a transition to occur, let alone a series of transitions.

As an illustrative example, we have repeated simulation 2 for direct, indirect and neutral primes, for short/long SOAs, but this time we manipulated the amplitude of the noise. In one condition, the noise was reduced after the first transition in the semantic network (implementing the first mechanism we suggested for expectancy). In the other condition, no such manipulation was conducted. Figure 5 presents the results. As can be seen, the manipulation increased the facilitation effect, echoing the results in the literature (e.g. Neely, 1991).

Figure 5: average convergence times of the lexical network with and without an expectancy mechanism

Another controlled process presented in the literature is semantic matching (Neely et al., 1989). This process mainly involves decision making strategies which occur after lexi-

cal access to the target is achieved. In principle, it suggests that subjects engage in comparison between prime and target, which enables them to facilitate word and nonword responses in the lexical decision task (and is also responsible, as a by-product, to inhibition in priming)

While the scope of this paper did not allow us to fully model the semantic matching mechanism (which would necessitate incorporating a decision making mechanism), we would like to point out that any comparison between prime and target must depend on the prime being constantly activated in semantic memory throughout the whole trial, which in turn may indicate that no semantic transitions should occur in the semantic network. This, of course, can be achieved in our model by assuming a reduction in the noise amplitude immediately after lexical access of the prime (as opposed to the expectancy strategy case, where such a reduction is applied only after one semantic transition). We would therefore expect the usage of semantic matching to place severe limitations on spreading activation behavior, and specifically eliminate the indirect priming effect. Interestingly, this is exactly the result found in the literature (e.g. McNamara, 1992; see Neely, 1991, for a review).

General Discussion

Our main goal in the current study was to implement classical semantic processes related to semantic priming, with an emphasis on spreading activation, in a biologically-plausible framework of attractor neural networks. The results demonstrate that the basic characteristics of SA can be embedded in attractor dynamics while maintaining the same explanatory power of the original process. In addition, we show that controlled mechanisms involved in priming such as expectancy can be implemented within the same network, where the definition of 'controlled' is narrowed to the subject's influence on some specific parameters of the network.

Our network implies that real automaticity is the product of correlated representations. Direct semantic priming is a purely automatic process since, by definition, one pattern cannot be activated without partially activating its correlated patterns. On the other hand, processes which require a transformation from one representation to another can in principle be the object of cognitive control. Indirect priming can therefore be avoided by eliminating transitions in the semantic network. Spreading activation, by this view, is best seen as a default mechanism rather than a process which is completely automatic (cf. Smith et al., 2001).

Finally, a pure mathematical interpretation of the dynamics would suggest that the nature of the transitions between patterns in our model takes the form of a Markov-chain, with the average correlation of the network with the various patterns forming a state vector and the transition probability matrix representing word association norms. Controlled strategies therefore represent a change in this matrix from the default values, based on the subject's expectations. Future inquiries may reveal the exact way by which accumulating data affect these probabilities, with Bayesian inference principles possibly governing this procedure.

Conclusion

Attractor neural networks have traditionally struggled with several important aspects of semantic priming compared to the more classical views. We have shown that an attractor network with latching dynamics can in fact implement some of these classical processes and serve as an equally competent model. The model may also be used to predict the time course of priming with SOA, which in turn could be validated by appropriate experiments. Future work will need to specify in a more precise manner the exact ways by which strategies may influence our model's dynamics and how priming is affected by them.

Cognitive Models and the Wisdom of Crowds: A Case Study Using the Bandit Problem

Abstract

The “wisdom of the crowds” refers to the idea that the aggregated performance of a group of people on a challenging task may be superior to the performance of any of the individuals. For some tasks, like estimating a single quantity, it is straightforward to aggregate individual behavior. For more complicated multidimensional or sequential tasks, however, it is not so straightforward. Cognitive models of behavior are needed, to infer what people know from how they behave, and allow aggregation to be done on the inferred knowledge. We provide a case study of this role for cognitive modeling in the wisdom of crowds, using a multidimensional sequential optimization problem, known as the bandit problem, for which there are large differences in individual ability. We show that, using some established cognitive models of people’s decision-making on these problems, aggregate performance approaches optimality, and exceeds the performance of the vast majority of individuals.

Keywords: Wisdom of crowds, Cognitive models, Bandit problem, Hierarchical Bayesian modeling

Introduction

An enticing idea in the study of individual and group decision-making is the phenomenon known as the “wisdom of crowds”. The idea is that, by aggregating the behavior of a group of people doing a challenging task, it is possible for group performance to match or exceed the performance of any of the individuals. Surowiecki (2004) provides an extensive survey of wisdom of crowds results over a diverse set of human endeavors and decision-making situations, ranging from guessing the weight of an ox at a county fair, to inferring the location of a missing submarine, to predicting the outcome of sporting events. Recent research in cognitive science has looked at issues including whether it is possible to have a “crowd within”, such that multiple estimates from the same person can be combined to improve their performance (Vul & Pashler, 2008).

While the exact conditions needed for group performance to exceed individual performance are not completely understood, it seems clear that crowds can be wise in any situation where people have some partial knowledge, and the gaps in their knowledge are subject to individual differences. Under these circumstances, aggregation of individual decisions can serve to amplify the

common signal and reduce the idiosyncratic noise, leading to superior group performance.

One challenge in producing wisdom of crowds effects arises when tasks are more complicated than estimating a single quantity, or predicting a simple outcome. Many interesting and real-world decision-making situations are inherently multidimensional or sequential. In these situations, it is often not possible to combine the raw behaviors of people, because they are not commensurate. For example, imagine trying to combine the expertise of basketball fans trying to predict the result of an eight-team single elimination tournament, with quarter-finals, semi-finals and a final. Based on their decisions about the quarter-finals, these people may be making decisions about different teams in the semi-finals and final. This makes simple aggregation based on their raw decisions impossible for the later rounds.

For more difficult decision problems like these, we believe cognitive science has a key role to play in wisdom of the crowd research. Rather than aggregating people’s behaviors, it is necessary to aggregate their knowledge, as *inferred* from their behavior. This inference needs models of cognition, accounting for how latent knowledge manifests itself as observed behavior within the constraints of a complicated task. Steyvers, Lee, Miller, and Hemmer (in press) present an example of this approach, using Thurstonian models of judgment to combine people’s ranking decisions for a variety of general-knowledge questions, such as the chronology of the US Presidents.

In this paper, we present a case study of the application of cognitive models for a sequential task known as the bandit problem. By applying a series of existing models of human decision-making on the task to a variety of data sets, we show that it is sometimes possible to produce aggregate performance that is near optimal, and far exceeds the performance of most of the individuals. We discuss what sort of properties cognitive models might need to achieve this sort of useful aggregation of individual knowledge.

Bandit Problems

Bandit problems are a type of sequential decision-making problem widely studied in statistics and machine learning (Gittins, 1979; Kaelbling, Littman, & Moore,

Figure 1: An experimental interface, giving an example of a Bandit problem.

1996; Sutton & Barto, 1998), as well as in cognitive science (Cohen, McClure, & Yu, 2007; Daw, O’Doherty, Dayan, Seymour, & Dolan, 2006; Steyvers, Lee, & Wagenmakers, 2009). In Bandit problems, a decision maker chooses from a set of alternatives with fixed but unknown reward rates, which are drawn from a fixed but unknown environment, with the goals of maximizing the total number of rewards after a fixed number of trials.

A representative experimental interface of Bandit problems is shown in Figure 1. The four large panels contain information of choices and outcomes on four alternatives. On each trial, an alternative is chosen, and either succeeds in giving a reward (green, light) or fails (red, dark). At the top of each panel, the ratio of successes, defined as the ratio of successes to total choices, is shown. The interface provides a count of the total number of rewards obtained up to the current trial. The current game and trial are also shown.

The bandit problem has a well-known optimal decision-making process (e.g., Kaelbling et al., 1996, p. 244), calculated by dynamic programming. This allows human decision-making, and plausible psychological models of decision-making, to be assessed in terms of their optimality. In particular, Bandit problems provide a natural task to study the inherent trade-off between exploration (seeking rewarding alternatives among those relatively unexplored) and exploitation (staying with alternatives known to be reasonably good) inherent in many real-world sequential decision-making situations.

Human Data

We use data from three experiments. In the first experiment, reported by Steyvers et al. (2009), a total of 451 participants completed a total of 20 bandit problems, each with 4 alternatives and 15 trials. Reward rates were drawn for each alternative independently from

a Beta(2, 2) distribution. The reward rates were drawn only once, but the order of the games was randomized.

The second and third experiments involve new data. A total of 47 and 31 participants, respectively, completed 100 bandit problems, all with 4 alternatives and 16 trials. For the second experiment, the reward rates were drawn independently for each game from Beta(8, 4) (called a “plentiful” environment, because reward rates tend to be high). For the third experiment, reward rates came from a Beta(4, 8) (called a “scarce” environment, because reward rates tend to be low)

Four Decision-Making Models

In this paper, we consider four well-established models of decision-making on bandit problems. These come from the reinforcement- and machine-learning literatures (see Sutton & Barto, 1998), and have previously been examined as models of human decision-making (e.g., Lee, Zhang, Munro, & Steyvers, 2009).

Win-Stay Lose-Shift

Perhaps the simplest reasonable approach for making bandit problem decisions is the Win-Stay Lose-Shift (WSLS) heuristic. In its deterministic form, it assumes that the decision-maker continues to choose an alternative following a reward, but shifts to the other alternative following a failure to reward. In the stochastic form we use, the probability of staying after winning, and the probability of shifting after losing, are both parameterized by the same probability γ .

Extended Win-Stay Lose-Shift

A natural, and psychologically-motivated, extension to the WSLS model is to have different rates for staying after a reward (i.e., reinforcement) and shifting after a lack of reward (i.e., negative reinforcement). Formally, in our extended WSLS model, a decision-maker stays with probability γ^w following a reward, but shifts with probability γ^l following a failure to reward.

ϵ -Greedy

The ϵ -greedy model assumes that decision-making is driven by a parameter ϵ that controls the balance between exploration and exploitation inherent in bandit problems. On each trial, with probability $1 - \epsilon$ the decision-maker chooses the alternative with the greatest estimated reward rate (i.e., the greatest proportion of rewards obtained for previous trials where the alternative was chosen). This can be conceived as an ‘exploitation’ decision. With probability ϵ , the decision-maker chooses randomly. This can be conceived as an ‘exploration’ decision.

ϵ -Decreasing

The ϵ -decreasing model is a variant of ϵ -greedy, in which the probability of an exploration move decreases as trials progress. In its most common form, which we use, the ϵ -decreasing model starts with an exploration probability ϵ'

Figure 2: Bayesian graphical model for the extended WSLS decision-making model.

on the first trial, and then uses an exploration probability of ε'/i on the i th trial.

Modeling Analysis

In this section, we implement the four decision-making models in a way that allows for differences in individual behavior to be aggregated, culminating in model-based wisdom of crowds analyses of our experimental data sets.

Bayesian Graphical Model Implementation

We implemented all four decision-making models using the formalism provided by Bayesian graphical models, as widely used in statistics and computer science (e.g., Koller, Friedman, Getoor, & Taskar, 2007). A graphical model is a graph with nodes that represents the probabilistic process by which unobserved parameters generate observed data. Details and tutorials are aimed at cognitive scientists are provided by Lee (2008) and Shiffrin, Lee, Kim, and Wagenmakers (2008). The practical advantage of graphical models is that sophisticated and relatively general-purpose Markov Chain Monte Carlo (MCMC) algorithms exist that can sample from the full joint posterior distribution of the parameters conditional on the observed data. More specifically, for our purposes, graphical models can be specified that naturally combine information across multiple sources, and so can model the individual differences at the heart of the wisdom of crowds phenomenon.

As a concrete example, Figure 2 shows the graphical model implementation of the extended WSLS model. The two model parameters, the probability of win-stay γ^w and lose-shift γ^l , are shown as unshaded (i.e., unobserved) and circular (i.e., continuous) variables. These determine the probability of the a th alternative being

Figure 3: Bayesian graphical model for a hierarchical version of the extended WSLS decision-making model, which allows for individual-level parameter variation.

chosen on the i th trials of the j th game, as

$$\theta_{ij}^a = \begin{cases} \gamma^w & \text{if succeeded on } a \text{ last trial} \\ 1 - \gamma^l & \text{if failed on } a \text{ last trial} \\ (1 - \gamma^w)/3 & \text{if succeeded on } \bar{a} \text{ last trial} \\ \gamma^l/3 & \text{if failed on } \bar{a} \text{ last trial,} \end{cases}$$

where \bar{a} refers to not choosing the a th alternative. Since θ_{ij} is a deterministic function of γ^w and γ^l , it is shown as a double-bordered node. Given the choice probabilities in θ_{ij}^a , the actual decision made by the i th trial of the j th problem—which is represented by a shaded square node d_{ij} , since it is observed, and discrete—is modeled as $d_{ij} \sim \text{Discrete}(\theta_{ij}^1, \dots, \theta_{ij}^4)$.

Parameter Differences

One obvious possibility for individual differences is that two people—even if they are both using, for example, extended WSLS—might not have the same probabilities of wining and staying or losing and shifting. To accommodate variation in these parameters on an individual-by-individual uses, we use a *hierarchical* or *multi-level* approach. The updated graphical model is shown in Figure 3. In this model, the parameters for individual people are drawn from over-arching Gaussian distributions, so that, for the k th person, $\gamma_k^w \sim \text{Gaussian}(\mu^w, \sigma^w)$, and $\gamma_k^l \sim \text{Gaussian}(\mu^l, \sigma^l)$. This allows different people to have different parameter values, while still estimating the mean parameter value of the group as a whole.

We implemented the graphical model in Figure 3, as well as analogous graphical models for the three other decision-making models, in WinBUGS (Spiegelhalter, Thomas, & Best, 2004). This software uses a range

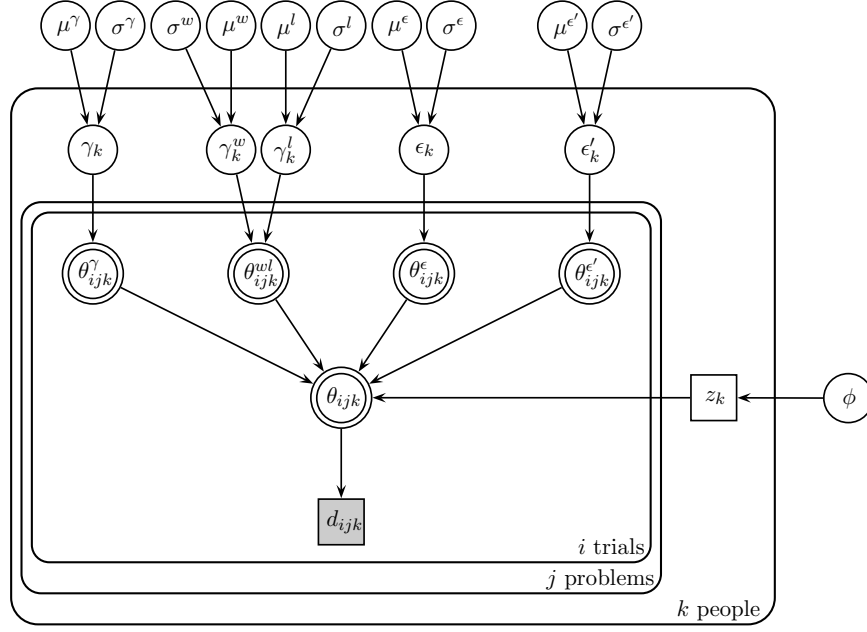

Figure 4: Graphical model using a hierarchical mixture of all four hierarchical decision-making models.

Table 1: Means, and standard deviations in brackets, of the group distributions for each parameter in the four decision-making models.

Parameter	Exp. 1	Exp. 2	Exp. 3
γ	0.71 (.10)	0.70 (0.10)	0.52 (0.10)
γ^w	0.99 (0.27)	0.97 (0.19)	0.81 (0.18)
γ^l	0.59 (0.25)	0.28 (0.23)	0.37 (0.23)
ϵ	0.24 (0.10)	0.18 (0.11)	0.42 (0.12)
ϵ'	0.61 (0.11)	0.61 (0.11)	0.90 (0.14)

of MCMC computational methods, including adaptive rejection sampling, splice sampling, and Metropolis-Hastings to perform posterior sampling (e.g., MacKay, 2003). For all four decision-making models, we made inferences about individual- and group-level parameters for all three data sets, using all of the participants. In each analysis, we collected 1,000 samples from 2 chains, collected after a burn-in period of 1,000 samples, and using standard checks for convergence.

Table 1 summarizes individual differences in parameters for each decision-making model, giving the means and standard deviations for each parameter in the hierarchical analysis. Remembering that experiments 1, 2, and 3 correspond to neutral, plentiful and scarce environments, the aggregated group parameters make sense. For example, there is more winning and staying (e.g., in the γ and γ^w parameters) in environments that deliver rewards, and there is more random exploration (e.g., in the ϵ and ϵ') in scarce environments that are not deliv-

ering rewards. The reasonably large standard deviations for most group distributions also indicate that there are significant individual differences.

Model Differences

An even more fundamental source of individual differences arises when different people use different decision processes. Rather than just varying the parameters of a model, people may differ in terms of which decision-making model they use. We accommodate this type of individual differences using a *mixture* or *latent assignment* model where people are categorized into different model-users.

The graphical model for achieving this mixture of decision models, while retaining the possibility of parameter variation within each model, is shown in Figure 4. Hierarchical versions of all four decision-making models—those used individual to assess parameter variation in the previous section—are all shown.

The key addition, in terms of individual differences, involves the model indicator variable z_k , which indexes which of the four models the k th participant uses. That is, depending on whether z_k is 1, 2, 3 or 4, the k th participant uses WSLS, the extended WSLS, ϵ -greedy or ϵ -decreasing to make their bandit problem decisions. The latent indicator variable has prior $z_k \sim \text{Categorical}(\phi)$, where ϕ is a latent base-rate, measuring the proportion of people who follow each model. We use the prior $\phi \sim \text{Dirichlet}(1/4, \dots, 1/4)$, so that there is no initial bias towards one decision model over another.

Table 2 gives the posterior expectation of the base-rate parameter ϕ , for all three experiments. This provides a natural summary of what proportion of people were us-

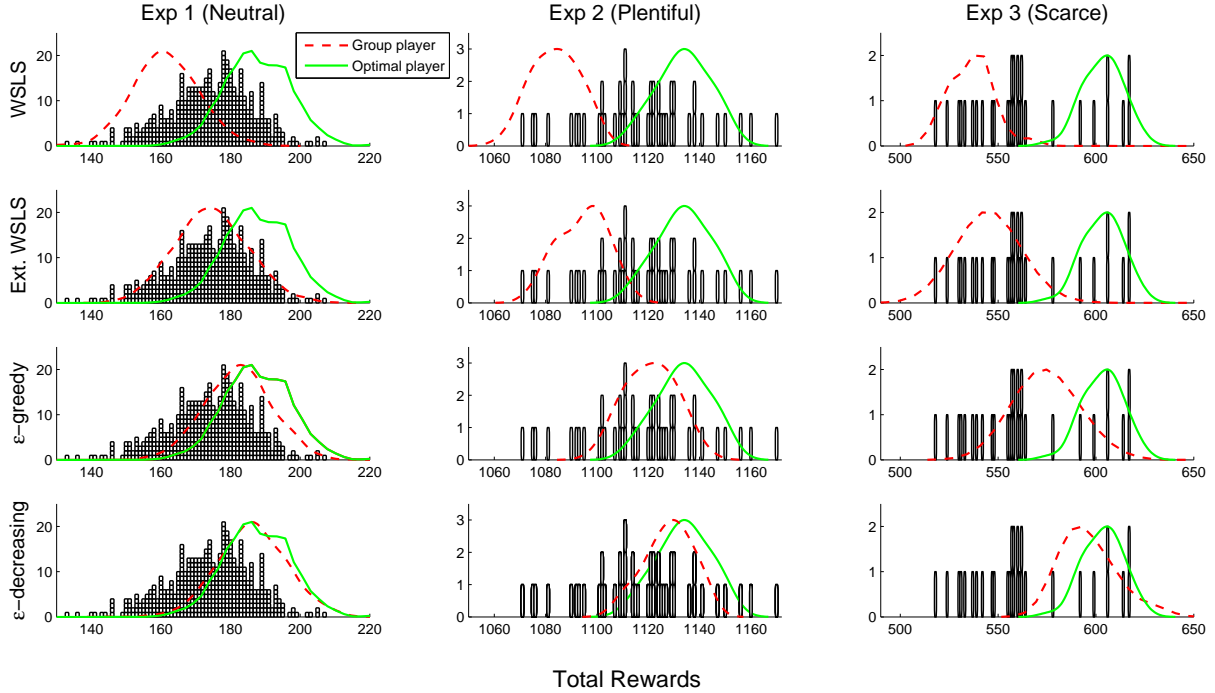

Figure 5: Distribution of rewards for individual participants, the group model, and the optimal decision-making process, for each decision-making model and each experiment. See text for details..

Table 2: Proportion of people using each model, for the three experiments, as measured by the posterior expectation of the ϕ parameter.

Model	Exp. 1	Exp. 2	Exp. 3
WSLS	0%	0%	0%
Extended WSL	75%	81%	70%
ϵ -greedy	22%	16%	29%
ϵ -decreasing	3%	3%	1%

ing each of the four models, and so summarizes individual differences results at this fundamental level. The findings are consistent across all three experiments—even though they have different distributions of reward rates—with the clear majority of the participants inferred to be using the extended WSL model, and a minority using ϵ -greedy. The proportion inferred to be using the other two models is negligible.

Wisdom of Crowds Analysis

Our modeling of individual differences in models and parameters immediately allows a range of wisdom of the crowd analyses. The most basic analyses involve taking each of our decision-making models, and using the inferred group mean in the hierarchical analysis, as shown in Table 1 as the aggregate of individual perfor-

mance.¹ This approach solves the problem of aggregating the knowledge of different people solving different, but related, bandit problems. Rather than aggregating their behavioral choices, we are aggregating the psychology parameter values that lead to those choices.

To complete the model-based wisdom of crowd analyses, we used the group mean parameter values to define a “group model” that used the same decision-process, and completed the same problems given to participants in each of the three experiments. Because the number of rewards obtained is inherently stochastic, we repeated this many times to approximate the distribution of rewards. We also applied the optimal decision-making process to each experiment, to approximate the best possible distribution of rewards for each experiments

The results are shown in Figure 5. The columns correspond to the three experiments. The rows correspond to the WSL, extended WSL, ϵ -greedy and ϵ -decreasing decision models. Within each panel, the squares piled into histograms show the distribution of performance (i.e., how many rewards were obtained) for the individual participants. The two curves then correspond to the distribution of performance for the group model (red, dotted line) and the optimal decision process (green, solid line).

Figure 5 shows that some of our decision-making

¹We tried more involved analyses, using the full mixture model in Figure 4 to sample a model, and then parameters, to define a group model. We never found a wisdom of crowd effect comparable to what was achieved with the basic analyses, so we just report those.

models do produce a clear wisdom of the crowds effect, whereas others do not. The distributions of rewards for the group model formed by the WSLs and extended WSLs models does not improve on the distribution of individual performance, and are not close to optimal. For the ϵ -greedy and ϵ -decreasing group models, however, there is significant improvement. In particular, the ϵ -decreasing group model has a distribution of rewards that is extremely close to the optimal distribution for all three experiments.

Discussion

There are some intriguing features of our wisdom of crowd results presented in Figure 5. Most obviously, it is very encouraging that it is possible to take a simple decision-making model like ϵ -decreasing, take the window it provides onto human decision-making, and produce an aggregate decision-maker that performs near optimally. But, we note that this wisdom of crowd effect is not achieved for all of the cognitive models we tried, and, most particularly, was not achieved for the extended WSLs that provided the best account of the vast majority of individual behavior, as detailed in Table 2.

We think the explanation for this finding is that, the ϵ -greedy and ϵ -decreasing models are able to match more closely optimal behavior. Detailed analysis showing this was presented by Lee et al. (2009) and makes intuitive psychological sense. Neither WSLs model is sensitive to which trial in the total sequence is being completed, which is important information in managing the trade-off between early exploration and late exploitation. As a consequence of this sub-optimality, it is not surprising a wisdom of crowd effect was not achieved for these simple models.

What is more surprising is that the effect could be achieved for a decision-making model like ϵ -decreasing that is not an especially good account of individual behavior. An important topic for future wisdom of crowds research is to identify what properties of cognitive models are important in producing good aggregations of individual knowledge. Being able to mimic optimal behavior is a start, but it is not currently clear how effective models must be able to account for what people do.

More generally, we think our case study with bandit problems demonstrates a very general approach for applying cognitive models to study and use the wisdom of crowds phenomenon. Using graphical models allows hierarchies of parameters, and mixtures of decision processes, to combine the individual differences in people, at the level of their basic knowledge about a task. This leads naturally to a principled sort of aggregation that is applicable to complicated, multidimensional and sequential tasks, which might be among those most needing the pooling of individual capabilities to achieve good performance.

Abstract

We measure the ability of people to estimate the price of familiar household items in a variety of contexts. We manipulate whether estimation is done alone or with others, whether it is done independently or with the knowledge of the estimates of others, and whether it is done in a cooperative or competitive environment. From these basic estimation data, we construct a series of aggregated group estimates, exploring the conditions under which a small group of three people provide the most accurate information. We compare the performance of various small-group estimates to standard Wisdom of Crowds analysis, and find that priming people, or placing them in a cooperative group setting, is less effective than averaging the independent estimates of individuals. We also find, however, that it is possible to extract relatively more information from the decisions people make in a competitive group setting, using cognitive models of their decision-making.

Keywords: Wisdom of crowds, group estimation, Price is Right, game show, cooperative vs competitive decision-making

Introduction

A basic question for cognitive and social psychology involves how best to extract information from people. There is a large literature on the performance of groups in reaching good decisions in various contexts (see Kerr & Tindale, 2004; Hastie, 1986, for reviews), with accompanying theoretical positions ranging from believing in the robust effectiveness of group decision-making (e.g., Hastie & Kameda, 2005) to the destructive possibilities of “group think” (e.g., Moscovici & Zavallone, 1969).

A recent contribution to the issue of whether and how groups of people make effective decisions involves the “Wisdom of Crowds” phenomenon (Surowiecki, 2004). This refers to the empirical finding that an aggregated decision, made by combining the individual decisions of many people, can often perform as well as or better than the majority of the individual decisions themselves.

In this paper, we examine group decision-making and the Wisdom of Crowds phenomenon in a simple estimation setting. We ask people to estimate the price of everyday household objects, with which they people are familiar, but are unlikely to have exact price knowledge. We ask for these estimates in a wide variety of individual and

group settings. These settings manipulate whether estimation is done alone or in the presence of others, whether it is done independently or with the knowledge of the estimates of others, and whether group estimation is done in a cooperative or competitive environment.

To examine how these manipulations affect the accuracy of small-group estimation, we focus on a specific research question. The question is: how well do different ways of using the knowledge of just three people to estimate the price perform, and how does this level of performance relate to standard Wisdom of Crowds aggregation with more people?

Experiment

Materials

Stimuli We used two sets of 50 household items, with pictures and descriptions sourced from on-line shopping websites. Both stimulus sets followed the same price distribution, with totals approximately uniformly distributed between \$5 and \$45.

Interface An example of the basic experimental interface is shown in Figure 1. On each trial, a picture and

Figure 2: Relationship between true item prices and individual estimates (left panel), and Wisdom of Crowds estimate formed by averaging over all individuals (right panel). (MAD=Mean Absolute Deviation)

description of a prize is shown. Once an estimate has been made, the true price is presented. A counter shows how many of the 50 trials have been completed.

Methods

Using the same sets of items and basic interface, we collected price estimates under a variety of experimental conditions. These conditions manipulated whether estimation was done in an individual or group setting, whether estimates were done independently or with knowledge of other estimates, and whether estimation was done in cooperative or competitive setting.

Individual Estimates The simplest experimental condition just collects individual estimates for each of the 50 items, presented in a random order. A total of 22 participants completed this condition.

Primed Individual Estimates The ‘primed’ or ‘calibrated’ condition was the same as the individual condition, except that when each item was presented, the estimates of two other people were also presented. These estimates were drawn at random from the estimates made for the same prize in the individual condition. A total of 25 participants completed this condition.

Cooperative Group Estimates In the cooperative group condition, three people were co-located, and viewed the same experimental interface. They were asked to provide estimates sequentially, hearing the earlier estimates. After all three estimates had been made, the group was asked to form a consensus estimate, through unstructured discussion. The same three people completed all 50 trials, and the order in which they estimated was rotated between each trial. A total of 15 people completed this condition, forming 5 groups.

Competitive Group Estimates In the competitive group condition, three people played a version of the “Price is Right” game show, which has been used previously as a formalism to study competitive decision-making (e.g., Berk, Hughson, & Vandezande, 1996). They were asked to provide bids sequentially, hearing the earlier bids, with the goal of bidding *as close as possible to the true price without exceeding the true price*. People were not allowed to repeat an earlier bid, and the order of making bids was again rotated systematically after each trial. A total of 15 people completed this condition, forming 5 groups.

Basic Results

Bounds on Performance There are two worthwhile preliminary analyses that can serve to give bounds on the accuracy of estimation. The first of these simply considers each individual estimate, and is shown in the left panel of Figure 2. The mean average deviation between the estimated and true price is \$9.45. This serves as a sensible baseline for accuracy, since it represents what how well a single person will perform on average.

The second preliminary analyses averages *all* of the individuals who gave estimates for each prize. This corresponds to a standard “Wisdom of the Crowds” analysis, and is shown in the right panel of Figure 2. The mean absolute deviation is a much-improved \$7.52, and can reasonably serve as an upper bound on performance.

Simple Three Person Estimates

Figure 3 shows the performance of four simple ways to combine the information provided by three people to estimate the prices. These involve, the individual, primed individual, and cooperative group estimation contexts.

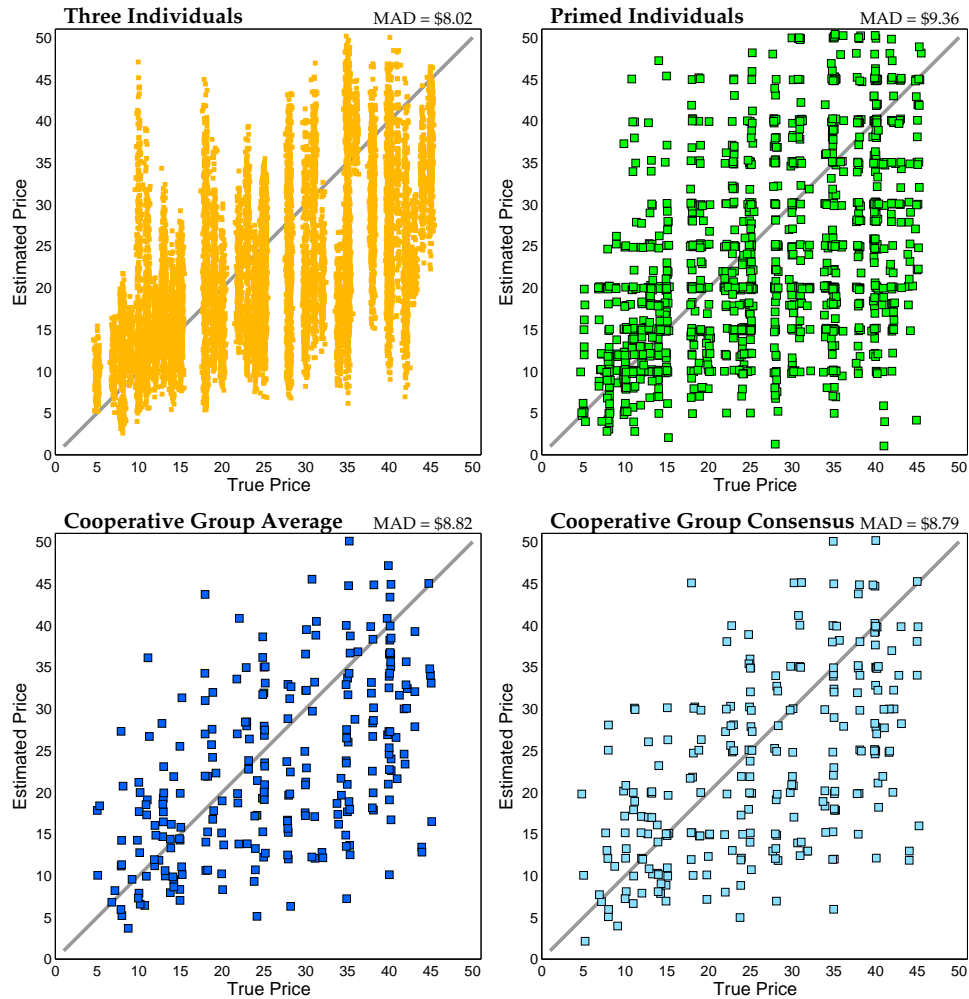

Figure 3: Relationship between true item prices and group estimates, formed from three people, by (top left) averaging the individual estimates of three people, (top right) priming an individual with the earlier estimates of two other people, (bottom left) averaging the estimates of three people made sequentially in a group setting, and (bottom right) the consensus opinion of a group of three people. (MAD=Mean Absolute Deviation)

Three Individuals The most obvious, given the estimates of three people, is simply to average them, as in a standard Wisdom of the Crowds analysis.¹ The performance of this approach is shown in the top left panel of Figure 3, which considers all possible groups of three people using individual estimates. The mean absolute difference is \$8.02. As would be expected, this difference lies between that already observed for single individuals, and for all individuals considered together.

Primed Individuals Another estimate based on the information provided by three people comes directly from the primed estimate. This is the estimate of a single individual working alone, but in the knowledge of two other people's estimates. The performance of primed estimates is shown in the top right panel of Figure 3. The mean absolute difference is \$9.36, which barely improves upon the accuracy of estimates of single non-calibrated individuals.

Cooperative Average The bottom left panel shows the performance of the average of the three people in the cooperative group condition. The mean absolute difference is \$8.82. This is better than single individuals, but does not come close to the level of performance achieved by averaging three estimates made independently.

¹For all of the analyses we present involving the averaging of estimates, we also examined taking the median, or rounding answers to the nearest dollar. Rarely did performance, as measured by the Mean Absolute Deviation, change by more than a few cents, and never did it suggest different conclusions from those we present based on the mean.

Cooperative Consensus Finally, the bottom right panel of Figure 3 shows the performance of the consensus estimates reached by the groups of three people. The mean absolute difference is \$8.79, which is very similar to the average of the group estimates. Taken together, these results suggest that being in a cooperative group setting hinders the generation of accurate estimates.

Competitive Group Analysis

Analyzing estimation performance for the competitive “Price is Right” condition requires more involved inference than averaging. This is because the bids that people make do not necessarily correspond to their actual best estimate of the price of a prize. In the competitive context formalized by the rules of the game, it is often sensible for a player to make a bid that is very different from what they believe the price to be.

This strategic relationship between bids and estimates is most easily seen for the final bid made by Player 3. If the previous bids are \$35 and \$40, then the best final bid is either \$1, \$36 or \$41. One of these choices is rational, in the sense that it will maximize the probability that Player 3 wins the game. Which choice is rational depends on what Player 3 knows about the price of the prize. If, for example, they believe it is most likely somewhere below \$35, then the \$1 final bid is optimal.

For this reason, it does not make sense to combine the bids from the competitive group setting as if they were estimates, and just average them. Instead, inferences need to be made about what estimates the players have in their heads, based on their bids. This inference requires a model of decision-making that accounts for how estimates become bids, in the context of the game.

Inferring a Group Estimate from Bids

The decision model we used for inference makes two key assumptions. The first is a representational assumption, which is that all of the players have partial knowledge of the price of a prize, and that their uncertainty can be represented by the same Normal distribution. The second is a decision-making assumption, which is that players make the bid that maximizes their probability of winning the game. Given these assumptions, our inferential goal is to find the mean of the Normal distribution, since it represents the average price, based on the players’ knowledge.

Formally, given a Normal distribution with mean μ and standard deviation σ , we can define a ‘win’ function $w_x(a, b, c, \mu, \sigma)$ for the probability the x th player will win, given bids a, b, c , for Players 1, 2, and 3, respectively. This win probability is just the area under the Normal curve between the bid of the x th player, and the next highest bid (or the maximum of \$50, if it is the highest bid). On the basis of this win function, we can formalize what constitutes optimal bidding for each player.

Player 3 Given existing bids a , and b the probability Player 3 will win if they made the bid c is just

$$\pi_3(c | a, b, \mu, \sigma) = w_3(a, b, c, \mu, \sigma),$$

and so one way of formalizing what it means to be a rational player, is that they will choose according to these probabilities, so that

$$p_3(c | a, b, \mu, \sigma) = \frac{\pi_3(c | a, b, \mu, \sigma)}{\sum_{c'} \pi_3(c' | a, b, \mu, \sigma)}.$$

Player 2 Given an existing bid a , the probability Player 2 will win if they made the bid b , assuming Player 3 subsequently ‘behaves optimally’ and bids according to $p_3(c | a, b, \mu, \sigma)$ above, is

$$\pi_2(b | a, \mu, \sigma) = \sum_c p_3(c | a, b, \mu, \sigma) w_2(a, b, c, \mu, \sigma).$$

So, if Player 3 makes their bid decision according to these probabilities, they will choose

$$p_2(b | a, \mu, \sigma) = \frac{\pi_2(b | a, \mu, \sigma)}{\sum_{b'} \pi_2(b' | a, \mu, \sigma)}.$$

Player 1 Player 1 provides the first bid. If they bid a , their probability of winning, assuming subsequent optimal behavior is

$$\pi_1(a | \mu, \sigma) = \sum_b p_2(b | a, \mu, \sigma) \sum_c p_3(c | a, b, \mu, \sigma) \times w_1(a, b, c, \mu, \sigma).$$

This gives the bid decision probabilities

$$p_1(a | \mu, \sigma) = \frac{\pi_1(a | \mu, \sigma)}{\sum_{a'} \pi_1(a' | \mu, \sigma)}.$$

Final Inference The joint posterior distribution over the parameters of the Normal representing people’s knowledge is given by Bayes Rule

$$\begin{aligned} & p(\mu, \sigma | a, b, c) \\ & \propto p(a, b, c | \mu, \sigma) p(\mu, \sigma) \\ & = p(c | a, b, \mu, \sigma) p(b | a, \mu, \sigma) p(a | \mu, \sigma) p(\mu, \sigma). \end{aligned}$$

We put a simple improper flat prior on $p(\mu, \sigma)$, and all of the other likelihood terms are available from the optimal decision-making analysis.

There are many potential ways the $p(\mu, \sigma | a, b, c)$ could be used to estimate the final group price. We use probably the simplest possible approach, and find the mode (i.e., the MAP estimate) $(\mu^*, \sigma^*) | a, b, c$, and use μ^* as the price estimate of the competitive group, based on their bids.

Demonstration of Inference

Figure 4 provides a concrete example of the inference process used to estimate the price of a prize from the bidding in the competitive “Price is Right” game. The example relates to one trial for one of our groups, in which the players bid \$13, \$10 and \$1. To find which Normal distribution best explains these bids, under the assumption that people bid to maximize their chance of winning, we

Figure 4: Inference process to find a group estimate from the bids in a competitive “Price is Right” game.

exhaustively test every Normal distribution with a mean of $1, 2, \dots, 50$ and standard deviation of $1, 2, \dots, 25$.

The first three panels of Figure 4—which correspond to the decision making of Players 1, 2 and 3—all show the same particular Normal in the background, with a mean of \$12 and a standard deviation of \$3. The black line then shows the probability of each player winning the game, if they made each possible bid between \$1 and \$50. The white circle represents the bid they actually made.

Intuitively, it is easiest to understand this analysis by looking at Player 3. Here, it is already known that the previous bids are \$13 and \$10. The black line shows that the probability of Player 3 winning peaks around \$14 and \$11, one above the earlier bids, and is also high for bids starting at \$1, up until the point where the Normal says it becomes possible the true price might lie.

Looking at all three players, it is clear that this particular Normal distribution gives predictions that are reasonably consistent with the bids actually made. It peaks at the right bid for Player 2, and gives appreciable probability to the bids of Players 1 and 3. In fact, the Normal shown corresponds to the most likely one, out of all the possibilities considered. This result is shown in the rightmost panel of Figure 4. In this plot, each point corresponds to a Normal distribution, and the darker it is shaded, the more probable that Normal made the observed bid data. The mode is at $\mu = 12, \sigma = 3$, and so the final estimate we infer is \$12. As it happens this is very close to the true \$11 price of the prize for this trial.

Notice that simply averaging the bids would not produce the same estimate, because it would treat the \$1 bid as a literal estimate, rather than a strategic attempt to win the game, based on the belief that earlier bids may have been too high.

Results

The performance of the inferred three-person estimates based on the competitive game bids is shown in Figure 5. The mean difference is \$8.05. This is a large improvement on the cooperative group average and consensus estimates, and is comparable to the accuracy obtained by averaging three individual estimates.

The results for all of the three-person estimates, and their relationship to Wisdom of Crowds averaging, are

summarized in Figure 6. The curve shows the accuracy of Wisdom of Crowds averages, starting with a single individual and finishing with all individuals. These start-and-end-points correspond to the bounds established in Figure 2.² A clear and interesting pattern evident in this curve is how quickly including additional independent people in the Wisdom of Crowds average fails to improve accuracy. There is little improvement beyond the fifth or sixth person.

Figure 6 shows the performance of all of the three-person estimates—primed individuals, cooperative average, cooperative consensus, and competitive Price is Right inference—in relation to the Wisdom of Crowds curve. Motivated by a similar analysis presented by Vul and Pashler (2008), we map from the mean absolute difference of each three-person estimate to the Wisdom of Crowd curve, and then down to the number of people. This mapping allows the performance of the various approaches to be conceived in terms of how many independent estimates worth of performance they achieve. The results show that a primed individual is the same as a single non-primed individual, putting three people in a cooperative setting produces the accuracy of about one-and-a-half independent people, but putting three people in a competitive setting constitutes three independent people’s worth of information.

Discussion

There are many analyses besides those reported here that could be pursued with the current data. For example, it would be interesting to compare the accuracy of individuals primed while working alone with those who gave the final estimate in the cooperative group setting. In a sense, these individuals have access (on average) to the same information, and so differences in their accuracy could be attributed to the social setting. We plan to pursue extensions and variants on the cognitive modeling of the competitive setting, including making different assumptions about how homogenous information is across participants, and how bidding decisions might be made.

²There were 22 individuals who provided individual estimates, so that 11 completed each of the two stimulus sets. The performance measures shown average over the two stimulus sets.

Figure 5: Relationship between true item prices and estimates inferred from an optimal decision-making analysis of three people competing in a “Price is Right” game. (MAD=Mean Absolute Deviation)

However, we can draw a number of interesting initial conclusions from the analyses reported here. The first is that the basic Wisdom of Crowds approach performs remarkably well. None of our alternative three-person estimation settings was superior to simply taking the average estimates of three random independent individuals. This averaging corresponds to a very simple generative model, in which each person estimates a signal with the addition of independent noise.

Our second conclusion applies to situations in which aggregate estimation must be done in a group setting, or when individuals share too much knowledge for independent estimates to be possible. These constraints could apply, for example, in situations where the goal is to pool the estimates of domain experts, who have overlapping training and knowledge. Here, our results argue for competitive rather than cooperative or passive approaches to extracting and combining information seem superior. The accuracy of the estimates from the simple “Price is Right” game were far superior to the other estimates we collected in group settings, and justified our effort to develop the much more complicated generative model for that setting.

We think the result highlighting the benefits of competition is suggestive, for both theoretical and applied reasons. Theoretically, it argues for the need to incorporate models of cognition and decision-making within Wisdom of Crowds research, to understand not just final behavior, but the underlying knowledge that generated that behavior. As we pointed out, it does not make sense to average the bids people make in the “Price is Right” game, but it does make sense to aggregate the knowledge they had that led them to decide on those bids. Practically, our results reinforce recent evidence for the effec-

Figure 6: Characterization of the three-person estimates in terms of wisdom of crowds averages including 1, ..., 11 individual estimates.

tiveness of competition instruments like prediction markets (e.g., Christiansen, 2007), rather than cooperative or collaborative groups settings, as better ways to combine knowledge across individuals.

Abstract

In some eyewitness situations, a group of individuals might have witnessed the same sequence of events. We consider the problem of aggregating eyewitness testimony, trying to reconstruct the true sequence of events as best as possible. We introduce a Bayesian model which incorporates individual differences in memory ability, as well as informative prior knowledge about event sequences, as measured in a separate experiment. We show how adding prior knowledge leads to improved model reconstructions, especially in small groups of error-prone individuals. This Bayesian aggregation model also leads to a “wisdom of crowds” effect, where the model's reconstruction is as good as some of the best individuals in the group.

Keywords: Eyewitness Testimony; Wisdom of Crowds; Rank Ordering; Bayesian Modeling; Serial Recall.

Introduction

Studies of eyewitness testimony have shown that human memory can be incomplete and unreliable (e.g., Loftus, 1975). In real world situations, there might be multiple eyewitnesses, all of whom witnessed the same set of events. This raises the possibility of recovering the true account of events by analyzing the similarities in the recalled memories across individuals. Different individuals might also recall different aspects of the events, such that an aggregate narrative, based on the group's memory, would be closer to the true sequence of events than that of any one individual. An investigator might try to manually reconstruct the aggregate narrative, or witnesses might be allowed to discuss the events in order to develop the group narrative. Communication between witnesses however, has been shown to lead to much worse performance (Gagnon and Dixon, 2008), and humans have been shown to be inconsistent in assessing group information from multiple sources (Stasser & Titus, 1985). To avoid these problems, we propose a model of aggregation that can integrate the recalled memories from a number of independent individuals, while also taking in other important factors, such as individual differences and prior knowledge, into account.

Research on the “Wisdom of Crowds” (WoC) has shown that an aggregation of independent judgments often leads to a group estimate that is closer to the ground truth than that of most of the individuals (Surowiecki, 2004). These group

estimates are often simply found by taking the mean, median, or mode of responses (Galton, 1907; Surowiecki, 2004). Much of the previous literature on aggregation of judgments has focused on tasks where individuals estimate numerical quantities and probabilities (Budescu, Yu, 2007; Hogarth, 1978; Wallsten, Budescu, Erev, & Diederich, 1997). It is, however, often the case that eyewitnesses have to retrieve information more complex than single numerical estimates.

The WoC effect can also be demonstrated with more complex problem sets. For example, the WoC effect has been demonstrated with solutions to problem-solving situations such as finding minimum spanning trees for a set of nodes (Yi, Steyvers, Lee & Dry, in press). Steyvers, Lee, Miller, and Hemmer (2009) showed that order information from semantic memory can also be combined across individuals to give high accuracy in reconstructing the true order of items along some physical or temporal dimension; when individuals recalled the order of US presidents, or the order of rivers according to length, many of the individual orderings were error-prone, but the aggregate orderings were more accurate, on average. In Steyvers et al. (2009), a number of aggregation models for order information were tested. It was found that using Bayesian models that incorporated psychologically plausible representations, cognitive processes and individual differences outperformed basic heuristic aggregation approaches, such as taking the mode.

When errors across individuals are uncorrelated (as they tend to be when individuals independently give their judgments) the errors will cancel out in the aggregate. Therefore, one expects the best results in WoC experiments with a large number of individuals. In eyewitness situations however, there is rarely a “crowd” available to witness the same set of events. In these cases, we have to rely on a small number of individuals (in many cases, just one) and significant errors might not cancel. Therefore, it might not be sufficient to just analyze the commonalities across the witness reports. We propose that it is better to combine the witness reports along with prior knowledge about the particular event sequence. Combining prior knowledge with noisy information has been shown in other domains to improve the recovered estimate (Hemmer & Steyvers, 2008; Konkle & Oliva, 2007; Kan, Alexander, Verfaelle, 2009).

We focus in this research on the problem of reconstructing event sequences. The goal is to reconstruct

the true ordering of a set of events by aggregating the recalled orderings from a small number of individuals, all of whom witnessed the same event sequence. The novelty of the current approach is that we incorporate informative prior knowledge in an aggregation model for order information in order to improve the aggregate estimate. This is especially helpful when aggregating across a small number of error-prone individuals.

We present our results as follows. We first report on behavioral experiments wherein we tested people's ability to reconstruct, from episodic memory, the order of stereotyped events (e.g., getting up in the morning), or random events (e.g., clay animation without a clear story line). We also report on experiments where we measured prior knowledge for the same set of events. We then describe a Bayesian approach that aggregates the orderings across individuals while taking prior knowledge into account.

Empirical Study on Serial Recall

Much research on serial recall has been done on random word and letter sequences that do not have any obvious organization. In such experiments, individuals are shown a sequence of words or letters, and the task is to recall the original temporal order as best as possible during a later test. Typical errors in the recalled orderings are transposition errors where the orderings are locally perturbed (Estes, 1997; Nairne, 1992) -- two events nearby in time tend to be reconstructed as occurring nearby but the amount of perturbation noise depends on many factors such as time elapsed between study and test, stimulus characteristics and individual differences. Similar patterns have been observed in more naturalistic experiments, such as naming the day of the week an event occurred (Huttenlocher, Hedges, & Prohaska, 1990), as well as for autobiographical memory, such as ordering the events of September 11th (Altmann, 2003). With more naturalistic event sequences, prior

knowledge about the event sequences can influence episodic memory. People have clear expectations for routine activities and are sensitive to the ordering of actions within an activity (Bower, Black & Turner, 1979).

We conducted a series of behavioral experiments using two types of event sequences. We used a number of *stereotyped* event sequences, such as getting up in the morning, or jumping on a bus, for which people have clearly defined expectations, and a number of *random* event sequence, such as clay animation sequences or Japanese pizza commercials, for which the temporal organization might be less structured. To assess the prior knowledge people have about these types of events, we first conducted a prior knowledge study where we asked participants to order the events in the most natural order possible without actually showing them the original, true event sequence. This allows us to estimate a model for the prior probability of each sequence.

In a separate experiment, we assessed serial recall for each of event sequences. It should be noted that our definition of serial recall differs from the standard use of the term in that our task only involves ordering the events, not recalling the items to be ordered, as in a standard serial recall task. In our task, we first showed a video of the original event sequence which was followed by a serial recall test in which individuals ordered image stills from the video as best as possible according to the original temporal sequence in which the events appeared. No communication between individuals was allowed in any of our tasks, and therefore the data consists of independent recollections from individuals.

Methods

Participants were undergraduate students at the University of California, Irvine. There were 16 participants in the prior knowledge experiment and 28 participants in the serial

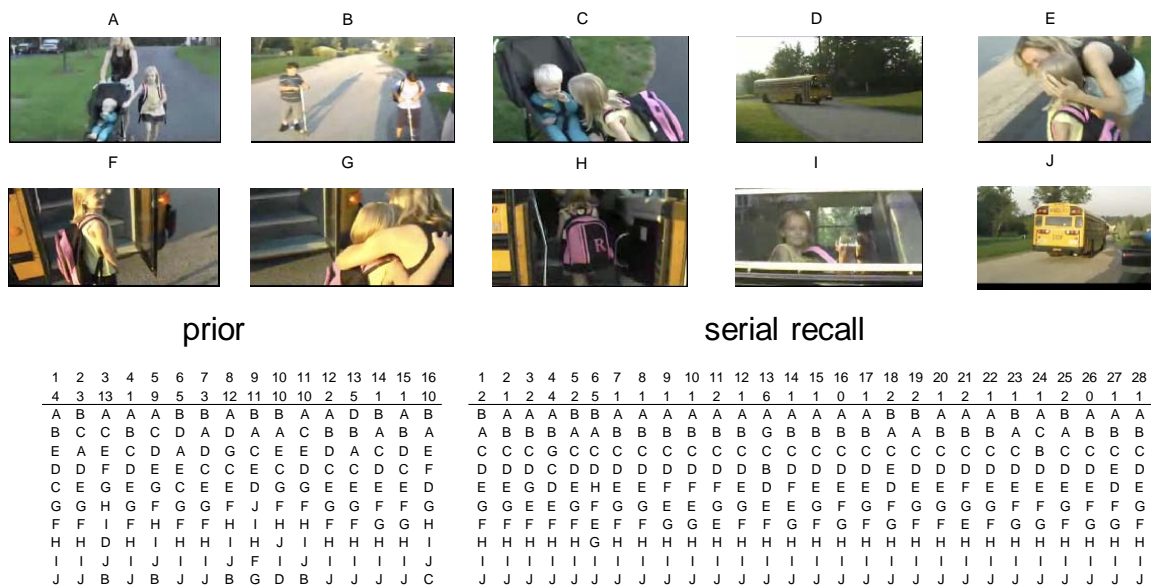

Figure 1. The sequence A-J shows the 10 images from the 'bus' video sequence in the correct temporal order. The two tables show the participant orderings in the prior knowledge and serial recall experiment. The first row is the participant id. The second row is the Kendall's tau distance between the true ordering and the recalled order for that participant.

recall experiment.

Materials. We sampled 6 videos from YouTube.com. Three videos depicted stereotyped events sequences (getting up in the morning, a wedding, getting on the school bus). Three videos depicted more random event sequences (a Japanese yogurt commercial, a Japanese pizza commercial, and a clay animation sequence). For each of the 6 videos 10 still images of individual scenes were drawn. See Figure 1 for an example.

Prior Knowledge Experiment. Participants were shown 10 image stills from a given event sequence (e.g., Wedding) and asked to order the 10 images based on their prior expectation of how the event in the slides might unfold. Importantly, in this experiment, participants were never shown the original video sequence from which the image stills were drawn. They responded using an interactive interface in which the images were randomly ordered on the screen and the instruction was to order the images in any way to make the sequence as natural as possible.

Serial Recall Experiment. Participants first viewed the original video sequence. Participants were then presented with the same interface as in the prior knowledge experiment. They were shown 10 image stills that they had to order in the original temporal order. For both the prior knowledge and memory experiment, the initial ordering of the 10 image stills, as well as the order of the 6 video sequences, was randomized across participants.

Results and Discussion

To evaluate the performance of participants, we measured the distance between the reconstructed and the correct ordering. A commonly used distance metric for orderings is Kendall's τ (Marden, 1995). This distance metric is the minimum number of adjacent pairwise swaps necessary to resolve any disagreements between the two orderings being compared. Values of τ range from $0 \leq \tau \leq (N-1)/2$, where N is the number of items in the order: $N=10$ for all of our event sequences. In our experiment, a $\tau=0$ indicates that the participant responded with the exact correct ordering. A $\tau=1$ indicates that one adjacent pair of items was swapped. When participants are using a random guessing strategy, their expected mean expected distance is $\tau = (N-1)/4 = 22.5$.

Figure 1 shows the raw data collected for the "bus" video sequence – a stereotyped event sequence. In the prior knowledge experiment, participants produced orderings that were much better than chance, suggesting that a priori, it is possible to guess the true ordering of events in these types of event sequences. In the memory experiment, 2 participants produced the correct ordering, and 15 more were within one swap of the true order. Note that very few identical orderings are produced between participants. We found that for all 3 random events, in both the prior knowledge experiment and the memory experiment, each participant produced a unique ordering. For the 3 stereotyped event sequences however, only one sequence led to unique orderings across all participants.

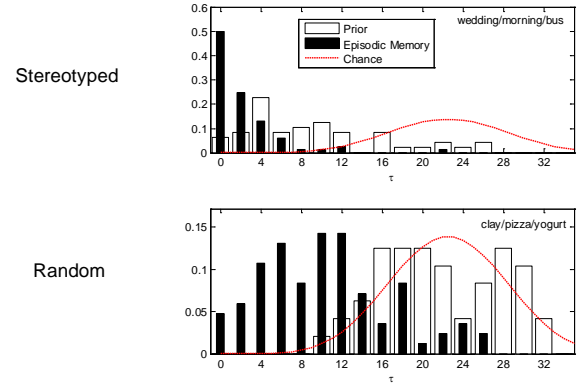

Figure 2. Distributions of Kendall τ distances.

Figure 2 shows the distributions of the Kendall τ distances for the serial recall and prior knowledge experiment. The top panel shows the distances for stereotyped event sequences and the bottom panel shows the distances for random event sequences. The dashed line shows the distribution of distances that can be expected from a random guessing strategy (this distribution can be calculated exactly, see Marden, 1995). For both the stereotyped and random event sequences, the distances are lower for the memory task than for the prior knowledge task. The distances are also lower for the stereotyped event sequences than for the random event sequences. Even when participants did not study the videos (the prior knowledge condition), they performed better than chance in the stereotyped condition, as compared to the random condition where prior knowledge performance led to a distribution of distances very similar to distances expected from chance performance. These results demonstrate that general knowledge about events can greatly contribute to the accuracy of recalling these events.

Modeling

We can conclude from our empirical study that prior knowledge can lead to improved average performance in recall. When ordering scenes from an event with strong prior expectations, the resulting orderings are relatively close to the true ordering. Of course, performance improves on average after observing the true event sequence and later recalling the sequence from memory. This raises the question of how one might incorporate an informative prior in a model for aggregating rank-ordered recall. Such priors might guard against errors from a small number of poorly performing individuals. In this paper, we explore very simple models to aggregate the orderings of individuals. The goal of the modeling is not to build a comprehensive model of recall that specifies all the representations and processes involved in storing and retrieving information from memory. Instead, we will focus on simple probabilistic models such as a Mallows model (e.g. Steyvers et al., 2009) that allow us to aggregate the retrieved orderings from a number of individuals using Bayesian inference. The current model incorporates two important differences to the

Figure 3. The graphical model representations for the Mallows model with an uninformative prior (a) and an informative prior about the group knowledge (b).

previous work by Steyvers et al. (2009). First, we generalize the model to allow for individual differences in memory performance. These individual differences are estimated by the model in a purely unsupervised fashion and do not require knowledge of past performance in other tasks or access to a known ground truth. With the individual differences, the model finds aggregates that are weighted towards solutions provided by the individuals that are estimated to have good memory performance.

Second, we develop a simple extension of Mallows models that allows for informative priors. This prior is estimated from the orderings produced in the prior knowledge experiment.

Mallows Model with an Uninformative Prior

In a basic Mallows model (Marden, 1995), all individuals are assumed to derive their orderings from a single underlying ordering, that we will refer to as the *group knowledge*. The group knowledge is a latent variable in the model that can be estimated from the data. Importantly, Mallows model assumes that each individual produces orderings centered on the group ordering with distant orderings less likely than orderings close to the group ordering. Although Mallows-type models have often been used to analyze preference rankings (Marden, 1995), they have not been applied, as far as we are aware, to ordering data from serial recall experiments. In our first extension of the standard model we allow for individual differences in memory performance. We evaluated this aggregation model by comparing the estimated group ordering to the ground truth. If the model is able to tap into the collective wisdom of a group of individuals, the estimated group ordering should be close to the true ordering.

Specifically, let \mathbf{y}_j represent the ordering from individual j , and $\boldsymbol{\omega}$ the latent group ordering. In a Mallows model, the

Figure 4. Calibration results for the two models for one event sequence.

probability of each individual ordering given the group ordering is given by

$$p(\mathbf{y}_j | \boldsymbol{\omega}, \theta_j) \propto e^{-d(\mathbf{y}_j, \boldsymbol{\omega})\theta_j} \quad (1)$$

where for simplicity we have omitted the normalization constant. The function d returns the Kendall τ distance between two orderings. The scaling parameter θ_j determines how close the observed order for individual j is to the group ordering. It can be interpreted as an individual (inverse) noise parameter -- good individuals tend to closer to the group consensus (high θ) whereas poor performing individuals return more idiosyncratic orderings further away from the group knowledge (low θ). We will assume a Gamma prior on the individual noise levels: $\theta_j \sim \text{Gamma}(\theta_0\lambda, 1/\lambda)$, where λ is a hyperparameter that sets the overall level of cohesion expected from the group. Notably, in this first model, we have assumed a uniform prior over group orderings, $\boldsymbol{\omega} \sim \text{Uniform}(\Omega)$, where Ω is the set of all orderings. Therefore, a priori, the model assumes no preference for a particular group ordering.

Figure 3, panel a, shows a graphical representation of the model. Shaded nodes represent observed variables while nodes without shading represent latent variables. The arrows indicate the conditional dependencies between the variables and the plate represents the repeated sampling steps across M subjects in the memory experiment.

Mallows Model with an Informative Prior

We now introduce a simple variant of this model that allows for an informative prior. The idea is that the group knowledge is itself sampled from a Mallows model:

$$p(\boldsymbol{\omega} | \boldsymbol{\omega}^0, \theta^*) \propto e^{-d(\boldsymbol{\omega}, \boldsymbol{\omega}^0)\theta^*} \quad (2)$$

where $\boldsymbol{\omega}^0$ is the prior ordering from which the group ordering is derived, and θ^* is a scaling parameter. This prior stage in Mallows model at first might not seem to gain any additional information because it is not clear how the prior ordering can be constrained. However, we have data in the prior knowledge experiment in which N participants tell us what orderings they expect from certain scenes. Let \mathbf{y}_j^0 represent the prior ordering given by individual j in the prior knowledge experiment. We assume that these are produced by a Mallows model with $\boldsymbol{\omega}^0$ as the "center":

Figure 5. Performance of individuals and model (with informative prior) averaged over six event sequences.

$$p(y_j^0 | \omega^0, \theta_j^0) \propto e^{-d(y_j^0, \omega^0) \theta_j^0} \quad (3)$$

Figure 3, panel b, shows the corresponding graphical model. With this model, we are setting a prior on the group ordering -- when there is only data available from a few individual in the memory experiment, the group ordering will be influenced by the data from the prior knowledge experiment leading to group orderings that are a priori deemed likely. When data from more individual becomes available in the memory experiment, the prior knowledge data will have a diminishing influence on the group ordering which will be mostly determined by the memory data.

Modeling Results

All latent variables in the model were estimated using a MCMC procedure, separately for each event sequence. The result of the inference procedure is a probability distribution over group orderings, of which we take the mode as the single answer for a particular problem. Note that the inferred group ordering does not have to correspond to an ordering of any particular individual. The model just finds the ordering that is close to all of the observed memory orderings.

Figure 4 shows the calibration for the two models on a single event sequence (the clay animation video). Each panel shows the relationship between the inferred θ (related to the distance of each individual to the group ordering) and the Kendall's τ distance of the individual's answer to the ground truth. The plots show that individuals who are close to the group ordering tend to be closer to the ground truth. This means that the models can calibrate the performance levels of individuals, even in the absence of any explicit feedback or access to the ground truth.

Figure 5 shows the Kendall's τ distance for each individual in the memory experiment averaged over the six event sequences. Note that there are substantial individual differences with some individuals coming relatively close to the ground truth. The figure also shows the average model performance. Comparison between individual and model

performance reveals a WoC effect: The model performs as well as some of the best individuals, with only one individual outperforming the model. Therefore, we can conclude there is a weak WoC effect (a strong WoC effect would correspond to a situation where the model outperforms all individuals in the group).

We now focus on applying the model to subsets of participants to mimic eyewitness situations that typically involve only small number of individuals. In the first analysis, we select a random set of K individuals from the original set of 28 individuals. We then apply the two models to the subset of individuals. Figure 6 shows model results for the model with the informative and uninformative prior separated for stereotyped and random event sequences. For random event sequences, where the prior is weak, there is no improvement in the aggregation between the two models (if anything, there is a small performance decrement for the model with the informative prior). For stereotyped event sequences however, people have strong prior expectations about the true ordering of events and there is a marked improvement in the aggregate response in the model with the informative prior. This improvement is most pronounced with low sample sizes ($K=1$ and $K=2$) when the prior can still exert an influence on the inferred group orderings. Note that when $K=1$, the model with the uninformative prior has no information other than the ordering given by a single individual -- therefore, the aggregate solution given by the model is equivalent to the ordering provided by the individual. This results in an average tau of around 15. However, performance for the model with the informative prior is much better resulting in a tau of around 8, because the aggregate solution combines the single remembered ordering with the a priori likely orderings.

To better highlight the benefit of the prior information, we also conducted a model analysis where we selected the *worst* performing individuals in the sample. In this sampling procedure, we sample the K worst individuals where we vary K from 1 (the single worst performing individual) to 28 (all individuals combined). Figure 7 shows model results for both models separated for stereotyped and random event sequences. The relative performance benefits can be seen most clearly for the stereotyped event sequences for low sample sizes ($K=1$ and $K=2$). In these cases, the worst individuals recall event sequences that are a priori unlikely and the prior "corrects for" the noise in the available data.

Therefore, these analyses suggest that an aggregation model with informative priors can be used to guard against the most egregious errors committed by the worst individuals in the memory task.

Conclusions

We have presented two approaches for aggregating recalled sequences of events in order to reconstruct the true event sequence as best as possible. Individuals are likely to differ in their ability to recall event sequences and pay attention to different parts on an event sequences. Therefore, by

Figure 6. Results from the models with an uninformative prior (model 1) and informative prior (model 2) for random subsets of K individuals from the memory task.

analyzing the consistencies in orderings across individuals, we can extract the collective wisdom in the group. We presented two aggregation approaches based on Mallows model that allow for individual differences. The models combine information at the group level with information at the individual level to explain orderings given by an individual. In the first approach, the model uses only the data from the individuals who all witnessed an event sequence. In the second approach, the model uses an additional source of data based on the prior knowledge about the events extracted from another group of individuals.

We demonstrated a weak WoC effect, where the average performance of the model was better than every individual, save one. We have also shown that a Mallows model with informative priors has a markedly improved ability to reconstruct the ground truth in cases where the event sequences are highly stereotyped and a small sample of poorly performing individuals is used for aggregation. This is particularly important in eyewitness situations where we typically have only a small number of individuals available.

Abstract

Simulations were completed using artificial reading “agents” that are subject to known physiological (e.g., limited visual acuity) and psychological (e.g., limited attention) constraints and capable of learning to move their eyes and allocate attention to read as efficiently as possible. These simulations indicate that agents learn when and where to move their eyes to attain maximal reading efficiency, generalize this behavior from training sentences to novel test sentences, and use word length to predict word-identification times and thereby make optimal decisions about when to initiate saccadic programming—even if word length is only moderately predictive of word-identification times. These results suggest that humans may exploit even modestly informative cues in learning to decide when to move their eyes during reading.

Keywords: Attention; Eye Movements; Genetic Algorithms; Neural Networks; Reading; Reinforcement Learning

Introduction

One of the outstanding unanswered questions in the psychology of reading (Rayner & Pollatsek, 1989) is: To what extent are the moment-to-moment decisions about *when* to move the eyes during reading determined by cognition? Attempts to answer this question can be divided into three theoretical “camps” (Reichle, 2006; Reichle, Rayner, & Pollatsek, 2003).

The first maintains that when the eyes move is largely determined by the constraints imposed by the visual and oculomotor systems (e.g., limited visual acuity). Advocates of this *oculomotor-control account* (Feng, 2006; McDonald, Carpenter, & Shillcock, 2005; Reilly & O'Regan, 1998; Suppes, 1990; Yang, 2006) argue against an eye-mind link in reading, and maintain that individual fixation durations provide only minimal information about ongoing lexical and/or linguistic processing difficulty.

According to the second “camp,” most decisions about when to move the eyes are determined by the activity of an autonomous random timer that causes the eyes to move at a rate that reflects a reader's comprehension goals and overall text difficulty, with cognition only intervening to inhibit saccadic programming when processing difficulty is encountered and thereby lengthening fixation durations. Advocates of this *autonomous-timer account* (Engbert, Longtin, & Kliegl, 2002; Engbert et al., 2005; Reilly & Radach, 2006) argue for a weak eye-mind link, with individual fixations occasionally reflecting ongoing lexical or linguistic processing difficulty.

Finally, the third “camp” maintains that the eyes and mind are tightly coupled, with the completion of some cognitive process (e.g., lexical access) being the “trigger” that normally causes the eyes to move from word to word during reading. Advocates of this *cognitive-control account* (Just & Carpenter, 1980; Reichle et al., 1998; Reichle, Warren, & McConnell, 2009; Reilly, 1993; Salvucci, 2001) argue for a strong eye-mind link, with individual fixation durations usually reflecting local processing difficulty.

Perhaps not too surprisingly, all three theoretical positions have been remarkably successful explaining the basic patterns of eye movements that are observed during reading; each position has provided one or more computational models that formally instantiates the core assumption of their respective positions and that simulate many or all of the “benchmark” findings related to eye-movement behavior in reading (Reichle et al., 2003). This makes it difficult to evaluate the models purely on the basis of their ability to account for data, and because the models make different *a priori* assumptions about the factors that guide readers' eye movements (e.g., how attention is allocated), model evaluation is like the proverbial problem of “comparing apples and oranges.” The present simulations therefore adopt an entirely different approach to understanding eye-movement control in reading.

Rather than developing a computational model around *a priori* assumptions about the precise manner in which perception, cognition, and motor control guide eye movements in reading, the present approach is a direct extension of the work reported by Reichle and Laurent (2006). In this work, artificial reading “agents” that were subject to known physiological (e.g., limited visual acuity) and psychological (e.g., limited capacity attention) constraints were given the task of learning how to move their eyes and attention so as to “read” (i.e., identify sequences of “words”) as efficiently as possible. The key results of this work were that the agents learned: (1) to direct their eyes towards the centers of words, the viewing location that afforded the most rapid identification of the words; (2) to use word length to predict when a given word would be identified, and then initiate saccadic programming to move its eyes from that word right as it was identified; and (3) to incur local fixation duration costs by identifying short, easy-to-identify words from peripheral vision, and thereby avoiding more costly saccades to those words.

The present simulations replicate and extend the Reichle and Laurent (2006) results using artificial agents that are capable of learning to move their eyes and attention via reinforcement learning (Sutton & Barto, 1998). However, in contrast to the Reichle and Laurent agents, the present agents were implemented using *artificial neural networks* (ANNs), and we demonstrated in two simulations that the behavior of these agents: (1) generalizes to novel sentences and words; (2) can be learned even in less than optimal learning conditions; and (3) is generally congruent with assumptions of cognitive-control theories. The theoretical implications of these results will be discussed after the simulation results are described.

General Simulation Method

The artificial reading “agents” that were used in the present simulations were given the task of learning how to “read” (i.e., identify sequences of words in their canonical order) as efficiently as possible. These words could vary in terms of their length (1-8 letters) and/or the time required for their identification (2-14 time steps). The agents learned to perform this task (subject to various constraints, discussed below) using *trajectory sampling*, a variant of the *value iteration* reinforcement-learning algorithm (Sutton & Barto, 1998) that is often used with large-scale problems. This algorithm is specified by:

```

i = 0
for all initial S:
  Vi(S) = ANN(S)
  repeat
    i = i + 1
    if (random value < greed) then:
      Vi(S) = Vi-1(S) + ε {maxaction ∈ M[reward(S, action)
        + γ Vi-1(S')] - Vi-1(S)}
    else random action
  until learning has completed.

```

where i indexes the learning iteration, $V_i(S)$ is the value associated with state S at time i , and M is the set of permissible actions from a given state. There are three parameters: ϵ ($= 0.5$) controls the learning rate, *greed* ($= 0.5$) controls how often an agent exploits what it already knows in selecting actions versus exploring the consequences of randomly selected actions, and γ ($= 0.9$) determines how much the agent weighs the reward that is anticipated from the next state, S' , versus the immediate reward that it receives from the action that it selects. Each state, S , consists of information that is available to the agent at any given point in time (see Table 1). The agents can perform one of three actions: (1) continue attending (i.e., lexically processing) the current word; (2) shift attention to the next word; and (3) request an eye movement of ± 10 character spaces. An agent selects the actions that result in the most (anticipated) reward, being “rewarded” +1 for every identified word and “punished” -1 for every time step

spent processing a sentence. Learning continues until the values of the states reach asymptote.

Table 1. State information (S) used by agents.

#	Available Information
1	Attended word (i.e., word _n) identified? (Y/N)
2	# time steps processing word _n
3	# spaces between center of word _n and fixation
4	Length of word _n
5	Length of word _{n+1}
6	Length of word _{n-1}
7	Saccade being programmed? (Y/N)
8	Length (# spaces) of intended saccade
9	# time steps programming saccade

As mentioned, the agents are subject to several constraints. First, visual acuity is limited, so that the rate of lexical processing decreases as the spatial distance between the agent’s center of vision and the center of the word being processed increases (i.e., a word that takes N time steps to identify when its middle letter is fixated will take 1 additional time step to identify for each character space of disparity between the letter being fixated and the center of the word). Saccades also require 3 time steps to program and 1 time step to execute, and are subject to Gaussian ($\mu = 0$; $\sigma = 1$) random error. Finally, because the perceptual span is known to be of limited spatial extent (Rayner & Pollatsek, 1989; Rayner, 1998), the agents were only allowed to process one word at a time, instantiating the assumption that attention is allocated serially during reading (e.g., Reichle et al., 1998) or approximating the assumption that attention is allocated as a gradient—albeit a tightly focused one (e.g., Engbert et al., 2005). Although this assumption about attention is quite controversial (e.g., see Reichle et al., 2009), it was intended as a simplifying assumption to make the simulations as tractable as possible.

In the Reichle and Laurent (2006) simulations, the value of each state, $V_i(S)$, was stored in a look-up table (i.e., one value per combination of dimensions in Table 1). In the present simulations, the values were learned and stored in the connection weights of an ANN whose architecture and principle weights were selected using *NeuroEvolution of Augmenting Topologies* (NEAT) (Stanley & Miikkulainen, 2002) and whose weights were optimized via the *Covariance Matrix Adaptation Evolution Strategy* (CMA-ES; Hansen, Müller, & Koumoustsakos, 2003) when trapped in local maxima. Figure 1 is a schematic diagram of how the NeuroEvolution and CMA-ES algorithms are used in conjunction with task-specific training to select network architectures that are well suited to solve the types of problems explored in this article.

Each network was comprised of nine input units (one per dimension in Table 1), one bias unit, one output unit (representing the learned value of each state), and an unspecified number of hidden units. In contrast to many neural networks, the hidden units were not strictly layered,

but could be configured in a variety of ways (e.g., as additional bias units; see Fig. 1). The activation of input unit i when given some value x of one of the dimensions in Table 1 was scaled to the interval $[-1, 1]$ using:

$$\text{act}_i(x) = \{x - [\max(x) / 2]\} / [\max(x) / 2]$$

where the function “max” returns the maximum value of the dimension. (Note that $\text{act}_i(x) = -1/1$ when Dimensions 1 and 7 equal false/true.)

Figure 1. Method use to evolve and train agents.

This NeuroEvolution algorithm was used to select network architectures that were adapted to use the value iteration reinforcement-learning algorithm (via using a residual algorithm to implement back-propagation in the ANNs) for the tasks that are the focus of this article—learning to move the eyes and attention to read efficiently. The CMA-ES algorithm was used to optimize weights when

optimization stagnated. Each reported simulation is based on populations of 100 individuals evaluated across 300 generations to solve the tasks of interest. Each individual networks agent also learned to perform its task using value iteration across five learning trials and using the specific training regimens.

Simulation 1

The first simulation replicated and extended the Reichle and Laurent (2006) results using agents implemented as ANNs (as described above) and various novel test sentences.

Method. Five agents were trained on a corpus of five 8-word “sentences” comprised of random permutations of 1-, 3-, 5-, and 7-letter “words.” (These sentences were randomly selected from 20 used by Reichle & Laurent, 2006.) The first and last words were always 1-letter in length and required 2 time steps to identify, and always excluded from our analyses because their processing started/ended abruptly. The remaining 1-, 3-, 5-, and 7-letter words respectively required 2, 6, 10, and 14 time steps to identify when fixated from their central letters. After training, agents were tested on: (1) the same five sentences; (2) five novel 8-word sentences comprised of different random permutations of 1-, 3-, 5-, and 7-letter words; and (3) five 8-word sentences comprised of random permutations of 2-, 4-, 6-, and 8-letter novel words.

Results. Figure 2 shows the simulated fixation landing-site distributions on the words, as a function of their length and whether the sentences being using used to evaluate the agents were old (i.e., used during training), novel, or comprised of novel words (i.e., 2-, 4-, 6-, and 8-letter words). (In all of the figures shown below, the data points indicate the condition means and the error bars indicate the standard errors of the means.) As indicated, the agents learned to direct their eyes towards the centers of the words because this was the viewing position that afforded the most rapid identification of the words. However, because of saccadic error, the fixation landing sites are approximately normally distributed, in line with what is observed with human readers (McConkie et al., 1988, 1991; Rayner, Sereno, & Raney, 1996). Finally, the behavior generalized across both novel sentences and words.

Figure 2. Simulated fixation landing-site distributions.

Figure 3 shows the mean probabilities of making a single fixation, making two or more fixations, or skipping, again as a function of word length and the nature of the test sentences. As the figure shows, agents tended to either make a single fixation on or skip the shorter words, and to make two or more fixations on the longer words. These results are consistent with what is observed with humans (Rayner et al., 1996) and did not vary by testing condition.

Figure 3. Simulated fixation probabilities.

Figure 4 shows the mean simulated values of five dependent measures (in time steps), again as a function of word length: (1) *first-fixation duration (FFD)*, or the duration of the first fixation on a word during the first pass through the sentence; (2) *gaze duration (GD)*, or the sum of all first-pass fixations; (3) *total-viewing time (TT)*, or the sum of all fixations, irrespective of whether they occur during the first pass; (4) *word-identification times (ID)*, or the time spent processing the words; and (5) *saccadic-programming initiation times (SPIT)*, or the time spent processing word_n prior to initiating the saccade that moved the eyes to word_{n+1}. As Figure 4 indicates, the measures increased with increasing word length (which is perfectly correlated with identification time), but with the mean processing time being longer than the minimal identification time because saccadic error often caused words to be processed from poor viewing locations, where lexical processing was slower. Importantly, if an agent spent N time steps processing word_n, then it on average spent approximately $N-3$ time steps processing word_n before initiating saccadic programming to move its eyes to word_{n+1}. This is an optimal strategy for deciding when to move the eyes because initiating saccadic programming any earlier would cause the eyes to leave word_n prematurely, resulting in it being processed more slowly from word_{n+1} (because of reduced visual acuity). Conversely, initiating saccadic programming any later would cause the fixations to be unnecessary long in duration. Thus, by initiating saccadic programming at the observed times, an agent insures that, in most cases, the eyes move from word_n right when it has been identified. (It is also worth noting that this strategy is similar to the “familiarity check” assumption of the E-Z Reader model of eye-movement control during reading, where a preliminary stage of lexical processing is the

“trigger” that initiates saccadic programming; Reichle et al., 1998, 2003, 2009.)

Figure 4. Simulated time-based dependent measures.

These results of Simulation 1 replicate and extend the key findings reported by Reichle and Laurent (2006) by showing that the reading agents, implemented as ANNs, are able to generalize from a small set of training sentences to sentences containing novel configurations of words. This is methodologically important because it shows how ANNs might be used to solve large-scale reinforcement learning problems that might otherwise be impossible to solve (e.g., a look-up table version of the agents would require the storage and updating of the more than 6 million different states listed in Table 1). This demonstration also makes it possible to explore more complex contingencies between eye-movement behavior and lexical variables, as described next.

Simulation 2

The second simulation examined the consequences of training on a more realistic sentence corpus—one in which word length is only moderately predictive of the time required to identify words.

Method. Five agents were trained and tested on five 8-word sentences in which 1-, 3-, 5-, and 7-letter words required 4-9 time steps to identify, and where word length was only moderately correlated to word-identification times across the corpus ($r = 0.31$).

Results. The simulated landing-site distributions, fixation probabilities, and time-based measures (grouped by both word length and identification time) are shown in Figures 5-7, respectively. As indicated in the left panel of Figure 5, the agents learned to direct their eyes towards the centers of words because this location afforded the most rapid identification of words. And as the left panel of Figure 6 shows, the agents were also more likely to make single fixations on or skip the shorter words, and make two or more fixations on the longer words. Both of these findings are consistent with human readers (McConkie et al., 1988, 1991; Rayner, 1996) and the results of Simulation 1. The right panels of Figures 5 and 6 indicate that similar word-targeting behaviors were evident when the words are grouped by their identification times, but that there are some irregularities (e.g., bimodal landing-site distributions with

the more-difficult-to-identify words) because these items included a mixture of both short and long words.

Figure 5. Simulated fixation landing-site distributions, by word length (left) and identification times (right).

Figure 6. Simulated fixation probabilities, by word length (left) and identification times (right).

Figure 7. Simulated time-based measures, by word length (left) and identification times (right).

Finally, the most striking result from Simulation 2 is that the agents learn to use word length information to predict the time required to identify words, and then used this knowledge to program saccades so that the eyes would leave a word right as it was identified. This “strategy” is similar to the one that was adopted by the agents in Simulation 1, even though the relation between word length and identification times was much weaker in Simulation 2 ($r = 0.31$) than Simulation 1 ($r = 1$). And as the left and right panels of Figure 7 indicate, this strategy was evident irrespective of whether the words are grouped by their length or by their identification times.

General Discussion

The simulations reported in this article replicated the Reichle and Laurent (2006) results by showing that

“intelligent” eye-movement behavior can emerge from artificial reading agents that are subject to fairly uncontroversial physiological and psychological constraints and that are capable of learning to coordinate attention and eye movements to support efficient reading. Simulation 1 extended the Reichle and Laurent results by implementing the reading agents within an ANN and then showing that the agents’ eye-movement behaviors generalize to novel sentences and words. And importantly, the agents used word-length cues to predict when words would be identified, and then used this knowledge to learn when to initiate saccadic programming. Simulation 2 indicated that the agents learned the same eye-movement behaviors, including learning to use word length to initiate saccadic programming in an optimal manner—even though word length was only moderately predictive of word-identification time.

The simulation results have important theoretical implications for our general understanding of eye-movement control in reading and the specific questions of what determines when our eyes move during reading. First, the simulations suggest how information that is predictive of when a word will be identified can be used to initiate saccadic programming in a manner that affords efficient reading. In the absence of such predictive information, it may be optimal to either simply wait until word_n has been identified before initiating saccadic programming to move the eyes to word_{n+1}, or to base the decision on the mean time required to identify word_n. Although both of these strategies prevent the eyes from moving prematurely (which would then slow reading considerably because words would have to be identified from poorer viewing locations), the strategies are also conservative because they often produce unnecessarily long fixations. This suggests that any strategy that simply ignores lexical processing difficulty and uses saccadic programming and visual acuity constraints to decide when to move the eyes will not be optimal because it ignores information (about the rate of lexical processing) that can be used to inform those decisions. This conclusion provides one argument against oculomotor-control theories of eye-movement control in reading (Feng, 2006; McDonald et al., 2005; Reilly & O’Regan, 1998; Suppes, 1990; Yang, 2006). And although our results admittedly say less about the feasibility of autonomous-timer theories (Engbert et al., 2002, 2005), such theories are not parsimonious if decisions about when to move the eyes can be made using information that is readily available to the reader (i.e., information about lexical processing difficulty). In other words, it is not parsimonious to posit an autonomous timer that is occasionally overridden by lexical processing difficulty if this information is itself sufficient to decide when to move the eyes in an optimal manner.

Second, the simulations suggest that humans may exploit cues that may be only modestly predictive of lexical processing difficulty in learning to decide when to initiate saccadic programming. These cues probably include word length, but also orthographic cues (e.g., prefixes and

suffixes, unusual letter sequences, etc.), and possibly cues that are generated via top-down processing (e.g., the syntactic and/or semantic constraints imposed by a word's prior sentence context). It is an open question as to how these different sources of information are combined in making moment-to-moment decisions about when to move the eyes during reading, but a vast experimental literature (e.g., for a review, see Rayner, 1998) indicates that these variables (and many others) do influence such decisions. Future simulations using our artificial reading agents will provide testable hypotheses regarding this question.

Rational eye movements in reading combining uncertainty about previous words with contextual probability

Abstract

While there exist a range of sophisticated models of eye movements in reading, it remains an open question to what extent human eye movement behavior during reading is adaptive given the demands of the task. In this paper, we help to answer this question by presenting a model of reading that corrects two problems with a rational model of the task, Mr. Chips (Legge, Klitz, & Tjan, 1997). We show that the resulting model is closer to human performance across two measures, supporting the idea that many components of eye movement behavior in reading can be well understood as a rational response to the demands of the task.

Keywords: computational modeling; rational analysis; eye movements; reading

Introduction

Choosing when and where to move one's eyes during reading is one of the most complicated skilled tasks humans perform. While there are a number of computational models achieving good numerical fits on eye movement data from reading (e.g., Reichle, Pollatsek, & Rayner, 2006; Engbert, Nuthmann, Richter, & Kliegl, 2005), it is still unclear to what extent the complex behaviors observed are rational responses to the demands of the problem itself and to what extent they arise from the idiosyncrasies and restrictions of human cognition. Legge, Klitz, and Tjan (1997) started to answer this question with Mr. Chips, a model which predicts eye movements that approximate an optimal solution to one formalization of the task of reading. Legge et al. pointed out that their model's behavior exhibits a number of patterns also found in human reading, providing evidence for understanding those behaviors as rational responses to the task. Despite its success, however, the Mr. Chips model oversimplifies two important aspects of the problem of reading, and also has empirical problems accounting for human reading behavior in two domains. In this paper, we propose a model extending Mr. Chips that removes these two oversimplifications to make the model's task more similar to that faced by humans. We show that the resulting model also remedies the two empirical deficiencies in Mr. Chips, further supporting the notion that many aspects of human reading behavior can be explained as rational responses to the demands of reading.

The essentials of the problem of making eye movements in reading are determining how long to leave the eyes in a given spot and – when a reader decides to move them – where to go. These decisions are made sequentially to produce the alternating sequence of fixations (relatively stable periods) and saccades (movements) that characterizes the eye

movement record. The past 30 years have seen a proliferation of experimental studies investigating this topic, which have answered a number of low-level questions such as the nature of the perceptual span and constraints on saccade latency as well as questions concerning the relationship between eye movements and higher-level cognitive processes such as the effect of word frequency and predictability (see Rayner, 1998 for an overview). Sophisticated computational models have been developed based on these findings, the most well-known of which are E-Z Reader (Reichle, Pollatsek, Fisher, & Rayner, 1998; Reichle et al., 2006) and SWIFT (Engbert et al., 2005). Both E-Z Reader and SWIFT assume that lexical processing (or word recognition) is the primary driver for eye-movements in reading, and both have enjoyed considerable success, in large part because they achieve very good fits to eye movement data from reading in a number of contexts, using a relatively small number of parameters. Despite their empirical strength, they fail to illuminate the reason why human reading behavior looks the way it does in one crucial respect – the extent to which it resembles a rational response to the problem posed by reading.

One leading approach for answering such questions is that of rational analysis (Anderson, 1990), a paradigm in which one formalizes the goals and cognitive and physical constraints relevant to a problem and develops a model of optimal behavior under those condition. To the extent that the behavior of the model is similar to that of humans, this provides a new way of understanding the reason why human behavior looks the way it does – it is the best way to solve the problem. The relationship between rational models and models such as E-Z Reader and SWIFT is well understood in terms of Marr's (1982) levels of analysis. Marr distinguishes three levels of mutually-constraining analyses that can be performed on cognitive processes: the *computational* level, which specifies the nature of the computation being performed, the information relevant to solving it, and the way to combine that information to solve it; the *algorithmic* level, which specifies the representation for the input and output and the algorithm by which the agent goes about solving it; and the *implementational* level, which specifies how the representations and algorithm are realized neurally. In these terms, rational models generally provide answers at the computational level of analysis. Models such as E-Z Reader and SWIFT help us to understand the algorithmic level, but cannot answer questions about the extent to which human reading is rational.

Legge et al. (1997) presented a computational level analy-

sis of reading, formalizing the central task – as in E-Z Reader and SWIFT – as one of serial word identification. They presented the Mr. Chips model, which approximates optimal behavior under their formalization, and shows a number of similarities with human reading behavior. Here, we point out two problems with their model of reading. First, their model takes the task to be to identify a string of independent words rather than a coherent sequence, i.e., their model does not make use of linguistic context, which experimental work suggests that humans use (McDonald & Shillcock, 2003). Second, it assumes that the task of the reader is to identify each word with complete certainty, yet recent evidence suggests that readers maintain uncertainty as to the identities of previous words (Levy, Bicknell, Slattery, & Rayner, 2009). In addition to these problems in their model’s design, the model also makes incorrect predictions for two relatively basic measures of eye movements in reading: saccade sizes and word skipping rates. The model we present fixes these two design problems by including linguistic context and using a flexible word identification criterion, and results in improved performance in accounting for human saccade sizes and word skipping rates.

The plan of the remainder of the paper is as follows. First, we describe the details of the Mr. Chips model, along with its empirical successes and failures. Next, we describe our extension of the Mr. Chips model, and finally present two experiments showing that fixing each of the two design problems results in performance more like humans.

Mr. Chips

The task of reading in the Mr. Chips model (Legge et al., 1997) is one of planning saccades for serial word identification. That is, the model works by gathering visual input from the current fixation location and using that visual input to plan a saccade. That saccade is then executed (with some motor error), visual input is obtained from the new location, and the cycle repeats. When one word is identified with 100% confidence, identification of the next word begins. Thus, the only decision the model makes is where to move the eyes next. There are just three sources of information relevant to making that decision. Visual input and knowledge of the language are combined to identify words, and knowledge of the motor error in the system assists in the planning problem. Since it forms the basis for our model, we describe the Mr. Chips model here in detail, discussing in turn each of the sources of information and then the algorithm by which the model combines them to choose saccades. To match the description of our model later, we use a notation a bit different than Legge et al. to describe Mr. Chips.

Information sources

Visual input The visual input in Mr. Chips consists of the veridical identities of the nine characters centered on the fixated character (representing the visual fovea), as well as partial information about the four characters on either side of this range (representing the visual periphery). This partial information is simply word boundary information, indicating

whether each character is part of a word or not (e.g., a space). The number of characters in each of these ranges was chosen to be representative of the perceptual span for readers of English, known to be around 17–19 characters (Rayner, 1998).

Language knowledge The model’s knowledge of language consists of simply word frequency information, i.e., a unigram model. Note that this means the model cannot make use of the linguistic context to aid in word identification.

Motor error The final component of the model’s knowledge of the task is that of motor error, the distribution of a saccade’s landing position given the intended target position the model chooses. In Mr. Chips, the i th landing position ℓ_i is normally distributed around the i th intended target position t_i with a standard deviation of 30% of the intended distance¹

$$\ell_i \sim \mathcal{N}(t_i, (0.3 \cdot |t_i - \ell_{i-1}|)^2). \quad (1)$$

Model

We now give the algorithm that the Mr. Chips model uses to select the intended target for the next saccade. First, note that given the visual input obtained by the model from the first to the i th fixation \mathcal{I}_1^i and the word frequency information, the model can calculate the posterior probability of any possible identity of a word w that is consistent with the visual input by normalizing its probability from the language model by the total probability of all visually consistent identities,

$$p(w|\mathcal{I}_1^i) = \frac{\chi(\mathcal{I}_1^i, w)p(w)}{\sum_{w'} \chi(\mathcal{I}_1^i, w')p(w')} \quad (2)$$

where $\chi(\mathcal{I}, w)$ is an indicator function with a value of 1 if w is consistent with the visual input \mathcal{I} and 0 otherwise, and $p(w)$ is the probability of w under the language model.

To identify a given word, the model selects the saccade target \hat{t}_i that, on average, will minimize the entropy in this distribution, i.e., that is expected to give the most information about the word’s identity

$$\hat{t}_i = \operatorname{argmin}_{t_i} E[H(w|\mathcal{I}_1^i)|t_i, \mathcal{I}_1^{i-1}] \quad (3)$$

$$= \operatorname{argmin}_{t_i} \sum_{\mathcal{I}_i} H(w|\mathcal{I}_1^i) p(\mathcal{I}_i|t_i, \mathcal{I}_1^{i-1}). \quad (4)$$

That is, the minimum can be found by calculating the conditional entropy produced by each possible new input sequence and weighting those entropies by the probability of getting that input sequence given a choice of target location. In information theory (Cover & Thomas, 2006), conditional entropy is standardly defined as

$$H(w|\mathcal{I}_1^i) = - \sum_w p(w|\mathcal{I}_1^i) \log p(w|\mathcal{I}_1^i). \quad (5)$$

¹In the terminology of the literature, this model has only ‘random’ motor error (variance) and not ‘systematic’ motor error (bias), under the assumption that an optimal model would just compensate for any systematic problems with its motor control system.

The second term in the formula for \hat{t}_i , the probability of a particular visual input given a target location and previous input, is given by marginalizing over possible landing positions

$$p(\mathcal{I}_i|t_i, \mathcal{I}_1^{i-1}) = \sum_{\ell_i} p(\ell_i|t_i) p(\mathcal{I}_i|\ell_i, \mathcal{I}_1^{i-1}) \quad (6)$$

and then possible words

$$p(\mathcal{I}_i|\ell_i, \mathcal{I}_1^{i-1}) = \sum_w p(\mathcal{I}_i|\ell_i, w) p(w|\mathcal{I}_1^{i-1}). \quad (7)$$

Putting these together, we have that \hat{t}_i is selected as

$$\operatorname{argmin}_{t_i} \sum_{\mathcal{I}_i} H(w|\mathcal{I}_i) \sum_{\ell_i} p(\ell_i|t_i) \sum_w p(\mathcal{I}_i|\ell_i, w) p(w|\mathcal{I}_1^{i-1}). \quad (8)$$

That is, we can calculate the expected conditional entropy for each possible value of t_i by summing over all possible inputs, whose probabilities are given by summing over all possible identities of the word and landing positions. To see that this sum ranges over a finite number of values, note first that there are only a finite number of possible word identities w to sum over. Given the possible word identities, there are only a finite number of landing positions ℓ_i for which the visual information could possibly help in identifying the word – any landing positions outside this range will not produce any reduction in entropy. Since there is a single visual input \mathcal{I}_i for each combination of landing position and word identity, this summation is over a finite range. To ensure finiteness of the search to find the value of t_i that produces the minimum entropy, Mr. Chips only searches those within the range of the ℓ_i that could give some information about the current word. In case of ties, the model selects the furthest position to the right.

Comparing Mr. Chips to humans

Legge, Hooven, Klitz, Mansfield, and Tjan (2002) present a number of ways in which the behavior of the Mr. Chips model is similar to human reading behavior. The model produces behavior that replicates a number of human findings in word skipping rates, initial fixation locations on words, and refixation rates. The result for word skipping rates – where word skipping for the model is defined as never having any of the word’s characters as the centrally fixated character – is that longer words are skipped less often, and the slope of the relationship between word length and skipping rate has a very similar slope for the model as for humans. For initial word fixation locations, or landing positions, the model replicates the human behavior of most commonly landing at or just to the left of the word’s center, and also the fact that the landing position shifts toward the left as the launch site of the saccade shifts further to the left. For refixations, the model mimics human behavior in showing the proportion of refixations to increase with word length, and in addition, within a given word length class, the model refixates low frequency words a higher proportion of the time than high frequency ones. Finally, as a function of landing position, refixations are the least likely for the model, as for humans, when the initial landing position is near the center of the word.

As noted above, however, it is also the case that the model exhibits some behavior very different from that of human readers. For example, the model’s average saccade length is just 6.3 characters, noticeably lower than that for humans, who are around 8 (Rayner, 1998). Second, although, as mentioned, the slope of the relationship between word skipping rates and word length has a similar slope for the model as for humans, the model skips far fewer words than humans do.² In short, judging by these two measures, a rational model that is using all the information available and expensively calculating the best saccades to reduce entropy in word identification appears to be reading slower than humans do.

In rational analysis, the fact that an ‘optimal’ model is performing worse than humans (here in terms of speed) suggests two likely problems: (a) the model is not making use of all the information that humans use or (b) the model’s computational goal is not the same as the one that humans are solving. As suggested above, we argue that in this case both reasons are partially to blame. Since it has only word frequency information as its model of language, the Mr. Chips model cannot make use of linguistic context to aid in word identification, while there is evidence that humans make heavy use of it. The model also assumes that the goal is to identify each word with 100% confidence, but experiments suggest that humans do not. In the next section, we modify the Mr. Chips model to include some information about linguistic context and a flexible identification confidence criterion.

Extending Mr. Chips

The model described here generalizes the Mr. Chips model in three ways. First, it can use an arbitrary language model as its source of language knowledge, and thus make use of information about the linguistic context in word identification, solving the first problem with Mr. Chips we pointed out above. Second, it can move on to the next word after it achieves a flexible level of certainty about the current word’s identity, solving the second problem. Finally, our model also allows for the standard deviation of the motor error to be an arbitrary linear function of the intended distance, allowing us to incorporate a more realistic motor error function. We describe the model in the same format as we described the Mr. Chips model, first describing its sources of information, and then its algorithm for selecting saccade targets.

Information sources

Visual input The visual input component is unchanged from the original Mr. Chips model.

Language knowledge The model’s knowledge of language is represented by an arbitrary language model that can generate string prefix probabilities, e.g., an n -gram model or a

²The graph given in Legge et al. (2002) appears to show remarkably similar word skipping rates between the model and humans, but that graph is from the sole simulation in the paper for which Legge et al. assumed no motor error. When motor error is included, the skipping rates are significantly lower for the model than for humans, as shown in Figure 1.

probabilistic context-free grammar (*PCFG*). Such models can capture the between-word dependencies needed for the model to make use of linguistic context in word identification.

Motor error In our model as in Mr. Chips, the i th landing position is normally distributed around the i th target location, except that the standard deviation is an arbitrary linear function of the intended distance

$$\ell_i \sim \mathcal{N}(t_i, (\beta_0 + \beta_1 |t_i - \ell_{i-1}|)^2) \quad (9)$$

allowing for the use of a more realistic motor error function. Experiments in this paper use the one from SWIFT (Engbert et al., 2005; $\beta_0 = 0.87$, $\beta_1 = 0.084$).

Algorithm

As in the original Mr. Chips model, at any given point in time, the model is working to identify one word. However, this revised model considers the goal of identifying this word achieved when the marginal probability of some identity for the word given the visual input exceeds a predefined threshold probability α . This flexibility requires the algorithm to be substantially modified to allow for uncertainty about previous word identities and the use of linguistic context. We denote the sequence of words as W , where the first word is W_1 .

Because every word in Mr. Chips was identified with complete certainty, the model always knew precisely at which position the next word to be identified began, and its goal was always to identify this next word. Now that the model has uncertainty about the identities of previous words, however, the goal must be changed. In the revised model, the reader is always focused on some character position n , and its goal is to identify whether some word $W_{(n)}$ begins at that position, and if so, which one, with confidence exceeding α . Once the model has achieved this goal, it then chooses a new character position n via a procedure whose description we leave for later. To be explicit about this goal, we slightly update our original equation for choosing \hat{t}_i , swapping w out for $W_{(n)}$,

$$\hat{t}_i = \operatorname{argmin}_{t_i} \sum_{\mathcal{I}_i} H(W_{(n)} | \mathcal{I}_1^i) p(\mathcal{I}_i | t_i, \mathcal{I}_1^{i-1}) \quad (10)$$

where the conditional entropy is calculated assuming that some word does in fact begin at position n . The fact that our language model can now make use of linguistic context means that the equation for finding the probability of the current word given some visual input (Equation 2) must also be changed to marginalize over identities of the preceding words

$$p(W_{(n)} | \mathcal{I}_1^i) = \sum_{W_1^{(n)-1}} p(W_{(n)} | \mathcal{I}_1^i, W_1^{(n)-1}) p(W_1^{(n)-1} | \mathcal{I}_1^i). \quad (11)$$

These probabilities of strings consistent with the visual input are again given probabilities according to their probability in the language model normalized by the probability of all other consistent strings (cf. Equation 2)

$$p(W | \mathcal{I}_1^i) = \frac{\chi(\mathcal{I}_1^i, W) p(W)}{\sum_W \chi(\mathcal{I}_1^i, W) p(W)}. \quad (12)$$

The second term in Equation 10 is expanded as in Mr. Chips by marginalizing over possible landing positions

$$p(\mathcal{I}_i | t_i, \mathcal{I}_1^{i-1}) = \sum_{\ell_i} p(\ell_i | t_i) p(\mathcal{I}_i | \ell_i, \mathcal{I}_1^{i-1}), \quad (13)$$

but now to incorporate information about the linguistic context, we must next marginalize over possible full sentence strings instead of possible words

$$p(\mathcal{I}_i | \ell_i, \mathcal{I}_1^{i-1}) = \sum_W p(\mathcal{I}_i | \ell_i, W) p(W | \mathcal{I}_1^{i-1}). \quad (14)$$

If we make the simplifying assumption that the model does not consider possible future input about words that are after $W_{(n)}$, this sum can again be finitely computed for a given t_i by a relatively straightforward dynamic programming scheme. The range of possible values of t_i to search through also grows relative to Mr. Chips, because the model must consider not only any position that can give visual input about $W_{(n)}$ itself, but also positions that can give information about any position of uncertainty, since that may indirectly help to identify $W_{(n)}$ through linguistic context. In the case where the language model is an n -gram model, it can be shown that the minimum value of t_i that can contribute toward helping to identify $W_{(n)}$ only extends back to the first uncertain character after the most recent string of $n - 1$ words for which the model has no residual uncertainty. Having established the method of selecting a saccade to identify $W_{(n)}$, we next give a description of the full algorithm of the model, including how to select n .

The model always begins reading by focusing on identifying $W_{(0)}$. Once the probability of some identity for $W_{(0)}$ is greater than α , all the possible identities of $W_{(0)}$ that have not been ruled out by visual input are combined into a set of possible ‘prefixes’. Each of these prefixes has a conditional probability given the visual input, and each one predicts that the next word in the sentence begins at a particular position (i.e., two characters past the end of that string). Thus, the set of prefixes specify a probability distribution over the possible positions at which the next word begins. The model simply selects the most likely such position as the next character position n to focus on identifying $W_{(n)}$.

Now in the general case, the system has a set of prefixes together with their conditional probabilities given the visual input, and a position n , which it is trying to identify the word beginning at. It plans and executes saccades according to the formula for \hat{t}_i , and after getting each new piece of visual information, the model rules out not only possible candidates for the current word, but also possible prefix strings, and renormalizes both distributions. The model’s attempt to identify $W_{(n)}$ can now end in one of two ways: (a) the model’s confidence in some identity of $W_{(n)}$ exceeds the confidence threshold α or (b) the model eliminates all possible candidates for $W_{(n)}$ and thus knows that no word begins at that position. In the former case, the model creates all possible concatenations of prefixes ending 2 characters prior to $W_{(n)}$ (i.e., prefixes whose next word begins at n) with all the possible identities of

$W_{(n)}$, and adds these new strings to the set of prefixes. Then, in both cases, it removes those original prefixes whose next word begins at n from the set. Note that this update of the list of prefixes leaves unaffected prefixes that are incompatible with a word beginning at position n , but still compatible with visual input. Finally, since the set of prefixes again gives a distribution over the starting position of the next word, the model selects the most likely new n and the cycle continues.

Experiment 1

With our new model in place, we can now describe the two experiments we performed to test our hypotheses about the reasons for the Mr. Chips model’s performance being below that of humans in terms of average saccade length and word skipping rates. In Experiment 1, we test the hypothesis that one of the reasons that its performance was below humans is due to its assumption that the goal of the reader is to identify each word with 100% confidence. Specifically, we compare the performance of our model using a 100% criterion vs. a 90% criterion. The former is equivalent to Mr. Chips except for the more realistic motor error function, so for ease of exposition, we will refer to it simply as Mr. Chips.

Methods

Confidence criterion We set $\alpha = 1.0$ to replicate Mr. Chips, and $\alpha = 0.9$ for the model using a slightly lower confidence criterion to trigger moving on to the next word.

Language model Both models used a unigram language model, smoothed with Kneser-Ney under default parameters (Chen & Goodman, 1998; equivalent to add- δ smoothing for a unigram model). As in Legge et al. (2002), the models were trained on a 280,000 word corpus of *Grimms’ Fairy Tales*, containing 7503 unique words. This corpus was normalized by Legge et al. to convert all letters to lowercase, remove all punctuation other than apostrophes, convert all numbers to their alphabetic equivalents, and remove all gibberish words.

Text Following Legge et al. (2002), we tested the models by simulating the reading of 40,000 words of text generated from the language model, ensuring that the reading models had a normative probability model for the text they were reading.

Results

The results for mean saccade size for both models are given in the top two rows of Table 1. As shown in the table, using a criterion of 90% increases the average size of saccades, bringing it a bit closer to the human estimate of about 8 characters. The results for word skipping rates for the two models are plotted as the lower two lines in Figure 1. The results show a modest increase in word skipping rates across almost all word lengths for the new model with a lower criterion, bringing it closer to human performance.

Discussion

Although the gain is modest, the results of Experiment 1 show that changing the goal of the model to one more sim-

Table 1: Mean saccade size (and std. error) for each model

Model	Mean saccade size
Mr. Chips	6.7 (.012)
Without context, 90% criterion	7.1 (.013)
With context, 90% criterion	7.5 (.014)
Humans	≈ 8 (Rayner, 1998)

Figure 1: Proportion of words skipped by word length for each model. In all cases, the standard error of the mean for the Normal approximation to the Binomial distribution is smaller than the symbols. The human data is from Rayner and McConkie (1976) and has no standard errors.

ilar to that of human readers, i.e., relaxing the assumption that words need to be identified with 100% certainty, alters the performance of the model across two measures to look more like human performance. Such a result adds some support to the idea that the relevant human behavior is well understood as a rational response to the demands of the task. It is also worth pointing out that the resulting model maintains and uses uncertainty about previous input, something for which most models of sentence processing do not allow.

Experiment 2

In Experiment 2, we test the effect of allowing the model to use the linguistic context as another source of information for word identification. Specifically, we compare the previous two models to one that includes a 90% confidence criterion as well as a simple bigram model of linguistic context.

Methods

The methods are the same as Experiment 1, except that the new model uses a bigram language model, again smoothed with Kneser-Ney under default parameters.

Results

The results for average saccade length for the new model is given in the third row of Table 1. As shown in the table, giving the model information about linguistic structure increases the

average size of saccades a bit more, bringing it still closer to the human estimate of 8 characters.

The results for word skipping rates for the new model is plotted as the second line in Figure 1. This new model gives an even larger increase in word skipping rates across all word lengths, on top of the increase seen previously, bringing it more in line with human results. Skipping rates are 30% closer to humans than the previous 90% criterion model on average, and for some word lengths are up to 75% closer.

Discussion

The results of this experiment show a case in which making more of the information that is available to a human reader also available to a rational model causes its behavior to more closely approximate human performance. Together with the previous result, this supports the notion that some aspects of reading are well understood as a rational response to the structure of the problem.

General Discussion

In this paper, we presented a new rational model of reading based on Mr. Chips, but which fixes two problems with it – it uses information about linguistic context in word identification and a flexible identification criterion. Experiment 1 showed that the model's performance looks more like humans' when the model's goal is shifted to one more like that of humans, 90% confidence in each word. Experiment 2 showed the model's behavior looks even more like humans' when the model can use information that is used by humans: linguistic context. Taken together, these results suggest that many facets of human reading behavior can be well explained as resulting from a rational solution to the problem of reading. This model adds to the growing literature on rational process models, exploring the extent to which human performance can be viewed as rational agents across a wide variety of complex behaviors, such as multiple object tracking (Vul, Frank, Alvarez, & Tenenbaum, 2009) and online change detection (Brown & Steyvers, 2009).

It is the case, however, that many aspects of human reading behavior cannot in principle be explained by a model such as those described in this paper. This is because much of what we know about human reading behavior is about fixation durations, and these models have no notion of duration. They cannot have a notion of duration because visual input is veridical categorical information about a range of characters, so that there is no reason to stay at a given location for more than one timestep. Reichle and Laurent (2006) overcome this problem by making the simplifying assumption that required processing times on words are a function only of their length.

We believe, however, that the way forward for rational models of reading is to incorporate a model of noisy visual input, so that the model can make decisions about fixation durations to get more or less visual information. In other work (Bicknell & Levy, 2010), we explore the use of such models to answer questions that are impossible to ask with non-rational models of reading such as when and why should

between-word regressions be made, and how should reading behavior change as accuracy is valued more or less relative to speed.

Acknowledgments

We are very grateful to Gordon Legge for sharing the corpus used in the original Mr. Chips experiments. This work also benefited greatly from useful discussion with Jeff Elman, Tom Griffiths, Andy Kehler, Keith Rayner, and Angela Yu, and feedback from the audience at the 84th Annual Meeting of the Linguistic Society of America. The research was partially supported by NIH Training Grant T32-DC000041 from the Center for Research in Language at UC San Diego to K.B., by a research grant from the UC San Diego Academic Senate to R.L., and by NSF grant 0953870 to R.L.

A New Perspective on Visual Word Processing Efficiency

Joseph W. Houpt (jhaupt@indiana.edu) and James T. Townsend (jtowsen@indiana.edu)

Indiana University, Department of Psychological and Brain Sciences

Abstract

As a fundamental part of our daily lives, visual word processing has received much attention in the psychological literature. Despite the well established perceptual advantages of word and pseudoword context using accuracy, a comparable effect using response times has been elusive. Some researchers continue to question whether the advantage due to word context is perceptual. We use the capacity coefficient, a well established, response time based measure of efficiency to provide evidence of word processing as a particularly efficient perceptual process to complement those results from the accuracy domain.

Keywords: Visual word perception; Efficiency; Workload capacity.

As a fundamental part of our daily lives, visual word processing has received much attention in the psychological literature. However, the interest in visual word perception extends beyond its value in communication. The written word is a complex stimulus with which most adults have a large amount of experience. Unlike faces, there is no reason to believe we have any innate ability to perceive words. Thus, word perception may represent the limit of perceptual learning in the absence of innate ability.

Due to the relative ease with which most adults read, it is reasonable to assume that word perception is an efficient process. This is further supported by the intuition that with more experience with a process we become more efficient and we are quite experienced with the written word. Often, the efficiency is measured using single letter perception as a base line. When word context offers an advantage in the accuracy or processing time of perceiving a letter, this supports the claim that word perception is efficient.

From the early days of experimental psychology, researchers have been interested in the value of a word context for perceiving letters. In one study, letters were displayed sequentially to participants at faster and faster rates until they could no longer correctly identify the letters. They found that participants maintained accuracy with shorter durations when the letters were presented as part of a word compared with random letter sequences (Cattell, 1886).

One problem with studies of this nature is that they do not control for the constraint on possible letters that a word context puts on the possible letters. Hence it is not clear from those early results whether the advantage is a perceptual advantage or a decisional advantage. In the late 1960's an alternative task was designed to eliminate the decisional advantage of word context so as to examine the perceptual effects. In this task a letter or word was tachistoscopically displayed to a participant. They then chose from two possible choices, one of which was correct. In the letter condition, the choices were letters. In the word condition, both choices were words

that differed in only a single letter. Since both alternatives were words, the word context was no longer informative as to the identity of the letter. Participants were still more accurate at perceiving letters in the word condition than the letter condition (Reicher, 1969). Furthermore, they found that participants are also more accurate with word contexts than random letter sequence contexts. This is known as the word superiority effect. An efficiency gain of context over letters alone is not unique to words though. If a sequence of letters conformed to the pronunciation rules of English, strings referred to as pseudowords, then participants were again more accurate than letters alone (e.g., McClelland & Johnston, 1977). This is known as the pseudoword superiority effect.

Despite the robustness of the word and pseudoword superiority effects, a comparable effect using response times (and controlling for decisional information due to context) has been elusive. This may be in part explained by the possibility that people will read an entire word even if the task does not require it. Indeed, this has been put forth as further evidence that word perception is special (LaBerge & Samuels, 1974). One of the goals of this paper is to demonstrate a response time based word superiority effect, and possibly a pseudoword superiority effect as well.

Even in the accuracy domain, some researchers continue to question whether there is a *perceptual* advantage due to word context. For example, Pelli, Farell, and Moore (2003) demonstrated evidence for a model of word perception in which letters are perceived independently and with separate detection decisions on each letter. Their evidence comes from comparing the efficiency of word perception as the number of letters in the word increases. Depictions of longer words have more information about their identity, since the more letters that are known, the fewer possibilities there are for the others. Hence, if a person is able to take advantage of this global information, they should need less per letter information as the number of letters increases. However, a model of word perception based on independent, separate decisions on the letters predicts that as the word length increases, the reader will still need the same amount of information per letter to maintain accuracy. In fact participants did need roughly the same amount of per letter information as the number of letters increased, supporting the latter model.

In the next section we describe the capacity coefficient, a response time based measure of efficiency. We propose that this measure, along with a task that controls for both the available information and possibly mandatory word reading, provides evidence of word processing as a particularly efficient process to complement those results from the accuracy domain.

Table 1: Stimuli used for capacity analysis.

The Capacity Coefficient

The capacity coefficient, $C(t)$ is an established response time based measure of the effect of increased load on processing efficiency (Townsend & Nozawa, 1995; Townsend & Wenger, 2004). Specifically, $C(t)$ is a measure of the change in processing rates as the task requires attention to more targets, or possibly more dimensions of a single target. The basic idea of the measure is to compare response times when reading the full string to the times that would be predicted if each character took the same amount of time, whether or not it was in a string.

The capacity function for an exhaustive task is defined using the natural log of the cumulative distribution function, $K(t) = \ln F(t); F(t) = \Pr\{RT \leq t\}$, and is similar to the cumulative hazard function used in survival analysis. If K_{c1} is the cumulative hazard for the first character response times, K_{c2} is the cumulative hazard for the second character, etc., and K_S is the cumulative hazard for the string condition, the capacity coefficient is given by $C(t) = [\sum_{i=1}^4 K_{c_i}] / K_S$.

This formulation is based on the predictions of the unlimited capacity, independent, parallel (UCIP) model. The assumptions of the UCIP model are sufficient conditions for there to be no change in the rates of processing with increased load. If these assumptions hold then the relationship between the processing times of the string to the processing times of the individual characters is as follows:

$$\Pr\{RT_S \leq t\} = \Pr\{RT_{c1} \leq t\} \Pr\{RT_{c2} \leq t\} \Pr\{RT_{c3} \leq t\} \Pr\{RT_{c4} \leq t\}$$

By taking the natural log of both sides of this equation, then dividing by the left hand side, we see that the UCIP model predicts $C(t) = 1$ for all $t \geq 0$. This gives us a baseline for comparison. If a person performs better than the baseline model, $C(t) > 1$, their performance is referred to as super-capacity. There are multiple ways performance could be super-capacity. For example, if there is facilitation between the characters, or in more extreme cases if the information from the characters is accumulated together toward a single decision (Townsend & Wenger, 2004).

Performance worse than the baseline model, $C(t) < 1$, is limited-capacity. In contrast to the case of super-capacity, inhibition between characters could result in limited-capacity. A standard serial model (independent and unlimited capacity) also predicts limited capacity. Furthermore, if the system only has a certain amount of resources to dedicate to the

task, limited capacity performance would be expected. For example, a fixed capacity parallel model (a finite amount of resources is evenly divided up among the current processes) also predicts limited capacity.

When performance is about the same as the baseline model, $C(t) \approx 1$, then we refer to it as unlimited capacity. Of course this would happen if all of the assumptions of the baseline model were met. Alternatively some blend of features that lead to limited capacity and features that lead to super-capacity could balance out and result in capacity around 1. It is not likely that people are truly unlimited-capacity or super-capacity in the extreme case of very long words, but it is reasonable for shorter words.

The capacity coefficient measures processing efficiency in isolation by comparing the capacity coefficient to predicted values of unlimited capacity, independent, parallel models. Thus, this measure also allows us to compare the efficiency of a variety of processes despite any possible differences in difficulty due to component processes. In particular, we are able to draw conclusions about the efficiency of word processing relative to pseudoword, non-word, upside-down non-word, and unfamiliar character string processing.

Method

To properly compare perceptual efficiency across words, pseudowords, non-words, upside-down words and unfamiliar characters, our task must eliminate the extra information available given a word context. Furthermore, the possibility that words are exhaustively processed automatically may lead to a disadvantage for words on response time measures. To address these issues, we adapted a task from Blaha, Busey, and Townsend (2009) which forces exhaustive processing of the characters in a string. This experiment consists of two components. First, we measure the participants response times to correctly identifying the target string. To ensure that participants base their identification on the entire string and not any subset, we include a distractor of a string with a single character different in each position in the string. For example if the target is "care" then "bare," "cure," "cave" and "card" are used as distractors (see Table 1). Second, the participants distinguish between letters in isolation. Whereas in the exhaustive case the participant needed to distinguish between "bare" and "care," we now only require them to distinguish between "b" and "c." The response times on these tasks are used for computing the predicted performance of the UCIP model.

Stimuli Stimuli were created using GIMP version 2.2. For each stimulus, the character or characters were written in black in 29pt Courier onto a gray (200) background. Then each stimulus was doubled in size. There were five types of stimuli used: words, pronounceable non-words (pseudowords), unpronounceable non-words, upside-down unpronounceable non-words, and strings of Katakana characters. All strings used were four characters long. Words were chosen so that the frequency of the target was roughly equal to the average frequency of the distractors. Pseudowords were taken from the ARC Nonword Database (Rastle, Harrington, & Coltheart, 2002). Table 1 summarizes the stimuli used for both the single character and exhaustive trials for each type.

Participants Participants were recruited from the Indiana University population. Eight females and two males participated in this study, all of whom were native English speakers and reported that they did not read or speak Japanese. Their ages ranged from 19-34. All participants reported having normal or corrected to normal vision, no difficulty reading English, and no prior diagnoses of a reading disorder. Participants were paid \$8 per session, and received a \$20 bonus upon completion of all sessions. Each session lasted between 45 and 60 minutes.

Procedure All experimental conditions were run using DMDX version 2.9.06 developed at Monash University and at the University of Arizona by K.I.Forster and J.C.Forster. Stimuli were presented on a 17 Dell Trinitron CRT monitor running in 1024x720 mode. Participants used a two-button mouse for their responses.

Each session was dedicated to a type of stimuli and there were ten total sessions, two sessions for each type. At the beginning of each session, we read the participant the general instructions for the task while those instructions were presented on the screen. The instructions encouraged participants to respond as quickly as possible while maintaining a high level of accuracy. Each session was divided into five blocks, one block of string stimuli and a block for each of the corresponding single character stimuli. Each block began with a screen depicting the button that corresponded to each of the categories. Participants had 40 practice trials, 20 of each category. Next participants were given 240 trials divided evenly between the two categories, the first 40 of which were not used in the analysis. Each trial began with a 30 ms presentation of a fixation cross. After a random delay (300-600 ms), the stimulus was presented for 80 ms. Participants had a maximum of 2500 ms to respond. If the participant responded correctly, the next trial started after a 400 ms delay. If the participant responded incorrectly, a tone was played then the next trial started after a 400 ms delay. The session order was counterbalanced among the participants so that participants completed the different types on different days and in different orders.

Analysis All data was analyzed using R. Analysis was limited to the correct responses on the target category. We com-

puted a repeated measures ANOVA of the response times in each condition. We then calculated the AND capacity coefficient, $C(t)$ for each participant and each condition. For each capacity coefficient, bootstrapped confidence intervals (95%) were calculated to determine if the function was reliably above or below 1 for any length of time.

To facilitate comparison between conditions, we analyzed the capacity functions using functional principal component analysis (fPCA, Ramsay & Silverman, 1997). In fPCA, each capacity function is treated as a weighted linear combination of a common set of basis functions. The set of weights is specific to each function and are therefore an alternative representation of the individual function. Similar to multivariate PCA, the basis functions each explain some percentage of the variance in the data. By treating those basis functions that explain only small amounts of variance as noise, we can achieve a concise representation of our data in terms of just the weights. The justification for applying fPCA is essentially the same as standard PCA; further details can be found in Ramsay and Silverman (1997).

To apply fPCA to capacity coefficient functions, we first calculated the empirical $K(t)$ by taking the natural log of the empirical cumulative distribution functions. Each of those functions were then interpolated using monotone cubic interpolation. The capacity coefficient for each condition was then calculated for each condition using those estimated K functions, then registered by aligning the median of each participants response time data in each condition. Functional principal components was then applied to the smoothed and registered functions, with the data weighted by the overall density function of the response time data and factor scores were computed based on a varimax rotation.

Results

Using a repeated measures ANOVA we found significant effects of condition [$F(4, 18713) = 937.75, p < 2.2e - 16$] and whether the stimulus was a target for each of the string stimuli [$F(1, 18713) = 10.75, p = 0.001$], along with a significant interaction effect [$F(4, 18713) = 57.73, p < 2.2e - 16$]. Eight of the ten participants were faster on words and pseudowords than the other two conditions. Participant 6 was fastest on non-words while Participant 1 was fastest with words, but faster with non-words and upside-down non-words than pseudowords. Eight of the ten participants were slowest with Katakana, while Participant 7 was slowest with non-words and Participant 9 was slowest with upside-down words. While these results are interesting, this level of analysis does not account for the varied difficulty of processing each of the components. Hence, we turn to the capacity coefficient.

The results for the capacity analysis are shown in Figure 1. Bootstrap confidence intervals were used to determine significance, but are not included due to space limitations. Significance in comparisons against the UCIP model was determined by overlap of 99% confidence intervals with $C(t) = 1$.

In the word condition, nine participants had capacity coef-

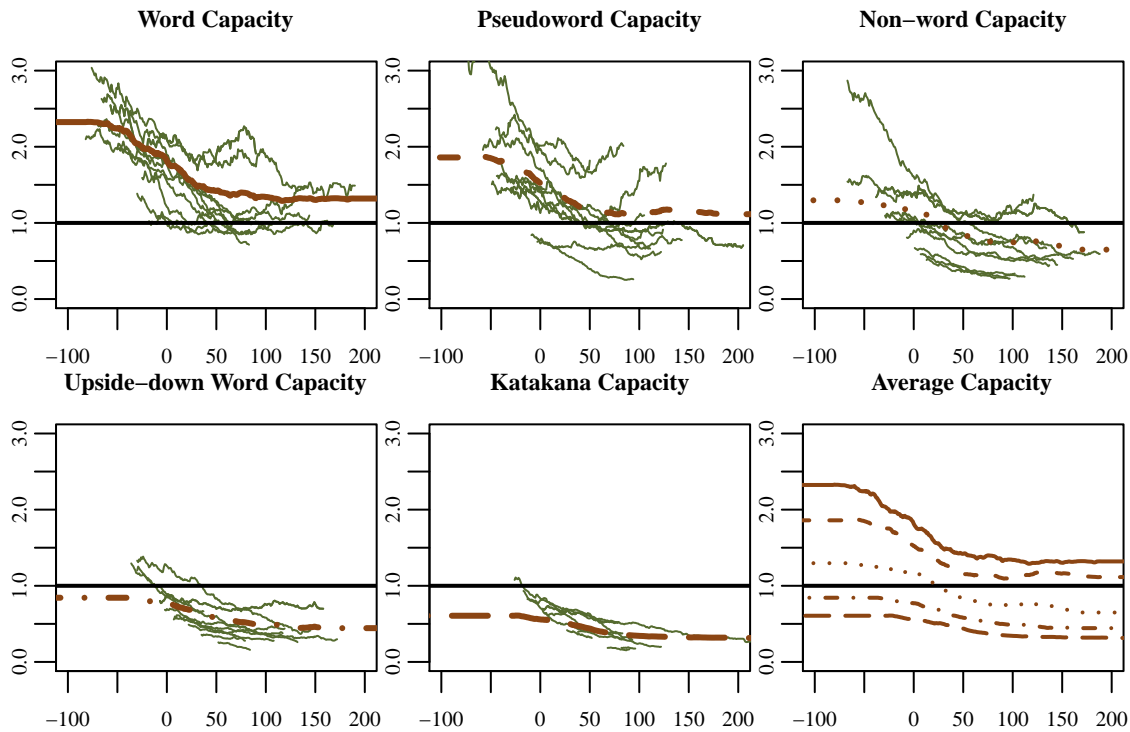

Figure 1: Capacity Coefficient values across time. Thin lines represent individual participant data and thick lines are the mean function across participants. The bottom right panel contains the mean function for each condition together.

ficient values significantly above one for at least some time (1-3, 5-10) and no participant had capacity values below 1 for any time. In the pseudoword condition, eight participants were super-capacity for some time (1, 2, 5-10), two of whom were limited capacity at later times (7, 8). The other two were limited capacity most of the time (3, 4). Three participants were super-capacity for some time in the non-word condition (1, 6, 8), one of whom was limited capacity for later times (8). The other seven participants were limited capacity for some time (2-5, 7, 9, 10), six of whom were limited capacity most of the time (3-5, 7, 9, 10). In the upside-down non-word condition, all participants were limited capacity for most times, with only three participants significantly super-capacity for early times (6-8). All participants were limited capacity for all times in the Katakana condition.

The bottom right panel of Figure 1 shows the capacity function averaged across participants for each condition. The average word capacity was the highest, followed by pseudoword, non-word, upside-down non-word, and lastly Katakana.

Figure 2 depicts the first principal component function of the capacity coefficients. This demonstrates that the feature that best distinguishes performance is a relatively large change in magnitude at early times, tapering off to a slight opposite change at later times. This first principal component describes 94% of the variance in the capacity functions. Furthermore, the condition was found to be a significant predictor of the factor score on this component in a repeated mea-

sures ANOVA [$F(4, 36) = 18.56, p < 2e-8$].

Discussion

Due to space limitations, we limit the majority of our discussion to the word and, to a lesser extent, the pseudoword results. We have demonstrated clear evidence of super-capacity processing of the word stimuli for nine of the ten participants. These participants are efficiently perceiving the whole word in comparison to individual letter perception. As mentioned earlier, evidence for the word superiority effect has been difficult to demonstrate with response times. These findings provide that evidence and thus agree with the majority of the word perception literature based on accuracy results. Based on comparisons across conditions, it is also clear that the word perception was more efficient than non-word, upside-down word, and strings of Katakana perception, findings that again match with the results reported for accuracy (e.g., McClelland & Rumelhart, 1981).

There is also evidence for a pseudoword superiority effect, another well established effect in the accuracy domain (McClelland & Johnston, 1977). Although the evidence was not as consistent as the word results, eight of the ten participants were super capacity for some time, with only two participants showing significantly limited capacity processing for most times.

The functional principal components analysis demonstrates that most of the differences in capacity across participants and types of stimuli occur early in the response time

Figure 2: The first principal component of the capacity coefficient functions, which accounts for 94% of the variance. The first panel shows the component function with the mean capacity function for comparison. The second panel shows the difference between the component and the mean functions. The third panel depicts the factor scores on this component for each participant in each condition.

distribution. For all participants except Participant 6, the factor scores are higher for words and pseudowords than any of the other three conditions. This indicates that the word and pseudoword superiority effects are most pronounced in faster response times.

There are multiple plausible explanations for the capacity coefficient results demonstrating particularly efficient processing of words. At least one of the assumptions of the UCIP model must have been violated, so we examine each of those assumptions in turn. Each of these violations have been considered previously for modeling the accuracy based superiority effects.

One assumption that may have been violated is that of independence. If there is any type of facilitation between the letter processes, each letter would be processed faster within a word which would explain the capacity coefficient values above one. There could be many explanations of this facilitation. For example, word processing mechanisms may in fact take advantage of the considerable amount of co-occurrence between letters in English. As is often observed, there are only a fraction of possible four letter combinations used for words and it would be surprising if we did not take some advantage of this reduction in uncertainty. This correlation between letters is an important part of how connectionist models explain the word superiority effect (McClelland & Rumelhart, 1981; Plaut, McClelland, Seidenberg, & Patterson, 1996; Coltheart, Rastle, Perry, Langdon, & Ziegler, 2001).

Another, related component of many visual word processing models is the phonological pathway. If a phoneme is activated as a possible interpretation of some letter combination, then it may in turn send positive feedback to those letters, speeding up their processing. Hence a phonological component of visual word processing could also lead to capacity coefficient values above one. Both the correlation between letters and the lack of a regular pronunciation of the non-words imply that these predictions are consistent with lack of evidence against the UCIP model of non-word processing. The

phonological explanation is also supported by the evidence of a pseudoword superiority effect.

Another assumption of the UCIP model is that the letters are processed in parallel, with a separate detection of each letter. An alternative architecture that does predict capacity coefficient values above one is the coactive architecture. By pooling activation from each of the letters when processing a word, the word is processed much faster than if each letter is processed separately. A coactive architecture in this sense can be thought of as an extreme version of a facilitatory parallel model, in which all activation in each of the letters is shared. Many connectionist models of visual word perception assume a type of coactive architecture. In these models the activation accumulated in favor of a letter is immediately passed on to the word level. In this framework the type of parallel model assumed in the UCIP would not pass on any activation until the letter process is complete. There is some middle ground between these two extremes. One example is that of squelching suggested by Pelli et al. (2003). In this case, the activation from the letter process would only be passed on once it is above a certain threshold. It is important to note that these results are not necessarily inconsistent with serial processing, but for a serial model to predict capacity-values above one it would need to include facilitation and/or be super-capacity.

A coactive architecture could also lead to violations of the assumption of unlimited capacity, so that seemingly more resources are available to each component when more components are present. Capacity values above one imply that the participant had more than four times as many resources dedicated to the word task compared to the letter task, so that none of the individual letter processes has less. In this sense the advantage is similar to chunking; when groups of letters are recognized together, fewer resources are needed for each individual letter. Participants probably do not have truly unlimited resources to dedicate to the task, but having enough to act super-capacity with four letters is not so unreasonable.

There were clearly individual differences present in these

data, particularly in word and pseudoword processing capacity. This finding mirrors results reported in accuracy based studies (e.g., Reicher, 1969) and it will be an interesting extension of this work to compare the capacity measure to established measures of individual differences in reading.

Finally, we reiterate the importance of going beyond the simple ANOVA analysis of these data. Merely finding an ordering of the means in the string conditions says nothing about the relative processing efficiencies. For example, faster word processing than non-word processing could be due to the letters in “care” being relatively faster to process than the letters “rlkf”. Workload capacity analysis, however, takes the processing of the components into account in estimating efficiency.

Summary

We have demonstrated response time based evidence for visual word perception as a particularly efficient process. This includes evidence that words are more efficiently perceived than predicted by the individual letter reading times, and evidence from comparing word perception efficiency to non-word stimuli. Based on the workload capacity analysis, there is also evidence for a pseudoword superiority effect in the response time domain although not as strong as for word superiority. The evidence we present negates models of word processing that assume parallel, independent processing of letters with separate decision thresholds on each channel. This deeper level of understanding of visual word perception required a shift from statistics based on comparing means toward a more theoretically rich, modeling-based approach.

The online processing of modal verbs: Parallel activation of competing mental models

Abstract

A simple audio-visual two-alternative forced-choice task was conducted to examine processing differences between the modal verbs *should* and *must*. Unambiguous propositions were either agreed with or disagreed with, and participants' eye movements were monitored as they heard and read the sentence. Reaction times reveal no differences in processing. However, closer time course analyses revealed a divergence in fixations to the target for *should*. These results suggest two mental models are simultaneously activated, entailing both agreement and disagreement with the statement in question.

Keywords: Language understanding, semantics, modal auxiliaries, eyetracking

Introduction

Modal verbs are a central part of modality, the part of language that broadly concerns the factual status of affairs (Frawley, 1992). These verbs are often used to express how the world should be (*deontic* modality) or how the world must be because of some inference (*epistemic* modality) (Sweetser, 1990; Nuyts, 2006). The primary semantic function of modals is to deintensify the meaning of what is stated, by indicating some degree of uncertainty (Close, 1975). Humans are uniquely equipped to think and communicate states of affairs that are ideal, that have never been witnessed first-hand, or that can only exist if some past action were different. For instance, the epistemic use of the modal *must*, as in "You must be bored" indicates an inference (e.g., somebody is nodding off or appears inattentive), while its deontic use, as in "You must pay your taxes" indicates an obligation to perform a series of actions that are ideal according to customs and laws. This initial line of research focuses on the perception of deontic modality. Spoken language is processed incrementally (Marslen-Wilson, 1975), and thus the parallel processing and certainty differences of *should* and *must* may be accessible when temporally sensitive metrics are used.

Modals are of interest to developmental psychologists who investigate reasoning. In one study, children predicted the outcome of a scenario in which a character used a phrase such as "You can't go outside" directed toward a fictitious character (Byrnes & Duff, 1989). Statements including *might*, *have to*, *can*, and *can't*, were used. The results revealed that children ages 3-5 are able to combine negation (*can't*) and modal auxiliary intensity to infer future actions in a story, specifically performing more accurately with *have to*, and less accurately with *might*. Children often responded with the opposite of the correct prediction with a

negated modal (i.e. "You can't go outside" was often interpreted as "Johnny went outside"), indicating some early competition in affirmative and negated reasoning. Even at an early age, children know how to make concrete, dichotomous decisions when modal verbs are used. (See also Bliss, 1988; Green, 1979; Hirst & Weil, 1982; Moore, Bryant & Furrow, 1989; Moore, Pure & Furrow, 1990.)

Adults also reason proficiently, in some cases facilitated by the use of modal verbs. In a Wason card selection task, participants made more errors with traditional if-then logic trials, when they were phrased as "if *p* then *q*" compared to those phrased with the deontic modal *must*, as in "if *p* then *must q*" (Cheng & Holyoak, 1985; see also Cosmides, 1989 and Girotto, Light, & Colbourn, 1988). These studies are offered as evidence for pragmatic constraints influencing decisions more than syntactic constraints. Thus, it is crucial to use natural stimuli one may hear in everyday conversation. This result also points to an amplification of certainty when *must* is used as compared with non-modal sentences.

These studies are informative because they provide insights into accuracy, but there remains a large gap between these and recent findings in decision-making and incremental, online speech perception. McKinstry, Dale & Spivey (2008) used computer-mouse tracking to study people's responses to phrases varying in degree of truth. They found that as uncertainty increases in a statement, deviations from a straight computer-mouse trajectory show up as a spatial attraction toward the competing response. For example, "You should brush your teeth everyday", rated as being completely true, showed a direct path to the "yes" response (with little curvature toward the "no" response), whereas the ambiguous phrase "Murder is sometimes justifiable" elicited substantially curved computer-mouse trajectories. Thus, making a decision about truth appears to be a process that unfolds over time, and is not made in terms of absolutes. Measurements of an ongoing response that begins while stimulus comprehension is still in progress can thus reveal subtleties in processing and brief considerations of alternative responses, which are not revealed in identification data (see Magnuson, 2005).

Some have referred to modal verb use as being indicative of degree of certainty, where deontic modal uses range from uncertain to certain (Close, 1975, p. 273). However, this hypothesis has not been tested perceptually, and it is unknown when or how this uncertainty is dealt with when a discrete response is required. Eyetracking can reveal probabilistic activations of two or more possible responses

unfolding over time, as eye fixations are closely time-locked to speech input. Studies that use this method have yielded much evidence for the idea that speech perception is incrementally processed (Allopenna, Magnuson & Tanenhaus, 1998; Altmann & Kamide, 1999; Spivey, Tanenhaus, Eberhard & Sedivy, 2002; Knoeferle, Crocker, Scheepers & Pickering, 2005), and that context is integrated continuously as a statement is unfolding (Sedivy, Tanenhaus, Chambers & Carlson, 1999). Thus, if modal verbs are simply contextual cues as to the intended strength of certainty, the process of coming to agreement or disagreement with a modal phrase should be quantifiable in terms of proportions of fixations over time.

Given that modal verbs presumably mitigate the truth of statements (Frawley, 1992), and that decisions about the truth appear to be probabilistically weighted according to degree of truth (McKinsty et al., 2008) it is reasonable to predict that different modal verbs will exert different forces on agreement dynamics. We predicted that *should* and *must* exert their influences differently, allowing for a temporary phase of considering an incorrect response. That is, the modal verb *should* may more readily allow the parallel consideration of both agreeable and disagreeable mental models of a given statement (or perceptual simulations of the possible states of affairs). If this uncertainty follows the Close (1975) scale, *should* will trigger more eye movements to the competing response than *must* because *should* is marking greater uncertainty.

The process of agreeing with a statement in an abstract sense may be made in terms of committing to reality, while simultaneously considering alternate, possible states of reality. We propose that predicates with modal verbs are processed as contingent statements, which are gradually resolved into one of the mental models, as they are being perceived.

The alternative hypothesis neglects interstitial stages of processing, and would be consistent with traditional linguistic definitions of modality. These grades of certainty hint at a probabilistic output, but make no predictions of competition being an intermediary mechanism in this decision-making process. Specifically, this would appear as a weakening or strengthening of looks to a target, with random looks to a competitor. This would be in line with certainty being a component, but the lack of competition would also predict reaction times to *must* statements would be faster than those to *should*. A lack of differences in looks to the competing response would also indicate a decision in terms of absolutes. In this case, the outcome could be modeled with traditional logical operations, which incorporate some degree of truth and/or certainty.

Methods

Participants. A total of 39 participants were run, 20 in the Should condition, and 19 in the Must condition. Each was right-handed or ambidextrous, native English speaking, and had normal or corrected to normal vision. Participants received course credit for participation. The study adhered

to the university's IRB standards, and included a debriefing session.

Stimuli. Thirty-one sentences were created, once using the modal *should* and then replicated for *must*, yielding 62 sentences. All were written in the second person (directed at the reader), for instance, "You must/should brush your teeth everyday" where 15 of each set were unambiguously agreeable, and 16 were unambiguously disagreeable as in "You must/should eat from a dirty plate". All stimuli are available from the first author upon request. A male speaker recorded these sentences in a quiet room multiple times, and each recording was selected on the basis of being similar and least variant in pitch, loudness and timbre. Silences were cut off the beginning and end of the recording at zero crossings to avoid audible pops, so there was no silence at the beginning or end of each file. All files were amplitude normalized. Final wav files were sampled at 44kHz in stereo sound, to be presented binaurally over headphones.

Text versions of the stimuli were rated by 100 undergraduate students at UC Merced. Survey participants were excluded from eligibility to participate in the main experiment. Each rated the sentences on a Likert scale of 1 to 7 on agreement-disagreement. For Disagree statements, 7 was the most disagreement, and 1 was the least disagreement, and for Agreement statements 7 was most agreement, and 1, least. All stimuli were on the high end of the scale for *must* (Agree: $M=6.1$, $SD=1.1$; Disagree: $M=6.1$, $SD=1.7$) and *should* (Agree: $M=6.1$, $SD=0.9$; Disagree: $M=5.7$, $SD=1.5$). Differences between Agree and Disagree were insignificant for each condition ($p>.1$).

Procedure. A screen displayed Agree or Disagree response boxes on the right and left side of the screen, with stimulus text presented in the middle approximately 200 pixels below the choices. In a drift correction before each trial, participants were required to press the spacebar on a keyboard while looking at a marker on the screen. This marker also functioned as a fixation point, to control eye position at the beginning of each trial. The left and right response boxes were 250x250 pixels, and contained the word "Agree" or "Disagree," with their relative positions randomized across trials. Simultaneous with the onset of the written sentence, a matching auditory file was played. The spoken instructions that were given to the participants in advance of the experiment informed them about the kinds of sentences they would encounter, and asked them to respond with either the left or right arrow key to indicate which side of the screen contained their chosen Agree/Disagree response. Modal verb (*should/must*) was a between subjects variable to disguise the key manipulation of the study.

Participants wore a head mounted Eyelink II eyetracker, sampling at 500 Hz. In addition to eyemovements, the response, reaction time, and side of screen were collected.

Results

Responses were extremely accurate, with an average of 30 correct responses ($SD: 2.6$) and with 14 of the total 39

participants responding accurately to all stimuli. The Should and Must accuracy averages were similar, with Should at about 95% correct (SD : 1%) and Must at about 96% correct (SD : 5%). Incorrect responses are excluded from all analyses.

The final response occurred at an average of 2534ms (SD : 799ms). Reaction times by condition are presented with standard deviations in parentheses here in Table 1.

Table 1: Reaction times by condition

	Positive	Negative
Should	2503ms (542ms)	2454ms (565ms)
Must	2645ms (797ms)	2535ms (1178ms)

A 2x2 mixed ANOVA was conducted to explore differences, with Should versus Must as a between-subjects variable, and Positive versus Negative as a within-subjects variable. Should and Must did not differ as well as Positive and Negative showing no difference or any interaction (all tests: $p > .1$). To further explore if one condition may contain differences, separate paired-samples t-tests were conducted. Both conditions contained no significant difference between Positive and Negative statements ($p > .1$).

Eyetracking. One participant in the Should condition was excluded from all eyetracking analyses due to experimenter error. Fixations were coded in a binary fashion over time to 1 of 4 areas of the screen: target, competitor, text, or blank regions. Each port was extended 100 pixels in each direction to allow for error in the track. Graphs of the time course for each condition can be found in Figure 1.

Overall proportions of fixations were subjected to independent samples t-tests, to examine differences between looks to the target, competitor, text and blank regions of screen between the two conditions, for both Positive and Negative stimuli. In a comparison of Should and Must for Positive trials only, looks to target, text and blank regions of screen did not reliably differ ($p > .1$). Looks to the competitor reliably differed ($t(36)=2.4$, $p=.02$), with more fixations to the competitor for the Should condition (M : 0.097, SD : 0.044) than for Must (M : 0.064, SD : 0.065). A similar trend is seen for Negative trials, with fixations to the target and blank regions no different from one another ($p > .1$), fixations to the competitor greater in the Should condition ($t(36)=2.9$, $p=.006$), and fixations to text marginally significant with more looks to text for Must ($t(36)=-1.8$, $p=.08$). Thus, the prominence of the competitor is greater for *should* than for *must* regardless of response type, but not at the cost of looking to the target in particular.

Figure 1: Timecourse by condition – Each panel represents one of four conditions, where Must and Should are between-subject conditions, and Negative (where the target is Disagreement) versus Positive (target Agreement) stimuli. Each line represents the probability of fixating on that particular region of the screen at that moment in time.

To test whether looks to the competitor in the Must condition were negligible or not, a one-sample t-test against a value of zero was performed. Positive Must was significant for the competitor against a value of zero ($t(18)=7.61$, $p<.001$) as was Negative Must ($t(18)=9.68$, $p<.001$). This analysis shows that there are still some looks to the competitor and thus, that processing statements with *must* is not likely to be an all or nothing process.

Because these tests examine positive and negative stimuli separately, it can be useful to look at the differences between Positive and Negative trial fixations over time. There may be a window of time during which there are more fixations to a certain region when Positive stimuli are heard, and another window during which a region is more prominent for a Negative stimulus. By pooling all time in previous analyses, there is a risk of averaging and washing out these differences. Graphically we can examine this by subtracting fixations in Negative trials from the Positive for each time step. Thus, the y-axis becomes a kind of valence scale, where 0 indicates no difference between looks for Positive and Negative stimuli. Positive y means a bias toward that particular port in Positive trials, and negative y is bias during Negative trials. Figure 2 shows that in the Should condition, between 1244ms and 2200ms there is a bias toward looking at the Negative Target, and a bias during this same time window toward looking at Positive Text. These differences were also mapped out for the Must condition, but were uninformative and will not be investigated further here.

Figure 2: Difference in average fixations over time – This graph is constructed by subtracting average fixations on Disagree trials from Agree trials. Divergence from no difference was observed at 900ms through 1799ms for Text and Target areas of the screen.

Time was binned into Beginning (0-899ms), Middle (900-1799ms) and Final (1800ms-3000ms). These time bins were analyzed in a similar way to the previous fixation analyses, where average proportions of fixations to each port were output for each subject in each condition, and then compared across the Positive / Negative dimension in a paired samples t-test. As predicted, there were no differences in looks to any regions of the screen in the Beginning time window or the Final window ($p>.1$).

Fixations to the Target in the Middle time window were greater for the Negative stimuli (Positive: $M=0.28$, $SD=0.11$; Negative: $M=0.322$, $SD=0.14$; $t(18)=2.17$, $p=.043$). Other ports revealed no differences ($p>.1$).

Discussion

For the Should condition, the increased looks to the competitor seemed to indicate that the competing response is more active throughout the trial than in the Must condition. A lack of differences in looks to the target where the competitor is prominent indicates that this increase is not competition, but rather an increase that comes at the cost of no particular region of the screen. Although there are very few looks to the competitor in the Must condition, a test against a value of 0 revealed that there are still some occasional looks here. However, because of the random assignment of side of response, we cannot rule out the possibility that this was due to scanning for the location of the correct response, instead of a brief consideration of responding in this way. Reaction times were uninformative, but further investigation of the middle of the trial revealed that the correct target Disagree is fixated on more, showing an earlier rise in looks to the target on Negative trials in the Should condition. For example, when the stimulus was “You should eat from a dirty plate”, the participant fixated on the correct Disagree port earlier than with a Positive stimulus such as “You should study hard for exams”.

Previous work has made bold claims for a domain-specific, innate, deontic-reasoning module (Cummins, 1996; see also Gigerenzer & Hug, 1992). Also, while not making direct comparisons between different modal verbs, Traxler, Sanford, Aked & Moxey (1997) indicate that one of their assumptions is that all modal verbs carry a possibility marker. As it has been shown here though, deontic reasoning takes place as the speech is being heard, as revealed by eye fixations. Because this decision is not solely driven by auditory information, but must rely on visual input and rapid sharing with areas that drive eye movements, it is unlikely that deontic-reasoning is domain-specific. Further, since the decision is being made as semantic and syntactic information are still coming in, it would be difficult to integrate a specific module for deontic reasoning without having continuous access to semantic and pragmatic constraints as this information arrives, which would be in line with constraint-based theories of sentence processing (e.g., Tanenhaus & Trueswell, 1995).

The semantic theory of possible worlds (Hintikka, 1975) fits with these results, where the set of possible worlds could be compared to output nodes in a dynamic neural network. Upon hearing a sentence with the word “should”, the set of output nodes would have some activation for semantic features of the proposition, some true (partial activation above some threshold), and some false (below threshold activation). For example “You should eat from a dirty plate” would perhaps simulate a dirty plate, a clean plate (an alternative based on experience), motor plans of eating motions, etc. As time moves forward, although

“dirty plate” is explicitly stated, the activation for the dirty plate node would gradually fade while the clean plate node ramps up. Thus, although it is possible to eat from a dirty plate, and there may be some temporary fleeting time in which this is true in some possible world, we gradually resolve into a set of possible worlds or nodes based on previous experience in our world. While we do not propose any mechanism of how differences in certainty might be learned, it is possible to create a kind of possible worlds network with a simulation of simple visual, auditory, sensory feature nodes in combination with a simple recurrent word learning network (Anderson, Huette, Matlock, & Spivey, in press; Howell, Jankowicz & Becker, 2005).

These results reveal that agreement with obvious, unambiguous, everyday standards of conduct can be strongly affected by the choice of modal verb. Highly unambiguous sentence processing unfolds over time, and is susceptible to the influence of subtle variation in verbal modality. It is likely that these intermediate stages of processing are crucial to how one perceives, and makes decisions when these modal auxiliaries are used in everyday discourse, and an integration of compatible linguistic and psycholinguistic theories will be necessary for resolving further debates on the nature of reasoning where modal verbs are involved.

Abstract

Grammatical gender is independent of biological sex for the majority of animal names (e.g., a male giraffe is grammatically treated as feminine). However, there is apparent semantic *motivation* for grammatical gender classes, especially in mapping human terms to gender classes. This research investigated whether this apparent motivation in mapping between grammar and biological sex affects deductive inference in German speakers. We identified two contexts in which speakers unconsciously over-generalize the grammar-semantics mapping to make inappropriate deductive inferences about sex-specific biological properties. They tended to erroneously accept deductions when the sex in the premise and the grammatical gender of the target animal agreed. The sex-gender agreement affected the inference even when the sex of the target was explicitly indicated (e.g., die_[FEM] männliche (male) Giraffe). Experiment 2 further suggested that these effects occur only when the gender-marking article accompanied the noun. Implications of the results for linguistic relativity is discussed.

Introduction

Many languages of the world have a system of grammatical gender, where nouns are assigned to one of the limited number of gender classes (Corbett & Fraser, 2000). Unlike languages that mark gender only semantically (e.g., English), languages with grammatical gender assign gender to all nouns regardless of whether or not referents have a biological sex. The link between gender assignment and conceptual properties of non-human referents has widely been said to be arbitrary (Aikhenvald, 2000; Fox, 1990), as grammatical gender is not relevant to biological sex for a majority of words. For example, in German, the word *giraffe* is grammatically feminine and *elephant* is masculine, but it is not the case that all giraffes are female or that all elephants are male. Nonetheless, the feminine article *die* (_[FEM]) must be applied when one refers to a grammatically feminine noun and the feminine pronoun *sie* must be used as an anaphoric reference, whether the referent is biologically female or male (e.g., *die männliche* (male) *Giraffe*). Here,

an interesting question is to what extent speakers are able to separate the biological sex of an animal from its grammatical gender. From the perspective of a speaker of language without grammatical gender, it appears confusing that one has to use the feminine article and the female pronoun even when the giraffe is actually male. Of course, speakers of a language with the grammatical gender system must know that grammatical gender does not directly reflect biological sex. However, are the speakers completely immune to the influence of grammatical gender when they draw inferences about the animal's sex-specific biological properties? It is possible that the few cases of semantic correspondence between grammatical gender and biological sex may have resulted in an overgeneralization during the process of language acquisition. In German, for example, salient female terms such as *woman*, *lady*, *mother* are grammatically feminine, while salient male terms such as *man*, *boy*, *father*, are grammatically masculine (*Natural Sex Principle*, cf. Zubin & Koepcke, 1986).

Thus, speakers may falsely generalize this *exceptional* mapping between gender class and biological sex to words for animated entities in general. This assumption is consistent with Vigliocco and colleagues' (Vigliocco, Vinson, Paganelli, & Dworzynski, 2005) *sex-and-gender-hypothesis*, which proposes that a conceptual influence of grammatical gender originates in speakers' first noticing the correspondence between grammatical classes and corresponding conceptual classes. In other words, acknowledging the link between biological sex and the grammatical gender class in the case of some salient human-specific terms leads speakers to develop a general anticipation that even non-human animals from the same grammatical gender class are more similar to one another than animals from different grammatical gender classes.

Most of the previous research has asked whether and to what extent grammatical gender influences speakers' concepts of entities in terms of typically feminine/masculine attributes assigned to those entities. Konishi (1993) looked at how Spanish and German speakers construe femininity or masculinity of non-animal objects by having them give gender-related ratings of various nouns on a potency scale

(e.g., weak vs. strong; tender vs. vigorous): German speakers rated *moon* (grammatically masculine in German and feminine in Spanish) to be higher on the scale of masculinity than *sun* (masculine in Spanish and feminine in German), while Spanish speakers showed the reverse pattern. Sera and colleagues (Sera, Berge, & del Castillo Pintado, 1994; Sera, Elieff, Forbes, Burch, Rodriguez, & Dubois, 2002) asked Spanish and French speakers to assign either a female or a male voice to artifact objects and reported that the judgments tended to agree with the grammatical gender of the objects (see also Boroditsky, Schmidt, & Phillips, 2003; Flaherty, 2001). However, to our knowledge, the question of whether speakers of a language with grammatical gender are at all influenced by grammatical gender when they make inferences about biological sex-specific properties of animals has not been addressed in the literature.

Importantly, Vigliocco et al. (2005) suggested that the relation between grammatical gender and speakers' concepts is weaker for languages with more than two gender classes, such as German. Using an odd-one-out categorization task, they in fact found an effect of grammatical gender on Italian speakers' construal of similarity among animals, but not on German speakers'. However, unlike judgments of abstract similarity among objects, inference about biological sex-specific properties is more directly linked to grammatical gender categories, and hence we might expect the influence of grammatical gender in German speakers in this case.

It is hard to imagine that German speakers are not aware of the motivated link between grammatical gender and biological sex, as human males are clearly mapped to the masculine gender and human females are mapped to the feminine gender. Yet, when thinking about animals at the level of generic species (dog, cat, giraffe, etc.), speakers have to separate grammatical gender and biological sex. Of course, adults speaking a language with grammatical gender must *consciously* understand that grammatical gender of basic-level animal names is independent of animals' biological sex. However, it may still be possible that their inference is still affected by the overgeneralization of the syntax-semantics mappings: For example, they may make a false deductive conclusion that grammatically feminine (or masculine) animals *in general* have a female (or male)-specific biological property.

Deductive reasoning plays a core role in human inference and learning, along with inductive reasoning (cf. Murphy, 2002). If grammatical gender affects deductive reasoning about biological properties even though people consciously understand that grammatical gender is independent of biological sex of animals, this will be taken as support for linguistic relativity.

Provided that such an effect is seen, however, it is important to be able to distinguish two possible mechanisms behind it. The effect may arise within the realm of syntactic processing but not at the conceptual representation of animal kinds. In other words, the effect may be seen only

when a speaker processes the gender-marking article or pronoun. The alternative possibility is that the overgeneralized syntax-semantic mapping penetrates into the conceptual level of generic-level animal kinds. If this is the case, the effect should be seen even when generic-level animal names are presented without the gender-marking article.

The present study

We tested German and Japanese speakers on deductive inferences about sex-specific animal properties. The Japanese speakers' performance served as a baseline because Japanese is a language without grammatical gender. We designed two experiments in such a way that we could identify at what level of processing the relation between grammatical gender and deductive reasoning is found, if it is found at all. In the first experiment, target words for deduction were presented in the singular form with their associated articles marking the gender class of each word. (In German, article + noun phrase can refer to a generic meaning.) In the second experiment, the target words were presented in plural form without any marking of gender class. Participants were asked to indicate whether the deductive conclusion would hold true or not; they were instructed to give a "No" response in cases in which the conclusion was logically indeterminable, in addition to the cases in which deduction would be clearly false.

Five conditions were set up within participants. The *Generic Animal Condition* was designed to test whether German speakers were more likely to draw a erroneous deductive conclusion when the sex specified for the biological property given in the premise and the grammatical gender class of the target animal's basic-level name were consistent (e.g., female – feminine) than when they were inconsistent (e.g., female – masculine). Here, the deductive conclusion is logically indeterminable, as the biological sex of the target animal is unknown, and thus, "No" is the correct answer. Nevertheless, German speakers may experience difficulties rejecting the deductive conclusion when the grammatical gender of the target animal agrees with the biological sex specified in the premise. In contrast, it should be easy for Japanese speakers to reject the deduction in this ambiguous case.

In order to test for possible baseline differences in deductive reasoning across the two language groups, we included the *Generic-Animal Control Condition*. Here, participants were to judge the correctness of the deductive conclusion about a property true for all animals regardless of their sex, while the targets were exactly the same as in the *Generic-Animal* condition.

The *Sex-specified Animal Condition* was set up to test whether grammatical gender affects deductive inference in German speakers even when the sex of the animal is explicitly specified in the conclusion. Here, unlike the *Generic Animal* condition, the target animal's sex was explicitly specified by the gender-specifying adjective and the specified sex and the grammatical gender of the target

animal was either consistent or inconsistent. Here, the deductive inference should of course be made based on the agreement between the sex in the premise and the target animal's sex indicated by the adjective. It is interesting to see if consistency between grammatical gender and sex affects German speakers' judgments in this obvious case.

The *Sex-specified Animal Control Condition* was included to rule out an alternative explanation for the potential gender effect in the *Sex-specified Animal Condition*. Provided that the expected effect was obtained, it may also have arisen from the difference in the difficulty in simply processing of the two types of (i.e., grammatical gender-sex specifying adjective matching and mismatching) noun phrases. To disambiguate the two possibilities, the conclusions in this condition were the same as those in the *Sex-specified Animal Condition*, but the property in the premise was not sex-specific. Finding the gender effect in German speakers in this control condition would indicate that the effect arises at the level of local phrase processing rather than during the deductive reasoning. In contrast, if there is no gender effect in this control condition, but the effect is found in the *Sex-specified Animal condition*, where the property in the premise is also sex-specific, this suggests that the grammatical gender affects deductive reasoning about a sex-specific property, even when the target animal's sex is explicitly given.

Finally, the *Artifact Condition* was included to examine whether German speakers' deductive reasoning about non-animate entities was affected by grammatical gender. The target object was an artifact whose grammatical gender was either consistent or inconsistent with the sex specified in the premise. The conclusion was logically determinable and should always be rejected. This condition allows us to see how pervasive the influence of grammatical gender on deductive inference about sex-specific biological properties: If the motivated sex-gender mapping is applied even in the realm of entities without sex, this would suggest that the influence of grammatical gender is overarching in German speakers.

Experiment 1

In this experiment, we tested whether there is a relation between grammatical gender and speakers' deductive reasoning about a sex-specific biological property when the grammatical gender of the target object was explicitly invoked by the gender-marking article.

Method

Participants

Twenty-one native German-speaking undergraduates from Zurich and 17 native Japanese-speaking undergraduates from Tokyo, both from a wide variety of majors, participated for payment.

Design and Materials

As described earlier, there were five within-subjects conditions: *Generic Animal*, *Generic Animal Control*, *Sex-specified Animal*, *Sex-specified Animal Control*, and *Artifact*. In each trial across the five conditions, the premise sentence containing a blank property X was shown, and followed by the target object. In the *Generic Animal*, *Sex-specified Animal*, and *Artifact* conditions, the premise stated that the property X was sex-specific. It said: "All and only male (or female) animal had X inside." In the two *Control* conditions, the premise statement was sex-general: "All and only animals had X inside." Prior to the experiment, the participants were told that X was an internal and important property.

In the *Generic Animal Condition*, 36 generic level animal names (half grammatically feminine, half masculine in German) that were commonly known to speakers of both languages, were used as targets. Each animal appeared once in the sex-gender consistent trials and once in the inconsistent trials, yielding a total of 72 trials in this condition. As described earlier, the correct response was "No" for all trials, as the deduction was not logically determinable. The same 36 animal names were used in the *Generic Animal Control Condition*, in which the property given in the premise sentence was general to all animals. Here, of course, the correct response was "Yes" for all trials.

In the *Sex-specified Animal Condition*, 18 animal names (half grammatically feminine, half masculine) that were not used in the *Generic Animal Condition* were presented twice, once in a consistent and once in an inconsistent trial. Here, the sex specified in the premise and the grammatical gender of the target animal always matched, but the specified sex and the grammatical gender of the target animal was either *consistent* ("die_[FEM] weibliche (female) Maus (mouse)") or *inconsistent* ("die männliche (male) Mous") for the "all and only female animals have X inside" premise). The same targets were used for the *Sex-specified Animal Control Condition*, but here, the property in the premise was not sex-specific (e.g., "all and only animals has X inside").

In the *Artifact Condition*, the premise concerned a sex-specific animal property, as in the other two main conditions, but 28 artifact names (half grammatically feminine, half masculine) served as targets. All artifact names appeared once in a sex-gender consistent and once in an inconsistent trial. The "No" response was correct for all trials.

Altogether, there were 208 trials including 90 trials with potential "Yes" responses and 118 trials with potential "No" responses.

Procedure

In each trial, a fixation cross appeared on the screen for one second. The premise statement was then shown for 1.5 seconds, followed by a blank screen for 0.5 seconds. For German participants, the name of the target object accompanied by the gender article was then presented until the participant made a response. For Japanese participants, the target object name was presented alone, without a classifier, as this was judged to be the most natural way of

presentation The participants were asked to indicate whether the deductive conclusion would hold true for the target by pressing a designated key for “Yes” or “No”. After the response, the screen remained blank for 1.5 seconds and the next trial was then started. The presentation order of the 208 trials of all conditions was completely randomized within and across participants.

Results and Discussion

We report the results separately for each condition.

Generic Animal Condition Here, we only analyze the error responses (i.e., Yes responses, see Figure 1). Response times were not submitted to the analysis because of the high error rates in German speakers. As expected, there was a significant Language (German vs. Japanese) X Consistency (sex-gender consistent vs. inconsistent) interaction effect, $F_1(1,31)=9.1$, $F_2(1,90)=98.8$, both $p<.01$). Paired t-tests were performed on subject (t_1) and item means (t_2) contrasting the performance in consistent and inconsistent trials across the different conditions. German speakers were more likely to erroneously accept a deductive conclusion when the sex in the premise and the grammatical gender of the target were consistent (53.4%) than when they were inconsistent (29.9%), $t_1(16) = 3.133$, $d = .626$, $p = .006$, $t_2(35) = 13.447$, $d = 2.898$, $p < .000$. No such difference was found in Japanese participants (17.0% vs. 17.2%), $t_1(15) = -.102$, $p = .920$, $t_2(35) = -.166$, $p = .869$. However, the performance in German speakers in the Control condition showed that they were in general no poorer in deductive reasoning than Japanese speakers (German:92.5%; Japanese:83.5%), $t_1(31) = 1.821$, $p = .078$; $t_2(70) = 4.597$, $d = .969$, $p < .000$. These results suggest that the grammatical gender effect seen in the Generic Animal condition was not a reflection of generally poor deductive inference on the part of German speakers.

Figure 1. Percentages of error responses in the *Generic Animal Condition* (with sex specific premises) of Experiments 1 and 2 and in the *Generic Animal Control Condition* (with sex-general premises) in Experiment 1.

Figure 2. Percentages of error responses in the *Sex-specified Animal Condition* (with sex-specific premises) and the *Sex-specified Animal Control Condition* (with sex-general premises) in Experiments 1 and 2.

Figure 3. Response times (in milliseconds) for correct responses in the *Sex-specified Animal Condition* (with sex-specific premises) in Experiment 1 and the *Sex-specified Animal Control Condition* (with sex-general premises) in Experiments 1 and 2.

Sex-specified Animal Condition In this condition, both the error rates and response times were submitted to analyses. Again, a significant Language X Consistency interaction effect on the error rates was found, $F_1(1,31) = 8.5$, $F_2(1,34) = 8.9$, both $ps<.01$. Unlike the Generic Animal condition, the correct/error deduction was logically determinable according to the agreement or disagreement between the *sex* in the premise and the specified *sex* of the target animal. Here, the inconsistent trials, in which the sex specified by the adjective and grammatical gender in the target were inconsistent (e.g., *die männliche Giraffe*), were expected to be more difficult than the consistent trials (*die weibliche Giraffe*). Indeed, German speakers were more likely to draw erroneous deductions in the inconsistent trials (16.1%) than in the consistent trials (3.9%), $t_1(16) = 2.917$, $d = .878$, p

= .010, $t_2(17) = 2.735$, $d = .766$, $p = .014$ (Figure 2). No such difference was found in Japanese participants (11.8% vs. 8.3 %), $t_1(15) = -1.274$, $p = .222$, $t_2(17) = -1.514$, $p = .148$. A similar pattern was found for response times. German speakers were slower in drawing deductive inferences in the inconsistent case (868ms) than in the consistent case (716ms), $t_1(16) = 3.442$, $d = .574$, $p = .003$, $t_2(17) = 4.986$, $d = 1.522$, $p < .000$, while no such difference was found in Japanese responses (706ms and 761ms), $t_1(15) = 1.342$, $p = .199$, $t_2(17) = 1.969$, $d = .559$, $p = .065$ (Figure 3). In the Control condition, there was no Language X Consistency effect on either accuracy, $F_1(1,31) = 0.3$, $F_2(1,34) = 1$, or response times, $F_1(1, 31) = 0.01$, $F_2(1,34) = 0.6$.

Thus, even when the biological sex of an animal was explicitly indicated, grammatical gender affected German speakers' inferences about sex-specific animal properties. The fact that German speakers' performance did not differ from that of Japanese speakers in the Control condition (where the premise was not sex-specific) indicates that the sex-gender consistency effect here emerged in the process of deductive reasoning rather than from mere disturbance of the local level processing of the target phrase due to gender-sex mismatch.

Artifact Condition In the *Artifact Condition*, no Language X Consistency effect was found, $F_1(1,31)=1.2$, $F_2(1,26)=0.9$, both $ps > .1$. In neither language group did sex-gender consistent and inconsistent trials differ with respect to the error rates (German: 3.8% vs. 0.4%; Japanese: 1.3% vs. 0.4%) nor response times (German: 729ms vs. 727ms; Japanese: 601ms vs. 623ms). Thus, the influence of grammatical gender on sex-specific biological properties found in the animal domain did not extend to the artifact domain.

The results of Experiment 1 showed that German speakers were not immune to the motivated (but logically orthogonal) gender-sex mapping when they make deductive inferences about sex-specific properties of animals. When the biological sex specified in the premise agreed with grammatical gender of the target animal, they often made a false deduction that a sex-specific biological property holds for the target animal in general even though its biological sex was unspecified. German speakers experienced difficulty in rejecting the deductive conclusion even when the target animal's sex was explicitly indicated otherwise by a sex-specifying adjective, when the biological sex specified for the property and grammatical gender of the target animal agreed.

These results naturally lead to a question of whether the same effects are obtained when the target animal name is presented without the article. If German speakers' representation of animals per se is affected by grammatical gender, the same effects should be observed without explicit invocation of the article. Alternatively, the gender effects in Experiment 1 may vanish when the animal name is presented without the gender article. If so, this would

indicate that the gender effect arises at the level of grammatical processing, but not at the level of the representation of animals. Experiment 2 was conducted to disambiguate these two possibilities.

Experiment 2

Method

Participants

Twenty-nine German-speaking undergraduates from Zurich participated in this study. None of them had participated in Experiment 1.

Design, Materials, and Procedure

The design, materials and procedure of Experiment 2 were identical to those in Experiment 1 with one exception: All target words were presented in plural form without articles marking grammatical gender. In the *Generic Animal Condition*, for example, the target “die _[FEM] Maus (mouse)” was now presented as Mäuse (mice) and in the *Sex-specified Animal Condition*, “die männliche (male) Maus” was now presented as “männliche Mäuse”.

Results

In stark contrast to Experiment 1, we found no significant difference between the gender-sex consistent and inconsistent trials in any of the conditions on the error rates or response times (for t_1 and t_2 : all $ps > .1$; see Figures 1-3). When the performance of German speakers in this experiment was compared to that of Japanese speakers in Experiment 1, in no condition (including the *Generic Animal* and *Sex-Specified Animal* conditions) was there any Language X Consistency effect.

The results of Experiment 2 indicate that the grammatical gender effects found in Experiment 1 arise only when the speakers see the target animal name with the gender-marking article. This suggests that it was the *gender article* that affected German speakers' deductive reasoning about sex-specific animal properties; the effect did not arise because German speakers' representation of animals per se was changed by gender grammar.

General Discussion

Grammatical gender *in principle* is independent of biological sex, as grammatical gender is assigned to non-sexuated entities as well as to sexuated ones. This is even true for a majority of (basic-level) animal names. At the same time, there is apparent semantic *motivation* for grammatical gender classes, especially in mapping human terms to gender classes. This research investigated whether this mapping between grammar and biological sex is over-generalized in deductive inference--a core domain of human reasoning. We identified two contexts in which German speakers unconsciously over-generalize this grammar-semantics mapping to make erroneous deductive inferences.

First, German speakers tended to erroneously accept deductions when the sex specified in the premise and the grammatical gender of the basic-level name of the target animal agreed. Second, the sex-gender agreement affected the inference even when the sex of the target animal was explicitly indicated: German speakers experienced difficulty in rejecting the deduction when, for example, asked to judge whether a female-specific property would be true for “die_[FEM] männliche Maus (male mouse)”. Experiment 2 further suggests that these effects occur only when the gender-marking article was processed. Thus, German speakers seem to project biological sex onto gender-marking articles but not onto the conceptual representation of animals per se. Furthermore, this mapping does not go so far as to affect inferences when the targets are non-sexuated entities.

Researchers investigating the relation between the speakers’ conceptual representation of objects and gender grammar have mostly approached the question in light of whether masculine or feminine images were projected on objects according to the grammatical gender of the name. This research examined the relation between gender grammar and cognitive processes more directly, asking how speakers handle the semantic motivation of gender classes on one hand and the fact that grammatical gender is independent of biological sex in animal terms on the other hand. The finding that German speakers could not help projecting biological sex on gender-marking articles (when they should not) can be taken as some evidence for linguistic relativity (Gentner & Goldin-Meadow, 2003, for an overview). On the other hand, our findings cannot be interpreted to be support for a strong version of linguistic relativity hypothesis, as the effect was not obtained without explicit invocation of the grammatical gender. Some researchers may argue that the gender effect here is only support for thinking for speaking (Slobin, 1996) but not for linguistic relativity per se, because the effect was obtained in a task using language (see also Vigliocco et al., 2005). Nevertheless, the influence of grammatical gender we found in this research should not be seen as trivial. For speakers of languages with grammatical gender, explicit gender marking by articles or pronouns is the *norm* rather than the exception in everyday discourse. If these speakers of languages unconsciously link the grammatical gender of an animal’s name to its biological sex (even though the two are orthogonal), and if this link is strong enough to serve as a basis for inferences about sex-specific properties of animals, then we may conclude that grammatical gender has non-trivial cognitive consequences for these speakers, be it characterized as a “true” linguistic relativity effect or not. This research is important for the literature of language and thought in that it specifies how (i.e., the mechanism) and in what contexts gender grammar might affect cognitive processes rather than simply providing evidence for linguistic relativity (see also Imai & Saalbach, 2010)

Abstract

One of the oldest and most reliable findings regarding human inference is that the order of evidence affects the final judgment. These order effects are non-Bayesian by nature and are difficult to explain by classical probability models. We use the empirical results of two jury decision-making experiments to compare two different models of human belief updating: the belief-adjustment model and the quantum inference model. We also provide evidence to suggest the belief-adjustment model has limited predictive power when accounting for tasks involving extreme evidence whereas the quantum inference model does not.

Keywords: inference; jury decision-making; order effects; recency effects; belief-adjustment model; quantum inference model

Introduction

Human inference provides a rich source of evidence for a non-Bayesian belief updating process. Consider a physician deciding whether a certain patient has an infection or not. The physician first examines the patient and takes a medical history. At this point, the physician has some degree of belief in the presence of the infection. Then the physician orders a laboratory test and revises those beliefs. Now, suppose the physician had proceeded by first administering the laboratory test followed by the physical examination. Would the physician ultimately have the same belief about the infection when the order of information is reversed? Bergus, Chapman, Levy, Ely, et Oppliger (1998) would argue that the order of information, physical examine followed by laboratory test versus laboratory test followed by physical examine, has a significant impact on the physician's final belief in the presence of the infection.

Order of information plays a crucial role in the process of updating beliefs across time (Hogarth & Einhorn, 1992). The presence of order effects makes a classical or Bayesian approach to inference difficult. Specifically, suppose a decision-maker must ascertain the probability that a certain hypothesis, H , is true after seeing two pieces of evidence, X and Y . Classical probability requires $P(X, Y|H) = P(Y, X|H)$, and by Bayes rule we must have $P(H|X, Y) = P(H|Y, X)$. Thus, a simple Bayesian model makes no distinction between different orders of information.

In this paper, we compare two possible explanations for order effects, the belief-adjustment model (Hogarth & Einhorn,

1992) and the quantum inference model (Busemeyer & Trueblood, 2009). The belief-adjustment model accounts for order effects by either adding or averaging evidence. The quantum inference model explains order effects by transforming a state vector with different sequences of operators for different orderings of information.¹ We first examine both models with data collected from a jury decision-making experiment conducted by McKenzie, Lee, et Chen (2002). Then we test both models using new data collected from two new experiments that extend the work of McKenzie et al.

A Jury Decision-Making Experiment

McKenzie et al. conducted two experiments to examine the effects of case order and strength on changes in subjects' confidence ratings. In this study, subjects were asked to read a criminal case concerning a burglarized warehouse and to rate their confidence in the defendant's guilt, G . In the first experiment, one group of participants read a strong prosecution, SP, followed by a weak defense, WD. The other group read the information in the reverse order, the weak defense followed by the strong prosecution. For the second experiment, the first condition was identical to the first condition in experiment 1. However, in the second condition, subjects read a weak prosecution, WP, followed by the weak defense. In both experiments, subjects provided confidence ratings as a number between 0 and 20 before reading either case, after reading the first case, and after reading the second case. A separate group of subjects rated the strength of the prosecution and defense and did not participate in the inference task. By averaging the data from condition one of experiment 1 with condition one of experiment 2 and converting the mean confidence ratings to probabilities, we have the results shown in Table 1.

One of the most interesting aspects of these results is that the weak defense increased confidence in guilt when preceded by the strong prosecution but decreased confidence in guilt when preceded by the weak prosecution. The interpretation of the defense as evidence for guilt when coupled with the strong prosecution and evidence for innocence when coupled with the weak prosecution resists explanation by the standard belief-adjustment model (McKenzie et al., 2002).

¹We use quantum theory as a mathematical tool and do not attach the physical meaning associated with quantum physics. This type of approach is similar to the use of stochastic processes outside the domain of physics.

Table 1: Probability of Guilt from Experiments 1 and 2

After first case	After second case
$\Pr(G \mid SP) = 0.672$	$\Pr(G \mid SP, WD) = 0.719$
$\Pr(G \mid WD) = 0.51$	$\Pr(G \mid WD, SP) = 0.75$
$\Pr(G \mid WP) = 0.600$	$\Pr(G \mid WP, WD) = 0.525$

An extended version of this model, the minimum acceptable strength model (MAS), uses a variable reference point to model these results (McKenzie et al., 2002). As an alternative to the MAS model, the quantum model uses a series of transformations to explain the phenomena. Before we proceed with fitting the two models, we will outline the belief-adjustment model and the MAS model. We will also provide an intuitive description of the quantum model.²

The Belief-Adjustment Model

The belief-adjustment model assumes individuals update beliefs by a sequence of anchoring-and-adjustment processes (Hogarth & Einhorn, 1992). The algebraic description of the model is

$$C_k = C_{k-1} + w_k \cdot (s(x_k) - R) \quad (1)$$

where $0 \leq C_k \leq 1$ is the degree of belief in the defendant's guilt after reading case k , $s(x_k)$ is the strength of case k , R is a reference point, and $0 \leq w_k \leq 1$ is an adjustment weight for case k . Hogarth et Einhorn argue that evidence can be encoded either in an absolute manner or in relationship to the current belief in the hypothesis. If evidence is encoded in an absolute manner and there exists a positive/negative relationship between the evidence and hypothesis, $R = 0$ and $-1 \leq s(x_k) \leq 1$. However, if evidence is encoded in relationship to the current belief, $R = C_{k-1}$ and $0 \leq s(x_k) \leq 1$. Also, Hogarth et Einhorn assume that the adjustment weight w_k depends on the level of current belief and the sign of the difference $s(x_k) - R$. Specifically, if $s(x_k) \leq R$, then $w_k = C_{k-1}$. However, if $s(x_k) > R$, then $w_k = 1 - C_{k-1}$.

Using this information, we can rewrite the belief-adjustment model as either an adding model or an averaging model. The adding model results when information is encoded in an absolute manner and is given by

$$C_k = \begin{cases} C_{k-1} + C_{k-1} \cdot s(x_k), & \text{if } s(x_k) \leq 0 \\ C_{k-1} + (1 - C_{k-1}) \cdot s(x_k), & \text{if } s(x_k) > 0 \end{cases}$$

On the other hand, the averaging model results when information is encoded in relationship to the current belief and is given by

$$C_k = \begin{cases} C_{k-1} + C_{k-1} \cdot (s(x_k) - C_{k-1}), & \text{if } s(x_k) \leq C_{k-1} \\ C_{k-1} + (1 - C_{k-1}) \cdot (s(x_k) - C_{k-1}), & \text{if } s(x_k) > C_{k-1} \end{cases}$$

Rearranging the terms above shows that the current belief is an average of the prior belief and the strength of the new evidence weighted by the prior belief.

²Trueblood et Busemeyer (2010) contains a complete mathematical description of the quantum inference model.

The MAS model extends the belief-adjustment model by defining the reference point as a case's minimum acceptable strength (McKenzie et al., 2002). Thus, equation 1 becomes

$$C_k = C_{k-1} + w_k \cdot (s(x_k) - m_{k-1}) \quad (2)$$

where m_{k-1} is the minimum acceptable strength of the previous case and $-1 \leq s(x_k) \leq 1$. Neither the adding or averaging models can predict that a defense would increase confidence in guilt. However, it is possible to select a value for m_{k-1} such that the difference between the strength of the weak defense and m_{k-1} is positive. Therefore, confidence in guilt increases as a result of the weak defense. The downside to the MAS model is the increase in parameters. The adding and averaging models specify a parameter for each case, namely $s(x_k)$. However, the MAS model also needs a minimum acceptable strength parameter for each case; thereby, doubling the number of parameters needed in the original model.

The Quantum Inference Model

There are several reasons for considering a quantum approach to human judgments. First, judgment is not a simple read out from a pre-existing or recorded state, instead it is constructed from the current context and question. Thus, making a judgment changes the context which disturbs the cognitive system. This implies that changes in context produced by the first judgment influence the next judgment resulting in order effects. Therefore, human judgments do not obey the commutative rule of classic probability theory suggesting that classical probability theory is too limited to fully explain various aspects of human judgment and decision-making. Other such phenomena include violations of the sure thing axiom of decision-making (Tversky & Shafir, 1992) and violations of the conjunctive and disjunctive rules of classic probability theory (Gilovich, Griffin, & Kahneman, 2002).

We describe the quantum inference model in terms of the specific jury decision-making task outlined above; however, this model can be extended to any number of hypotheses and pieces of evidence (Busemeyer & Trueblood, 2009). The quantum inference model assumes that a decision-maker can view the two complementary hypotheses, guilty (h_1) and not guilty (h_2), from three different points of view. The first point of view is considered neutral (N) and is associated with the judgment made before either case is read. The second point of view is associated with the prosecution's case (P), and the third point of view is associated with the defense's case (D). The prosecution is assumed to present evidence for guilt (e_1), and the defense is assumed to present evidence for innocence (e_2). Considering all possible combinations of hypotheses and evidence, we have four patterns of the form $h_i \wedge e_j$. These four patterns or joint events define a four dimensional vector space. An individual's beliefs about these events are represented as a four dimensional state vector, ψ , situated within this four dimensional vector space. The three points of view are represented mathematically as three different bases for this vector space. Thus, there are three different vector repre-

representations of ψ corresponding to the neutral basis, the prosecution basis, and the defense basis: $\psi_N = \omega$, $\psi_P = \alpha$, and $\psi_D = \beta$. The four dimensional unit column vectors ω , α , and β represent the probability amplitudes for the joint events, $h_i \wedge e_j$, with respect to the different bases, or points of view.³

A set of matrix operators act on ψ to transform an individual's beliefs in correspondence with changes of perspective. Specifically, the probability amplitudes for one point of view are transformed into the probability amplitudes for a different point of view by unitary transformations:

$$\alpha = U_{pn} \cdot \omega$$

$$\beta = U_{dn} \cdot \omega.$$

For example, suppose an individual makes a judgment after reading the prosecution and then again after reading the defense. First, the individual sees the prosecution present evidence (e_1) favoring the guilty hypothesis. We project $\psi_P = \alpha$ onto the subspace corresponding to the evidence:

$$\psi_P = \begin{bmatrix} \alpha_{h_1 \wedge e_1} \\ \alpha_{h_1 \wedge e_2} \\ \alpha_{h_2 \wedge e_1} \\ \alpha_{h_2 \wedge e_2} \end{bmatrix} \Rightarrow \begin{bmatrix} \alpha_{h_1 \wedge e_1} \\ 0 \\ \alpha_{h_2 \wedge e_1} \\ 0 \end{bmatrix}.$$

We then normalize this projection to ensure that the length of the new state vector, $(\psi_P | e_1)$, equals one. When the individual is questioned about the conditional probability of guilt given the prosecution, the revised state is projected onto the guilty subspace. With the presentation of the defense, the revised state vector, $(\psi_P | e_1)$, is transformed from its vector representation associated with the prosecution basis to its vector representation associated with the defense basis by $U_{dp} = U_{dn} \cdot U_{pn}^\dagger$.⁴ Now, we project our revised state onto the e_2 subspace since the defense is assumed to present evidence for innocence. Again, we normalize the state vector and project it onto the guilty subspace to calculate the conditional probability of guilt given the prosecution followed by the defense. Order effects arise because the unitary transformations are non-commutative. Figure 1 provides a schematic for the different sequences of transformations used for the different case orderings.

The model parameters define the specific matrix operators, U_{pn} and U_{dn} , used to transform one representation of ψ to another. We define a parameter for each case. So, there is a parameter associated with the strong prosecution, weak defense, and weak prosecution. Thus, to model the data collected by McKenzie et al. the quantum model uses three parameters.

Fitting the Data

We fit both the MAS model and the quantum model to the six probabilities shown in Table 1. Both models capture the

³Probability amplitudes determine the belief about a particular event. Probabilities are calculated from probability amplitudes by taking the modulus of the amplitude and squaring.

⁴ U^\dagger is the conjugate transpose of U . For unitary matrices, U^\dagger is also the inverse of U .

Figure 1: Transformations for different case orderings: defense followed by prosecution (top) and prosecution followed by defense (bottom).

qualitative properties of the data. Namely, $Pr(G | SP) < Pr(G | SP, WD)$ and $Pr(G | WP) > Pr(G | WP, WD)$. The quantum model fit the data with three parameters with the sum of squared error (SSE) equal to 0.00056; whereas, the MAS model fit the data with four parameters with the SSE = 0.0022. The SSE for the models is very small since we are examining differences in probabilities. Of the four parameters in the MAS model, three were associated with the minimum acceptable strength. The fourth parameter was the gradient parameter of a logistic function used map the average independent strength ratings from participants into the interval $[-1, 1]$. If we compare the SSE from the quantum model to the SSE from the MAS model, we see that the SSE for the quantum model is much smaller than the SSE for the MAS model:

$$\frac{SSE_{MAS}}{SSE_{qt}} = \frac{0.0022}{0.00056} = 3.93.$$

Furthermore, since the quantum model has less parameters and a smaller SSE, it will have a lower BIC value than the MAS model.

Experiment 1: Extending McKenzie

McKenzie et al. did not examine all possible combinations of case strength and order. Assuming there are only two possible strengths, weak and strong, there are twelve total possible conditional probability judgments that can be made (see Table 2). Thus, we designed a new experiment to collected data for these twelve probabilities. Participants in this new study read eight different scenarios involving a defendant standing trial for either robbery, larceny, or burglary. Each participant was placed into one of eight conditions for each scenario. These eight conditions arise from the eight possible sequential judgments that can be made when taking into consideration order and case strength (e.g. weak prosecution followed by strong defense). Participants were placed in a different condition

for each crime so they would experience all eight conditions by the end of the experiment. The participants reported the likelihood of the defendant's guilt before reading either case, after the first case, and after the second case.

Table 2: Conditional Probabilities for Jury Task

After first case	After second case	
Pr(G WP)	Pr(G WP, WD)	Pr(G WP, SD)
Pr(G SP)	Pr(G SP, WD)	Pr(G SP, SD)
Pr(G WD)	Pr(G WD, WP)	Pr(G WD, SP)
Pr(G SD)	Pr(G SD, WP)	Pr(G SD, SP)

Method

Participants in the study were 299 undergraduate students from Indiana University who received experimental credit for introductory psychology courses. For each scenario, there were approximately 38 participants in each condition. All stimuli were presented on a computer and students entered their responses using the computer keyboard. For each scenario, participants were asked to imagine that they were jurors on the trial. They were also told that in each crime, the defendant was arrested after the police received an anonymous tip. One of the eight scenarios was directly patterned after the crime used by McKenzie et al. Likelihood of the defendant's guilt was reported on a continuous scale from 0 to 1 with 0 = certain not guilty, 0.5 = equally likely, and 1 = certain guilty.

Results

Eight of the 299 participants were excluded from the analyses because the majority of their initial ratings (before being presented with the prosecution or defense) were 0. These participants most likely assumed a literal interpretation of 'innocent until proven guilty'.

We first analyzed each scenario alone, and our analysis revealed a prevalence of recency effects. These effects arise when decision-makers place disproportionate importance on recent evidence (e.g. $Pr(G | SP, SD) < Pr(G | SD, SP)$). For each crime, there were four defense-prosecution pairs (SD v. SP, SD v. WP, WD v. SP, and WD v. WP) that could exhibit order effects. A two sample t-test showed the majority of pairs exhibited a significant recency effect ($p < 0.05$).

Since the scenarios were designed to be very similar, we reanalyzed the data by collapsing across all eight scenarios. A two sample t-test showed a significant recency effect for each of the four defense-prosecution pairs ($p < 0.001$).

Fitting the Data

The presence of recency effects in this new data set confirms earlier findings and provides the largest data set so far for comparing models that explain recency effects. Hogarth et Einhorn discovered that recency effects are prevalent in simple, step-by-step tasks with short series of evidence. Furthermore, there is evidence of recency effects in studies involving

mock trials (Furnham, 1986 ; Walker, Thibaut, & Andreoli, 1972). Unlike the study conducted by McKenzie et al., none of the cases in this study caused a reversal in likelihood judgment when paired with opposing cases of different strengths. This might be due to the use of a standard numeric measure instead of a 21-point confidence scale. There is research showing that standard numeric measures can be insensitive to some judgment phenomena (Windschitl & Wells, 1996).

Since the data does not exhibit the effects found by McKenzie et al., we can fit the standard belief-adjustment model instead of the extended MAS model. We fit the averaging model, the adding model, and the quantum inference model to the mean likelihood of guilt for the eight different crimes as well as the averaged data. All three models use four parameters to fit the twelve data points associated with each crime. These parameters were fit by minimizing the sum of squared error between the data and model predictions. The four parameters used by the averaging and adding models arise from the four case strengths, $s(x_k)$, in equation 1. The four parameters for the quantum model arise from the matrix operators used to transform the state or belief vector. The minimized SSE for all three models are shown in Table 3. From this table, we see that both the adding and quantum models fit better than the averaging model. Also, the quantum model fits slightly better than the adding model in most cases.

Table 3: Model Fits

Crime	Averaging	Adding	Quantum
1	0.0719	0.0112	0.0132
2	0.0634	0.0083	0.0056
3	0.1185	0.0213	0.0070
4	0.0939	0.0156	0.0127
5	0.0913	0.0091	0.0109
6	0.0656	0.0130	0.0113
7	0.0913	0.0217	0.0089
8	0.0620	0.0164	0.0023
Average	0.0704	0.0059	0.0058

Figure 2 shows the model fits for the averaging model and quantum model for the strong defense-weak prosecution pair for the averaged data. From the figure, we see that the quantum model provides a much better fit. Fits for the remaining defense-prosecution pairs are similar.

Experiment 2: Extreme Evidence

To provide even more of a distinction between the quantum model and the belief-adjustment model, we conducted a second jury decision-making experiment involving extreme evidence. In this task, subjects read about an individual on trial for a crime in which the defense had an irrefutable argument. Specifically, the defense stated that the defendant was giving a public lecture when the crime was committed. The prosecution's argument was moderately strong: a witness claimed to

Figure 2: Averaging and quantum model fits to the mean likelihood of guilt for the strong defense-weak prosecution pair. Error bars on the data show the 95% confidence interval.

have seen the defendant near the scene of the crime. It seems reasonable to believe that the probability of guilt after hearing the defense will be near zero. Now, if the prosecution is presented after the defense, it is unlikely that the probability of guilt will increase by much. In terms of the belief-adjustment model, this places tight restrictions on the value of the prosecution strength parameter, $s(x_p)$. To see this, let's examine the adding version of the model:

$$C_p = C_d + (1 - C_d) \cdot s(x_p)$$

where C_p is the evaluation of the guilty hypothesis after hearing the prosecution's case and the irrefutable defense. We might assume the evaluation of the hypothesis after hearing just the defense, C_d , is near zero, say $C_d = \epsilon_1$. Thus, $s(x_p)$ must also be a near zero, say $s(x_p) = \epsilon_2$, in order for C_p to remain small:

$$C_p = \epsilon_1 + (1 - \epsilon_1) \cdot \epsilon_2 = \epsilon_1 + \epsilon_2 - \epsilon_1 \cdot \epsilon_2 \approx 0.$$

Now, suppose the prosecution is presented before the defense. According to the adding model,

$$C_p = C_0 + (1 - C_0) \cdot s(x_p)$$

where C_0 is the evaluation of the guilty hypothesis before hearing either the prosecution or defense. We might assume

that $C_0 \approx 0.5$. Thus, we have

$$C_p = 0.5 + 0.5 \cdot \epsilon_2 \approx 0.5$$

showing the prosecution has little impact on the initial evaluation of the hypothesis. However, it seems unlikely that initial beliefs will be unaltered by the presentation of the prosecution. On the contrary, we might expect this prosecution to be very effective when no prior defense is presented. Essentially, the problem arises from the model's assumption that the strength of the prosecution, $s(x_p)$, is determined independently of other evidence.

This study used 164 undergraduate psychology students. Subjects were placed into one of two conditions corresponding to the two possible case orders: prosecution followed by defense or defense followed by prosecution. Similar to experiment 1, subjects entered responses on a computer and were told that the defendant was arrested after the police received an anonymous tip. Instead of providing the likelihood of the defendant's guilt, subjects were asked to rate their confidence in guilt on the same 21-point scale used by McKenzie et al. Like experiment 1, a significant recency effect was found ($p < 0.023$).

We converted the confidence ratings to probabilities and fit the quantum model and the adding model to the mean of these probabilities. We did not fit the averaging model since experiment 1 shows the adding model outperforms the averaging model. Figure 3 shows the model fits for the two models. Both the quantum model and the adding model use two parameters to fit the data. The SSE for the quantum model was 0.0002; whereas, the SSE for the adding model was 0.0158. By comparing the ratio of the SSE from the two models, we see that the quantum model provides a much better fit to the data:

$$\frac{SSE_{adding}}{SSE_{qt}} = \frac{0.0158}{0.0002} = 79.$$

The standard belief-adjustment model cannot capture dependences between the strength of the prosecution and the irrefutable defense. As a result, the model provides a poor fit to the data. Unlike the belief-adjustment model, the quantum model does not assume individuals combine evidence by simple arithmetic procedures such as adding or averaging. Instead, the quantum model supports the idea that evidence is viewed from different perspectives, and it is these different, or incompatible, points of view that allow the quantum approach to capture the effects of extreme evidence.

Conclusion

One might question the extent to which quantum probability models are rational. Like classic (Kolmogorov/Bayesian) probability theory, quantum theory is based on a coherent set of axioms. Then the question falls back on which set of axioms is most appropriate for an application. For example, models based on the axioms of quantum probability theory have been used to explain paradoxical phenomena arising in cognitive science such as violations of rational decision

Figure 3: Adding and quantum model fits to the mean probability of guilt from experiment 2. Error bars on the data show the 95% confidence interval.

making principles (Pothos & Busemeyer, 2009), paradoxes of conceptual combination (Aerts, 2009), human judgments (Khrennikov, 2004), and perception (Atmanspacher, Filk, & Romer, 2004).

Here we provide evidence in support of a quantum probability explanation of order effects. Using data collected by McKenzie et al., we show that the quantum inference model out performs the minimum acceptable strength model. We also provide evidence that the quantum model performs as well or slightly better than the belief-adjustment model when fitting data from experiment 1. Finally, we describe some of the limitations of the belief-adjustment model in relationship to irrefutable evidence. We argue that the quantum inference model is not faced with these limitations and provides more reasonable predictions. In the future, we plan to continue empirically investigating the quantum inference model in the hope of developing a more coherent theory concerning human inference tasks.

Information Relevance in Pseudodiagnostic Reasoning

Abstract

When faced with two competing hypotheses, people sometime prefer to look at multiple sources of information in support of one hypothesis rather than to establish the diagnostic value of a single piece of information for the two hypotheses. This is termed pseudodiagnostic reasoning, and is understood to reflect a pervasive confirmation bias. Past research suggests that diagnostic reasoning may be more easily fostered when participants seek data to help in the selection of one of two competing courses of action as opposed to situations where they seek data to help inferring which of two competing hypotheses is true. In the experiment reported here, we provide the first empirical evidence demonstrating that the facilitating effect observed in action problems is driven by considerations of information relevance, reasoners' motivations and the numerical value of the first piece of information presented. The discussion of these findings focuses on implications for the ability to engage in diagnostic hypothesis-testing.

Keywords: decision making; utilities; pseudodiagnostic reasoning

Introduction

A sales manager advertised a new position for a sales assistant. After reviewing the curriculum vitae of the candidates, she selects two promising applicants, Ms. A. and Ms. B. The manager initially leans towards the first candidate, Ms. A., and discovers that she successfully completed 70% of her sales transactions in the last month in her previous position. The manager must now engage in inductive reasoning: She needs to collect more information in order to decide whether Ms. A or Ms. B. is the best candidate for the job. A long tradition of psychological research suggests that her search for information will be driven by a need for evidence confirming the hypothesis she is entertaining. Thus, if, at this point, the manager believes Ms. A. is the best candidate, she would naturally seek more information about Ms. A rather than checking Ms. B.'s sale performance. Yet, this strategy is potentially shortsighted: Ms. B. could well have outperformed Ms. A. on the sales front in her previous job, in which case, seeking more information about Ms. A. could be misguided and lead to the employment of a candidate with less potential. Without establishing the sales performance of Ms. B, the diagnostic value of Ms. A's sales performance is undetermined, and hence cannot judiciously inform the

decision-making process.

More generally, the diagnosticity of a datum D for a given hypothesis X (H_X) is defined in terms of the ratio of the probability that D is observed given that H_X is true, $P(D|H_X)$, and the probability that D is observed given that an alternative hypothesis Y is true, $P(D|H_Y)$. Hence, diagnosticity can only be assessed from the perspective of *multiple* hypotheses. The likelihood ratio in Bayes's Theorem is the normative metric of the diagnosticity of information (Doherty, Mynatt, Tweney, & Schiavo, 1979).

People's Search for Information Is Not (Always) Driven by Considerations of Diagnosticity

Early research examining how people gather information in order to make inferences suggested they did not fully appreciate that diagnosticity is defined in terms relative to at least two hypotheses, not just one (Beyth-Marom & Fischhoff, 1983; Doherty et al. 1979; Kern & Doherty, 1981; cf. Trope & Bassok, 1982, 1983). For example, Beyth-Marom and Fischhoff (1983, Experiment 1) told participants that an individual possessed a distinguishing feature and asked them what information they deemed relevant to determine whether that individual was a member of Group A. Nearly 90% of their participants indicated that it was relevant to know $P(D|\text{group A})$, but of those 'only' 50% deemed important to know the probability that this information would also be observed given membership in a different group, or $P(D|\text{group B})$. Yet both probabilities must be examined in order to gauge the diagnosticity of the distinguishing feature.

Mynatt, Doherty and Dragan (1993) argued that people's hypothesis testing process is predominantly concerned with gathering evidence in favour of one hypothesis, rather than determining the diagnosticity of any given piece of information for multiple hypotheses. In one of their reasoning scenarios, participants were asked to determine which of two cars, X or Y , their "sister" purchased. They were told about *two features characterising this car*, its petrol consumption (D_1 : "25 miles per gallon" –mpg) and its mechanical reliability (D_2 : "no major mechanical problems in the first two years of ownership"). In addition, participants were given *an anchoring piece of information*: "65% of car X s do over 25 mpg", or $P(D_1|H_X) = .65$. Participants were then asked to choose which of the following three pieces of information would help them

decide which type of car was owned by their sister (the participants did not see the information presented here in brackets).

1. The percentage of car Ys that do over 25 mpg. [Diagnostic, $P(D_1|H_Y)$].
2. The percentage of car Xs that have had no major mechanical problems for the first two years of ownership. [Pseudodiagnostic, $P(D_2|H_X)$].
3. The percentage of car Ys that have had no major mechanical problems for the first two years of ownership. [Switching, $P(D_2|H_Y)$].

The first choice would establish the diagnosticity of the petrol consumption data. If more than 65% of car Ys do over 25 mpg, then the sister's car is more likely to be a Y car. Otherwise, it is more likely to be an X car. The second choice would determine the mechanical reliability of car Xs. This choice leaves the reasoner with two pieces of information, and the diagnosticity of neither can be established. Learning that a high percentage of car Xs also featured good mechanical reliability could make one confident that the sister owned a car X, but this feeling of confidence would only be illusory: here again, car Xs could well be outperformed by car Ys. Hence, choosing to learn about $P(D_2|H_X)$ is considered a pseudodiagnostic choice. We term the third choice *switching* because the focus switches from the initial information (D_1) to the second piece of information (D_2) and from the initial hypothesis (H_X) to the alternative one (H_Y).

In Experiment 1 of Mynatt et al. (1993), 60% of the participants chose to learn about the percentage of car Xs with good mechanical reliability in order to determine the identity of the car, while only 26% chose to know the percentage of car Ys that do 25 mpg. The majority of participants thus made what is considered a pseudodiagnostic choice, since opting to look at the mechanical reliability of car Xs cannot determine the diagnosticity of being informed that 65% of car Xs do over 25 mpg.

In contrast, there is evidence demonstrating that people *will*, under various circumstances, seek to know information that would establish the diagnosticity of the anchoring information. For example, if the anchoring information defines a relatively rare feature, for example 65% of cars of make X have a top speed of 165 miles per hour, participants are more likely to want to know the proportion of the alternative make of cars that reach that top speed (Feeney, Evans, & Venn, 2008, Experiment 1). The rare, and arguably more interesting feature (it's plausibly more interesting to be told about a top speed of 165 mph than that the car has an ashtray), thus invite participants to gauge its frequency given the alternative category, thereby encouraging diagnostic data selection. In addition, if the dimensions that define the target object (e.g., 'your sister's car') are couched in terms of an actor's motivation (e.g., you sister *wanted* a car with good petrol consumption) then anchoring information that appears to

run counter to this motivation (e.g., car X does 20 miles per gallon) elicits *less* pseudodiagnostic reasoning. Likewise, a low value for the initial anchoring information (e.g., 35% of car Xs do over 25 mpg) encourages more diagnostic choices (Mynatt et al., 1993, Experiment 2). Thus, upon learning that $P(D_1|H_X)$ is relatively low, more participants are interested in $P(D_1|H_Y)$. Conversely, if the anchoring information given plausibly endorses the focal hypothesis, that is when $P(D_1|H_X)$ is high, participants appear less motivated to determine the diagnosticity of that information.

Information Relevance and Initial Values in Action Problems

Another important characteristic that seems to determine whether people will make diagnostic search choices is the goal of the task. Mynatt et al. (1993) distinguished between *inference* and *action* problems. The car example discussed above, they argued, represents an inference problem. The car has already been purchased and is owned by someone, the goal is to determine whether it is a car X or a car Y. In effect the problem is a categorization inference, and in principle the categorization can be true or false. In contrast, an action problem is one where hypotheses represent two courses of action. One might be better than the other, but the decision cannot in principle be evaluated in terms of whether one action is true and the other false. In a separate experimental condition, Mynatt et al. instructed participants to imagine *buying* a car, considering car X or car Y and told them they were "concerned about (...) petrol consumption and mechanical reliability" (p. 768). Participants were then given the same anchoring piece of information ("65% of car Xs do over 25 mpg") and were asked to choose one among the same three pieces of information in order to help them decide which car to buy (see options 1. through 3. above).

In that action problem, 52% chose the piece of information that could determine the petrol consumption of car Ys (the diagnostic choice) and 41% chose the piece of information that could determine the mechanical reliability of car Xs (a pseudodiagnostic choice). To explain the high proportion of diagnostic choices in action problems, Mynatt et al. propose that the choice among the three alternatives is determined by the datum which bears more utility for each individual participant: "Precisely how many subjects will select (the diagnostic choice) will depend on the content of a given problem and subjects' *idiosyncratic* utility function and decision strategies" (pp.765-766, emphasis added). On this account, those who consider petrol consumption to be more important than mechanical reliability would be motivated to establish the petrol consumption of car Ys and hence chose the diagnostic option. In contrast, those who are more concerned about mechanical reliability should seek information about car Xs' mechanical reliability, a pseudodiagnostic choice.

The authors, however, did not manipulate explicitly the perceived relevance of the two dimensions characterising each alternative (e.g., petrol consumption and mechanical reliability in the car scenario) nor did they seek to assess how relevant their participants believed these dimensions to be. Moreover, there is conflicting evidence showing that action problems may not necessarily promote diagnosticity. Maggi, Butera, Legrenzi and Mugny (1998, Experiment 1) asked participants to imagine having to choose between two cars or two political candidates. These authors found over 60% choices to be pseudodiagnostic. There was, however, an important methodological difference between their task and that of Mynatt et al. (1992): Maggi et al. (1998) presented participants with *four* possible pieces of information to choose from for each alternative (e.g., the car price, reliability, fuel consumption and performance). In addition, the authors found that people tended to be more diagnostic in their choices when the anchoring information concerned a characteristic they believe to be important (e.g., the price of a car or the competence of a political candidate). In light of these incongruous findings, one important issue to resolve would thus be to determine whether those who made a diagnostic choice by choosing to look up $P(D_1|H_Y)$ did so *because* they were more interested in D_1 than in any other piece of information D .

Another important difference between inference and action problems outlined by Mynatt et al. (1993) is the role of the initial $P(D_1|H_X)$ value of the anchoring information. According to the authors, in inference problems this initial value could be a cue to the truth value of H_X and, as such, dictate participants' information search. By contrast, the authors predicted and found that this initial value would not affect choices in action problems since, in those situations, information search would solely be determined by the perceived relevance of the anchoring information D_1 . The authors, however, tested this prediction by comparing relatively narrow values, hovering modestly below and above the 50% mark (viz. 35% vs. 65%). It is therefore reasonable to assume that participants who believed, for example, petrol consumption was *the* most important attribute for a new car would always wonder if car Y s outperformed car X s, even upon learning that 65% car X s did over 25 mpg. However, this does not necessarily imply that participants' information search strategy will never be affected by the $P(D_1|H_X)$ value in action problems. It is not implausible to expect, for example, that participants may no longer search to establish a diagnosticity ratio when told that 95% of car X s do over 25 mpg. In this case, the $P(D_1|H_X)$ value could be a cue to the superiority of H_X . Consequently, under such circumstances, participants might then be more interested in learning more about car X s than in finding out whether car Y s outperform car X s. Hence, when the $P(D_1|H_X)$ value is deemed satisfactory in action problems, we should expect more pseudodiagnostic choices.

The Present Study

In the experiment reported here, we examined the role of information relevance and initial values in determining diagnostic and pseudodiagnostic choices in problems structurally isomorphic to the one developed by Mynatt et al. (1993). The first aim of this experiment was to test the hypothesis that diagnostic choices in action problems occur because people believe D_1 is more relevant than D_2 in deciding whether to take action X or action Y . We manipulated the relative importance of D_1 and D_2 in two scenarios so that participants would care more about D_1 than D_2 . We anticipated the higher perceived relevance of D_1 would lead to a higher proportion of diagnostic choices, since participants would seek to determine the probability of D_1 given the alternative course of action. Second, this experiment aimed to assess the degree to which people may revert to a pseudodiagnostic search for information when the initial value of the anchoring information $P(D_1|H_X)$ is deemed satisfactory. To do so, we manipulated the motivation underpinning participants' action. One scenario was designed to motivate people to find *the highest value* of $P(D_1|H)$. In this case, we anticipated that participants would never be satisfied by the initial value of $P(D_1|H_X)$ and hence we predicted that their search for information would not be affected by this initial value. The alternative scenario was designed to motivate people to find *a satisfactory value* of $P(D_1|H)$. In such a situation, we predicted that when the initial $P(D_1|H_X)$ presented could be deemed satisfactory, the rate of pseudodiagnostic choices would be greater.

Method

Participants

Participants were recruited by third-year psychology students at the University of Toulouse, France, as a course requirement. Each student made a list of several men and women who were older than 18 and not studying psychology, randomly drew one man and one woman from his or her list, and asked them to take part in a general survey which included the present study. Of the 1040 participants in the final sample (520 men, 520 women; mean age = 31.37, $SD = 13.24$), 11% had completed graduate school, 53% had an undergraduate education, 20% had graduated from high school only, and the remaining 16% had not graduated from high school. The sample included a large proportion of students (40%), but also working professionals (51%) and retired or unemployed individuals (8%). The survey was conducted in French.

Design and Procedure

The current experimental manipulation was embedded in a longer questionnaire. The experiment used a 2×2

between-subjects design. The independent variables were the implicit motivation of the decision-maker (maximizing vs. satisficing – Simon, 1955) and the numerical value of the anchoring piece of information (high or low). Participants were randomly allocated to one of the resulting four conditions. Their task was presented as follows: they were asked to imagine they were the director of a large zoo and that they had set up a programme aiming to promote reproduction in captivity of African elephants, a species at risk of extinction. Their calves, however, were facing a severe health issue. They were informed of the presence of a parasite whose eggs could lodge in the calves’ aortic artery, causing strokes and killing the calves if left untreated, threatening the success of the reproduction programme. The experimental manipulation concerned the animals needed to be treated in order to rid the zoo of parasites. Half the participants were told the deadly parasites were infecting the calves directly and treatment was, therefore, to be administered to calves (satisficing scenario). The remaining half was told the deadly parasites were carried by roaming rats which were to be treated directly (maximizing scenario). In all cases, the zoo’s chief veterinary suggested using one of two treatments to save the calves: treatment A or treatment B. Participants were then told about the mortality rate of calves (rats) treated with treatment A and that both treatments could also potentially cause infertility in calves (rats). The initial value of the anchoring piece of information was either high or low. Thus, half were told treatment A could cause the death of 80% calves (rats) whereas the remaining half were told it could cause the death of 20% calves (rats). Before making their choice, however, they were allowed to consult one additional piece of information among three alternatives: they could choose to consult the mortality rate of calves (rats) treated with treatment B (a diagnostic choice). They could also choose to learn more about treatment A and ask to consult the percentage of infertile calves (rats) among those treated with treatment A (a pseudodiagnostic choice). Finally, they could choose to learn about the rate of infertility observed in calves (rats) treated with treatment B (a switching choice). The order of the choices remained constant in all experimental conditions.

In both scenarios, we anticipated that people would be more concerned about mortality rates (D_1) than about infertility rates (D_2). Specifically, we anticipated people to place more value on the mortality rate of rats than on their infertility since rats made infertile would not eliminate their status as a contamination vector. Likewise, we anticipated people would be more concerned about avoiding the death of the endangered calves than about their potential infertility. A few pages later in the survey, all participants were asked to consider the calves (rats) task again and to rate the importance of avoiding killing the calves (rats) as well as the importance of avoiding making the calves (rats) sterile. Both ratings were recorded on an

8-point scale ranging from 1 (Absolutely not important) to 8 (Extremely important).

We expected that the greater relevance of the anchoring dimension (the mortality rate) induced by the scenarios would result in a large proportion of diagnostic choices. In the maximizing scenario, we predicted that participants would be motivated to find the best treatment to kill *all* the rats, and that consequently, short of a 100% mortality rate, they would be more interested in determining the mortality rate of the alternative treatment *regardless* of the mortality rate for treatment A. As a result, we expected high proportions of diagnostic choices in these scenarios when the mortality rate for treatment A was set at either .20 or .80. In the satisficing scenario, we anticipated that mortality would bear unacceptable consequences to a degree that varied with the rate associated with treatment A. We predicted that participants would deem it important to save as many calves as possible and that, consequently, the 80% chance of killing the host organism associated with treatment A would be deemed unacceptably high. In this situation, we predicted a strong preference for enquiring about the mortality rate associated with treatment B, the diagnostic option. With a lower mortality rate of .20, however, we predicted that some participants might deem it satisficingly low and hence be tempted to enquire about the infertility rate associated with treatment A, resulting in higher proportion of pseudodiagnostic choices in this condition.

Table 1: Mean and standard deviation of the importance ratings of preventing killing or preventing infertility in the host organism (rats or calves) in the conditions where the rats and elephant calves are treated as a function of the mortality rate for treatment A, .2 and .8.

		Motivation			
		Maximizing (rats)		Satisficing (calves)	
		Mortality Rate of Treatment A		Mortality Rate of Treatment A	
		.2	.8	.2	.8
Prevent Killing	<i>M</i>	3.37	3.59	7.19	7.18
	<i>SD</i>	2.30	2.48	1.17	1.32
Prevent Infertility	<i>M</i>	3.09	3.30	6.93	6.87
	<i>SD</i>	2.32	2.57	1.36	1.64

Results

Importance Ratings

Participants were asked to rate the importance of not killing the host animals or not making them infertile. These mean importance ratings are reported in Table 1. The importance of saving the calves was consistently rated higher than that of saving the rats. The same was true for the infertility ratings: Participants judged it more important to prevent infertility in the calves than in the rats. Most notably, as we had anticipated, participants deemed it more important to prevent mortality than infertility.

A 2 (goals: maximizing, satisficing) \times 2 (mortality rate of treatment A: .2, .8) \times 2 (rating type: killing, infertility) mixed analysis of variance (ANOVA) confirmed these observations. The main effect of goal was significant, $F(1, 1036) = 1255, p < .001, MSE = 5.69, \eta^2 = .55$, the main effect of the mortality rate was not significant, $F < 1$, and the main effect of rating type was significant, $F(1, 1036) = 20.1, p < .001, MSE = 2.11, \eta^2 = .02$. None of the interactions were significant, largest non reliable $F(1, 1036) = 1.46$.

Choice Preferences

Two participants did not make a choice and were discarded from subsequent analyses. Consistent with our predictions, the diagnostic option was by far the most frequently chosen in all experimental conditions with over 70% of participants opting for this type of information (see Fig. 1). In the maximizing scenarios (treating the rats), nearly 80% of the participants elected to examine the mortality rate associated with treatment B, and the remaining 20% of the participants were evenly split between the other two options (the infertility rate for treatment A or B). Moreover, this pattern of choice was identical whether the value of the mortality rate of treatment A was said to be 20% or 80%. In contrast, in the satisficing scenarios (treating the calves), while most participants still elected primarily to determine the mortality rate of treatment B (the diagnostic choice), the frequency of pseudodiagnostic choices was nearly twice as large when treatment A had a relatively low mortality rate (20%) compared to when it had a high mortality rate (80%). Approximately one fifth of the participants chose the irrelevant option, the infertility rate of treatment B in both versions of the satisficing scenario.

A number of χ^2 tests were conducted. The first determined that the choice frequencies in all four experimental conditions differed significantly, $\chi^2 (df = 6, N = 1038) = 35.2, p < .001$. The proportion of diagnostic choices was significantly higher when the implicit goal was to maximize the number of rats killed, $\chi^2 (df = 1, N = 869) = 5.46, p < .02$. Separate tests were then conducted within the maximizing (rats) and the satisficing (calves) scenarios, excluding the switching choice frequencies. Within the maximizing scenarios, the frequencies of diagnostic and pseudodiagnostic choices did not differ as a function of the mortality rate of treatment A, $\chi^2 (df = 1, N = 463) = .11, p > .05$. In contrast, within the satisficing scenarios, the frequencies differed significantly as a function of the mortality rate of treatment A, $\chi^2 (df = 1, N = 406) = 9.22, p < .005$.

Discussion

This experiment successfully manipulated the relative importance of the information dimensions available in a two-alternative action problem where participants were asked to choose which treatment they should use to save endangered calves whose life was threatened by a deadly parasite. Specifically, ratings of the importance of not killing the animals and not making them infertile confirmed that the mortality dimension was judged more important than the infertility dimension whether the animals were the calves themselves or rats hosting the parasite.

The examination of information search patterns in turn confirmed that when the anchoring dimension was perceived as being the most relevant, participants were strongly drawn to check the diagnostic option: nearly 71% of the 1038 responses collected were diagnostic. This high

Figure 1: Percentage of participants making a diagnostic, pseudodiagnostic, or switching choice for the maximizing scenarios (involving the rats) and the satisficing scenarios (involving the calves) for both values of P(death|treatment A).

degree of consensus is all the more impressive given the size and the variety of the sample from which it originated. This result supports Mynatt et al.'s (1993) initial, albeit untested, assumption that individuals' search for information is driven by considerations of utility in action problems.

We note the large inconsistency between the rate of diagnostic choice observed in our action problems (on average, more than 70% of our participants chose the diagnostic option) compared to those observed by Maggi et al. (1998) with a similar task (on average, less than 40% of their participants did so). These authors, however, had also found that people were more diagnostic when the anchoring dimension was one they judge to be important. Recall that an important methodological difference between their task and the original action problems used by Mynatt et al. (1993), as well as that used in the present study, was the number of dimensions participants could choose from. Whereas our participants and Mynatt et al.'s (1993) could only choose to look up the probability associated with two dimensions (D_1 and D_2) for each of two alternatives, Maggi et al.'s participants were presented with four such dimensions (D_1 , D_2 , D_3 , and D_4). Moreover, the authors rotated the dimension defined as the anchoring dimension so that some participants would be first given information about D_1 , others about D_2 and so on. Suppose that participants' search strategy is primarily driven by the importance of the dimension and suppose D_1 was the dimension they deemed most important. This means that whenever the anchoring dimension was *not* the most important dimension (3 times out of 4), participants would seek to learn more about D_1 for the current alternative and hence make a pseudodiagnostic choice. In other words, perhaps the reason why so many people made pseudodiagnostic choices in Maggi et al.'s (1998) task was because most of the time the anchoring dimension was not the dimension bearing the highest utility.

Finally, in line with our initial predictions, but contrary to Mynatt et al.'s (1993) conclusions, we were able to demonstrate that the numerical value of the anchoring dimension could affect people's search strategies when their motivation was to find a satisficing alternative. In such circumstances, a more satisficing value (viz., a relatively low mortality rate of endangered calves) resulted in almost twice as many pseudodiagnostic choices than a plainly unsatisfactory value (viz., a high mortality rate). This suggests that people will *also* engage in confirmatory search for information when they aim to choose between

two courses of actions (and not only when they seek to make an inference, as the authors had previously concluded). These data therefore offer strong support for the hypothesis that the perceived relevance of the dimensions that define two courses of action governs the information search strategies adopted by reasoners. In addition, they establish that such strategies can also be modified depending on what the decision-maker is motivated to achieve, namely either identify a satisficing alternative or identify a utility maximizing alternative.

Abstract

When faced with a sentence like, “some of the toys are on the table”, adults, but not preschoolers, compute a scalar implicature, taking the sentence to suggest that not all the toys are on the table. Although this difference is sometimes attributed to children's difficulties in processing and pragmatic understanding, this paper explores the hypothesis that children fail to compute scalar implicatures because they lack knowledge about relevant lexical alternatives to words like “some”. Four-year-olds were shown pictures in which two objects fit a description and a third object did not, and were asked to judge the truth value of statements that relied on context-independent alternatives (e.g. *only some of the toys are on the table*) or contextual alternatives (e.g. *only the drum and the ball are on the table*). Children computed scalar implicatures only in the case of contextual alternatives, and only when the statements were grammatically strengthened, supporting the hypothesis that children's difficulties with scalar implicature result from a lack of knowledge of the relevant alternatives.

Keywords: scalar implicature; pragmatic reasoning; processing limitations; contextual alternatives

Introduction

As children acquire language, their task is complicated by the fact that speakers' intended meanings go beyond the literal meanings of their utterances. Word learning is not simply a process of mapping strings of words to speaker intentions. Instead, children must infer the core lexical meanings of words by distinguishing what is logically entailed from that which is merely implied. For example, given a dialogue like (1), John is likely to infer that Mary did not eat all of his cake.

(1) John: Did you eat my cake?

Mary: I ate some of it.

Although Mary's statement would be literally true if she had eaten the whole cake (eating *all* entails eating *some*), her utterance implies that she did not. This inference relies on the assumption that, if Mary had eaten the whole cake, and was communicating cooperatively, she would have uttered a more informative statement like “I ate *all* of it” (Grice, 1989).

The language acquisition literature is filled with examples of children learning words by making inferences about

speaker intentions. A classic demonstration of this comes from experiments investigating mutual exclusivity. When a child is shown two objects, one of which has a known label (e.g., a car), they infer without difficulty that a novel label (e.g., *dax*) refers to the previously unlabeled object. Such an inference follows from the assumption that the speaker would not use two words to denote one kind of object (i.e., words exhibit *mutual exclusivity*, or *contrast*; Markman, 1989; Clark 1987). Children apply such strategies not only when learning nouns, but also when interpreting other classes of words, such as numerals. For example, when 2-year-olds who know the meaning of the word *one* (but no higher number) are shown two sets – e.g., 1 balloon and 5 balloons – they readily infer that *five* refers to the set of five objects (Wynn, 1992; Condry & Spelke, 2008).

Amidst such evidence, and further studies which find that children are sensitive to subtle intentional cues like eye gaze, speaker desires, etc. (Baldwin, 1993; Tomasello, 1992) children also exhibit striking failures in computing some simple inferences, including the inference in (1), which is a type of *scalar implicature*. Following Horn (1989), it is typically assumed that the quantifier *some* belongs to a larger class of terms called “scalar items”. Scales are used to generate sets of alternative meanings, which are ordered according to their informativeness, and are implicitly contrasted during interpretation. In the case of *some*, the relevant scale includes other quantifiers – e.g., *a, some, many, most, all*. Examples of such scales are shown in (2):

- (2) a. <*some, many, most, all*, etc.>
b. <*warm, hot, boiling*, etc.>
c. <*one, two, three*, etc.>

By most accounts, deriving a scalar implicature involves at least four steps, summarized in I - IV. First, the listener computes the basic, *literal*, meaning of the expression (Step I). Second, she considers the alternative sentences that might have been uttered (by substitution of scalar alternatives; Step II). Third, she restricts these alternatives by removing those that are less informative (Step III). Finally, she “strengthens” the interpretation of the sentence by negating the remaining alternatives – e.g., “I ate some (but not all) of the cake” (Step IV).

I. Compute basic meaning of a sentence *S* containing *L*, a scalar item.

II. Generate a set of alternatives (a_1, a_2, \dots, a_n) to *S*, called S_{alt} . These are all the sentences that can be generated by replacing *L* with its scalar alternatives.

III. Restrict the alternatives in S_{alt} by removing any alternative that is entailed by the original utterance *S*. Call this restricted set S^* .

IV. Strengthen the basic meaning of *S* (containing *L*) with the negation of all of the members of S^* .

A large number of studies have found that children fail to derive such implicatures. This has been shown for many scalar contrasts, including *might* vs. *must* (Noveck, 2001), *a* vs. *some* (Barner, Chow, & Yang, 2009), *some* vs. *all* (Huang & Snedeker, 2009; Papafragou & Musolino, 2003; Noveck, 2001), and *or* vs. *and* (Chierchia et al., 2001). For example, in a study by Papafragou and Musolino (2003), 5-year-old children were shown a scene including three horses, in which all three jumped over a log. When asked whether the sentence, “Some of the horses jumped over the log” was a good description of the event, most children said yes. Adults, in contrast, denied that this was a good description, since *all* of the horses jumped over the log. Adults, unlike children, computed a scalar implicature. Children do not always lack a so-called *strengthened* meaning. Papafragou and Musolino found that children provided adult-like responses when tested with numerals. Children denied that “Two of the horses jumped over the log” when three horses did. Thus, although children failed to have adult-like response with *some* and *all*, they interpret numerals with an *exact*-meaning just like the adult controls.

Previous studies have suggested factors that could affect children’s derivation of implicatures, including limitations on working memory, limited understanding of context and meta-linguistic tasks, and the salience or availability of relevant scalar alternatives (see Chierchia et al., 2001; Papafragou & Tantalou, 2002; Pouscoulous et al., 2007; Reinhart, 2004). According to Papafragou and Musolino (2003), since each of these factors might limit children’s computation of implicatures, and since children readily assign exact interpretations to numerals, children must not be using implicatures to derive exact meanings of numerals. Instead, by their view, the difference between quantifiers and numerals is due to the fact that numerals have lexically strengthened, exact meanings (see also Huang, Snedeker, & Spelke, under review).

Context clearly affects whether children (and adults) will compute implicatures (e.g., Papafragou & Musolino, 2002). It is also well established that working memory capacity grows over the course of development (e.g., Gathercole & Baddley, 1990). Nevertheless, the role of these factors in children’s pragmatic difficulties has not been empirically established. First, although previous studies find that implicatures are more likely in some contexts than others (e.g., Papafragou & Musolino, 2002), the fact that strong contextual cues can push children towards one interpretation over another does not demonstrate that their difficulties are

due to contextual misunderstanding. For example, strong contextual cues may compensate for difficulties that originate elsewhere in the process of deriving implicatures.

Second, there is currently no direct evidence that processing constraints are responsible for limiting children’s implicatures. Studies that attribute their problems to processing limitations (Chierchia et al., 2001; Pouscoulous et al., 2007; Reinhart, 2004) do not actually assess working memory, nor do they demonstrate that individual differences in processing capacity predict differences in pragmatic abilities. For example, Chierchia et al. (2001) tested 3- to 6-year-old children’s interpretation of *or*. Unlike adults, when children were told, “Every boy chose a skateboard or a bike,” they accepted situations in which a boy chose both objects. Thus, they accepted the weak inclusive interpretation of *or*, when adults did not. However, when explicitly presented with a sentence containing *and* as an alternative, children strongly preferred it over a sentence containing *or*. This study shows that when children are presented with explicit scalar alternatives, they know when to use the stronger statement. However, it does not single out working memory as the source of children’s difficulty. Instead, we suggest that it is also consistent with the idea that children lack knowledge of scales, and which words are activated as relevant alternatives during interpretation (Step II, see also Papafragou & Tantalou, 2004). An inability to generate relevant scale-mates could explain numerous failures in the literature, as well as the apparent discrepancy between children’s difficulty with implicatures and their relatively sophisticated use of pragmatic cues elsewhere in language acquisition. Further, this account, as noted by Barner and Bachrach (2010), could explain children’s ability to assign exact interpretations to numerals, which belong to an explicitly memorized set of alternatives – the count list.

Barner and Bachrach (2010) argued that young children routinely make inferences that are similar in structure to scalar implicatures when interpreting unknown numerals. As noted earlier, when a child who knows the meaning of *one* is shown two sets – e.g., one containing one balloon, and the other containing five – they systematically point to the larger set when asked to find *five balloons*. However, they do not do so when asked to find *blicket balloons*. According to Wynn (1992), “Since all the children knew that the word ‘one’ refers to a single item, then if they knew that, for example, the word ‘five’ refers to a numerosity, they should infer that it does not refer to a single item since they already have a word for the numerosity one.” (p. 229).

This inference – that *five* refers to the larger set by virtue of *not* referring to *one* – requires all of the processing resources that an implicature would require, as well as several of the same steps. The child must generate a weak meaning for *five* (Step I), generate *one* as an alternative (Step II), and strengthen the interpretation of *five* by negating *one* (Step IV). The only missing component of implicature is that weaker items are not exhausted by appeal to stronger ones (this would be impossible here, since stronger numeral words have not yet been acquired). Still,

once children acquire a meaning for *two*, they should be in a position to compute an implicature for *one*, meaning that even 2-year-olds could compute implicatures to derive exact meanings for numerals.

Children do not have difficulty accessing *one* as a relevant alternative to *five*. Also, once children have accessed *one* as an alternative, they appear capable of inferences not far from a full-fledged scalar implicature. These facts suggest that children's failure to compute implicatures for other scales may be due to a failure to generate relevant scalar alternatives. While children begin to explicitly memorize a count list well before they learn any numeral meanings (see Fuson, 1988), no child is taught to recite a list of quantifiers.

The present study tested the hypothesis that children's difficulty computing implicatures is caused by a failure to generate relevant alternatives. We asked whether children could strengthen their interpretation of utterances containing the quantifier *some* when used with the focus word *only*. In English, the algorithm for calculating scalar implicatures is grammatically mirrored by the semantics of *only*, a fact that allows us to isolate the role of access to alternatives in implicature. As with implicatures, *only* triggers the negation of alternative sentences. For example, consider the sentence in (5).

(5) I ate only some of the cake.

This sentence indicates that the speaker did not eat all of the cake, like Mary's statement in (1). The difference between the sentences in (1) and (5) is that in (5) the denial of the alternative "*I ate all of the cake*" is logically entailed by the sentence's core, literal meaning (it is not merely implied). Still, in order for this entailment relation to be realized, the listener must access *all* as a relevant alternative and negate it. Therefore, evidence that children comprehend *only* but fail to strengthen sentences containing *only some* would suggest that their difficulty is caused by a failure to access scalar alternatives.

To manipulate the accessibility of alternatives, we contrasted children's interpretation of *some*, whose scale members are specified in a context-independent way, with their interpretation of words that have contextually specified alternatives (for discussion, see Hirschberg, 1985). Previous studies find that young children are able to strengthen utterances that rely on contextual alternatives. For example, Goro, Minai & Crain (2006) found that children rejected sentences like "Only Bunny Rabbit will eat a carrot or a pepper" in contexts where another character ate a pepper.

We tested the hypothesis that children's difficulty is due to difficulty generating relevant alternatives by (1) manipulating the availability of alternatives by contrasting utterances that involve context-independent scales like *<some/all>* to utterances that draw on contextually specified sets of alternatives, and (2) forcing the exhaustification of utterances by including the focus element *only* in sentences. Critical trials in the experiment presented situations involving three things (e.g., three animals sleeping), and asked children to evaluate one of the questions in (6):

(6) a. Are some of the animals reading?

- b. Are only some of the animals reading?
- c. Are the cat and the dog reading?
- d. Are only the dog and the cat reading?

If children's difficulty computing implicatures for context-independent scales is due to a failure to access alternatives, then they should accept statements like (6a) and (6b) regardless of whether *only* is present. They should fail to construct an alternative sentence containing *all*, and therefore be unable to strengthen either sentence. In contrast, children should have no difficulty strengthening a sentence like (6d), since the alternative contrast set is contextually specified and therefore readily available.

Method

Participants

Sixty 4-year-olds ($M=53.94$ months, age range: 48.7–59.8 months) participated in this experiment. Two additional children were excluded due to failure to complete the task.

Stimuli

Stimuli were twelve picture cards, each depicting a scene of three items. Four cards were used in a familiarization phase, and eight in the test phase. Familiarization cards depicted sets of animals with distinct characteristics, such as color or clothing. The test cards depicted four scenes (in 1 – 4).

- (1) Cookie Monster holding fruit (an orange, an apple, and a banana)
- (2) Animals sleeping (a dog, a cat, and a cow)
- (3) Animals reading (a dog, a cat, and a rabbit)
- (4) Toys on a table (a ball, a drum, and a train)

Two versions of each scene were created: one in which all three items shared a property (e.g., Cookie Monster is holding all three fruits), and one in which two of the three items shared the property (e.g., Cookie Monster is holding two fruits, and one is on the floor). An example is provided in Figure 1.

Figure 1: Example test stimulus card.

Procedure

Children were first shown the familiarization cards one at a time and asked to identify each animal ("What's this? That's right, it's a cow!"). If the child labeled an animal incorrectly, they were given the correct label and encouraged to repeat it ("That's a cow, can you say 'cow?'").

Children were then asked a question about the scene (e.g., “Is the cow wearing a hat?” when the *fish* is wearing a hat). This exercise was designed to accustom children to answering both yes and no to questions. If a child answered any question incorrectly, the experimenter moved on to the next familiarization card, but returned to the problematic card after completing the remaining familiarization trials. If a child failed twice on any single familiarization trial, the experimenter ended the testing session.

At test, children were given nine trials using the test cards, presented in one of two counterbalanced orders. Again, children were asked to identify all of the items in the picture, and then to evaluate the truth-value of a statement.

Each child participated in one of four conditions. In Conditions 1 and 3 (*Context-Independent Alternatives*), children were asked questions that required them to evaluate the meanings of the quantifiers *some* and *all*, e.g. *Is Cookie Monster holding some / all of the fruits?* In Conditions 2 and 4 (*Contextual Alternatives*), the individual animals, fruits, etc. were labeled separately, e.g., *Is Cookie Monster holding the banana, the apple and the orange?* The questions in each condition were identical, except that in Conditions 3 and 4 (*Grammatically Exhaustified* conditions) the word *only* was inserted—e.g., *Are only some of the animals reading?* or *Are only the dog and the rabbit reading?*

There were 9 questions in each condition. On “2-item, False” questions, children were shown a picture in which only two of the three items fit a description, and were asked whether the description was true for all the items (e.g., *Is Cookie Monster holding all of the fruits?* or *Is Cookie Monster holding the apple, the orange, and the banana?*). These were used as control trials, to be sure that children were attending to the task, and were presented identically in conditions 1 and 2 and conditions 3 and 4. On “2-item, True” questions, children saw pictures where two of the three items fit a description, and were asked whether the description was true for a subset of the items (e.g. *Are (only) some of the animals reading?* or *Are (only) the rabbit and the dog reading?*). Lastly, on “3-item, Test” questions, children were shown pictures in which all three items fit the description, and asked whether the description was true for a subset of the items (questions were identical in the 2-item, True and 3-item, Test trials).

Neither the word *only* nor the quantifier was emphasized by the experimenter’s prosody.

Results

The use of the word *only* had a significant effect on how children interpreted sentences involving contextual alternatives, but had no effect on their interpretation of sentences involving context-independent alternatives (*some* and *all*). A 2x2x2 repeated measures ANOVA was conducted with Trial Type (“2-Item True” vs. “3-Item Test”) as a within-subjects variable and Scale Type (context-independent vs. contextual) and Grammatical Exhaustification (*only* vs., *no-only*) as between-subjects variables. Two-Item False Trials were excluded from this

analysis as children were expected to reject these sentences (results for these trials are described below).

Overall, children were significantly more likely to accept sentences on 2-Item True Trials (87.9%), than on 3-Item Test Trials (59.6%), $F(1,56)=37.05$, $p<.001$. They were also less likely, overall, to accept sentences with *only*, such as “only the drum and the ball are on the table” (84.8% of trials) than those that did not contain *only* (62.7% of trials, $F(1,56)=672.2$, $p<.001$). There was no main effect of Alternative Type ($p>0.05$). Crucially, there were two-way interactions between Alternative Type and Grammatical Exhaustification ($F(1,56)=13.74$, $p<.001$), Trial Type and Grammatical Exhaustification ($F(1,56)=15.08$, $p<.001$), Trial Type and Alternative Type ($F(1,56)=8.87$, $p<.01$), and a three-way interaction between Trial Type, Alternative Type, and Grammatical Exhaustification ($F(1,56)=13.28$, $p<.001$). These interactions were due to the fact that *only* had a significant effect on children’s judgments only for contextual alternatives, and only on 3-item Test trials.

Figure 2 shows the percentage of children who said “yes” to questions in the contextual alternatives conditions. In contexts involving 2 items (e.g., Cookie Monster holding an apple and a banana), children correctly agreed to sentences like, “Is cookie monster holding the apple and the banana?” on 95.8% of trials, and correctly denied that he was holding “the apple, the banana, and the orange” on 80.5% of trials. As expected, adding the word *only* had no effect on either trial type ($ps>.05$). In contrast, on critical 3-item Test trials, children tested with contextual alternatives were highly sensitive to the presence of *only*. These children said “yes” when asked, “Is cookie monster holding the apple and the banana?” on 92.9% of trials, but rarely said “yes” when *only* was added: “Is cookie monster holding only the apple and the banana?” (14% of trials; $t(28)=8.98$, $p<.001$).

Figure 2: Percentage of children who said “yes” to sentences in contextual alternatives conditions.

When children were tested with the word *some* (*Context-Independent Alternatives* conditions), they also correctly said “yes” on 2-item true trials (80.0% of trials), and correctly said “no” 2-item false trials (87.2% of trials). The insertion of *only* again had no effect on children’s responses for these trial types ($ps>0.05$). As in other studies, children did not strengthen utterances containing *some* in absence of *only*. There was no significant difference in children’s response for 2-item True trials and 3-item Test trials

($t(14)=1.0$, $p>.3$). For example, children were equally likely to agree that *some* animals were reading when all three of them were, relative to when only two were. The insertion of *only* did not improve matters and had no effect on the 3-item test trials ($t(28)=.16$, $p>.8$). For example, when three animals were reading, children were equally likely to say “yes” when asked, “Are some of the animals reading” and “Are only some of the animals reading”. Thus, whereas *only* had a huge impact on children’s interpretation of utterances including contextual alternatives, it had no effect at all when children interpreted utterances containing the word *some*.

Figure 3. Percentage of children who said “yes” to questions in context-independent conditions.

Discussion

Children’s ability to generate scalar alternatives places a significant constraint on their ability to compute scalar implicatures. In this study, children assigned strengthened interpretations to utterances when they included the focus element *only*, if alternatives were provided contextually. For context-independent scales (e.g., *some/all*) children failed to compute implicatures, even when *only* was added. Since *only* forces exhaustification grammatically (and did so for contextual alternatives), children’s failure to derive strengthened readings for *some* must be attributed to a failure to generate relevant scalar alternatives – in this case the quantifier *all*.

These data also suggest, contrary to speculation in the literature (e.g., Chierchia et al, 2001; Pouscoulous et al., 2007) that children’s difficulties are not purely attributable to processing constraints. Children were perfectly capable of deriving strengthened interpretations for utterances that involved contextual alternatives, but failed for identical sentences that involved *some*. This result is not predicted by theories that posit processing limitations, since the sentences in these conditions did not differ in grammatical complexity. They only differed with respect to the type of scale that they implicated. The possibility that there are differences in processing difficulty between these conditions cannot be completely ruled out. However, no previous study has provided direct evidence that children’s failures are related to processing limits or working memory. Also, as they are presented, the previous accounts of processing limits are too vague to explain why they would affect Horn scales but not context dependent scales. Thus, we see no compelling

reason to conclude that processing limits are at the root of children’s difficulties on this task or with scalar implicature generally. Instead, we submit, children lack *knowledge* that is scale-specific – i.e., they lack the knowledge that *all* is a relevant alternative when interpreting *some*.

Our hypothesis – that children interpret “only” like adults but fail to compute scalar implicatures because they lack knowledge of specific scales – allows us to explain a much wider array of data than previous accounts, while explaining why children appear pragmatically sophisticated in some domains but not in others. As noted in the introduction, previous studies of children’s number word acquisition find that children can make inferences that resemble scalar implicature from a very early age (Wynn, 1992; Condry & Spelke, 2008). These inferences – e.g., that *five* cannot refer to sets of one, because *one* does – involve processes similar to those needed for scalar implicature. (see Barner & Bachrach, 2010).

Children’s ability to make such inferences for numerals and contextual scales, but not for scales like *<some, all>*, points to differences in scale-specific knowledge. In the case of contextual scales, no scale-specific learning is required since these scales are constructed on the fly in context. In the case of number words, children begin acquisition by learning numerals as an ordered list of alternatives. They acquire a partial count list *before* learning any individual numeral meanings (for review, see Carey, 2009). Thus, the first thing that children learn about the numeral *five* is that it is a member of the count list. In contrast, normal children never learn to recite a sequence of quantifiers like *some, many, most, all*, etc. This view of acquisition suggests, contrary to previous reports (e.g., Papafragou & Musolino, 2003; Huang, Snedeker, & Spelke, under review) that children may derive exact meanings of early numerals via scalar inference (by contrasting numerals with one another).

The idea that children’s difficulties are scale-specific, rather than due to pragmatic immaturity, is also consistent with reports of pragmatic sophistication in other domains, such as noun learning (see Baldwin, 1993; Clark, 1987, 1988; Markman, 1989; Tomasello, 1992). For example, when shown a novel object next to an alternative with a known label – e.g., a shoe – children readily infer that a novel label like *blicket* must refer to the new object (Clark, 1987, 1988; Markman, 1989). Similarly, children infer that a novel color word, like *chromium*, must refer to a novel color, and not to known colors like *red* or *blue* (Carey & Bartlett, 1978). Children fail to respect mutual exclusivity if they believe the novel word is not at the same level of description as the label for the known object, or if they are told the word is from another language (Au & Glusman, 1990). In these cases, the known label is not considered a relevant alternative to the novel label. These simple inferences, though distinct from implicatures in many ways, nonetheless require both pragmatic understanding (including ascription of speaker intent), and the processing abilities needed to entertain and restrict possible alternatives. These abilities would be difficult to explain if children’s

difficulties with scalar implicature were due to processing limits or a general insensitivity to pragmatics.

What must children learn about scales to use them for implicature? Clearly children must learn the meanings of scale mates, and how these meanings differ in informational strength in different contexts. At 4 years of age, children easily differentiate meanings like *some* and *all*, and are able to correctly choose stronger descriptions over weaker ones when provided with a forced choice (e.g., Chierchia et al., 2001). Children's difficulty, it seems, is in recognizing that, for communicative purposes, these scale mates are alternatives to one another – i.e., that using one implies that the others are not true. Thus, a failure to generate words as alternatives does not mean that children have difficulties with lexical retrieval. Rather, our claim is that even when children can retrieve *all* when interpreting *some*, they do not access it as a relevant alternative to *some*.

A remaining puzzle, and one that is not addressed by the current study, is how children eventually come to acquire such scales. Our results, and others from the literature, suggest that children are capable of strengthening utterances by appeal to alternatives, so long as these alternatives are contextually specified or memorized explicitly as a list. It is not clear children they come to associate scale mates, such as quantifiers, that they do not learn as a list. We suggest that the association of these lexical items may take place by trial and error learning – by hearing words used contrastively in context, or via explicit cancellations of implicature in the speech of adults. Future studies should explore the effects that such input has on children's pragmatic reasoning, and how experience with different scales affects their ability to compute implicatures.

Computational Modeling; Theory of Mind

Adults effortlessly and automatically infer complex patterns of goals, beliefs, and other mental states as the causes of others' actions. Yet before the last decade little was known about the developmental origins of these abilities in early infancy. Our understanding of infant social cognition has now improved dramatically: even preverbal infants appear to perceive goals, preferences (Kushnir, Xu, & Wellman, in press), and even beliefs from sparse observations of intentional agents' behavior. Furthermore, they use these inferences to predict others' behavior in novel contexts and to make social evaluations (Hamlin, Wynn, & Bloom, 2007).

Inspired by this work, computational modelers have in the last few years begun to formalize the knowledge and inference mechanisms underlying infants' social reasoning (Baker, Saxe, & Tenenbaum, 2009; Lucas, Griffiths, Xu, & Fawcett, 2009; Ullman et al., 2010). Many of these models share deep similarities, explaining social inference in terms of an intuitive understanding of how an agent chooses among actions. For instance, the principle of rational action, suggested in seminal work on infant social cognition (Gergely, Nádasdy, Csibra, & Biró, 1995), states that agents will select the best action to achieve their goals, given the constraints of their environment – or in a more sophisticated version, given their beliefs about the environment. This principle has been formalized using notions of planning and decision-making from economics and computer science. It underlies models that make accurate quantitative predictions of the social inferences of adults and young children in a variety of experimental tests.

The goal of this symposium will be to bring together developmental psychologists and computational modelers in a dialogue on the social inferences made by young infants, the mechanisms by which these inferences work and become

more sophisticated in older children. The first talk of the symposium (Baker et. al) will briefly survey now-classic work on infants' understanding of goals and beliefs, and will introduce a general computational framework for modeling these social inferences based on intuitive principles of rational action. Next will be two pairs of developmental and computational talks, focusing on recent advances where there has been important exchange between empirical work and models. Kushnir, et al, and Lucas, et al, will describe work on understanding of others' preferences. Hamlin, et al, and Ullman, et al, will describe attribution of "prosocial" goals (such as helping). The symposium will conclude with a discussion led by Spelke, highlighting gaps in our understanding of infant social cognition, areas where more computational work is needed, and where computational ideas might suggest new areas for developmental experiments.

Close interaction and collaboration between developmentalists and computational modelers studying infant social cognition is a fairly recent trend, yet it has already proven fruitful, as the talks in this symposium hope to demonstrate. Previously, the research to be presented here has been discussed primarily at conferences on computational modeling (e.g., NIPS) or developmental psychology (e.g., the Cognitive Development Society), or in small workshops bringing together modelers and experimentalists. The Cognitive Science Conference would be an ideal venue for a broad symposium on this emerging, interdisciplinary subfield, due to its tradition of bringing together theorists and experimentalists from a broad array of disciplines. We expect the symposium will interest a wide audience and lead to new research directions and collaborations engaging different segments of the Cognitive Science audience.

Probabilistic models of belief-desire psychology

Baker, Goodman & Tenenbaum We propose a computational

framework for modeling how humans interpret intentional actions in terms of the mental states that cause behavior: chiefly, beliefs and desires. The framework represents a schema for intentional action using rational models of belief- and goal-based planning from economics and computer science known as partially observable Markov decision problems. Agents' beliefs and desires are inferred by inverting this model of rational planning using Bayesian inference, integrating the likelihood of the observed actions with the prior over mental states. This approach formalizes in precise probabilistic terms the essence of previous qualitative approaches to infant action understanding, (e.g. Gergely et al., 1995). We will present results showing that our models account for infants' and adults' social judgments from a body of experiments, from simple inferences about goals, to joint inferences of preferences and beliefs. We will also consider how a set of alternative, heuristic-based models compare to our account.

Young children use statistical sampling to infer the preferences of others

Kushnir, Wellman & Gelman Psychological scientists use statistical information to determine the workings of fellow humans. We argue so do young children. In a few years, children progress from viewing human actions as intentional and goal-directed to reasoning about the psychological causes underlying such actions. Here we show that preschoolers and 20-month-old infants can use statistical information – namely, a violation of random sampling – to infer that an agent is expressing a preference for one object over another. Children saw a person remove 5 items of one type from a container of objects. Preschoolers and infants only inferred a preference for that type of object when there was a mismatch between the sample and population. Mere outcome consistency, time spent with and positive attention toward the objects did not lead children to infer a preference. The findings provide an important demonstration of how statistical learning could underpin the rapid acquisition of early psychological knowledge.

A rational model of preference learning and choice prediction by children

Lucas, Griffiths, Xu & Fawcett We present a rational model of preference learning that explains the behavior of children in several recent experiments, as well as a developmental shift in which children come to understand that people have distinct preferences. We first show that a simple econometric model can account for young children's use of statistical information in inferring preferences and their ability to generalize others' preferences from one category to another. We then consider the question of how children begin to treat other individuals as having preferences that can differ from their own, showing that such a transition is consistent with Bayesian inference, given a model in which all people share preferences and one in which preference can vary across possibilities. Finally, we discuss novel predictions made by our model concerning preference understanding and the developmental shift.

The enemy of my enemy is my friend: Infants interpret social behaviors in context

Hamlin, Wynn & Bloom Recent research suggests that young infants prefer prosocial to antisocial individuals (Hamlin et al., 2007). While a preference for those who help others is certainly adaptive, there are potentially situations in which unhelpful behavior is more appropriate (e.g. punishing others for their wrongdoing) or more socially diagnostic (e.g. "The enemy of my enemy is my friend," Aronson & Cope, 1968). This talk examines whether infants always prefer those who are prosocial, in contexts in which antisocial behavior could be seen as punishment, or in which an individual's antisocial behavior may be an indication that he or she shares a negative opinion toward a disfavored other. Results suggest that even in the first year of life, infants evaluate behaviors not only in terms of their valence, but also in terms of certain qualities of their recipients.

Help or hinder: Models of social goal inference

Ullman, Baker, Goodman & Tenenbaum Everyday social interactions are heavily influenced by our snap judgments about others' goals. Even young infants can infer the goals of intentional agents from observing how they interact with objects and other agents in their environment: e.g., that one agent is 'helping' or 'hindering' another's attempt to get up a hill or open a box. We propose a model for how people can infer these social goals from actions, based on inverse planning in multiagent Markov decision problems. The model infers the goal most likely to be driving an agent's behavior by assuming the agent acts approximately rationally given environmental constraints and its model of other agents present. We also present behavioral evidence in support of this model over a simpler, perceptual cue-based alternative.

Discussion: Open challenges and future directions

Spelke The closing discussion will draw out gaps in our current understanding of infant social cognition, areas where more computational work is needed, and places where computational ideas might suggest new areas for developmental experiments.

Abstract

To use natural language, speakers must map the participants in events or states in the world onto grammatical roles. There remains considerable disagreement about the nature of these so-called *linking rules* (Levin & Rappaport Hovav, 2005). In order to probe the nature of linking rules, we investigate verbs of psychological state, which demonstrate complex linking patterns both within and between languages. We find that the typical duration of the psychological state guides the application of linking rules to novel verbs in both English and Japanese, consistent with a universal constraint. Nonetheless, there are marked differences in the baseline preferences for the individual linking rules across the two languages. We discuss these findings both in terms of theories of exceptionless linking rules and accounts on which linking rules are governed by probabilistic biases as well as cross-linguistic variation.

Keywords: syntax; semantics; linking; UTAH; universal grammar; over-hypotheses.

The Linking Problem

To interpret *Mary broke the vase*, one must minimally identify the event described (*breaking*), the participants in that event (*Mary, vase*), and identify which participant played which role (*Mary* = breaker, not break-ee). This *linking problem* has received considerable attention both by theorists trying to correctly characterize the semantics-syntax links (see Levin & Rappaport Hovav, 2005, for review), and by developmental psychologists interested in how children discover these links (Bowerman, 1990; Pinker, 1984, 1989).

A key issue is identifying the right level of generalization for the *linking rules*. Many data points suggest linking rules

are highly regular. Regularity is seen both within verbs and across verbs. Not just *Mary* but all breakers are the subject and not object of *break* (*John/the baby/the wind broke the vase/window/glass*). Similarly, in English the object of a transitive change-of-state verb is systematically the entity that changes state while the subject effects that change (*Mary broke/cleaned/opened the box*). These intuitions generalize to novel words. If interpretable, *The dax broke the blicket* must mean that the dax is the breaker and the blicket is broken. Adults and children prefer an interpretation on which *The bear pilked the horse* means the bear did something to the horse, not vice versa (Marantz, 1982; see also Pinker, 1989). Moreover, these patterns are sufficiently regular across languages to suggest that some (Pinker, 1984) or all (Baker, 1988) linking rules are innate.

However, there are numerous examples of apparent variation and exceptionality. An object moving from Mary's possession to John's can be described by *Mary gave/lent/sent the package to John* or *John received/took/obtained the package from Mary*. The same activity might be called *Mary chasing John* or *John fleeing Mary*. Many emotion verbs put the experiencer in subject position (*John feared/hated/loved Mary*), while others put the experiencer in object position (*Mary frightened/angered/delighted John*). Moreover, a relatively small number of languages appear to exhibit linking rules quite distinct from what is seen in languages like English (Dixon, 1994).

In the present study, we investigate linking rule regularity and variation within and across two unrelated languages with respect to one such problematic case: psych verbs.

Psych Verbs

Unlike change-of-state verbs, verbs of psychological state are highly variable in terms of their surface syntax. The experiencer of the mental state may appear as the verb's subject (experiencer-subject verbs: *Mary likes/hates/misses John*) or its object (experiencer-object verbs: *Mary surprises/confuses/angers John*). Both classes are seen in a wide variety of languages, though the subjects of experiencer-subject (ES) verbs can appear as dative subjects in languages that have such constructions (Levin, 1993). Interestingly, there appears to be some variation across languages in terms of which psychological states appear in which form: for instance, the apparent French equivalent to the ES psych verb *miss* is experiencer-object (EO; *manquer*; see also Croft, 1993).

Most authors have assumed there is no systematic semantic distinction between ES and EO verbs, and thus each verb must be marked for taking one linking rule or the other (e.g., Bowerman, 1990; Dowty, 1991; Jackendoff, 1990; Pinker, 1989). However, Pytkanen (1999) finds that in Finnish, ES psych verbs describe individual-level predicates whereas EO psych verbs describe stage-level predicates.¹ Stage-level and individual-level predication differ in several ways; one relevant difference is that stage-level predicates can be narrowly bound temporally and physically (1), whereas individual-level states typically cannot be (2).

- (1) a. John was sleepy yesterday in the kitchen.
b. John angered Mary yesterday in the kitchen.
- (2) a. *John was tall yesterday in the kitchen.
b. *John hated Mary yesterday in the kitchen.

Thus, it may be that those psychological states which are deemed more likely to be bound in time and space are also more likely to be realized as EO verbs.

Interestingly, the psychological literature on emotional states typically distinguishes between *emotions* and *dispositions* (Ekman, 1999). The former are tied to specific physiological states and are brief in duration, whereas the latter are long-lived tendencies to feel or act in a particular way. Commonly-given examples of emotions are *surprise* and *anger*; frequent examples of dispositions are *love* and *hate*. Note that the former are EO verbs and the latter ES verbs.

Informal inspection of English psych verbs by the authors suggested that in fact ES verbs do typically describe dispositions thus defined while EO verbs typically describe emotions. This was further confirmed in an unpublished study in which naïve participants rated the states described by ES verbs as typically lasting longer than those described by EO verbs (Hartshorne, 2009).

In the present study, we investigate whether differences in the nature of the psychological state influence whether participants apply the EXPERIENCER→SUBJECT linking rule or the EXPERIENCER→OBJECT linking rule to novel psych verbs. We focus on the notion of duration: are long-lived

psychological states (dispositions/individual-level states) more likely to be realized as ES verbs relative to short-lived psychological states (emotions/stage-level states)?

In order to investigate both linguistic universals and variation, we investigated the degree to which this proposed distinction guides generalization of linking rules in two historically unrelated and linguistically distinct languages: English and Japanese.

Experiment 1: English

Participants in Experiment 1 were introduced to novel transitive verbs describing psychological states for which there was no existing verb. To encourage participants to take the task seriously, the novel verbs were introduced as loanwords from Japanese. Half the verbs described long-lived psychological states; half described short-lived psychological states. For each verb, participants decided whether an ES structure or an EO structure was more likely to be "correct."

In English there is a preference for simple present tense verbs to be interpreted as generic statements (contrast *Bats frightened John* vs. *Bats frighten John*; see Carlson, 1988). As this may affect whether the novel psych verbs are seen to describe short-lived (event-like) or long-lived states, we tested separate groups of subjects using both simple present and past tenses (Experiments 1a and 1b). As ES verbs cannot be naturally used the progressive form (**John was fearing bats*), we used simple tense only.

Method

Participants

Forty native English-speakers participated in Experiment 1: twenty in 1a (18-60yo, M=25.3, SE=2.2) and twenty in 1b (18-39yo, M=23.1, SE=1.2). Participants, who were recruited outdoors on Harvard's campus, gave informed consent and were compensated with a small snack.

Materials

Sixteen Japanese nouns describing psychological states without clear English verbal equivalents were selected and turned into verbs, applying any necessary phonological accommodations. Eight were judged by the authors to be long-lived states (e.g. *tekitaishin*: *the feeling of rivalry*; *hankan*: *the feeling of being opposed to something or someone*) and eight to be short-lived states (e.g., *wabi*: *a sense of beauty of silence discovered in simplicity*; *tokimeki*: *the feeling of a heart beating because of encountering an attractive person or thing*). For each verb, an appropriate animate experiencer argument was chosen. The other argument was an inanimate *stimulus* of the emotion. Two sentences were constructed by placing the experiencer in either subject or object position (3). To further bias participants into conceiving of the long-lived states as long-lived states and short-lived states as short-lived states, the inanimate arguments for the former were themselves long-lived (e.g., *Harvard's basketball team*; *his company's*

¹ See also discussion of Pesetsky (1995) below.

policy) and the inanimate arguments for the latter were short-lived (*the unexpected rainbow; seeing the gorgeous necklace*). Four additional filler sentence pairs describing non-psychological events (*The ocean wave tsunamis the village* vs. *The village tsunamis the ocean wave*) were also constructed. Experiments 1a and 1b differed only in the tense of the verb: simple present in 1a and simple past in 1b.

Procedure

Participants were told that they would try to correctly use new Japanese loanwords. For each verb, they were given a definition and the two possible sentences. An example trial is shown below:

- (3) *Tekitaishin*
The feeling of rivalry
 a. *Richard tekitaishins Harvard's basketball team.*
 b. *Harvard's basketball team tekitaishins Richard.*

They were asked to choose the sentence they thought most likely to be correct. Four test forms were constructed as follows: the order of verbs was pseudorandomized such that the same condition (emotion/disposition) did not occur more than twice in a row. We counter-balanced whether the ES sentence or EO sentence was displayed first within each condition. The second form was made by switching the order of the sentences for each verb. Forms 3 and 4 were made by reversing the order of the verbs in Forms 1 and 2.

Results and Discussion

As predicted, participants were more likely to choose the ES frame for long-lived verbs than for short-lived verbs, in both Experiment 1a ($M=62.5\%$, $SE=4.3\%$ vs. $M=32.5\%$, $SE=4.2\%$) and 1b ($M=58.7\%$, $SE=5.5\%$ vs. $M=33.1\%$, $SE=5.0\%$).² The main effect of short-lived/long-lived was significant ($F(1,38)=60.8$, $p<.001$; $F(1,14)=6.2$, $p=.03$),³ and this effect did not interact with tense ($F_s<1$). Thus, semantics guides the preferences of native English-speakers for certain verbal syntactic forms. Interestingly, although the past tense is more amenable to the description of events, participants were not more likely to choose the object-experiencer frame when the verb was presented in the past tense ($F_s<1$), perhaps because the inanimate arguments used for the short-lived verbs strongly implied events (e.g., *Seeing the gorgeous necklace tokimekis Mary*).

Thus, the underlying semantics of the sentence (the verb and/or inanimate argument) biased participants to choose a particular syntactic frame: ES for short-lived states and EO for long-lived states. In Experiment 2, we test whether this distinction is cross-linguistically relevant by turning to Japanese, a language historically unrelated to English.

² Means and standard errors here and elsewhere calculated by subject.

³ Items analyses consider a given verb in present or past tense to be the same verb. Treating them as separate items does not affect the pattern of results.

Experiment 2: Japanese

Japanese is widely considered to be a language isolate, and its grammar is distinguished from that of English in a number of important ways (Tsujimura, 2007). First, Japanese is a scrambling language, allowing considerable word-order variation, with the basic order being Subject-Object-Verb, while in English the word order is rigidly Subject-Verb-Object. Second, unlike in English, the grammatical roles of noun phrases are overtly marked by particle suffixes: the subject is generally marked by *-wa*, and the direct object is marked by *-o*. Third, in the verbal domain, Japanese is a highly agglutinative language in which a verbal stem must at least bear a tense suffix and also may appear with a number of other suffixes expressing various grammatical functions. One such verbal suffix that is relevant for our purposes is the causative suffix (*(s)ase-*). For example, *aruk-ase-* is the causative form of the verbal stem *aruk-* ‘walk’, meaning ‘to make somebody walk’. This suffix is productive and can combine with almost all verbal stems.

Interestingly, while English contains more morphologically simple EO verbs (220) than ES verbs (44; Levin, 1993), our survey of Japanese found only 5 morphologically simple EO verbs, with the vast majority (74) ES.⁴ Additional, morphologically complex, EO verbs can be formed in Japanese by adding the causative *-(s)ase-* affix to a ES verb:

- (4) a. *Taro-wa koomori-o kowagat-ta.*
 Taro-TOP bat-ACC fear-PAST
 Taro feared bats
 b. *Koomori-wa Taro-o kowagar-ase-ta.*
 bat-TOP Taro-ACC fear-CAUS-PAST
 Bats frightened Taro.

As in Experiment 1, we tested verbs in both the present and past tense. However, since in Japanese ES verbs are unnatural in simple tenses (**John-wa Mary-o nikum-u*; *John-TOP Mary-ACC hate-PRES*), we used the more natural progressive form (*John-wa Mary-o nikun-dei-ru*; *John-TOP Mary-ACC hate-PROG-PRES*; “John hates Mary”) for both verb classes. Note that with certain stative verbs the progressive morphology does not force a progressive meaning (e.g. the previous example does not mean “John is hating Mary”).

Method

Participants

Forty native Japanese-speakers participated in Experiment 2: twenty in 2a (20-35yo, $M=22.3$, $SE=2.8$) and twenty in 2b (19-65yo, $M=31$, $SE=3.3$). Participants, who were recruited in public spaces around Tokyo, gave informed consent and were compensated with a souvenir pencil.

⁴ Throughout this paper we consider only transitive verbs that take direct objects (*John fears/frightens Sally*). Future research will investigate intransitive verbs that take oblique objects (*John cares about/matters to Sally*).

Materials and Procedure

Materials and procedure were modeled closely on Experiment 1. Participants were introduced to novel English-derived loanwords in Japanese (long-lived: reverence, greed, phobia, envy, credence, affection, loathing, pride; short-lived: déjà vu, anguish, grief, jolt, nostalgia, trepidation, glee, chagrin). Loan words in Japanese can be made using the semi-productive verbalizer *-r-* (e.g., *gugu-r-u*: ‘to google’) or the light verb *suru* (e.g., *enzyoi-suru*: ‘to enjoy’). While the latter is more productive, it often carries an explicitly causative meaning, particularly when applied to states. Since our goal was to avoid explicit morphosyntactic markers of meaning (with any concomitant argument selection biases), we used the more neutral *-r-*.

Again, care was taken to ensure that the loanwords did not approximate any extant Japanese monomorphemic words (e.g. *hatred* was avoided, since Japanese already contains *nikum-u*, which means *to hate*). As in Experiment 1, long-lived psychological states were paired with long-lived inanimate arguments (e.g., *the mountain*; *the theory of evolution*) and short-lived psychological states with short-lived inanimate arguments (e.g., *news of her brother's accident*; *seeing the foreign town*). The four filler verbs were existing English-derived psych verbs.

Experiments 2a and 2b differed only in that the verbs were in the present-progressive in 2a and in the past-progressive in 2b. Two of the filler verbs in 2a were problematic and were replaced in 2b. An example trial for a short-lived verb from Experiment 2b are shown below:

guriifu (grief): deep sorrow (especially that caused by someone's death)

- a. Tooru-wa aiken-no shi-o guriifu-t-tei-ru
Toru-TOP pet.dog-GEN death-ACC grief-V-PROG-PAST
Toru grieves the pet dog's death.
b. Aiken-no shi-wa Tooru-o guriifu-t-tei-ru
pet.dog-GEN death-TOP Toru-ACC grief-V-PROG-PAST
The pet dog's death grieves Toru.

Results and Discussion

Like English speakers, Japanese participants were more likely to select the ES interpretation for the long-lived verbs than for the short-lived verbs in both Experiments 2a ($M=90.6\%$, $SE=1.0\%$ vs. 73.7% , $M=0.9\%$) and 2b ($M=73.1\%$, $SE=0.9\%$ vs. $M=55.6\%$, $SE=0.9\%$). The overall main effect of short-lived/long-lived was significant ($F(1,38)=28.6$, $p<.001$; $F(1,14)=16.8$, $p=.002$) and did not interact with tense ($F_s<1$). Unlike in English, there was a significant main effect of tense, with ES interpretations more likely in present tense than past ($F(1,38)=6.3$, $p=.02$; $F(1,14)=21.5$, $p<.001$).

These results suggest that linking rules in Japanese, as in English, are sensitive to the duration of the psychological state. Interestingly, however, Japanese participants were overall more likely than English speakers to choose the ES frame ($M=72.5\%$, $SE=3.5\%$ vs. $M=46.7\%$, $SE=2.8\%$;

$t(78)=5.8$, $p<.001$; $t(30)=3.5$, $p=.001$). This could show a broad preference for the EXPERIENCER→SUBJECT linking rule in Japanese. Alternatively or in addition, Japanese participants may have been sensitive to the fact that the novel verbs were all morphologically simple, and nearly all morphologically simple psych verbs in Japanese are ES (see above). EO verbs are typically formed with the addition of the causative affix *-(s)ase-*. We tested whether participants would be more likely to choose the EO form for *-(s)ase-* affixed verbs in Experiment 3.

Experiment 3: Causative Psych Verbs in Japanese

In Experiment 3, we tested whether Japanese participants would choose EO frames for *-(s)ase* affixed psych verbs.

Method

Participants

Twenty participants (19-34yo, $M=22.5$, $SE=1.3$), recruited in public spaces around Tokyo, gave informed consent and were compensated with a souvenir pencil.

Materials and Procedure

Materials and procedure were identical to Experiment 2b, except all verbs were causativized by the addition of the *-(s)ase-* affix and presented in the present progressive (*guriifu-r-ase-tei-ru*).

Results and Discussion

As in Experiment 2, Japanese participants were more likely to choose the ES interpretation for the long-lived verbs than the short-lived verbs ($M=33.1\%$, $SE=5.2\%$ vs. $M=21.2\%$, $SE=3.5\%$; $t(19)=2.41$, $p=.03$; $t(14)=2.83$, $p=.01$). As predicted, participants were overall much less likely to choose the ES interpretation relative to Experiment 2a ($M=27.2\%$, $SE=3.7\%$ vs. $M=80.6\%$, $SE=3.6\%$; $t(38)=10.3$, $p<.001$; $t(15)=20.5$, $p<.001$). Thus, the preference for the ES interpretation in Experiment 2 was not due to a global preference for EXPERIENCER→SUBJECT linking, but rather was specific to the verb form used (monomorphemic).

General Discussion

In order to discuss events and states, speakers must map the participants in the event or state onto grammatical roles. There remains considerable disagreement about the nature of these mappings or linking rules (Levin & Rappaport Hovav, 2005). Linking rules are typically defined in terms of features of the arguments such as agentivity or causativity (Dowty, 1991; Pesetsky, 1995; Pinker, 1984; 1989) or aspects of the predicate such as stativity and telicity (Hooper & Thompson, 1980). In this paper, we present evidence that in the case of psych verbs, linking rules are sensitive to duration of the psychological state: if the state is short-lived, the EXPERIENCER→OBJECT rule is more likely to apply; if the state is long-lived, the EXPERIENCER→SUBJECT rule

applies. This distinction appears in both English and Japanese, historically unrelated and grammatically distinct languages. Coupled with the fact that the this distinction may also characterize existing verbs in Finnish (Pylkkanen, 1999) and Mandarin (Hartshorne, 2009), which are unrelated to each other or to English or Japanese, these results suggest this distinction *could* be universal across languages.

Causes, Stages and Emotions

The data in this paper demonstrate that the mapping from semantics to syntax for psych verbs is governed at least in part by the meaning of the verb. Although we discussed our manipulation in terms of the expected duration of the psychological state, that may not be the correct distinction.

Our experiments above were partly motivated by the distinction in the psychological literature on emotion between emotions and dispositions. Since one of the defining distinctions between emotions and dispositions is their duration, this distinction is fully confounded with our short-lived/long-lived distinction.

Similarly, we noted that Pylkkanen (1999) argues that Finnish ES verbs are individual-level predicates and Finnish EO verbs are stage-level predicates. Stage-level and individual-level predicates are usually defined in terms of the genericity of predicates—typically formalized as whether the predicate refers to a single event or quantifies over many events (Carlson, 1988). Genericity can be diagnosed by linguistic tests such as the permissibility of the progressive (see Pylkkanen, 1999). As noted above, at least one of the linguistic tests has apparent semantic consequences. One distinguishing factor of EO predicates is that they can be bounded by brief temporal durations, making the notion of *stage-level* similar to our notion of *short-duration*. Whether the two can be de-confounded is a question for future research.

Note that while it may be that *stage-level*, *short-lived* and *emotion* may simply be three ways of capturing the fundamental distinction that influences the semantic-syntactic mapping, the same may not be true for the other semantic distinction that has been suggested in the literature: Pesetsky (1995) presents linguistic analyses suggesting that EO verbs encode caused events, while ES verbs do not. Intuitively, brief states like emotions seem related to changes of state, which is a necessary component of *cause*, perhaps suggesting a way of integrating the notions.⁵ Relatedly, Pylkkanen (1999) argues causally-affixed Finnish psych verbs either describe events or stage-level (rather than individual-level) states, providing another potential association. Nonetheless, the associations here are tenuous. Whether *cause* is a factor in the semantics-syntax

linking rules for psych verbs – and, if so, whether it is a factor independent of the one(s) described above – remains a question for future research.

Universals

There have been several proposals suggesting that linking rules are universal, innate and exceptionless. Baker proposes his Uniformity of Theta Assignment Hypotheses (Baker, 1988), which posits a simple, exceptionless, many-to-one rules linking semantics roles (AGENT, EXPERIENCER) to syntactic position (SUBJECT, DIRECT OBJECT), at least at the level of deep structure. Pinker (1984) argues that linking rules may be innate. Such claims not only greatly simplify linguistic theory, but they also simplify the job of the language learner.

However, such theories have been challenged by apparent variation in the application of linking rules in some domains, such as psych verbs. The data presented here suggest a solution to this problem compatible with exceptionless linking rules: a rigid, innate linking rule that maps EXPERIENCER→SUBJECT for long-lived psychological states and EXPERIENCER→OBJECT for short-lived psychological states. Whether such rules apply beyond English and Japanese (and perhaps Finnish and Mandarin) remains an empirical question. This may suggest that other such cases of variation may similarly be resolved by closer inspection of the semantics (see also Pesetsky, 1995, for discussion). While this is an intriguing possibility, it is not the only possible conclusion (see below).

Variation

Despite the potentially universal sensitivity of linking rules to psychological state duration described above, Japanese and English speaking participants showed a striking difference in their baseline preference for the two argument mappings: Japanese participants were over 50% more likely than English-speakers to chose the ES form. At least three explanations for this cross-linguistic variation are possible.

First, although stimuli for the English and Japanese studies were constructed in an identical manner, the stimuli were not identical (the *different-stimuli hypothesis*). It may be that the semantics of the Japanese stimuli were biased in favor of the ES mapping; perhaps the short-lived verbs were less short-lived than those in the English study. Although such a possibility is difficult to rule out with certainty, the relative size of the effect limits the likelihood that poor stimulus selection explains the effect. Moreover, the discrepancy was highly consistent across stimuli: all but one of the short-lived English verbs in Experiment 1a had more EO attributions than *any* of the short-lived Japanese verbs in Experiment 2a. Similarly, all but one of the long-lived English verbs in 1a had more EO attributions than *any* of the long-lived Japanese verbs in 2a (the comparison for 1b and 2b is similar).

A second possibility is that linguistic differences between Japanese and English led the participants to construe the

⁵ Consistent with this possibility, an additional experiment using novel Japanese psych verbs created with *-suru*, which typically gives rise to a causative interpretation, found that Japanese participants overwhelmingly chose the EO reading.

meanings of the novel verbs differently (the *different-construal hypothesis*). There are a number of reasons this might happen. For example, Pesetsky (1995) has argued that only EO verbs describe caused events. Japanese can mark verbs overtly as causal with the *-(s)ase* affix, and in fact there are only a handful of EO verbs lacking the causal affix. In Experiment 2, the verbs presented to the Japanese participants lacked the causal affix. These participants may then have made the inference that the verbs do not describe caused events, leading them to choose the ES reading. Since English does not explicitly mark verbs as causal or not, the English-speaking participants faced a more ambiguous inference problem.

Note that the *different-stimuli hypothesis* and the *different-construal hypothesis* are both consistent with rigid, exceptionless linking rules. The English and Japanese participants apply the linking rules in the same way; they simply disagree as to the meanings of the verbs. Another possible conclusion is that linking rules are constrained by universal biases but allow some cross-linguistic variation in their exact formulation (the *soft-universals hypothesis*). Imagine that based on the available cues Japanese and English speakers arrive at the same guess about the underlying semantics. They may still show different baseline preferences if argument mappings are probabilistic.

Our data provide evidence for a universal bias in argument mappings, however, they do not show that such mappings have to be either exceptionless or deterministic. Instead, semantics-to-syntax mappings for arguments could themselves be probabilistic and influenced by both soft universals and language-specific factors.

For example, as discussed above, unmarked psych verbs in Japanese are overwhelmingly ES while the opposite is true (to a lesser degree) in English (see above). Suppose that in addition to universal (and presumably innate) biases, mappings are also influenced by similarity to other verbs. In such a scenario, the baseline statistics of psych verbs in the two languages would predict the baseline difference in performance.

Models that allow for within-language, across-item generalizations of this form have a long history in both generative linguistics (where they often take the form of *parameter-setting* models) and non-generative approaches such as construction grammar. Recent work in computational modeling has shown how such systems can be expressed by hierarchical Bayesian models. These models encode the across-item generalizations as *overhypotheses*—hypotheses about hypotheses (see e.g. Perfors, et al., *in press*).

It remains for future work to determine whether cross-linguistic differences are better attributed to variation in how speakers of various languages construe situations, to probabilistic linking rules, or to some combination of both.

Abstract

Language theorists have argued that processing negated statements (“The eagle is not in the sky,”) differs from affirmative propositions. However, evidence for these claims comes from studies that did not control for the possibility of numerous states (e.g., the eagle is perched on a branch or on the ground). Here, we explore whether constraining this number of possibilities provides more information about processing negation. In Experiment 1, the stimuli described binary states. For example, a coin can be either heads up or tails up; if it is not heads up it is necessarily tails up. In Experiment 2, preceding contexts constrained the number of possible locations of a negated proposition. The results, consistent with earlier evidence for negation’s increased complexity, offer new data suggesting that perceptual simulation of negated proposition may be experimentally detected when the states or locations are sufficiently constrained, using binary states or contextual descriptions.

Keywords: Language Processing; Negation; Embodied Cognition; Perceptual Simulation

Negation is a fundamental part of everyday communication. Throughout the course of a typical day, people frequently have to report where things are *not* located, for instance, “Your keys are not on the table” or “My car is not in the garage.” They must also describe events that are *not* happening, such as, “The Patriots are not playing tonight” or “Your car will not start.” Despite the ubiquity of negated statements, surprisingly little is known about how they are processed and what their conceptual structure is.

One of the earliest and most reliable findings about negation is that people are slower to read negated sentences than they are to read affirmative sentences, due to their increased complexity (see Barres & Johnson, 2003; Carpenter & Just, 1975; Chase & Clark, 1972; Mayo, Schul, & Burnstein, 2004). Such findings have provided invaluable insights into sentence processing, but many important questions about processing negation remain. In particular, how do negated statements influence everyday cognition? Are negated sentences comprehended differently than affirmative sentences? The goal here is to further consider negation’s influence on sentence comprehension.

Negation has been of interest to philosophers and language theorists for centuries (for review, see Gilbert, 1991), but only recently has its processing received close attention. Early cognitive work on processing suggested that negated statements about spatial relations are processed differently from similar affirmative statements. For instance, participants

in Clark and Chase (1972) were presented with sentences followed by pictures and then asked whether the sentence was true or false of a corresponding picture. For example, a “true” trial might consist of the sentence, “The star is above the cross,” followed by a picture with a star above a cross, accurately depicting the relationship expressed by the sentence. Participants responded true or false more quickly to a picture following the sentence, “The star is above the cross,” than to the sentence, “The star is not above the cross.” These differences suggested that affirmative and negated statements are processed differently, but the nature of this difference was unclear. One possibility is that the increased processing time associated with negation is the result of evaluating the core proposition and then applying a negation marker to this proposition.

More recent evidence also supports the hypothesis that negating or affirming a statement involves subtly different processes. McKinstry, Dale, and Spivey (2008) presented participants with questions of varying truth-values and asked them to answer “yes” or “no” using a mouse to click on a corresponding, visually presented box on the computer screen. A sentence’s truth-value was defined as the proportion of participants who agreed the statement was true in an on-line survey. Therefore, the question, “Should you brush your teeth every day?” had a truth-value of 1.0, and the question, “Is murder sometimes justifiable?” had a truth value of .6. In addition to recording the end response and reaction time, the trajectory of the mouse as it moved across the computer screen to click on the appropriate answer was also recorded. These mouse-movement trajectories provide a continuous motor response that has been used to illustrate competition between alternatives in a number of cognitive tasks (Dale, Kehoe, & Spivey, 2007; Farmer, Anderson, & Spivey, 2007; Spivey, Grosjean, & Knoblich, 2005). McKinstry and colleagues’ findings were consistent with those of Clark & Chase (1972) in that participants had more difficulty in evaluating a false statement than a corresponding true statement. Participants were also slower to respond negatively to a statement, and the “no” response trajectories showed more competition than the “yes” response trajectories. Similar effects also arise in research exploring the influence of negation on memory (Fiedler, Walther, Armbruster, Fay, & Naumann, 1996), supporting a general cognitive bias towards affirmative propositions.

Similarly, negated and affirmative sentences seem to be handled differently in language comprehension (e.g., Hasson & Glucksberg, 2006; Kaup, 2001; MacDonald & Just, 1989), and this may be due to differences in their corresponding

perceptual simulations. Recent experimental evidence suggests that understanding a single word embedded in a sentence is associated with the way people would actually perceive the noun they are asked to identify. Zwaan, Stanfield, and Yaxley (2002) asked participants to read sentences and to decide whether or not a subsequent picture was mentioned in the sentence they had just read. When a sentence such as, “The eagle was in the sky,” was presented, participants were quicker to respond that a picture of an eagle with outstretched wings had been mentioned in the preceding sentence than when they saw a picture of an eagle with folded wings. These results support claims that participants construct an image to represent the sentences they read; this in turn makes that image more accessible, leading to faster subsequent responses to that image. Such images, constructed through the partial activation of the neurons used to actually perceive or interact with the objects, are called *perceptual simulations* (see Barsalou, 1999; Barsalou, Simmons, Barbey, & Wilson, 2003, for a more complete overview). When the test picture matched the image that had been mentally created, reaction times were faster than if the test picture did not match the state of the object described in the text. These data provide evidence that comprehending language may be grounded in perceptual representations.

Perceptual simulations seem able to explain the comprehension of affirmative sentences (Zwaan, Stanfield, and Yaxley, 2002), yet recent experimental results suggest that negated sentences are processed differently. Kaup, Yaxley, Madden, Zwaan, and Lüdtke, (2006b) presented participants with sentences like, “The eagle was not in the sky,” and asked participants to judge whether a subsequently presented picture was mentioned in the sentence they had read. If participants perceptually simulate negation in the same way they simulate affirmative sentences, they should be quicker to respond “yes” to pictures that match the sentence (e.g., an eagle with its wings folded). The experimenters found that when participants read negated sentences, response times to a picture that matched the *affirmative* version of the proposition (eagle with wings spread) were faster than pictures that actually matched the negated sentence, suggesting that a perceptual simulation of the affirmative proposition was created in response to negated sentences. This suggested that negation is handled differently from other aspects of sentence processing, and specifically not through perceptual simulation.

Another possibility is that the experimental materials were not able to capture the perceptual simulation of the negation, similar to on-line research in verbal aspect. Madden and Zwaan (2003) examined potential differences produced by processing different verbal aspectual forms in narrative reading. In these experiments, participants were quicker to respond to pictures showing completed action after they had read a sentence containing a simple past verb than when they had read a sentence containing a past progressive verb, because simple past verbs emphasize the completion of a verb’s action. Conversely, no such latency differences were found when participants read sentences containing past

progressive verbs and then saw pictures of intermediate action. Like affirmative and negated sentences, these results suggest that perhaps one form of aspect is comprehended through perceptual simulations and that the other is comprehended via another mechanism.

However, the authors suggest that the past progressive’s lack of effect was due to readers representing the ongoing action at different stages of completion. Simple past verbs place emphasis on the end state of the action, which typically corresponds to only a single state, while past progressive verbs place emphasis on the ongoing nature of the verb. After reading narratives containing past progressive verbs, participants may simulate a number of locations. In other words, past progressive aspect produces a diffuse number of possible stages of intermediate action that are un-captured by the task. Therefore, even though past progressive verbs, like simple past verbs, may be comprehended via perceptual simulations, the static images used in the task simply do not match the particular point in the action they are simulating.

Similarly, it may be that when participants read a negated sentence, they do create a perceptual simulation of the negation, but the pictures they are asked to respond to do not capture the simulation. Whereas an affirmative sentence identifies a particular state or location for the noun that is responded to more quickly when presented visually, the negated sentences do not. For example, when “the eagle is in the air,” its wings are necessarily open to accommodate flying. However, when “the eagle is not in the air,” there are many states it could be in other than sitting with its wings folded. Thus, when hearing a negated sentence of this sort, participants may appear to simulate the eagle in the air not because perceptual simulations are incapable of negation but instead because the alternative simulations are too numerous and too diffuse. If this is the case, then constraining the possible simulations to only two for a given object, one corresponding to the affirmative proposition and one to the negated proposition, should further inform this research.

Here, we wanted to explore this in sentence comprehension by constraining the possible states and locations of the event. In general, we hypothesized that binary states would allow us to capture the simulation of negation in sentences. Similarly, we hypothesized that creating contexts to limit the possible locations to only two options would allow us to observe and further extend results on processing negated sentences.

Experiment 1: Binary States

Evidence from recent research in sentence comprehension suggests that creating targets that themselves refer to binary states is promising for investigating the role of perceptual simulation in negation processing. Kaup, Lüdtke, & Zwaan (2006a) investigated the way participants perceptually simulate sentences like those used in the earlier negation research (Kaup, et al., 2006b), but created materials that were binary, or had contradictory predicates. In Kaup, et al., (2006a), participants read binary sentences in the self-paced reading paradigm, and then after an SOA of either 750ms or

1500ms, they saw a picture of an object that they had to name as quickly as possible. At the 750ms SOA, responses to pictures that matched the non-negated state of affairs, even when the target sentence was negated, were significantly faster than pictures depicting the negated state of affairs. In other words, for the sentence “The door was not closed,” reaction times to a picture of a closed door (matching the proposition of the sentence) were significantly faster than to pictures of an open door. At the 1500ms SOA, when the target sentence was negated, responses to pictures matching the negated state of affairs were significantly faster than pictures depicting the proposition.

Here, we wanted to further expand these findings. In Experiment 1, we used the picture verification task used in the earlier negation (Kaup, et al., 2006b) and perceptual simulation (Zwaan, et al., 2002) research. We anticipated that this method might be more robust and allow for a full statistical interaction to emerge from the data. Additionally, we used an intermediate SOA of 1000ms, in order to provide data on processing at this intermediate point.

Method

Participants. A total of 32 Cornell University undergraduates participated in the experiment for extra course credit. All participants were right-handed, born in the United States, and native English speakers.

Materials. Sixteen target sentence frames were constructed. These frames were manipulated in order to produce two versions of each: a negated (The coin is not heads up) and an affirmative (The coin is heads up) version. The sentences were created such that they described a proposition that was true only in one way and untrue only in one way, thereby making the materials binary. Sixteen filler sentences, half of which were affirmative and half of which were negated, were also constructed. The target sentences contained binary state objects similar to the examples provided above, while the filler sentences did not contain binary objects.

Two pictures were created for each target frame: a picture matching the proposition of the sentence, and a picture matching the negation of that proposition. For example, for the sentence frame, “The coin is (not) heads up,” the picture corresponding to the proposition would be a heads up coin (see Figure 1a) and the picture corresponding to the negation of the proposition would be a tails up coin (see Figure 1b). The correct response for either the negated or affirmative sentence and either picture is “yes,” because the sentence is about a coin and the picture depicts a coin. Filler sentences also had corresponding pictures, although these pictures did not match anything in the sentence. All of the images were black and white ink drawings, created by a senior art major, with as much simplicity and as few lines as possible; this was done in order to make sure all pictures were as similar as possible. All the pictures were scanned into the computer in the same size to control for discrepancies between the objects.

Figure 1: Example Visual Stimuli for Experiment 1

1a) Picture Matches Proposition
1b) Picture Matches Negated Proposition

Procedure. Participants were seated at the computer and asked to make themselves comfortable. They read a page of instructions where they were informed that it was important for them to make decisions about the picture as quickly and accurately as possible. During the task, participants first read a sentence located in the center of the screen, pressing the spacebar when they had understood the sentence. A fixation cross appeared in the center of the screen for 1000ms and then a picture appeared. Participants indicated whether the pictured object had been mentioned in the previous sentence by pressing the f-key, covered with a “yes” sticker, or the j-key, covered with a “no” sticker. The correct response to all target trials was yes, and the correct response to all the filler trials was no. Half of the trials were followed by comprehension questions, in order to insure participants were paying attention. On these trials (half of the filler sentences, and half of the target sentences), a question regarding the sentence was presented next. Participants were asked to respond to the question as accurately as possible by clicking on the appropriate “yes” or “no” key. Participants were not given feedback on any of their responses. They were first given two practice trials before beginning the task (similar in construction to the filler items), and the task lasted approximately 10 minutes.

Results and Discussion

Incorrect trials (trials on which a participant responded “no,” and the pictured object was not in the sentence they had just read) were removed before analyzing reaction time. Data from two participants were excluded from the analysis because they incorrectly answered one block of trials. In addition, the incorrect responses to 18 items from 9 different participants were discarded prior to the analysis.

There was a significant interaction of Sentence and Picture, $F(1,29) = 4.308$, $p < .047$. See Figure 2 below. Affirmative sentences that were followed by propositional pictures (“The coin was heads up” before a picture of a heads up coin) were responded to more quickly, $M = 1245.12$, $SD = 84.98$, than affirmative sentences that were followed by negated-propositional pictures (“The coin was heads up” before a picture of a tails up coin), $M = 1467.02$, $SD = 113.05$. These results are consistent with earlier perceptual simulation research (Zwaan, et al. 2002). Additionally, negated sentences followed by negated propositional pictures (“The coin is not heads up” followed by a picture of a tails up coin) were responded to more quickly, $M = 1550.17$, $SD =$

99.81, than were negated sentences followed by propositional pictures (“The coin is not heads up” followed by a picture of a heads up coin), $M = 1828.79$, $SD = 255.49$. These results moderately extend the results obtained in Kaup et al. (2006a) by providing support that perceptual simulation does seem to operate for comprehending negated sentences whenever the experimental conditions are sufficiently constrained to capture it at an intermediate SOA.

Figure 2: Binary states reaction times per condition

In examining the main effects, the affirmative sentences, $M = 1467.02$, $SD = 619.18$, were responded to significantly faster, $t(29) = 2.08$, $p < .05$, than negated sentences, $M = 1245.12$, $SD = 465.47$. These results are consistent with earlier research, like that of Clark and Chase (1972) and McKinstry et al. (2008), suggesting that there is a bias in favor of affirmative sentences over negated sentences. Also, there was no main effect of picture type, implying that the type of picture did not impact comprehension.

Finally, in examining accuracy, there was a main effect of picture type within the affirmative sentences, $F(1,29) = 6.916$, $p < .014$. When the sentence was affirmative, participants were less accurate when responding to pictures that did not match. Accuracy did not differ for the two picture conditions in the negative sentence condition. This implies that the effects that have been described so far are not to the result of a speed accuracy trade off in the negated sentence condition.

Experiment 2: Binary Locations

Using the picture verification task of other perceptual simulation research (Kaup, et al., 2006b; Zwaan, et al., 2002), Experiment 1 converges with other negation research (Kaup, et al., 2006a): When the possible states of the items themselves are constrained to only two possibilities, perceptual simulations underlie the processing of these sentences at the intermediate 1000ms SOA. However, the materials that were used in Experiment 1 relied on binary *state* objects, leaving many questions regarding the processing of negation unanswered. Here, we sought to further extend these findings to investigate the role of context in the creation of binary *locations*. In Experiment 2, we again used the picture verification task was employed in the earlier

negation (Kaup, et al., 2006b) and perceptual simulation (Zwaan, et al., 2002) research as well as the intermediate 1000ms SOA. Rather than relying on binary states, context sentences describing two possible locations for an item were created.

Method

Participants. A total of 62 Cornell University undergraduates participated in the experiment for extra course credit. All participants were right-handed, born in the United States, and native English speakers.

Materials. Thirty-two target sentence frames were constructed. Each frame consisted of a context sentence, describing two possible locations for an item (i.e., The apple is either on the plate or on the cutting board), and a target sentence, identifying the location of the item. The context sentences were designed such that they limited the possible locations to only two; therefore, they could be true only in one way and untrue only in one way. The target sentences were manipulated in order to produce four versions of each: an affirmative version identifying the first location mentioned in the context sentence (The apple is on the plate); an affirmative version identifying the second location mentioned in the context sentence (The apple is on the cutting board); a negated version identifying the first location mentioned in the context sentence (The apple is not on the plate); and a negated version identifying the second location mentioned in the context sentence (The apple is not on the cutting board). Thirty-two filler sentences, one quarter of which corresponded to each of the four conditions described above, were also created.

Two pictures were created for each target frame: a picture matching the proposition of the sentence, and a picture matching the negation of that proposition. For example, for the target sentence frame, “The apple is (not) on the cutting board,” the picture corresponding to the proposition would show an apple on a cutting board (see Figure 3a) and the picture corresponding to the negation of the proposition would show an apple on a plate (see Figure 3b). Pictures were also constructed for the filler items, although these pictures did not match anything in the sentence. All of the images were taken from clip art. The target item (i.e., the apple) was spliced into the different locations to maintain similarity in the pictures.

Eight lists were constructed such that each participant would respond to all of the conditions but only one version of each sentence frame and picture. Conditions were created as follows: 1) affirmative target, identifying first location of context, picture matching proposition; 2) affirmative target, identifying first location, picture matching negated

Figure 3: Example Visual Stimuli for Experiment 2

3a) Picture matches proposition for “The apple is (not) on the cutting board.”

3b) Picture matches negated proposition for “The apple is (not) on the cutting board.”

Pictures match final prepositional phrase of target regardless of the target’s negation status.

proposition; 3) affirmative target, identifying the second location, picture matching proposition; 4) affirmative target, identifying the second location, picture matching negated proposition; 5) negated target, identifying the first location, picture matching proposition; 6) negated target, identifying first location, picture matching negated proposition; 7) negated target, identifying second location, picture matching proposition; and 8) negated target, identifying second location, picture matching negated proposition.

Procedure. The procedure of Experiment 2 was the same as that of Experiment 1, except it did not include comprehension questions and lasted 20 minutes.

Results and Discussion

Incorrect target trials (or trials on which a participant responded “no,” the pictured object was not in the sentence they had just read) were removed before analyzing reaction time. Two hundred fifty-four trials, 12% of the data, were excluded from the reaction time analysis, resulting in the loss of fourteen participants. Each participant had at least one trial excluded from the reaction time analysis due to these criteria.

There was no significant three-way interaction of Sentence, Picture, and Context, $p > .28$. Also, the main effect of context was not significant, $p > .7$. Therefore, the order of the items in the context sentence did not significantly impact the results. However, there was a significant interaction of Sentence and Picture, $F(1,47) = 6.343$, $p < .015$. See Figure 4. Affirmative sentences (“The apple is either on the plate or on the cutting board. The apple is on the plate”) followed by propositional pictures (a picture of the apple on the plate as in Figure 3b) were responded to faster, $M = 1155.497$, $SD = 413.419$, than affirmative sentences followed by negated propositional pictures (a picture of the apple on the cutting board as in Figure 3a), $M = 1365.495$, $SD = 701.461$. Similarly, negated sentences (“The apple is either on the plate or on the cutting board. The apple is not on the plate”) followed by propositional pictures (a picture of the apple on the plate as in Figure 3b) were responded to slower, $M = 1335.8032$, $SD = 690.602$, than negated sentences followed

by negated propositional pictures (a picture of the apple on the cutting board as in Figure 3a), $M = 1258.295$, $SD = 539.869$. These data further extend the results of Kaup et al. (2006a), providing support that perceptual simulations operate in comprehending negated sentences when contextual descriptions constrain possible locations to only two.

Figure 4: Reaction time for Sentence by Picture interaction

In examining the main effects, responses to negated sentences were not significantly slower than responses to affirmative sentences, $p > .8$. Also, there was a main effect of picture type, $F(1,61) = 7.67$, $p < .01$, such that pictures of the proposition were responded to faster, $M = 1221.829$, $SD = 563.79$, than pictures of the negated proposition, $M = 1300.929$, $SD = 622.402$. These results, combined with the percentage of incorrect responses, suggest that the complexity of the task may have caused problems or that some subjects employed strategies. For instance, it may have been possible to read the context sentence and respond to the pictures based on this information alone. Future work will further refine these preliminary data by using auditory files, rather than written text, in such a picture verification task. Such auditory presentation of the stimuli is less strategy prone than text presentation.

Finally, in examining accuracy, there was an interaction of negation and picture, $F(1,61) = 17.8$, $p < .001$. Participants responded more accurately when the target sentence matched the picture. Hence, participants responded more accurately to negated sentences when the picture matched the negated proposition than when the picture matched the proposition. Similarly, participants responded more accurately to affirmative sentences when the picture matched the proposition than when the picture matched the negated proposition. None of the other main effects were significant, p 's $> .2$. This implies the effects described so far are not due to a speed accuracy trade off in the either sentence condition.

General Discussion

The materials of Experiment 1 were designed to reflect *binary state* propositions, such that affirmative and negated forms each referred to only one possibility. The interaction of picture and sentence types at the intermediate SOA of 1000 ms supports the hypothesis that appropriate perceptual simulations (of the negated proposition) may be used for

comprehending negated sentences. Further, Experiment 2 demonstrated that extrasentential context can constrain the possible perceptual simulations to reflect *binary locations*. Again, the interaction of picture and sentence types supports the hypothesis that perceptual simulations may be used in comprehending both affirmative and negated sentences. While the experiments here used the intermediate SOA of 1000 ms, future planned research, specifically in eye-tracking, will further investigate the time course of processing negated sentences.

The results reported here are promising, but future research is needed to further explore the mechanisms of negation. The exact mechanism underlying perceptual simulations in negation has not been thoroughly explored, and its explication is likely to require computational modeling. To this end, we have begun some preliminary explorations with a simple recurrent network (Elman, 1990). In addition to the word-prediction relation between 91 input word-nodes to 91 output word-nodes, this model includes 63 perceptual features on the output layer that are prominent properties of the relevant perceptual simulations (see also, Howell, Jankowicz, & Becker, 2005). Thus, combined with its learning to predict the next word in a sentence, this network also learns to activate the appropriate set of features for the perceptual simulation associated with the sentence (Anderson, Huette, Matlock, & Spivey, in press). In this network model, the only difference between an affirmative sentence and a negated sentence is that the input from the negated sentence has the word “not” immediately preceding its critical adjective (e.g., flying, not flying, heads-up, not heads-up). Thus, without a specialized logical operation of negation, this network can nonetheless reverse its perceptual simulation as a result of the presence or absence of the word “not” in the sentence. Current extensions of this model are exploring ways to include some temporal dynamics that may simulate the experimental results with different SOAs.

Abstract

What role does *grammatical aspect* play in the time course of understanding motion events? Although processing differences between past progressive (*was walking*) and simple past (*walked*) aspect suggest differences in prominence of certain semantic properties, details about the temporal dynamics of aspect processing have been largely ignored. The current work uses mouse-tracking (Spivey, Grosjean, & Knoblich, 2005) to explore motor output in response to contextual descriptions and aspectual forms. Participants heard descriptions of terrain (difficult or easy) and motion events described with either the past progressive or simple past while placing a character into a scene to match this description. Overall, terrain descriptions modulated responses to past progressive more than to simple past in the region of the screen corresponding to the path. These results, which suggest that perceptual simulation plays a role in the interpretation of grammatical form, provide new insights into the understanding of event descriptions.

Keywords: Language Processing; Event Understanding; Mouse-Tracking; Embodied Cognition; Motion Verbs

The emerging consensus is that language influences thought (see Boroditsky, 2000; Lucy, 1992; Matlock, Ramscar, & Boroditsky, 2005), but the extent to which this generalizes is uncertain. *How* does language influence the way people think about everyday events? Can grammar influence the way events are conceptualized, and if so, how? Does hearing just “-ed” versus “-ing” on a motion verb influence listeners’ cognitive processing and motor response, and if so, how? The goal here is to explore the influence of grammatical aspect on the conceptualization of motion events. The main question is how grammar and contextual descriptions differentially influence motor output as people understand language.

Many language theorists have observed that grammatical aspect provides temporal information about the internal structure of a verb, specifically providing information about the completion, duration, or repetition of the action (Comrie, 1976; Frawley, 1992). This temporal information, though subtle, can exert a substantial influence on the way a sentence is understood. Take, for example, the following sentences: “David ran to the university,” and “David was running to the university.” Both convey information about an event that occurred in the past, although they use different aspectual forms. The first sentence uses the simple past form of the verb “ran,” emphasizing the completion of the action. In contrast, the second uses the past progressive form, emphasizing the ongoing nature of the action. Despite agreement that aspect provides such temporal “coloring” of a verb’s information, potential processing differences between

these aspectual forms have received little attention in psycholinguistic research.

More recently, however, aspect was explored in a series of offline studies that examined spatial outcome differences in response to simple past and past progressive verbs (Matlock, Fausey, Cargill, & Spivey, 2007). Participants read a sentence like “This morning David walked to the university” (simple past) or “This morning David was walking to the university” (past progressive), and looked at a schematic drawing that showed a path leading to the destination described in the sentence and ten unevenly spaced identical silhouette characters on the path (e.g., pedestrian with leg extended forward and arms bent as if in motion). Participants were instructed to “circle the man that the sentence is most naturally referring to.” In brief, participants were more likely to circle a character in the middle region of the path with sentences containing past progressive verbs (*was walking*), and more likely to circle a character in the latter region of the path in response to sentences containing a simple past verb (*walked*). A similar pattern emerged in a subsequent experiment in which participants were asked to indicate where along the path an object had been dropped after reading simple past or past progressive sentences. These and other results suggest that when participants read simple past sentences, they focus on the end of the path, or the location of the completed action in the scene. In contrast, when participants read past progressive sentences, they focus on the middle section of the path, where the ongoing action would be taking place. These data suggest that different aspectual forms have consequences for thinking about motion events, but questions about the time course of processing remain.

On-line processing differences were initially addressed in a series of experiments by Madden and Zwaan (2003), in which the authors demonstrated different aspectual forms produce reaction time differences in narrative reading. Their participants were quicker to respond to pictures showing a completed action after they had read a sentence containing a simple past verb (e.g., The car sped through the intersection) versus a sentence containing a past progressive verb (e.g., The car was speeding through the intersection). However, no such latency differences were found when participants read sentences containing past progressive verbs and saw pictures of intermediate action. The authors suggest that the effect was missing in the past progressive condition because readers represented the ongoing action at different stages of completion. In other words, past progressive verbs could potentially correspond to any of a number of intermediate actions, and this could be un-captured by picture verification

and reaction time tasks. Therefore, their results suggest that different aspectual forms lead to processing differences in real time. (For other work on aspect and spatial representation, see Ferretti, Kutas, & McRae, 2007; Magliano & Schleich, 2000; Morrow, 1985).

Such reaction time data have revealed valuable insights into the processing of aspect. However, as suggested by the work of Madden and Zwaan (2003), they are somewhat limited when investigating diffuse representations. In addition to such offline and reaction time experiments, there is a great deal of information about real-time cognitive processing in the dynamics of the response. For example, evidence suggests that factors influencing latency to respond also influence later aspects of response dynamics meaning that the temporal dynamics of the motor movement that executes a response contain volumes of virtually untapped data. As a simple example, Abrams and Balota (1991) asked participants to perform a lexical decision task by making rapid limb movements in opposite directions to indicate whether a string of letters was a word or not. As expected, they found that the frequency of the word influenced reaction time, with high frequency words eliciting faster responses than low frequency words. Also, they found that word frequency influenced response kinematics after the response was initiated. Responses to high frequency words were executed with greater force than responses to low frequency words (Abrams & Balota, 1991). These findings suggest that word frequency not only influences the time required to recognize a word, but also influences response dynamics, implying that the response system is not slavishly executing a completed command regarding the categorical status of the word. This makes a compelling case for looking not only at reaction time differences, but also at variables of the motor movements themselves initiated in response to a stimulus.

To better understand the potential differences in the on-line processing of different aspectual forms, we have employed the methodology of *computer-mouse tracking*. Monitoring the streaming x- and y-coordinates of goal-directed mouse movements in response to spoken language is a useful indicator of underlying cognitive processes. In contrast to ballistic saccades, arm movements allow for a continuous, smooth motor output within a single trial to complement eye-tracking research. Spivey, Grosjean, and Knoblich (2005) demonstrated that these mouse movements can be used to index the continuous activation of lexical alternatives. By recording the x,y coordinates of the mouse as it moved with the goal-directed hand motion to click on the appropriate object, competition between the partially activate lexical representations was revealed in the shape and curvature of the hand-movement trajectories.

Further, some of our own data indicates that mouse-tracking is useful and informative for exploring research questions on the on-line processing of grammatical aspect (Anderson, Fausey, Matlock, & Spivey, 2008). In one experiment, participants listened to sentences like, "Tom jogged to the woods and then stretched when he got there," or "Tom was jogging to the woods and then stretched when he got there." While participants heard these sentences, they

saw scenes consisting of a path curving upwards from left to right, and terminating at the destination described in the sentence. A character was located to the right of the beginning of the path and under the destination, separated from the scene by a black box framing the destination and path. Similar to our earlier offline results, participants dropped the character closer to the center of the path with past progressive verbs and closer to the destination with simple past verbs. Further, the two aspectual forms elicited significantly different movement durations: Participants moved the character into the scene for a longer duration of time with past progressive verbs than when they heard sentences containing simple past verbs. These drop location and movement duration results converge with and further inform earlier research, supporting that past progressive aspect focuses attention on the on-going nature of the action while simple past aspect focuses attention on the end state of that action, even during real time processing.

In the current experiment, we sought to extend these findings by investigating the way verbal aspect may interact with terrain descriptions. Research has shown that context descriptions interact with fictive motion verbs to produce both differences in patterns of eye movements and in reaction times (Matlock, 2004; Richardson & Matlock, 2007). However, the impact of such descriptions on grammatical aspect has not been explored. Here we use mouse-tracking methodology to investigate how different aspectual forms interact with similar context descriptions. Participants heard two sentences. The first provided a contextual description of the path and the second manipulated grammatical aspect. For example, on target trials participants heard a context sentence describing the path as either difficult (i.e., "The road to the university was rocky and bumpy") or easy ("i.e., "The road to the university was level and clear"), before a target sentence containing either a simple past verb (i.e., "David walked to the university where he sat in class") or a past progressive verb (i.e., "David was walking to the university where he sat in class"). While hearing these sentences, participants saw scenes containing a diagonal path that originated halfway up the screen and extended from the extreme left to the top and center of the screen (corresponding to the destination in the sentence). The orientation of the path was changed to this short, diagonal path from the long, curvy path of earlier research (Matlock, et al., 2007; Anderson, et al., 2008) to allow for more thorough and precise investigations of potential spatial and movement duration differences. A character was located to the right of the beginning of the path and under the destination. It was separated from the scene by a black box framing the destination and path.

We explored several hypotheses. If past progressive verbs sentences elicit more attention to the path, then the effect of context description was expected to be greater with past progressive verbs than when they contained simple past verbs. Specifically, we predicted that context would modulate movement durations and spatial attraction to the path more in the past progressive sentences than in the simple past verb sentences. Further, we wanted to explore the influence of the visual scene's path on movement durations.

The visual scene---with a path starting halfway up the screen---would enable us to examine if the trajectories produced in response to each aspectual form would reliably differ for the entire trajectory of the hand or only in the region of the screen corresponding to the path. If differences emerged across the entire trajectory, then the effect of grammatical aspect would appear to be more global, and to exert influence across the entire event description. However, if differences emerged only in the region of the screen corresponding to the path, then the effect of grammatical aspect would appear to be specific to the parts of the event it describes.

Method

Participants. A total of 64 undergraduates at Cornell University participated in the experiment for extra credit in psychology courses. All participants were right handed and native speakers of American English.

Materials. Twelve sentences were created from adapting the stimuli used in the offline studies of Matlock et al. (2007). As we hoped to elicit movements across the extent of the scene, from which we could extract differences in motor dynamics between the two conditions, a final clause that described an event at the destination was added, encouraging movement all the way to the destination. Similarly, two contexts for each stimulus were created. Hence, four versions of each of the 12 experimental items were created, as shown in (1) below: (1a) rough context description, simple past verb, (1b) rough context description, past progressive verb, (1c) smooth path description, simple past verb, (1d), smooth path description, past progressive verb.

- 1a) *The road to the university was rocky and bumpy.* / David walked to the university where he sat in class.
- 1b) *The road to the university was rocky and bumpy.* / David was walking to the university where he sat in class.
- 1c) *The road to the university was level and clear.* / David walked to the university where he sat in class.
- 1d) *The road to the university was level and clear.* / David was walking to the university where he sat in class.

Sentences were recorded using a Mac-based speech synthesizer program. Each of the 12 experimental items was spliced in order to produce both a past progressive and a simple past version, ensuring that the prosody of both of the targets were otherwise identical. Similarly, the context description was spliced onto the beginning of each of these target sentences. A pause of one second separated the offset of each context sentence from the onset of the target sentence. The experimental items were counterbalanced across four presentation lists. Each list contained three instances of each condition, so that all participants heard all twelve target sentences, but only heard one version of each.

Corresponding visual scenes were created for each target sentence pair. Each target visual scene consisted of a diagonal path starting halfway up and on the extreme left side of the screen. The path slanted to the right, terminating in the middle at the top of the screen. A character was located to the

right of the beginning of the path and under the destination, separated from the scene by a black box framing the destination and path. See Figure 1. The depicted items in the scene were taken from clipart and edited in Adobe Photoshop. The only moveable item in the scene was the character, which subtended an average of 1.53 degrees of visual angle in width by 2.05 degrees in height. The destinations were an average of 11.22 degrees of visual angle in width by 4.09 degrees in height, and the path itself occupied a square of 8.42 degrees of visual angle in width by 6.11 degrees of visual angle in height. The character was located 14.25 degrees of visual angle from the destination. The stimuli were presented using Macromedia Director MX, and mouse movements were recorded at an average sampling rate of 40 Hz. The display resolution was set to 1024 x 768.

Figure 1: Example target visual scene accompanied by target sentences (1a, 1b, 1c, or 1d).

Additionally, to keep participants from developing strategies specific to the experimental sentences, 12 filler items were created. The fillers were of the same form as the target sentences: each contained a context description and either a past progressive or simple past verb. These filler trials varied from the target trials such that the context description provided no information about the path (i.e., “The weather in the valley was warm and humid”) and such that they described no movement along the path (i.e., “Janet swam in the pool and then dried in the sun,”). These filler items were accompanied by 12 filler scenes, created using a short path beginning on the right side of the screen and slanting to the top, center of the screen. Besides the direction of the path, each filler scene was quite similar to the target scenes, for instance, character outside of a scene that contained the path and destination mentioned in the filler sentence.

Procedure. Participants were asked to make themselves comfortable in front of the computer, and allowed to adjust the mouse and mouse-pad to a location that suited them. First, participants read instructions to place the character in the scene to make the scene match the sentences they heard. Upon signaling to the experimenter that they understood the task, they were next presented with two practice trials (similar in form to the filler trials), followed by the experimental task. At the onset of each trial, participants were presented with the entire visual scene. After a 500 ms preview, the sound file began. After the participant had

moved the character (though not to any particular location), a “Done” button appeared in the bottom left corner of the screen. Participants clicked this button to move to the next trial. A blank screen with a button in the center labeled “Click here to go on” separated trials from each other. The entire experiment lasted approximately 20 minutes.

Results

Mouse movements were recorded during the grab-click, transferal, and drop-click of the character in the experimental trials. Prior to the analyses, the data were screened to remove extremely long trials. Movement durations 20 seconds or more were removed because they constituted an unusually long time for a mouse-movement. Using this criteria, only three trials (less than 0.4%) of trajectories, were excluded.

Drop Locations. Previous offline results revealed that participants chose a location closer to the middle of the path as the best representative of a sentence containing a past progressive verb, while selecting a location closer to the destination as the best representative of a sentence containing a simple past verb (Anderson, et al., 2008, Matlock, et al., 2007). By plotting the drop point (location along the path where each participant let go of the mouse to “drop” the character) in each of the four conditions, the current results demonstrate a similar trend. See Figure 2. There was not a significant interaction of terrain description and verb aspect (p 's > .5). However, there was a main effect of verb aspect when comparing the average drop x-coordinate, $F(1,62) = 8.462$, $p < 0.05$, with the average drop x-coordinate being further left (closer to the path) when participants heard past progressive verbs ($M = 476.71$, $SD = 68.81$) than when they heard simple past verbs ($M = 494.82$, $SD = 61.74$). Similarly, there was a main effect of aspect when comparing the average drop y-coordinate, $F(1,62) = 6.048$, $p < 0.05$, with the average drop y-coordinate being lower (further from the destination) when participants heard past progressive verbs ($M = 219.04$, $SD = 37.02$) than when they heard simple past verbs ($M = 210.65$, $SD = 41.01$). This tendency to drop a character closer to the path in the past progressive condition, and close to the destination in the simple past condition, replicates previous evidence that the ongoing nature implied by a past progressive verb draws attention to the middle portion of the path, whereas there is a tendency to focus attention on the destination in response to simple past verbs.

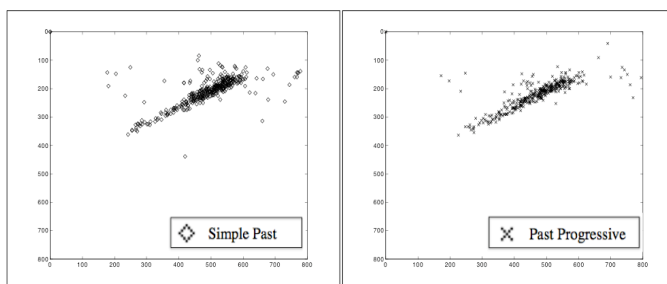

Figure 2: Drop locations in response to simple past verbs (left panel) and past progressive verbs (right panel).

Movement Durations. We began our investigation of online processing by looking at the temporal dynamics of the movement of the character. There was no significant interaction of context and aspect when comparing overall movement durations (i.e., the length of time from the initial grab of the character to the final drop of the character into the scene), p 's > .2. There was a significant interaction of context and aspect on movement durations specifically *within in the region of the screen corresponding to the depicted path*, $F(1, 63) = 4.6$, $p < .05$. See Figure 3. In the region of the path, the average movement duration for simple past verbs was not substantially different when the context was first described as rough ($M = 2448.33$, $SD = 1848.88$) or smooth ($M = 2478.72$, $SD = 1527.17$). On the other hand, the average movement duration in the region of the path for the past progressive verbs was slower when the context was first described as rough ($M = 2667.70$, $SD = 1679.86$) than when it was described as smooth ($M = 2121.88$, $SD = 1240.13$). Because simple past verbs focus attention on completed action, context descriptions do not significantly impact the movement dynamics. On the other hand, because past progressive verbs encourage attention to the ongoing-ness of the action, context descriptions of the location of that ongoing action do influence processing. These data extend previous research significantly, suggesting that aspect influences the real-time movement dynamics of the event being matched and that these dynamics are sensitive to visual information. Also, as predicted, the context descriptions modulate this on-line measure when aspect focuses attention to the ongoing action of the verb.

Figure 3: Movement duration differences in the region of the visual scene corresponding to the path.

Raw Time Analyses: To begin looking at the differences in spatial attraction to the visual scene's path across conditions, we first looked at average x- and y-coordinates within eight 500ms time-bins of the movement duration. There was no significant interaction between aspect and terrain, p 's > .1, or main effect of either variable, p 's > .2. However, breaking the movement into time bins serves only as an approximation of actual attraction over raw time. These 500ms time-bins were not time locked to the sound files, and hence did not have a

fixed starting time. Because the offset of verb occurred late within the sound files and because many participants did not begin to move the character until after the end of the sound file (with an average 1400 ms lag between offset of verb and end of sentence), these data are not synchronized to a fixed point. Future work will address potential raw time spatial differences more fully.

Spatial Attraction. Figure 4 shows the average time-normalized trajectories in each of the four conditions. The mean simple past and past progressive trajectories at each of the 101 time-steps in the top panel of Figure 4 illustrate that in the rough terrain context, the average past progressive trajectory curved more toward the path than the average trajectory elicited by the simple past sentences, but only near the end of the trajectory. However, in the smooth terrain description, (Figure 2, bottom), there appears to be greater attraction toward the path across a greater portion of the trajectory for the past progressive verbs.

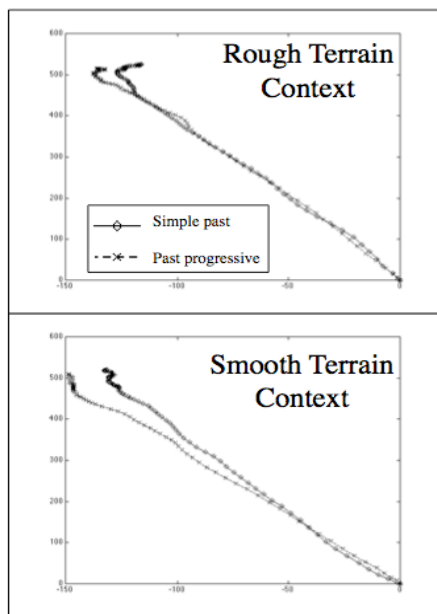

Figure 4: Average time-normalized simple past and past progressive trajectories in rough and smooth terrain contexts.

To determine whether the divergences observed across the simple past and past progressive sentence trajectories in the rough and smooth terrain descriptions were statistically reliable, we conducted a series of t-tests. These analyses were conducted separately on the x- and the y-coordinates at each of the 101 time-steps. In order to avoid the increased probability of a Type-1 error associated with multiple t-tests, and in keeping with Bootstrap simulations of such multiple t-tests on mouse trajectories (Dale, Kehoe, & Spivey, 2007), an observed divergence was not considered significant unless the coordinates between the simple past- and past progressive-sentence trajectories elicited p-values $< .05$ for at least eight consecutive time-steps.

In the rough context description condition, there was significant divergence of the past progressive x-coordinates

away from the simple past x-coordinates and toward the path between time-steps 89 and 101, p 's $< .05$, and no significant divergence in the y-coordinates. This difference is commensurate with the observed differences in drop locations for past progressive and simple past verbs described earlier. Even though there was no significant interaction between aspect and context description on drop location, this significant divergence so late in the time-normalized trajectories may simply be an artifact of drop locations.

On the other hand, in the smooth context description, there were significant divergences of the past progressive x-coordinates away from the simple past x-coordinates towards the path between time steps 48 and 60, p 's $< .05$, and again between time steps 65 and 89, p 's $< .05$. There was also significant divergence of the average past progressive y-coordinates away from the average simple past y-coordinates and towards the path between time steps 89 and 101. Again, this divergence late in the trajectory may be an artifact of the drop locations in each condition.

While these results are encouraging, they are not as convincing as the path-movement duration results (Figure 3). It is curious that the spatial attraction differences were detected in the smooth context description but not as robustly in the rough context description. Perhaps the visual stimuli used to depict the path simply did not appear to afford difficult or uneven travel, and the incongruence in the linguistic description and the visual appearance of the path hindered the emergence of full spatial differences in this context description. Future work is slated to investigate this possibility.

General Discussion

The results reported here are consistent with previous research using mouse-tracking (Anderson, et al., 2008), narrative reading (Madden & Zwaan, 2003), and offline judgment tasks (Matlock, et al., 2007). They also provide new evidence that different grammatical forms influence the processing of event descriptions, with the simple past (e.g., *walked*) focusing attention on the end of the path and the location of the completed action, and past progressive (e.g., *was walking*) focusing attention to the “middle” of the event and the spatial region of that ongoing action. In addition to corroborating previous work on grammatical aspect, these data also reveal new insights about processing through the examination of continuous motor output in response to aspectual and contextual differences.

First, drop locations reliably differed between aspectual forms, with the past progressive condition eliciting drop locations closer to the path, and the simple past condition eliciting drop locations closer to the destination. These data are in line with earlier research, and were not significantly altered by terrain description. Contextual descriptions did interact significantly with verbal aspect in movement durations, specifically within the region of the screen depicting the path. Contextual descriptions did not significantly modulate simple past movement durations, because of the simple past's emphasis on the completed

action. However past progressive movement durations were significantly faster when preceded by an easy terrain description than when preceded by a rough terrain description. Because these differences emerge only in the region of the path in the visual scene, but not in the overall trajectory, these data suggest that grammatical aspect exerts processing influences specific to the parts of the event it describes.

Similarly, while the coarse measure of raw-time spatial attraction to the path did not reveal statistically significant results, there was a significant spatial divergence of the past progressive trajectory away from the simple past trajectory and toward the destination in both contextual descriptions. Divergences late in the trajectory may be a result of differences in drop location, but divergences across the trajectories after the smooth context description provide further evidence for processing differences between these two aspectual forms. More specifically, our results may suggest that differences in underlying perceptual simulations, resulting in these differences in the dynamics of the motor response, may account for observed processing differences.

The current research has notable implications for several areas of research. Although grammatical aspect has been considered to provide minimal semantic information by providing subtle temporal nuance, our results indicate that aspect can significantly influence on-line processing. This work also investigates grammatical aspect using a novel approach, allowing for the examination of more fine-grained temporal information, which complements the existing reaction time data. In addition, our results provide evidence to support cognitive linguists' claims regarding meaning as a conceptualization of linguistic descriptions, and the idea that aspect, like many domains of language, involves dynamic conceptualization (Langacker, 1987; Talmy, 2000).

More broadly, this work resonates with embodied cognition work on perceptual simulation and language understanding (Barsalou, 1999). It also dovetails with the methodological advances of Balota and Abrams (1995) by providing new evidence from the temporal dynamics of a response after the response has been initiated, and demonstrating that the motor system is not a robot-like automaton triggered by completed cognitive processes. Rather, motor processes are co-extensive with cognitive processes during perceptual/cognitive tasks (e.g., Balota & Abrams, 1995; Gold & Shadlen, 2000; Spivey et al., 2005; This work also comports with our understanding of how mental models and visual information are coordinated in motor output. Similarly to the way understanding of spatial events is created and observed through tracking eye movements (Richardson & Matlock, 2007; Spivey & Geng, 2001), this work demonstrates that event understanding takes place differently as a function of changes in context descriptions and grammatical aspect. Finally, the work explores a new way that language may influence thought.

Abstract

We present two visual world studies indicating that local syntactic coherences interact with binding constraints (Chomsky, 1981) of both reflexives and pronouns. Gazes to depicted referents or events suggest that when sentences containing a local coherence with a pronoun or reflexive are presented, locally coherent antecedents become activated. Our results strengthen the assumption that local syntactic coherences are interpreted and extend the effect to online anaphora resolution and complementary binding constraints.

Keywords: anaphora, anaphora resolution, local syntactic coherences

Introduction

To arrive at a coherent interpretation of a sentence, we need to bind referring expressions to their correct referent. Binding theory (Chomsky, 1981) provides a syntax-driven structural account for the dependencies of co-reference within sentences. Principles based on c-command are assumed to constrain the possible co-referents of anaphoric expressions on a global level. Reflexives and pronouns have complementary structural binding domains, i.e. within sentence boundaries, the accessible antecedents for both anaphora types are mutually exclusive. In sentences like (1-a) and (1-b) determining the referent of the anaphoric expression *himself* or *him* is straightforward.¹

- (1) a. Ken_i who likes John_j saw himself_{i/*j} in the mirror.
b. Ken_j who likes John_i saw him_{i/*j} in the mirror.

Recent findings question strictly structure-driven accounts of anaphora resolution. Runner, Sussman, and Tanenhaus (2006), for instance, report violations of the binding domain complementarity assumption. They examined preferences for pronoun and reflexive binding in picture noun phrases in a series of *visual-world* studies. Fixation probabilities on depicted referents revealed violations of the binding theory assumption. They concluded that reflexives should rather be explained in terms of logophors, deposing reflexives beyond the scope of Binding theory explanations.

Converging evidence was found by Kaiser, Runner, Sussman, and Tanenhaus (2009), suggesting that the interpretation of reflexives is not only sensitive to structural but also semantic information. Moreover, they found differing degrees of

sensitivity towards different sources of information for pronouns and reflexives.

Sturt (2003) on the other hand showed that the constraining principle for reflexives operates at the very earliest stages of processing. In eye-tracking-while-reading experiments, he found early effects of binding preferences. He concludes that the responsible binding principle is an early filter for the processing of referring expressions.

Interpretation of locally syntactic coherences

Local syntactic coherences (LSCs) have been shown to interfere with the global sentence interpretation. Tabor, Galantucci, and Richardson (2004) found increased reading times on the spill-over of *tossed* in sentences like *The coach chided the player tossed a frisbee by the opposing team*. Moreover, Konieczny, Müller, Baumann, Hachmann, and Wolfer (2009) have shown that LSCs temporarily affect the interpretation of globally unambiguous sentences.

Interestingly, there are locally coherent substrings in (1), leading to the opposite binding of the reflexive or the pronoun: In Sentence (1-a), *himself* is restricted to be bound to *John* if only the local subparse *John saw himself* is taken into account. In the global parse however, *himself* is bound to *Ken*. In Sentence (1-b), *him* is bound to *Ken* or any other (unmentioned) referent if the LSC *John saw him* is interpreted.

It is still an open question though, whether or not LSCs can affect anaphora resolution, and if pronouns and reflexives are affected equally.

In the remainder of the paper, two experiments will be reported providing insight into the time-course of binding and its interaction with local syntactic coherences. We chose the *visual-world* paradigm (Cooper, 1974; Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995) over reading times, as fixations on visual objects can indicate binding preferences in a much more direct way, without inferencing over processing difficulty. The results suggest that LSCs indeed have an effect on the binding of reflexives and pronouns in a way that strong constraints like *Principle A* are also applied to the local parse, temporarily overriding the globally correct binding.

Experiment 1: Depicted referents in the visual world

In the first experiment, the visual stimuli showed the depictions of three persons, two of which were depictions of the referents introduced in the spoken sentence. When the

¹Subscripted indices mark coreference. A star * indicates that coreference with the indexed referent is not acceptable considering the global parse but suggested considering the local parse.

antecedents get reactivated when a pronoun or reflexive is processed, we should see increased gaze proportions on the corresponding referent. Following this logic, the gaze pattern should indicate how local syntactic coherences affect anaphora resolution.

Materials and design

We tracked participant's gaze on depictions of three referents (cf. Figure 1) while they listened to sentences like (2). Materials were constructed according to a 2x2-design crossing the factors anaphor type (reflexive vs. pronoun) and presence of LSC (present vs. prevented), leading to four experimental conditions: reflexive with LSC (Sentence (2-a)), reflexive without LSC (Sentence (2-b)), pronoun with LSC (Sentence (2-c)), and pronoun without LSC (Sentence (2-d)). We prevented the LSC by inserting an adverb before the verb of the relative clause. Each participant was presented with 48 experimental sentences and an equal amount of sentence-picture pairs of comparable complexity. The task was to look at the pictures while listening to the sentences. Immediately after the sentence, participants had to click on the agent they considered to be most important in the scene. 25 participants took part in Experiment 1.

Auditory stimuli

We recorded 48 sentences with normal speech tempo. Locally coherent sequences were recorded separately – as main clauses (*Der Sohn kämmte sich im Wohnzimmer ...*) – and spliced into surrounding sentences (without the starting determiner of the LSC to prevent sentence-initial prosody). By doing so, we wanted to minimize prosodic cues induced by the relative clause boundary and thereby destroying the local coherence. To minimize prosodic differences between conditions, control conditions were produced by splicing the adverbs (*gründlich/thoroughly*) into the first two conditions. This method was necessary since earlier findings indicated strong sensitivity to prosodic cues (Konieczny et al., 2009). These effects are outside the scope of this study. The resulting experimental stimuli still sounded natural, as was established in a pre-test with native speakers who were naïve with respect to the research questions at hand.

(2) a. Reflexive, LSC

Während der Vater_i, den der Sohn_j kämmte,
While the father_i, who the son_j combed,
sich_{i/*j} im Wohnzimmer anzog, ...
himself_{i/*j} in the living room dressed, ...
While the father who the son combed dressed himself in the living room, ...

b. Reflexive, no LSC

Während der Vater_i, den der Sohn gründlich
While the father_i, who the son combed,
kämmte, sich_i im Wohnzimmer anzog, ...
thoroughly himself_i in the living room dressed, ...
While the father who the son combed thoroughly dressed himself in the living room, ...

c. Pronoun, LSC

Während der Vater_i, den der Sohn_j kämmte,
While the father_i, who the son_j combed,
ihn_{j/*i} im Wohnzimmer anzog, ...
him_{i/*j} in the living room dressed, ...
While the father who the son combed dressed him in the living room, ...

d. Pronoun, no LSC

Während der Vater, den der Sohn_j gründlich
While the father, who the son_j thoroughly
kämmt, ihn_j im Wohnzimmer anzieht, ...
combs, him_j in the living room dresses, ...
While the father who the son combed thoroughly dresses him in the living room, ...

Visual stimuli The visual stimuli of Experiment 1 consisted of three referents. The globally suggested agent, the agent contained in the LSC and a third, non-mentioned referent (see Figure 1). The positions of the referents was cross-balanced over all trials and participants.

Figure 1: A picture of three referents from Experiment 1. The father (top), the son (right), and a clown (left).

Hypotheses

We expect the LSC to have an influence on fixation probabilities when the anaphor is heard or shortly after. If the LSC has an effect, we expect fixation probabilities on the referent denoted by the LSC to be increased, compared to sentences where no LSC is present. Therefore, when sentences like (2-a) are heard, fixation probabilities on the *son* should increase compared to sentences like (2-b) because the son is the only possible referent of the local interpretation of *sich/himself*. Accordingly when sentences like (2-c) are heard, we expect fixation probabilities on the *father* to increase compared to sentences like (2-d) because the father is one possible referent of the local interpretation of *ihn/him*. We expect the effect for the reflexive condition to be stronger than for the pronoun, because the reflexive

sich/himself corefers in its local interpretation with the agent of the LSC (the *son*) whereas the pronoun *ihn/him* corefers in its local interpretation with the first-mentioned agent (the *father*) but also with every other referent except the *son*.

Results

For reflexives (Figure 2), there are significantly more fixations on the referent denoted by the LSC, when the LSC was present than when it was absent. Fixation probabilities differ significantly in the range from 500 ms to about 1600 ms after the onset of the reflexive in the spoken stimulus. The referent denoted by the global meaning of the sentence is fixated the most after about 1200 ms after the synchronization point, indicating that the participants understood the spoken stimuli. The non-overlapping standard errors indicate significant differences of mean fixation probabilities in the different conditions. This was further validated by fitting a linear mixed effects model using the statistical software R (R Development Core Team, 2010) with the package lme4 (Bates, 2007). Analyses of fixation patterns for the relevant sections revealed significant differences, as tested with MCMC-sampling (all $ps < .05$). However, for the pronoun condition, we found no reliable difference in fixations on the referent denoted by the LSC when a LSC was present compared to when it was absent (Figure 3).

Figure 2: Results for *reflexives*: Proportion of fixations on the *globally correct referent* (blue lines), the *local referent* (red), and on an *unmentioned person* (green). Zero marks the onset of the reflexive in the spoken stimulus. There are significantly more fixations to the local referent (red lines), when a LSC was present (solid) than in the control condition (dashed), in the range of about 500 ms to 1600 ms.

Discussion

The results clearly indicate that binding can be disturbed by a local syntactic coherence, at least for reflexives. The lack of a local coherence effect for pronouns in this experiment might have several reasons: Due to their complementary binding domains, pronouns would have their antecedent outside the

Figure 3: Results for *pronouns*: Proportion of fixations on the *globally correct referent* (blue lines), the *local referent* (red), and on an *unmentioned person* (green). Zero marks the onset of the pronoun in the spoken stimulus. There was no reliable difference in fixations to the local referent (red lines), when a LSC was present (solid) than in the control condition (dashed).

actual local coherence. Another possibility is that participants might have looked at both of the two actors (the *agent* and the *patient*) in transitive events, such that the gazes are not as informative for the pronoun cases as for the reflexive cases, where there is only one actor (the *agent*) in each event. These, and other potential problems of Experiment 1 were dealt with in Experiment 2.

Experiment 2: Depicted events in the visual world

In Experiment 2, we used depicted events instead of referents. By doing so, we were able to provide a unique depiction even for the transitive (i.e. pronoun) cases. We also used a different control condition (i.e. locally non-coherent condition), which is more effective than inserting an adverb before the verb, as in Experiment 1. We used particle verbs, such as *an-ziehen*, in the non-local conditions. In main clauses, the particle *an* would have to be separated and placed at the end of the clause, as in: *der Sohn zieht sich an*.

Materials and design

Again, we used a 2x2-design crossing the type of anaphora (reflexive vs. pronoun) and the presence of the LSC (present vs. absent). Note, that the type of scene (depiction of transitive or reflexive actions) was always presented with the corresponding type of anaphor. So, reflexive scenes like those in Figure 4 were always presented with sentences like (3-a) and (3-b), transitive scenes (Figure 5) were presented with sentences like (3-c) and (3-d). The task was to click on (one of the) correct scenes after hearing the sentence. 36 participants took part in Experiment 2.

Auditory stimuli We recorded 24 sentences and used the double amount of sentence-picture pairs as fillers. Again, the local coherent substring was spliced into the surrounding sentence. To create the control conditions, we swapped the verb of the relative clause (*kämmte/combed*) with the second verb of the sentences (3-a) and (3-c) (*anzog/dressed*), which was always a particle verb. When a particle verb is placed inside the relative clause, the LSC is no longer valid (**Der Sohn anzog sich/ihn im Wohnzimmer ...*).

(3) a. *Reflexive, LSC*

Während der Vater_i, den der Sohn_j kämmte,
While the father_i, who the son_j combed,
sich_{i/*j} im Wohnzimmer anzog, ...
himself_{i/*j} in the living room dressed, ...
While the father who the son combed dressed himself in the living room, ...

b. *Reflexive, no LSC*

Während der Vater_i, den der Sohn anzog, sich_i
While the father_i, who the son dressed, himself;
im Wohnzimmer kämmte, ...
in the living room combed, ...
While the father who the son dressed combed himself in the living room, ...

c. *Pronoun, LSC*

Während der Vater_i, den der Sohn_j kämmte,
While the father_i, who the son_j combed,
ihn_{j/*i} im Wohnzimmer anzog, ...
him_{i/*j} in the living room dressed, ...
While the father who the son combed dressed him in the living room, ...

d. *Pronoun, no LSC*

Während der Vater, den der Sohn_j anzog, ihn_j
While the father, who the son_j dressed, him_j
im Wohnzimmer kämmte, ...
in the living room combed, ...
While the father who the son dressed combed him in the living room, ...

Visual stimuli We used scene depictions instead of referents. Sentences with reflexives were always presented with scenes depicting reflexive actions (Figure 4), whereas sentences with pronouns were always presented with scenes depicting transitive actions (Figure 5). This procedure lead to a total of 192 scenes. The positions of the scenes were cross-balanced over all trials and participants.

In the reflexive conditions (Sentences (3-a) and (3-b)) the global interpretation of Sentence (3-a) refers to the scene where *the father is dressing himself* (the lower left scene in Figure 4). The LSC is referring to *the son combing himself* (the upper left scene in Figure 4).

Because we generated the control conditions by swapping the verbs, the depicted target and control events were different. That is, for locally coherent sentences the target scene was *the son combing himself* (the upper left scene in Figure

4), whereas for the non-coherent controls, the corresponding scene was *the son dressing himself* (the upper right scene in Figure 4). Accordingly, the globally correct scene for Sentence (3-b) changes from *the father dressing himself* (the lower left scene in Figure 4) to *the father combing himself* (the lower right scene in Figure 4).

Figure 4: A picture of four scenes depicting reflexive actions from Experiment 2. The son combing himself (upper left), the son dressing himself (upper right), the father dressing himself (lower left), and the father combing himself (lower right).

In the pronoun condition with an LSC (Sentence (3-c)) the global sentence meaning refers to the scene where *the son is combing the father* (the upper left scene in Figure 5) as well as to the scene where *the father is dressing the son* (the lower right scene in Figure 5). The meaning of the LSC is also referring to the scene where *the son is combing the father*. Importantly, in the pronoun condition with an LSC, both global and local meanings are referring to the same scene.

Again, the control condition was generated by swapping the verbs, therefore the depicted target control events were also different. For locally coherent sentences the target scene was the *the son combing the father* (the upper left scene in Figure 5), whereas for the non-coherent controls, the corresponding scene was *the son dressing the father* (the upper right scene in Figure 5). Accordingly, the globally correct scene for Sentence (3-d) changes from *the father dressing the son* (the lower right scene in Figure 5) to *the father combing the son* (lower left scene in Figure 5).

Hypotheses

Reflexive condition We again expect a contrast in fixation probabilities between sentences with LSC (Sentence (3-a)) and sentences without LSC (Sentence (3-b)), such that the picture depicting the event expressed by the LSC (*Der Sohn kämmt sich im Wohnzimmer*) is fixated more often when the LSC is present than when it is not (**Der Sohn anzog sich im Wohnzimmer*). This effect should show up shortly after the offset of the reflexive. The other event, which is described by the main clause (*the father dressing* (LSC) or *combing* (no

Figure 5: A picture of four scenes depicting transitive actions from Experiment 2. The son combing the father (upper left), the son dressing the father (upper right), the father combing the son (lower left) and the father dressing the son (lower right).

LSC) *himself*) should be fixated later as soon as the event is mentioned.

Pronoun condition In the pronoun condition both the global and the local meaning of the sentence refer to the same scene (*the son combing the father*), therefore we expect a “boost effect” on fixation probabilities on this scene, i.e. we expect fixation probabilities to be high in the control condition (Sentence (3-d)), but even higher in the local coherent condition (Sentence (3-c)). Furthermore, fixation probabilities on the event described in the main clause should rise as soon as the corresponding event is mentioned, i.e. in the LSC condition, the fixations on the main verb action depiction should be delayed until after the offset of the local coherence.

Results

For reflexives (Figure 6)², there are significantly more fixations to the scene denoted by the LSC when the LSC was present than when the LSC was absent. This effect ranges from about 800 ms to after 2000 ms from the onset of the reflexive. Of course, during the matrix clause at the end of the sentence, the highest proportion of fixations is on the scene denoted by the matrix clause (after about 2200 ms from the onset of the reflexive).

For pronouns (Figure 7), the meaning of the LSC coincides with the globally correct meaning of the relative clause, which are therefore depicted by the same scene. The significant difference between the LSC and the non-LSC condition demonstrates the expected “boost effect”. This effect lasts from 200 ms to about 1000 ms after the onset of the pronoun. When the event denoted by the matrix clause is described, there are the most fixations on the corresponding scene (after

²For expository reasons only fixation probabilities on the locally and globally denoted scenes were plotted.

about 2200 ms). Again, the indication of significant differences by non-overlapping standard errors were further validated by fitting a linear mixed effects model (all $ps < .05$).

Figure 6: Results for *reflexives*: Proportion of fixations on the depicted event with the *globally correct binding* (blue lines), the *local binding* (red). Fixations on the other depictions are not plotted. Zero marks the onset of the reflexive in the spoken stimulus. There are significantly more fixations to the local binding depiction (red lines), when a LSC was present (solid) than in the control condition (dashed), in the range of about 800 ms to after 2000 ms.

Discussion

Experiment 2 replicates the results for reflexives in Experiment 1. Ignoring for a minute the period where the effect seems to be reversed, about 800 ms after the reflexive we see the local coherence effect, i.e. more looks to the locally coherent, or the control scene, respectively, when there is a local coherence in the speech input, than when there is none. Different from experiment 1, we also found a local coherence effect with pronouns. As discussed above, this might be due to the fact that the target picture in Experiment 2 is a single scene including the directionality of the action, whereas there are two depicted target actors involved in transitive actions in Experiment 1. Most notably, interpreting the pronoun within the local coherence overlaps with the meaning of the relative clause itself, so that the effect amounts to boosting the correct interpretation. The short inverse effect for reflexives starting even before the reflexive and lasting to about 200 ms after the onset of the reflexive might seem worrying at first glance. Note however that this effect is likely due to the fact that different target scenes were used for the target and the control condition (due to swapping the verbs). This difference could hence be attributed to differences in visual saliency between the two depictions. Moreover, the swapped verbs themselves might have added to the effect: particle verbs clearly morphologically indicate a clause boundary, whereas the verbs used for local coherences do not. Detection of a clause boundary might have triggered a short-lived attention-shift towards pic-

Figure 7: Results for *pronouns*: Proportion of fixations on the *globally correct scene described by the matrix clause* (blue lines) and the *scene described by the LSC and the global meaning of the relative clause* (red). Fixations on the other depictions are not plotted. Zero marks the onset of the pronoun in the spoken stimulus. There are significantly more fixations to the local binding depiction (red lines), when a LSC was present (solid) than in the control condition (dashed), in the range of about 200 ms to after 1000 ms.

tures depicting the verb's action. Note that the same holds for the pronoun cases, where we also see an early and short-lived advantage for the "local" picture in the non-local condition. The early appearance of the effect however, as in the reflexives, renders it unlikely that the effect is due to the local coherence itself.

Conclusions

Both experiments have shown that local syntactic coherences can influence the binding of pronouns and reflexives. The results suggest that LSCs open a short-lived window, during which binding constraints can work both locally and globally. With respect to the time course, shortly after an anaphoric expression is heard, potential referents or scenes corresponding to the binding of the anaphor are fixated. This argues for very early constraints (from both global and local interpretations) exerting their influence on co-reference assignment. This result is in line with Sturt (2003) who showed that *Principle A* operates at the very earliest stages of processing. However, we could also show that globally correct binding can be delayed when a local syntactic coherence interferes.

Furthermore, our findings suggest that the effects for pronouns are more fragile than those for reflexives, replicating similar findings by Kaiser et al. (2009) and Runner et al. (2006) who found that binding constraints for reflexives are harder than those for pronouns. Different to their findings, our results are not dependent on the specific semantic nature of the stimuli, as is the case with picture noun phrases.

On a larger scale, our results can be interpreted in two

ways. They could be seen as an indicator that binding principles for pronouns and – especially – for reflexives are too restrictive because they only capture the by nature global structural characteristics of sentences. On the other hand our results speak for the validity of Binding Theory, because it is even applicable in non-global structures like the local syntactic coherences presented here.

What seems quite clear considering our results, is that LSCs are processed and interpreted in such a profound way that they exert a clear influence, even on the binding of anaphoric expressions.

Acknowledgments

We would like to thank Anne Karina Feldmeth, David Kühner and Minkus Teske for their detail work on the auditory and visual stimuli. We also want to thank Sarah Schwarzkopf for her voice and for recording the auditory stimuli. This work was supported by the German Research Foundation (DFG, grant KO 1932/3-1).

Abstract

A major part of learning a language is learning connections between spoken words and their referents in the world. An open question concerns the consequence this learning has for cognition and perception. According to the label feedback hypothesis (Lupyan, 2007), processing a verbal label can change ongoing perceptual processing, e.g., actually hearing “chair” compared to simply thinking about a chair temporarily makes the visual system a better chair detector. Here, we test whether engaging in a non-communicative verbal act—speaking to oneself—also affects visual processing. Participants searched for common objects, sometimes being asked to speak the target’s name aloud. Speaking facilitated search, but only when there was a strong association between the name and the visual target. Speaking appeared to hurt performance when there was even a slight discrepancy between the name and the target. Together these results speak to the power of words to evoke associated visual information.

Introduction

Learning a language involves, among other things, learning to map words onto categories of objects in the environment. In addition to learning that chairs are good for sitting on, one learns that this class of objects has the name “chair.” Clearly, this learning is critical for linguistic communication. But beyond communication, what consequences does naming things—hearing and producing verbal labels—have on perception and nonverbal cognition?

On one account language is a “transparent medium through which thoughts flow” (H. Gleitman, Fridlund, & Reisberg, 2004, p. 363). Therefore, words are mapped onto concepts, but do not affect them (e.g., L. Gleitman & Papafragou, 2005; Gopnik, 2001). Thus, while word-learning is significantly constrained by nonverbal cognition, nonverbal cognition is not significantly influenced by learning or using words (Snedeker & L. Gleitman, 2004).

The alternative is that words are not simply mapped on to concepts, but actually change them, affecting nonverbal cognition, and even perception. The idea that words can affect the concepts to which they refer is not new: William James, for example, remarked on the power of labels to make distinctions more concrete (James, 1890, p. 333), and it has been argued that words stabilize abstract ideas in working memory and make them available for inspection (Clark, 1997; Clark & A. Karmiloff-Smith, 1993; Dennett,

1994; Goldstein, 1948; Rumelhart, Smolensky, McClelland, & Hinton, 1986; Vygotsky, 1962). This is not to say that different languages necessarily place strong constraints on the speaker’s *ability* to entertain certain concepts. Rather, it is a claim that language richly interacts with putatively nonlinguistic processes such as visual perception.

Insofar as performance on putatively nonverbal tasks draws on language, interfering with language should interfere with performance on those tasks (Goldstein, 1948). Indeed, verbal interference impairs certain types of categorization in a way strikingly similar to impairments observed in aphasic patients (Lupyan, 2009). Interfering with language can also affect perception. A number of studies have shown that interfering with language impairs categorical color perception (e.g., Gilbert, Regier, Kay, & Ivry, 2006; Roberson & Davidoff, 2000; Roberson, Pak, & Hanley, 2008; Winawer et al., 2007), suggesting that language actively modulates visual processing.

An additional way to study affects of language on perception is by attempting to *increase* rather than decrease its putative effect. A surprising finding is that when asked to find a certain visual item among distractors actually hearing its name immediately prior to performing the search—even when the label is entirely redundant—improves speed *and efficiency* of searching for the named object (or searching among the named objects). For example, when participants search for the numeral 2 among 5’s (for hundreds of trials), actually hearing the word “two” (or hearing “ignore fives”) immediately prior to doing the search, improves search RTs and reduces search slopes (Lupyan, 2007a, 2008a). Indeed, hearing an object name can even make an otherwise invisible object visible (Lupyan & Spivey, 2008; under review).

One way to understand such findings is in terms of an interactive activation framework (Rumelhart & McClelland, 1982; Spivey, 2008) in which recognition involves the combination of bottom-up perceptual information, with higher-level top-down (conceptual) information. As one learns a verbal label, it becomes associated with features that are most diagnostic (or typical) of the named category. With such associations in place, hearing the label provides top-down activation of visual properties associated with the label. In effect, the object name makes an object a “better” object by augmenting the idiosyncratic perceptual features of a given object with features typical to the named category (Lupyan, 2007b, 2008b).

Aims and Hypotheses

In the present work, we investigate whether non-communicative (self-directed) speech can affect visual processing in the context of a visual search task. Does producing the name of a pre-defined target object enable subjects to find it faster? Participants were asked to find an object among distractors while speaking its name or not. We predicted that actually speaking the object's name would facilitate visual search—even though such speaking can be seen to constitute a form of distraction. We also predicted that the effect of speaking would be largest for items most strongly associated with the label, and speaking might actually be detrimental when searching for objects having weaker associations with the label, e.g., objects judged as being less typical of their categories.

Experiment 1

The participants' task was to find and click on a target object among 35 distractors, positioned randomly in a 6×6 grid on a computer screen (Figure 1). For half the trials, participants were asked to speak the name of the target as they searched for it.

Participants

Twelve University of Pennsylvania undergraduates participated for course credit.

Materials

The targets and distractors were drawn from a set of 260 colored images of common objects (Rossion & Pourtois, 2004). For the targets, we selected 20 images having 100% picture-name agreement, as assessed by Rossion and Pourtois (2004) (airplane, banana, barn, butterfly, cake, carrot, elephant, giraffe, chicken, ladder, lamp, leaf, truck, motorcycle, mouse, mushroom, rabbit, tie, umbrella, windmill).

Figure 1: A sample search trial from Exp. 1

For a given trial, any of the 259 non-target images could serve as distractors. Rossion and Pourtois provide a number

of measures for these pictures, which we included for item-analyses. Most relevant to the present work are: RT to name the picture, familiarity, subjective visual complexity, and imagery-concordance. The latter measure was derived by presenting participants with a picture name (e.g., butterfly), asking them to form a mental image of the object, and then, on seeing the actual picture, providing a rating of imagery agreement. For the lexical items themselves, we obtained log frequency from the British National Corpus, word length in phonemes and syllables, actual age-of-acquisition (AoA) norms (Morrison, Chappell, & Ellis, 1997), and several measures from the MRC Psycholinguistic Database (www.psych.rl.ac.uk/): imageability, concreteness, and word familiarity.

Procedure

Each trial began with a prompt informing the participant what object they would need to find. The prompt also informed them whether they should repeat the object's name as they searched for it, or not. For example, immediately prior to a no-speaking trial, participants saw a prompt such as "Please search for a butterfly. Do not say anything as you search for the target" For a speaking trial, the second sentence was replaced by "Keep repeating this word continuously into the microphone until you find the target." The speech/no-speech trials were intermixed, as were the target identities. Participants completed 320 trials: 20 targets × speech condition (speaking vs. not speaking) × 8 blocks. A block included all target × speech condition combinations. Participants used a computer mouse to click on the target object.

Results and Discussion

Participants showed excellent compliance with the instruction to speak the name of the target on the label trials and to remain silent on the no-speaking trials. We focus on accuracy and median RTs to find the target as the main dependent measures. Comparisons between conditions were made using a mixed-effects ANCOVA with speech condition as a fixed effect, subject as a random effect, and block as a covariate. For reasons described in Thomas et al., (2009), separate tests were run to assess fixed factor main effects and those of the covariate × factor interaction.

Accuracy was extremely high, $M=98.8\%$, revealing that (1) subjects had no trouble remembering which item they were supposed to find, and (2) the word cues were sufficiently informative to locate the correct object. Despite this very high accuracy, saying the object's name during search resulted in significantly higher accuracy, $M=99.2\%$ than not repeating the name, $M=98.4\%$, $F(1,11)=12.19$, $p=.005$. Participants' accuracy increased over the course of the experiment, $F(1,11)=10.90$, $p=.001$, but there was no reliable speech-condition × accuracy interaction, $F(1,11)=1.49$, $p>.2$.

The analysis of median RTs included correct responses only. Unsurprisingly, participants' speed improved over the course of the experiment, $F(1,11)=22.85$, $p<.0005$. There

Figure 2: RTs in Exp. 1: Speaking significantly decreased RTs for the second half of the task. Error bars show ± 1 SE of the mean condition difference. Accuracy was significantly higher for the speaking condition throughout the task; see text.

was no main effect of the speech-condition on RTs, $F < 1$, but there was a highly reliable speech-condition \times block interaction, $F(1,11)=8.1$, $p=.004$. As shown in Figure 2, performance on the speech trials tended to be slower than on no-speech trials for the initial blocks, but this pattern reversed for the latter part of the experiment. Collapsing the last three blocks, participants were faster on speech trials than no-speech trials, $t(11)=2.91$, $p=.01$ (two-tailed). This finding suggests that although the target objects were very familiar, speaking the name decreased RTs only when participants had several opportunities to associate the picture name with the target picture, which presumably strengthened the picture-name association.

We next turn to the item analysis. A number of item factors predicted overall search performance. Search was faster, $r(18)=.55$, $p=.01$, and more accurate, $r(18)=-.54$, $p=.02$, for pictures that were visually simpler according to Rossion and Pourtois's (2004) norms. Search was faster, $r(18)=-.55$, $p=.01$, and slightly more accurate, $r(18)=.34$, $p=.15$ for pictures with higher imagery-concordance. Familiarity did not predict search times or accuracy. Lexical

Figure 3: Relationship between item familiarity and effects of speaking on accuracy. Y-axis shows % correct when speaking - % correct when not speaking.

variables did not predict overall search performance, though there were marginal correlations of search times with word frequency, $r(18)=-.38$, $p=.10$, and of accuracy with age-of-acquisition (AoA) provided by adults, $r(18)=-.40$, $p=.08$.

Finally, we examined which items were most affected by self-directed speech by subtracting performance on speech trials from performance on no-speech trials. Overall, speaking improved RTs most for the items which took, on average, the least time to find, $r(18)=-.57$, $p=.009$, and ones for which accuracy was, on average, the highest, $r(18)=.47$, $p=.037$. Recall that familiarity was not related to overall accuracy. However, separating accuracy into speech and no-speech trials revealed a very different pattern. Familiarity was unrelated to performance on no-speech trials, $p>.3$, but was highly correlated with performance on speaking trials, $r(18)=.55$, $p=.01$. The interaction was significant: speaking improved accuracy most for the more familiar items, $r(18)=.51$, $p=.02$ (Figure 3). Finally, RTs were improved marginally more for the items with the highest imagery-concordance, $r(18)=.39$, $p=.08$.

We also observed a relationship between AoA and self-directed speech. This relationship changed over the course of the experiment: for the first half of the task, AoA (both subjective and objective), correlated with the effect of speaking on search times, $r_{\text{objective AoA}}(28)=-.54$, $p=.02$, $r_{\text{subjective AoA}}=-.62$, $p=.003$: performance was impaired by saying words having higher AoA. By the second half of the task, these correlations disappeared entirely, $r_s < .1$.

For interpretive ease, we performed a median split on the familiarity and imagery-concordance values. The label advantage ($RT_{\text{without-speaking}} - RT_{\text{speaking}}$) was larger for items having imagery-concordance scores above than below the median, $F(1,18)=6.32$, $p=.022$. Search items below the median were actually slowed by speaking, $t(10)=2.24$, $p=.049$ (two-tailed). The label advantage in accuracy trended in the same direction, being (marginally) larger for items with above-median familiarity ratings, $F(1,18)=4.19$, $p=.056$.

To summarize: speaking facilitated search for pictures judged in a separate norming study to be most familiar, and targets having the highest concordance between the actual image and the mental image formed by reading the name.

One way in which self-directed speech may help visual search is through verbal rehearsal: saying the name of the target might have helped participants remember what it was they were looking for. This account is not supported for two reasons. First, accuracy was extremely high, making it unlikely that difficulties in remembering the target played a significant role. Second, a memory-based account would predict that speech should help most for items that were most difficult to find. We found exactly the opposite pattern.

The item effects presented above place some constraints on the mechanisms by which labels affect visual search. One possibility is that saying the target name helps to find the target by activating and/or keeping active the visual features typical to that object (e.g., saying "cherry" makes it easier to attend to red things). Alternatively (or addition-

ally), repeating a label helps to reject distractors. If speaking facilitated search only by improving rejection of distractors, one would not predict correlations between the magnitude of the speaking advantage and properties of the target. The presence of these correlations supports the hypothesis that speaking the target's name facilitates deployment of attention to the target item over and above seeing the printed name of the target.

The present results can be viewed as an extension of findings showing that hearing a label, even when it is entirely redundant, facilitates visual search, and this facilitation is greatest for the stimuli most strongly associated with the label (Lupyan, 2007a, 2007b, 2008a). When visual quality of the item is reduced, or the item is made more ambiguous, hearing a label can impair performance (Lupyan, 2007b). Thus, compared to just being told what to find, speaking a target name—just like hearing it—affects visual search.

Experiment 2

The goal of Experiment 2 was to test whether self-directed speech affects performance on a more difficult and ecologically valid “virtual shopping” task in which participants search for supermarket products in a visually complex display and were required to find several instances of a category.

Participants

Twenty-two University of Pennsylvania undergraduates (14 women) participated for course credit.

Materials

We photographed products on supermarket shelves in the Philadelphia area and selected 30 to serve as targets, e.g., apples, Pop-Tarts, Raisin Bran, Tylenol, Jell-O. For each product, we obtained three pictures depicting instances of the product in various sizes and orientations. Some pictures depicted multiple instances of the product, e.g., a shelf containing multiple cartons of orange juice. See Figure 4 for some examples.

Procedure

As in Exp. 1, participants were instructed that they would need to search for various items while being asked to sometimes speak the items' names. Each trial included all three instances of the product and 13 distractors. Clicking on an object made it

Figure 4: Samples of 2 search categories used in Exp. 2.

disappear, thus marking it as being selected. Once satisfied with their choices, participants clicked on a large “Done” button that signaled the end of the trial. To make the task more challenging, some of the distractors were categorically related to the target, e.g., whenever searching for “Diet Coke,” some distractors were of other sodas, e.g., “Ginger Ale.” There were a total of 240 trials (30 targets by \times 8 blocks). Within each block, half the items were presented in a speech trial and half in a no-speech trial. Speech and no-speech trials alternated. Across the 8 blocks, each item was presented an equal number of times in speech trial and no-speech trials.

Prior to beginning the search task, participants rated each item on typicality (“How typical is this box of Cheerios relative to boxes of Cheerios in general?”), and visual quality (“How well does this picture depict a box of Cheerios?”). For each item category (i.e., all three images of Cheerios), participants rated its familiarity (“Overall, how familiar to you are the objects depicted in these pictures?”) and visual similarity (“Considering only the visual appearance of these picture, how different are they from each other?”). In addition to providing us with item information, this task served to pre-expose participants to all the targets. We also obtained an imageability measure from a separate group of participants ($N=28$) who were shown the written product names, e.g., “Cheerios” and asked to rate how well they could visualize its appearance on a supermarket shelf.

Results and Discussion

The data were analyzed in the same way as in Exp. 1. Overall, participants were very accurate, averaging 1.5% false alarms and 97.7% hits (2.93 out of 3 targets). Overall performance (RTs, hits, and false alarms) correlated with all four item variables (visual similarity, visual quality, familiarity, and typicality). Correlation coefficients ranged from .35 to .65 (ps between .035 and $<.0005$). Items that were familiar, typical, of higher quality, and having least within-category similarity were found faster and with higher accuracy. Of course, the item variables were not all independent, e.g., familiar items and those of higher quality tended to be rated as more typical. The typicality and familiarity measures clustered together and were not independently predictive of performance (familiarity was the stronger of the two predictors). Within category visual similarity predicted performance independently of familiarity; multiple regression: $F(2,27)=9.15, p=.001$.

There was a reliable difference in hits between the two speech conditions: $M_{\text{speech}}=97.9\%$, $M_{\text{no-speech}}=99.1\%$, $F(1,21)=11.19, p=.003$. While speaking the product name, participants were more likely to miss one or more of the targets. As reported below, however, this effect was modulated strongly by the different targets in predictable ways. Speech-condition was not a reliable predictor of false alarms, $F(1,21)<1$. There were no differences in total or per-click RTs between the speech and no-speech conditions, $F<1$. The speech-condition \times block interaction was not reliable, $F<1$.

The item analyses in Exp. 1. suggested that effects of self-directed speech may be modulated by the relationship between the item and its name. Indeed, the cost in the hit rate incurred by speaking ($Hits_{no-speech} - Hits_{speech}$) was correlated with within-category similarity, $r(28) = -.34$, $p = .04$: the categories having the most dissimilar items incurred the highest cost when their names were repeated during search. The effect of self-directed speech ($RT_{no-speech} - RT_{speech}$) was also mediated by familiarity, $r(28) = -.51$, $p = .004$: labels tended to hurt performance for the less familiar items, but *improve*

Figure 5: Speaking advantage (no-speech – speech trials) as a function of familiarity (median split). RTs were decreased by speaking the names of the more familiar items and increased by speaking the names of the least familiar items. Errors bars indicate $1 \pm SE$ of the mean difference.

performance for the more familiar items (Figure 5). The label advantage also correlated positively with product imageability, $r(28) = .44$, $p = .01$. As an added confirmation of this finding, we divided the targets into those having characteristic colors ($N = 11$), e.g., bananas, grapes, cheerios, raisin bran and those with weaker color associations, e.g., Jell-O, Pop-Tarts. The speaking advantage was greater for color-diagnostic items (for which speaking significantly improved RTs) than for non color-diagnostic items (for which speaking marginally increased RTs), $F(1,28) = 7.35$, $p = .01$.

Exp. 2 revealed a striking gender difference in performance. Men had a significantly lower hit rate, $F(1,20) = 5.02$, $p = .037$, and were significantly slower, $F(1,20) = 6.37$, $p = .02$ to find the targets. The gender effect on RTs was substantial: men took on average 350 ms longer per trial. This effect was replicated in an item analysis, $F_2(1,29) = 43.40$, $p < .0005$ (the *only* item on which men were faster than women was “Degree Deodorant”). There was a marginal gender \times speech-condition interaction for hit rates, $F(1,20) = 3.79$, $p = .066$: labels hurt performance slightly more for men than women. An examination of item ratings revealed that there were no gender differences in subjective ratings of familiarity, visual-quality, or visual-similarity, $F_s < 1$, and only a marginal difference in typicality: women believed our items to be slightly more typical than did men, $F(1, 20) = 2.66$, $p = .12$. In an effort to better understand the origin of this gender difference, we correlated the magnitude of the female advantage with various ratings of the stimuli. We observed a mildly reliable relationship between the

magnitude of the female RT advantage and the measure of visual similarity: $r(26) = .38$, $p = .049$. The advantage was greatest for the most visually similar items (two items were excluded, as statistical outliers). There were no other reliable correlations.

Using a larger, more perceptually varied and true-to-life item set, the item analyses of Exp. 2 reinforced the conclusions of Exp. 1. As in Exp. 1, speaking aided search for the more familiar items. In contrast to Exp. 1, accuracy (hit rate) was actually decreased by speaking, though this decrease was limited to the items having low within-category similarity. This finding is consistent with the idea that speaking an object name activates a (proto)typical representation of the category. When the task requires finding items that diverge from this prototype (as when participants need to find visually heterogeneous items from the same category), speaking can impair performance.

General Discussion

Can language affect ongoing perceptual processing? A growing body of literature argues that it can. The present work is the first to examine effects of non-communicative (self-directed) speech on a visual task.

The findings show that speaking the name of the object that one is searching for improves search performance, provided that the object’s name is strongly associated with the visual depiction of the object.

The present results are somewhat less reliable than those of hearing labels on visual search (Lupyan, 2007a, 2008a). Subsequent work has shown that the effects of speech on visual processing have a characteristic timecourse, peaking about 0.5-1.5 seconds after the presentation of the label, and declining afterwards (Lupyan & Spivey, 2010, under review). In the present studies we did not have precise control over the timing of the label. Recordings of participants’ speech from the present work revealed a wide variability in the onset, speed, and duration of self-directed speech. Thus, more reliable effects may be obtained with finer control over speaking onset and rate.

Our results join work arguing for cognitive functions of self-directed speech. For example, even mild forms of articulatory suppression impair adults’ ability to switch from one task to another (Baddeley, Chincotta, & Adlam, 2001; Emerson & Miyake, 2003; Miyake, Emerson, Padilla, & Ahn, 2004). The present results are consistent with Vygotsky’s claim that the function of self-directed speech extends far beyond verbal rehearsal (Carlson, 1997; Vygotsky, 1962)—itself a learned strategy (Flavell, Beach, & Chinsky, 1966).¹

The present work comprises a first step in understanding effects of self-directed speech on visual processing. One unanswered question is whether effects of speaking on visual search arise from the act of production itself, or from

¹ It is worth noting that these articulatory suppression effects on putatively nonverbal task-switching were compelling enough for Baddeley et al., 2001, p. 655).

hearing one's speech. Although this distinction is of little practical importance—one almost always hears oneself speak—a full understanding of the mechanism by which speech and visual processing interact requires the two explanations to be teased apart. Despite these unknowns, the present results show that in the context of searching for a familiar object, knowing what an object is called is not the same as actually saying its name.

Acknowledgments

We thank Ali Shapiro, Joyce Shin, for their help with data collection and for assembling the stimulus materials.

Abstract

Recent research has argued that categorization is strongly tied to language processing. For example, language (in the form of verbal category labels) has been shown to influence perceptual discriminations of color (Winawer et al., 2007). However, does this imply that categorical perception is essentially verbally mediated perception? The present study extends recent findings in our lab showing that categorical perception can occur even in the absence of overt labels. In particular, we evaluate the degree to which certain interference tasks (verbal, spatial) reduce the effect of learned categorical perception for complex visual stimuli (faces). Contrary to previous findings, our results show that a verbal interference task does not disrupt learned categorical perception effects for faces. Our results are interpreted in light of the ongoing debate about the role of language in categorization. In particular, we suggest that at least a sub-set of categorical perception effects may be effectively “language-free”. **Keywords:** Perceptual Learning, Categorization, Concept Learning, Language.

Introduction

It is now well-known that the categories we know often influence the things that we perceive. For example, the phoneme categories in the native language of a listener dramatically influence their ability to perceive physical differences between two speech sounds. In particular, differences that span phonemic category boundaries are much more accurately discriminated than differences that fall within the same phonemic category (Liberman, Harris, Hoffman, & Griffith, 1957). This effect, known as Categorical Perception (CP), has been shown for many types of perceptual stimuli, and is known to be influenced by both innate and learned factors (e.g., Harnad, 1987; Goldstone, 1994; see Goldstone & Hendrickson, 2009 for a review).

Given the fact that CP effects are so ubiquitous, it is perhaps surprising that so little is known about how they arise. Theoretical analyses suggest that the very act of associating category labels with items can warp the representations of those items in the service of categorization. For example, Harnad, Hanson, & Lubin (1995) showed through neural network simulations that adding such a label, even without changing the

representation space, changed the similarity of item representations in that space in a way consistent with CP effects. However, such simulations simply show how CP might *arise* without explaining the exact psychological factors that may contribute to it in humans.

On the other hand, recent work by Winawer et al. (2007) has argued that the change in representation that produces such a CP effect may be due to the inclusion of a “language-specific” component to the representation of an item in memory. In their study, Winawer and colleagues found that Russian speakers, who have unique words in their language for ‘light blue’ and ‘dark blue,’ show a standard CP effect: a higher accuracy for perceptual discriminations of blues that span the light-dark category boundary relative to blues within one category. English speakers, who only use one basic word for blue, did not show a similar CP effect for the same stimuli. Interestingly, the CP between-category advantage was eliminated for the Russian speakers when they were given a verbal interference task (repeating a string of digits) while performing the perceptual discriminations, though the CP effect was preserved if the interference task involved a spatial task (remembering a pattern) instead of a verbal task. From this, Winawer, et al. argue that linguistic processing not only influences the category learning processes, but has an online influence during perceptual discrimination as well (see also Lupyan, 2008).

Somewhat consistent with this viewpoint, learned CP effects are most often found in supervised learning tasks, where feedback about an item’s correct category label drives learning to reduce classification error of category labels (Harnad, 1987; Goldstone & Hendrickson, 2009). However, Gureckis and Goldstone (2008) presented an interesting finding which would appear to challenge this view. In their study, a set of morph faces was created with varied along two arbitrary dimensions (Figure 1). Four “clusters” of items were created in the space by withholding a subset of the items from the training phase (the grey stimuli in Figure 1). Two of the clusters were assigned to category “A” and the other two clusters were assigned to category “B” by applying either a vertical or horizontal category boundary. Both before and after category learning participant’s ability to make pair-wise discriminations

between items was measured. The results showed that discrimination of items within each small cluster was reduced following learning. In addition, discrimination of items across the category boundary was improved (a pattern consistent with the standard CP effect). They also found that discrimination performance was improved between clusters that belonged to the same category. These CP effects were largest in blocks in which performance on the categorization judgment task was highest, suggesting that learning drove both improvements in categorization performance as well as the changes in perceptual discrimination.

The improvement in perceptual discrimination *within* a category (and along the category-irrelevant dimension) would not be predicted if CP was only the result of verbal labeling processes since all of these items share the same label. Instead, it appears to suggest that a non-verbal learning mechanism is engaged during category learning that is sensitive to the internal structure of the categories (e.g., Love, Medin, & Gureckis, 2004). In this study we explore the hypothesis that the effect of this non-verbal learning is not impacted by verbal interference.

In our experiment, we taught participants to categorize the same set of morphed faces that have been previously shown to induce categorical perception effects in Goldstone (1994) and Gureckis & Goldstone (2008). Following the learning phase we had participants make perceptual discriminations between pairs of faces that span both the category and cluster boundaries while performing a set of spatial or verbal interference tasks. Similar to the approach adopted by Winawer, et al, our goal was to assess the impact that verbal interference has on CP of these stimuli relative to a spatial interference task. In light of these previous findings, we predict that verbal interference will disrupt the standard CP effect of improved discrimination across the category-relevant boundary by preventing online linguistic processing while a spatial interference task does not. In contrast, we predict that verbal interference would have little impact on the improved discrimination of items that belongs to different clusters within the same category (since such effects are unlikely to be driven by differences in verbal labeling). In line with previous work, we further predict that these effects will be most pronounced for perceptual discrimination judgments in blocks where categorization performance is most accurate. Our results replicate the effects of previous studies, but we found that the interference tasks had overall little effect on learned CP for our face stimuli.

An Experiment

Method

Participants 172 students at Indiana University participated in partial fulfillment of a course requirement and were assigned into one of two conditions based on which dimension (1 or 2 in Figure 1) was relevant for

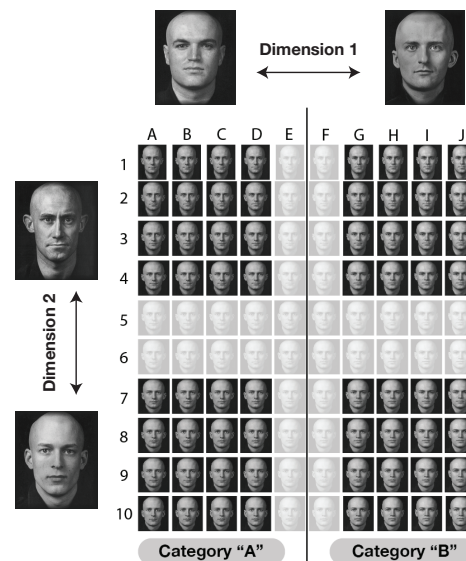

Figure 1: Stimuli varied along two arbitrary dimensions (1 and 2) forming a 10-by-10 grid of blended faces. The light grey stimuli were not included in category learning, introducing a source of within-category structure (two clusters of faces within each category). The vertical line between columns E and F shows an example category boundary used during category learning (the other category boundary was a horizontal line between rows 5 and 6).

categorization (87 had dimension 2, and 85 had dimension 1). 61 participants were excluded who did not perform significantly above chance on either categorization or discrimination trials with no interference task (the threshold used for both tasks was 0.52, the upper threshold of a 95% confidence interval based on a binomial distribution centered at 0.5).

Materials

The stimuli were morphs of bald male faces selected from Kayser (1997) using the blending technique outlined in Steyvers (1999). A stimulus space was constructed that varied along two arbitrary dimensions, each one formed by morphing between two anchor faces to create 10 faces per dimension that formed a continuum from one anchor face to the other (see Dimensions 1 and 2 in Figure 1). The two specific dimensions used in this study were selected because they were roughly equally salient and roughly orthogonal when subjected to a MDS analysis in preliminary work (Gureckis & Goldstone, 2008). A 10 by 10 matrix of stimuli faces were created by combining each face along dimension 1 with each face along dimension 2 to create a blended face that is the average of the two faces. Not all 100 faces in the 10 by 10 matrix were presented during categorization trials. In particular, a subset of faces was never presented (the light grey faces in Figure 1), creating two "clusters" of faces within each category.

Procedure

Categorization Task On each categorization trial, a single face was presented for 500 ms in the center of the display for study followed by a blank screen for 300 ms. Instructions were then presented directing participants to indicate if the correct category label for the item was ‘P’ or ‘Q.’ After a participant responded, the stimulus was again presented for 2000 ms along with feedback indicating whether the response was correct and the correct category of the stimulus.

Discrimination Task On each trial, a target stimulus was presented for 500 ms in the center of the display for study followed by a blank screen for 300 ms. For discrimination trials, immediately after the blank screen two stimuli were simultaneously presented: one stimulus that exactly matched the target stimulus and a foil stimulus. Participants were instructed to indicate by pressing one of two keys which stimulus matched the target. No feedback was provided after discrimination trials.

Sixteen stimuli were used as targets and foils in the discrimination task: the four corners of each of the four clusters shown in Figure 1 (e.g. stimuli A7, A10, D7 and D10 of the lower left-hand cluster). Each foil stimulus was two values away from the target stimulus on one of the two dimensions or two values away from the target stimulus on both dimensions (e.g. for stimulus A1 the set of foils was D1, A4, and D4; for stimulus D4 the set of foils was: A4 and G4 along Dimension 1, D1 and D7 along Dimension 2, as well as A1, G1, G7, and A7 along both dimensions).

Interference Tasks The verbal and spatial interference tasks involved participants memorizing a verbal string or a spatial pattern and recalling that information after a mini-block of categorization and discrimination trials. Verbal interference mini-blocks were preceded by the presentation of a string of 6 digits for 8 s followed by an interval of 3 s. Participants were instructed that they should memorize this string and would be tested on it later. At the end of the mini-block, memory for the studied string was probed by presenting the original string along with a foil stimulus (which had two randomly selected digits swapped). Participants simply indicated which string they recognized as the studied item by pressing one of two keys.

Spatial interference mini-blocks were preceded by the presentation of a 6 by 6 grid composed of half white squares and half black squares for 8 s followed by an interval of 3 s before the mini-block began. Participants were instructed to memorize this pattern and that they would be tested on it. At the end of the mini-block, recall of the pattern was tested by presenting the original pattern and a foil pattern that had the black-white state of one randomly selected square different than the original pattern.

A pilot study was done to control for the relative difficulty of the spatial and verbal interference tasks. The number of squares in the spatial interference task (36) and the length of the number of digits in the verbal interference task (8) were selected such that participants performed equally well at the discrimination task for the two

interference tasks (0.72 vs. 0.73, spatial vs. verbal interference, $t(21) < 1$, $p = 0.58$). Participants in the pilot study were not exposed to any categorization trials.

The complexity of the verbal and spatial tasks differed from those used by Winawer et al. (2007). They used a verbal string of length 8 and a 4 by 4 grid for their spatial pattern. Using a pretest they found no significant differences in accuracy on the interference judgment for those two tasks. In our pilot study, we found a significant difference on discrimination performance (with no categorization training) between their two conditions (0.76 vs. 0.71, spatial vs. verbal, $t(21) = 2.26$, $p = 0.03$).

Phase 1: Mixed Categorization and Discrimination Phase one consisted of two blocks of 120 categorization learning and discrimination trials presented without interference tasks. This allowed participants to begin learning the correct categories before introducing interference tasks. Trials were randomly mixed such that for each mini-block of 15 consecutive trials, 8 trials were categorization and 7 were discrimination, randomly ordered and intermixed. Note that participants did not know the type of judgment they would have to make (categorization or discrimination) until after the stimulus disappeared. This manipulation increases the relevance of processing category-level information during discrimination. The first block of phase one discrimination trials was used as a baseline measurement of performance before learning.

Phase 2: Interference Tasks with Mixed Categorization and Discrimination Phase two consisted of 21 mini-blocks composed of eight categorization and eight discrimination trials presented in a random order. Of the 21 blocks, seven had a verbal interference task, seven had a spatial interference task, and seven had no interference task. The order of mini-blocks was randomized across participants.

Results

For all analyses presented below, responses faster than 150 ms (less than 2% of all responses) were excluded from analysis. Including these fast trials in the analyses does not change the significance of the results.

Interference Task Performance In phase two participants demonstrated above chance performance on the spatial interference task ($M = 0.89$, $SD = 0.08$, $t(110) = 31.5$, $p < 0.001$) and the verbal interference task ($M = 0.95$, $SD = 0.13$, $t(110) = 59.4$, $p < 0.001$). A paired-sample t -test found a significant difference in performance between accuracy on the two test types ($t(110) = 4.51$, $p < 0.001$). Participants were more accurate on the verbal interference task.

Categorization Performance In phase two participants demonstrated above chance categorization performance in the no interference condition ($M = 0.83$, $SD = 0.12$, $t(110) = 28.3$, $p < 0.001$), the verbal interference condition ($M = 0.82$, $SD = 0.12$, $t(110) = 28.9$, $p < 0.001$), and the spatial interference condition ($M = 0.82$, $SD = 0.12$, $t(110) = 28.2$, $p < 0.001$). There was not a significant difference in

categorization performance across interference conditions ($F(2,220) = 0.1$, $Mse = 0.0003$, $p = 0.9$).

Discrimination Performance Discrimination trials were classified based on the relationship of the target and foil face stimuli and the category boundary. Trials were classified as *within-cluster* if both faces were contained in the same group, and therefore within the same category as well. If the faces were in different clusters but still in the same category, those trials were classified as *within-category*. All remaining trials contained faces that were in different categories and were classified as *between-category*.

Discrimination performance during phase two, containing interference tasks (blocks 3 and 4), was assessed as a change in performance relative to a baseline performance on discrimination trials. The average for each participant of all discrimination trials in the first block (all possible 56 discrimination pairs) of phase one was used as this baseline measure. Removing baseline performance minimizes the variance due to any initial differences in discrimination ability across individuals. In all the following analyses this change in discrimination performance was used as the dependent measure.

Discrimination Performance across all Interference Tasks A repeated-measures ANOVA with discrimination type (3 levels) as a within-subject variable found a significant main effect of discrimination type on change in discrimination performance ($F(2, 220) = 14.83$, $Mse = 0.06$, $p < 0.001$). Planned comparisons between discrimination types found significant differences between *between-category* and *within-category* conditions ($t(110) = 2.63$, $p = 0.010$), between *within-category* and *within-cluster* conditions ($t(110) = 2.61$, $p = 0.010$), and between *between-category* and *within-cluster* conditions ($t(110) = 5.98$, $p < 0.001$).

Figure 2: The change in discrimination performance relative to baseline averaged across interference condition. Participants show an increase in discrimination performance for all discrimination types relative to baseline (block 1), but a larger increase for judgments that cross category or cluster boundaries than are within-cluster. All error bars are standard errors.

Figure 2 shows these results support the predicted pattern of results and replicate the general pattern of results reported in Gureckis and Goldstone (2008). The learned CP effect was found: perceptual discriminations that span category boundaries showing the largest increase. Participants also learned the internal structure of categories, reflected in the significant difference between *within-category* and *within-cluster* perceptual discriminations, where discriminations that span within-category clusters had a larger increase. The main difference from Gureckis and Goldstone (2008) was that an increase in perceptual discrimination was found for all discrimination types (Gureckis and Goldstone (2008) found a non-significant decrease in the *within-cluster* condition).

Discrimination Performance within Interference Tasks

A repeated-measures ANOVA with interference condition (3 levels: none, verbal, and spatial) and discrimination task (3 levels: as above) was performed with change in discrimination performance as the dependent measure. A main effect of discrimination type was found ($F(2,220) = 14.78$, $Mse = 0.19$, $p < 0.001$). Surprisingly, there was no main effect of interference task ($F(2,220) = 0.29$, $Mse = 0.003$, $p = 0.75$), nor a significant interaction between discrimination type and interference condition ($F(4,440) = 0.77$, $Mse = 0.008$, $p = 0.55$). Figure 3 shows this result.

Figure 3: The effect of discrimination type and interference condition on change in discrimination performance relative to baseline (block 1). Participants show a consistent pattern in which *Between-category* improvement is greater than *Within-category* improvement, which is greater than *Within-cluster* improvement. There is no effect of interference condition or an interaction with discrimination type. All error bars are standard errors.

Within each interference condition the same pattern of results hold as across all conditions. *Between-category* discriminations increase more relative to baseline than *within-category*, which increases more than *within-cluster*. The difference in improvement between *between-category* and *within-category* is marginally significant for the no interference ($t(110) = 1.80, p = 0.075$) and the spatial interference conditions ($t(110) = 1.79, p = 0.077$), and not significant for the verbal interference condition ($t(110) = 1.34, p = 0.18$). The difference between *within-category* and *within-cluster* improvement is significant in the verbal interference condition ($t(110) = 2.50, p = 0.01$), marginally significant for the no interference condition ($t(110) = 1.81, p = 0.073$), and not significant in the spatial interference condition ($t(110) < 1, p = 0.75$). The difference in improvement between *between-category* and *within-cluster* is significant for all interference conditions (none ($t(110) = 3.75, p < 0.001$), spatial ($t(110) = 4.47, p < 0.001$), and verbal ($t(110) = 4.47, p < 0.001$)).

Discrimination Performance grouped by Categorization Performance Following Gureckis and Goldstone (2008), an analysis was performed on the effect of discrimination task on discrimination performance within mini-blocks as a function of the accuracy of categorization trials within that mini-block. For each participant, mini-blocks selected from trials in phase two were grouped based on categorization accuracy within the mini-block into high categorization (75-100%, 322 mini-blocks among 107 subjects), medium categorization (50-75%, 312 mini-blocks among 79 subjects), and low categorization (0-50%, 124 mini-blocks among 22 subjects). Figure 4 shows these results.

Figure 4: All bars are standard error bars but not all conditions had the same number of participants.

Participants who did not have any low categorization accuracy mini-blocks did not contribute to the number of participants in the low categorization conditions. The small number of observations in the *within-category* low accuracy condition may have contributed to what appears to be a spuriously high increase in that condition.

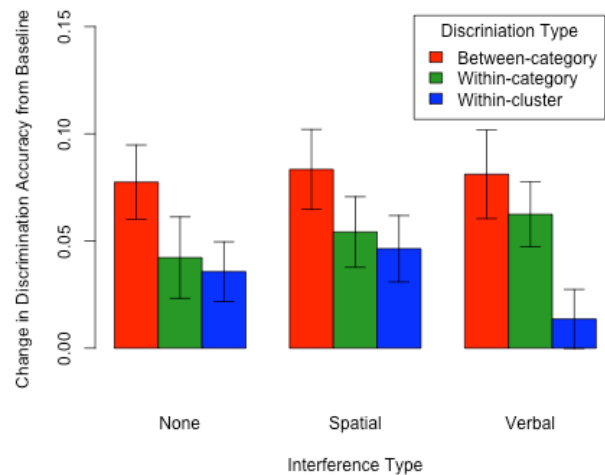

Figure 5: The effects of discrimination type and interference condition on change in discrimination performance relative to baseline for mini-blocks in which categorization accuracy was above 75%. Participants show a consistent pattern in which *Between-category* improvement is greater than *Within-category* improvement, which is greater than *Within-cluster* improvement. There is no effect of interference condition or an interaction with discrimination type. All error bars are standard errors.

The pattern of results in the high categorization accuracy set follows those of Gureckis and Goldstone (2008). The pattern among low categorization performance mini-blocks may be an artifact of having few participants at that level.

Looking specifically in the high categorization performance group (figure 5) where CP effects were predicted to be strongest and thus easiest to see an influence of interference condition, a repeated-measures ANOVA was performed with interference condition (3 levels) and discrimination type (3 levels) as within-subject factors. There was a significant main effect of discrimination type ($F(2, 214) = 8.56, Mse = 0.19, p < 0.001$) but not of interference condition ($F(2,214) = 0.4, Mse = 0.009, p = 0.66$) and no significant interaction between the two factors ($F(4,424) = 0.68, Mse = 0.02, p = 0.60$).

The high-categorization mini-block results echo our previous results (Figure 3) showing a strong effect of discrimination type but no influence or interaction with interference condition.

Discussion

Consistent with Gureckis and Goldstone (2008), we found strong evidence for learned categorical perception across the category boundary as well as learned sensitivity to the structure of information within the categories. This learning effect was strongest when averaged across all interference conditions, but the same pattern was exhibited in each interference condition: *between-category* discriminations improved the most, followed by *within-category* discriminations, and *within-cluster* discriminations

improved the least. This pattern was found within each interference condition with varying degrees of reliability. As predicted, it was also consistently found in mini-blocks that had high accuracy on categorization trials, more so than in blocks with low categorization accuracy.

Surprisingly, we did not find any indication that the interference tasks modulated the effects of increased discrimination. No main effect of interference condition was found in any discrimination types, across either category boundaries or within-category structures. This pattern was also found in mini-blocks with high categorization accuracy and in all discrimination types. The lack of interaction between interference condition and discrimination type is less startling than the lack of main effect of interference condition on overall discrimination performance because the difficulty of the spatial and verbal interference tasks was selected based on pilot data to have a relatively equal effect on perceptual discrimination tasks. The lack of main effect of interference condition is consistent with the results of Russian speakers in the Winawer et al. (2007) study (who only found an interaction between interference condition and the CP effect), though their interference tasks were pretested to equate for accuracy on the interference task itself. Winawer et al. also did not find an interaction between categorical perception and interference condition among the English speakers who did not show a main effect of categorical perception. This is not consistent with learners in our task who did show categorical perception, as well as sensitivity to inter-category structure, but did not show an interaction with interference condition.

This current work suggests that firmly entrenched verbal labels, such as color names (Winawer et al., 2007) or basic shapes (Lupyan, 2009), may be necessary to see verbal interference effects in perceptual discrimination. The incidentally learned information about the structure of categories that underlies the results found in Gureckis and Goldstone (2008) and replicated here may not have verbal labels attached that are influenced by an interference task. Instead, the preservation of this pattern across interference conditions is consistent with the non-verbally mediated account of CP that directs the focus of learning toward learning to weight perceptual dimensions rather than rely on verbal labels for categories. Clearly, the lack of effect of interference task does not justify strong claims about the nature of learned CP effects. However it does suggest that for non-automated categories verbal labels might not tell the whole story about what learning drives CP. Further work is needed to bridge the gap between our understanding of entrenched categories that do show verbal interference effects and newly-learned categories that might not, and how representations may change to incorporate more information about verbal labels.

Abstract

The factors affecting search guidance to categorical targets are largely unknown. We asked how visual similarity relationships between random-category distractors and two target classes, teddy bears and butterflies, affects search guidance. Experiment 1 used a web-based task to collect visual similarity rankings between these target classes and random objects, from which we created search displays having either high-similarity distractors, low-similarity distractors, or “mixed” displays with high, medium, and low-similarity distractors. Subjects made faster manual responses and fixated fewer distractors on low-similarity displays compared to high. On mixed trials, first fixations were more frequent on high-similarity distractors (bear=49%; butterfly=58%) than low-similarity distractors (bear=9%; butterfly=12%). Experiment 2 used the same high/low/mixed conditions, but now these conditions were created using similarity estimates from a computer-vision model that ranked objects in terms of color, texture, and shape similarity. The same patterns were found, suggesting that categorical search is indeed guided by visual similarity.

Introduction

You have probably had the experience of searching for your car in a parking lot and finding several other vehicles of the same color or model before finally finding your car. This is an example of visual similarity affecting search; the presence of these target-similar distractors made it harder to find the actual target of your search.

Such visual similarity effects have been extensively studied in the context of search, with the main finding from this effort being that search is slower when distractors are similar to the target (e.g., Duncan & Humphreys, 1989; Treisman, 1991). Models of search have also relied extensively on these visual similarity relationships (e.g., Pomplun, 2006; Treisman & Sato, 1990; Wolfe, 1994; Zelinsky, 2008). Despite their many differences, all of these models posit a very similar process for how similarity relationships are computed and used; the target and scene are represented by visual features (color, orientation, etc.), which are compared to generate a signal used to guide search to the target and to target-like distractors in a display. In general, the more similar an object is to the target, the more likely that object will be fixated.

All of these models, however, assume knowledge of the target’s specific appearance in the creation of this guidance signal. This assumption is problematic, as it is often violated in the real world. Descriptions of search targets are

often incomplete and lacking in visual detail; exact knowledge of a target’s appearance is an artificial situation that typically exists only in the laboratory. Particularly interesting are cases in which a target is defined categorically, as from a text label or an instruction (i.e., no picture preview of the target). Given the high degree of variability inherent in most categories of common objects, search under these conditions would have few visual features of the target that could be confidently compared to a scene to generate a guidance signal. Indeed, a debate exists over whether categorical search is guided at all, with some labs finding that it is (Schmidt & Zelinsky, 2009; Yang & Zelinsky, 2009) and others suggesting that it is not (e.g., Castelano et al., 2008; Wolfe et al., 2004).

The present study enters this debate on the existence of categorical guidance, focusing it on the relationship between target-distractor visual similarity and guidance to categorically-defined realistic targets. Guidance from a pictorial preview is known to decrease with increasing visual similarity between a target and distractors; does this same relationship hold for categorically-defined targets? Given that the representation of categorical targets is largely unknown, it may be the case that target descriptions are dominated by non-visual features, such as semantic or functional properties of the target category. If this is the case, guidance to the target may be weak or even nonexistent, potentially explaining the discrepant findings. To the extent that categorical search does use non-visual features, effects of target-distractor visual similarity would therefore not be expected. However, if target categories are represented visually, one might expect the same target-distractor similarity relationships demonstrated for target-specific search to extend to categorical search.

It is unclear how best to manipulate visual similarity in the context of categorical search. Traditional methods of manipulating target-distractor similarity by varying only a single target feature are clearly suboptimal, as realistic objects are composed of many features and it is impossible to know *a priori* which are the most important. This problem is compounded by the categorical nature of the task; the relevance of a particular target feature would almost certainly depend on the specific category of distractor to which it is compared. It is not even known how best to derive specific target features for such a comparison; should an average be obtained from many target exemplars or should features be extracted from a particular exemplar that is representative of the target class?

In light of the difficulties associated with directly manipulating the specific features underlying visual

similarity, we opted for a more holistic approach—to use ratings of visual similarity obtained from subjects. Specifically, we obtained ratings from Zhang et al. (2008), who used a web experiment to collect visual similarity estimates between random objects and categorical targets for the purpose of comparing these estimates to the behavior of a computational model of object class detection. Subjects were randomly assigned to either a butterfly target class or a teddy bear target class, and their task was to rate real-world objects (from the Hemera collection) to these target categories. They did this by rank-ordering groups of five objects; each trial showed five random objects, and the subjects' task was to give each a 1-5 ranking, where "1" indicated low target similarity and 5 indicated high target similarity (objects given the 2-4 rankings and objects with low inter-subject ranking agreement were considered medium similarity). There were 142 subjects, yielding a total of 71,000 butterfly and teddy bear similarity estimates for 2,000 different objects. Importantly, subjects were instructed to use only visual similarity and to disregard categorical or associative relationships between the objects and the target category when making their judgments. Consult Zhang et al. (2008) for additional details regarding this web-based collection of visual similarity estimates.

Using these estimates of visual similarity, Experiment 1 asked whether the visual similarity relationships known to affect search for specific targets also extends to categorical search. Previous arguments for the existence of categorical search guidance relied on evidence showing the preferential direction of initial saccades to targets (Schmidt & Zelinsky, 2009; Yang & Zelinsky, 2009). Although there is good reason to believe that these initial saccades are dominated by visual features, and occur too early in search to be influenced by semantic relationships between targets and distractors, it is still possible that the preferential fixation of categorical targets might have been influenced by non-visual factors. More compelling would be a demonstrated relationship between categorical guidance and a manipulation of target-distractor visual similarity; providing this evidence was the primary goal of this experiment.

We were also interested in determining whether explicit visual similarity judgments are predictive of effects of target-distractor visual similarity on categorical search. Search guidance is a largely implicit process, and as discussed can be expressed in even the first search saccade (Chen & Zelinsky, 2006); the task of assigning rankings to objects in a web experiment is comparatively slow and far more explicit. Do these two tasks use fundamentally different sources of information, or can visual similarity estimates obtained from explicit judgments be useful in describing guidance during search? Answering this question was a secondary goal of this experiment.

If categorical search is guided by target-distractor visual similarity, and if this relationship can be captured by explicit similarity judgments, we would expect a relatively high proportion of initial saccades to high-similarity distractors, and relatively few initial saccades to low-

similarity distractors. However, if categorical guidance is mediated by non-visual factors, or if the visual similarity estimates obtained from an explicit task cannot be extended to search, we would expect no effect of our similarity manipulations on guidance or manual search efficiency.

Experiment 1

Method

Participants Twenty-four students from Stony Brook University participated in exchange for course credit. All subjects reported normal or corrected to normal vision.

Stimuli and Apparatus Targets and distractors were selected from the objects used by Zhang et al. (2008). The target categories were teddy bears, obtained from Cockrill (2001), and butterflies, obtained from the Hemera collection. The distractors were also Hemera objects. Each object was sized to subtend $\sim 2.8^\circ$ of visual angle.

Gaze position was recorded using an SR Research EyeLink® II eye tracking system. This eye tracker is video-based and has a sampling rate of 500 Hz and a spatial resolution of $\sim 0.2^\circ$. Target present/absent search decisions were made using a GamePad controller connected to a USB port. Head position and viewing distance were fixed at 72 cm from the screen with a chin rest. Trials were displayed on a flat-screen monitor at a resolution of 1024×768 pixels (subtending $28^\circ \times 21^\circ$) and a refresh rate of 85 Hz.

Design and procedure Half of the subjects searched for a teddy bear target, the other half searched for a butterfly target. This search was categorical; subjects were not shown a specific bear or butterfly target preview prior to each search trial. Rather, subjects were told the target category at the start of the experiment. They were also shown examples of the target category, none of which were used as actual targets in the experimental trials.

Each trial began with the subject fixating a central dot and pressing a button on the controller to initiate the search display. The search display consisted of six evenly-spaced objects arranged on an imaginary circle with a radius of 300 pixels (8.4°) relative to the center of the screen. On target present trials (50%), one object was either a bear or a butterfly, depending on the condition, and the other five objects were randomly selected distractors. On target absent trials (50%), distractors were selected based on the similarity rankings from the Zhang et al. (2008) web task.

There were three target absent conditions: high-similarity trials (all distractors were similar to the target category), low-similarity trials (all distractors were dissimilar to the target category), and "mixed" trials, where two distractors were selected from the high-similarity category, two from the low-similarity category, and two from the medium similarity category (see Figure 1). The high and low similarity conditions were included to determine whether visual similarity affects search accuracy and manual reaction times (RTs). The mixed condition allowed us to

directly examine which distracters were preferentially fixated (i.e., search guidance) as a function of target-distractor similarity.

Target presence/absence and similarity condition were within-subjects variables, and both were randomly interleaved throughout the experiment. Subjects were asked to make their present/absent judgments as quickly as possible while maintaining accuracy. Accuracy feedback was provided following each response.

Results and Discussion

As only the target absent trials contained the similarity manipulation, analyses were restricted to these data.

Errors were less than 6% in all conditions, and were excluded from all subsequent analyses. This low false positive rate means that subjects were not confusing the high-similarity distractors for targets (e.g., a stuffed bunny distractor was not recognized as a teddy bear).

RTs were longest in the high-similarity condition and shortest in the low-similarity condition, with the mixed condition yielding intermediate RTs (Table 1). These differences were significant for both butterfly targets ($F(2,22) = 46.87, p < .001$) and for bear targets ($F(2,22) = 53.85, p < .001$). The number of distractors fixated during search also differed between the similarity conditions, and this again occurred for both butterfly ($F(2,22) = 30.41, p < .001$) and bear targets ($F(2,22) = 59.55, p < .001$). Distractors were fixated most frequently on the high-similarity trials (3.16 ± 0.23 for bears; 2.50 ± 0.36 for butterflies), followed by the medium-similarity trials (2.53 ± 0.24 for bears; 1.83 ± 0.31 for butterflies), and finally the low-similarity trials (1.51 ± 0.23 for bears; 1.29 ± 0.26 for butterflies); as distractor similarity to the target increased, so did the number of fixations on these distractors. All of these patterns are consistent with the suggestion that visual similarity rankings are predictive of search efficiency.

One of the most conservative measures of search guidance is the first fixated object—the object looked at first following search display onset. Consistent with the RT analyses we found that distractor similarity to the target determined which objects were fixated first on mixed condition trials (Figure 2A). High-similarity distractors were more often fixated first compared to medium-similarity distractors, which were more often fixated first compared to low-similarity distractors, and this pattern was found for both butterflies ($F(2,22) = 10.13, p < .01$) and for bears ($F(2,22) = 30.15, p < .001$).

Two conclusions follow from our data. First, categorical search guidance is affected by target-distractor visual similarity. As the visual similarity between a distractor and a target category increases, search efficiency decreases. This decreased efficiency is due to distractors becoming more distracting, as evidenced by an increase in the number of first fixations on the high similarity distractors. More generally, this finding adds to the growing body of evidence suggesting that categorical search is indeed guided (Schmidt & Zelinsky, 2009; Yang & Zelinsky, 2009), a question that

Figure 1: Objects from a typical mixed trial. (A) low-similarity, (B) medium-similarity, and (C) high-similarity distractors, as ranked to the teddy bear target category.

had been the topic of debate (Castelhano et al., 2008, and Wolfe et al., 2004). Not only is categorical search guided, it is guided by matching visual features to a visual representation of the target category.

The second conclusion following from our data is that explicit visual similarity rankings from a web task are highly predictive of categorical search. Given the dramatic differences between these tasks, this finding is surprising. Judgments in the web task were highly deliberative. In piloting, a subject was observed agonizing over whether a wooden box or a backpack was visually more similar to a teddy bear. These highly explicit similarity judgments can be contrasted with the largely implicit visual similarity computations that drove search guidance. Whereas the web-based judgments could be measured in seconds, effects of similarity on search guidance appeared almost immediately, at least within the first 199 ms following search display onset (the average latency of initial saccades in this experiment). Our data suggest a common thread between these two processes. Regardless of whether a visual similarity relationship has to be completed in time for an initial eye movement, or the opportunity exists to deliberate on this relationship for an extended period, the same features seem to be represented and compared.

Table 1: Manual RTs by similarity condition, in seconds

	Experiment 1		Experiment 2	
	Butterfly	Bear	Butterfly	Bear
High	1.17 (.06)	1.48 (.14)	1.59 (.13)	1.24 (.15)
Medium	0.97 (.06)	1.15 (.11)	1.25 (.10)	1.07 (.15)
Low	0.82 (.05)	0.84 (.08)	0.92 (.09)	0.74 (.09)

Note. Values in parentheses indicate one standard error.

Experiment 2

Were subjects from Experiment 1 confining their similarity judgments to purely visual dimensions? The fact that this was the instructed task does not guarantee that non-visual factors were not creeping into the similarity judgments, raising the possibility that these factors, and not visual similarity, were responsible for the observed categorical guidance. Experiment 2 addressed this possibility.

It is unclear how best to separate visual from non-visual factors in estimates of similarity. Even when stimuli are oriented bars with no compelling semantic properties, semantic features might still influence perceptual decisions (Wolfe et al., 1992). The task of separating these factors

Figure 2: Percentage of mixed condition trials in which the first object fixated had a low, medium, or high target-distractor similarity for (A) Experiment 1 and (B) Experiment 2. Error bars show one standard error. Dashed lines indicate chance.

using purely behavioral methods is even more daunting in the present study, as our stimuli are realistic objects having an untold number of visual and semantic dimensions.

In Experiment 2 we take a different approach to this problem—turning to the computer vision literature to obtain similarity estimates. Recent years have seen considerable success in the development of automated methods for the detection of object categories in realistic scenes, a task with obvious relevance to categorical visual search. At the core of these methods is the computation of visual similarity relationships between visual images and features extracted from a target class. These similarity relationships are potentially useful for our current purpose, as they provide estimates of purely visual similarity between distractors and a categorically-defined target, free from any contamination by semantic properties. Whereas the similarity estimates used in Experiment 1 may have been based on some mix of visual and non-visual information, the similarity estimates obtained from a computer vision method are incontrovertibly exclusively visual.

To obtain these purely visual similarity estimates we used the computer vision method described in Zhang et al. (2008). We chose this method for two reasons. First, it works by having multiple visual features contribute flexibly to target classification (see also Zhang et al., 2005). Specifically, it combines state-of-the-art color histogram features (Swain & Ballard, 1991), texture features (the Scale Invariant Feature Transform, or SIFT; Lowe, 2004), and global shape context features (Belongie et al., 2002) with a well-studied machine learning technique (AdaBoost; Freund & Schapire, 1997) to create classifiers having features tailored for the detection of specific target categories. The advantage of this method over other automated object classification techniques is that similarity estimates can be based on the contribution of multiple features, not just one.

Our second reason for choosing the Zhang et al. (2008) model is that it has already been successfully applied to the

identical target and distractor objects used in the present study. Specifically, it successfully classified the high-similarity and low-similarity objects from the above-described web task, regardless of whether the target category was a teddy bear or a butterfly. This makes the Zhang et al. model an obvious choice for our goal of collecting computer-vision-based similarity estimates; not only was this model able to learn classifiers to discriminate our target categories from random objects, these classifiers were also shown to be partially successful in capturing human visual similarity relationships between these random objects and the bear and butterfly target classes.¹

To the extent that the Zhang et al. model is successful in capturing human visual similarity relationships, and to the extent that these similarity estimates extend to a search task (as we found in the previous experiment), then displays constructed of high-similarity or low-similarity distractors, as rated by the model, should produce the same patterns of guidance found in Experiment 1. Initial saccades should be preferentially guided to high-similarity distractors, and preferentially guided away from low-similarity distractors, with guidance to medium similarity distractors falling between these two levels. Replicating these patterns in the context of new search displays, assembled using the purely visual similarity estimates from a computer vision model, would offer converging evidence for our claim that visual similarity affects categorical search. Of course failing to replicate these patterns would weaken this claim, and would raise concerns that the evidence for guidance reported in

¹ Note that this agreement to human behavior does not mean that the features and learning method used by this model accurately describes how humans arrive at their visual similarity estimates. Making this correspondence is a goal to which we aspire, but one that we believe is still out of reach. However, this modest level of agreement does suggest that the model's multi-feature approach has the potential to generate visual similarity estimates having behavioral significance, which makes it relatively unique with respect to purely automated computational approaches.

Experiment 1 might have been due to semantic, associative, or other non-visual sources of information.

Method

Participants Twenty-four Stony Brook University students participated in exchange for course credit, none of whom participated in Experiment 1. All subjects reported normal or corrected to normal vision. Half searched for a teddy bear target, the other half searched for a butterfly target.

Stimuli and Apparatus Experiment 2 was conducted using the same equipment as in Experiment 1. The stimuli were also objects selected from the same image set, although the new selection criteria (described below) required the potential placement of these objects into different conditions. The search displays were therefore different, but were assembled from the same set of objects.

Design and procedure Experiments 1 and 2 had the same conditions and followed the same procedure, with the only difference being the distractor composition of target absent trials; distractors were now selected based on visual similarity estimates obtained from the Zhang et al. (2008) model rather than from similarity rankings from the web task. To derive these similarity estimates we again trained an AdaBoost-based classifier for each target class using color, shape, and texture features, then evaluated these same features for the distractors to compute target-distractor similarity. This resulted in the creation of two rank ordered lists, one indicating visual similarity to teddy bears and the other to butterflies. High-similarity trials for each target category were then constructed from distractors ranked in the top third of each list, and low-similarity trials were constructed from distractors ranked in the bottom third. Mixed trials consisted of high-similarity distractors from the top third, low-similarity distractors from the bottom third and medium-similarity distractors from the middle third.

Results and Discussion

Errors were less than 3% in all conditions and were again excluded from subsequent analyses. These infrequent errors were likely just motor confusions rather than cases of confusing teddy bears or butterflies with random objects.

If categorical search is affected by the visual similarity between our target categories and random distractors, and if the Zhang et al. (2008) model is able to capture these relationships, then RTs should be the slowest on high-similarity trials, faster on mixed trials, and the fastest on low-similarity trials. These predictions were confirmed (Table 1). Search efficiency varied with target-distractor visual similarity for both teddy bears ($F(2,22) = 35.84, p < .001$) and butterflies ($F(2,22) = 60.95, p < .001$); post-hoc *t*-tests with Bonferroni correction showed slower RTs in the high-similarity condition relative to the mixed condition ($t(11) = 5.77, p < .01$ for teddy bears and $t(11) = 6.50, p < .01$ for butterflies) and faster RTs in the low-similarity

condition relative to the mixed condition ($t(11) = 5.15, p < .01$ for teddy bears and $t(11) = 6.22, p < .01$ for butterflies).

Analysis of the number of distractors fixated during search revealed the same patterns. Fixated distractors varied with visual similarity for both butterfly targets ($F(2,22) = 74.55, p < .001$) and bear targets ($F(2,22) = 93.55, p < .001$). More distractors were fixated on high-similarity trials (2.42 ± 0.20 for bears; 3.66 ± 0.24 for butterflies) compared to either mixed trials (2.10 ± 0.17 for bears; 2.88 ± 0.23 for butterflies) or low-similarity trials (1.01 ± 0.19 for bears; 1.94 ± 0.24 for butterflies).

The availability of high-, medium-, and low-similarity distractors in mixed condition displays again enabled us to look for direct oculomotor evidence for categorical search guidance. Analyses of these trials showed a relationship between visual similarity and the probability of first fixation on an object ($F(2,22) = 19.42, p < .001$ for butterflies; $F(2,22) = 36.60, p < .001$ for bears – see Figure 2B). Moreover, first fixations on high-similarity distractors were well above chance ($t(11) = 5.89, p < .01$ for bears; $t(11) = 10.01, p < .01$ for butterflies), and first fixations on low-similarity distractors were well below chance ($t(11) = 25.47, p < .01$ for bears; $t(11) = 8.32$ for butterflies), indicating that initial saccades were guided towards target-similar distractors and away from target-dissimilar distractors.

We also analyzed initial saccade latencies to see whether these patterns could be attributed to speed-accuracy tradeoffs, but none were found; initial saccade latencies did not reliably differ between the similarity conditions for either butterfly ($F(2,22) = 1.29, p = 0.30$) or bear targets ($F(2,22) = 0.76, p = 0.48$). The observed effects of visual similarity reflect actual changes in search guidance.

The conclusion from this experiment is clear. While the results of Experiment 1 could have been confounded by the unintentional inclusion of non-visual features in the behavioral similarity rankings, the same cannot be said for the similarity estimates used in Experiment 2. Even when estimates reflected purely visual features, target-distractor similarity still predicted categorical search performance. This strongly suggests that categorical guidance not only exists, but that it may operate in much the same way as search guidance from a pictorial target preview. The visual features used to represent a categorical target may be different and come from a different source (learned and recalled from memory rather than extracted from a target preview), but the underlying process of comparing these visual features to the search scene and using this signal to guide search may be the same. A goal of future work will be to determine what these categorical features are for a variety of real-world target classes. The present work constrains this goal by requiring that these features capture target-distractor visual similarity relationships.

Conclusions

Previous research had suggested that search is unguided to categorical targets (e.g., Castelano et al., 2008; Wolfe et al., 2004). In light of recent evidence, this suggestion

should be revisited. Multiple studies have now shown guidance in the very first saccades made to categorical targets (Schmidt & Zelinsky, 2009; Yang & Zelinsky, 2009). The present work extends this finding to non-target objects from categories that are visually similar to the target class. Specifically, in the absence of a target our subjects preferentially directed their initial saccades to distractors that were target-similar, and away from distractors that were target-dissimilar (mixed condition; Figure 2). This pattern, when combined with the patterns of manual search efficiency found in the high-similarity and low-similarity distractor conditions (Table 1), provides strong converging evidence for categorical search guidance in our task. The fact that these results were obtained despite the highly non-obvious similarity relationships between random objects and teddy bears / butterflies, makes the clear expression of guidance reported here all the more striking.

We can also conclude that these effects of similarity on categorical search guidance are visual, and can be well described by explicit similarity estimates regardless of whether these estimates were obtained from behavioral rankings using a web task (Experiment 1) or generated by a computer vision model of object category detection (Experiment 2). This too is a striking finding. The lengthy deliberations that accompanied the behavioral judgments, and certainly the simplistic visual features underlying the model's estimates, might have easily resulted in no success whatsoever in predicting categorical search behavior. The fact that these radically different methods both successfully predicted patterns of search guidance is informative, suggesting that the computation of visual similarity is not only a core cognitive operation, but one that is remarkably stable across method. We speculate that visual similarity is computed early and automatically during perception, and once derived is used to mediate a variety of perceptual (e.g., search guidance) and cognitive (similarity judgments) behaviors. To the extent that this is true, it bodes well for the diversity of researchers in cognitive psychology, human-computer interaction, and vision science, all attempting to better understand human visual similarity relationships.

Abstract

In laboratory experiments, infants can learn patterns of features that co-occur (e.g., Fiser & Aslin, 2002). This finding leaves two questions unanswered: What do infants do with the knowledge acquired from such statistical learning, and which patterns do infants attend to in the noisy and cluttered world outside of the laboratory? Here, we show that 9-month-old infants form expectations about co-occurring features remaining fused, an essential skill for object individuation and recognition (e.g., Goldstone, 2000; Schyns & Rodet, 1997). We also show that though social cues may temporarily detract attention away from learning events, they appear to stimulate infants to display learning better in complex situations than when infants learn on their own without attention cues. These findings suggest that infants can use feature co-occurrence to learn about objects and that social cues shape such foundational learning in a noisy environment during infancy.

Introduction

Knowing *what* to learn is fundamental to all aspects of development. In particular, recognizing important features in a display and the relationships between them supports essential skills such as object recognition (Biederman, 1987), categorization (Mareschal, Quinn, & French, 2002; Rakison & Butterworth, 1998; Schyns & Rodet, 1997; Younger & Cohen, 1986), and word learning (Smith & Yu, 2008). Fiser and Aslin (2002) showed that 9-month-olds prefer to look at shapes that have co-occurred previously, rather than at shapes that did not co-occur. These findings suggest that infants are sensitive to statistical information about features in their visual environment, and support a growing literature showing that infants recognize such co-occurrence information within auditory and visual modalities (Kirkham, Slemmer, & Johnson, 2002; Kirkham, Slemmer, Richardson, & Johnson, 2007; Saffran, Aslin, & Newport, 1996). These findings raise two important

questions. Do infants simply register these statistical patterns, or do they actually use them in order to make further predictions and inferences? In the literature on causal inference (e.g., Gopnik et al., 2004; Sobel & Kirkham, 2006), there is clear evidence that toddlers, and even infants, will go beyond the simple detection of statistical regularities among events and will use that information to make new predictions about what an object will do. Will infants similarly use the co-occurrence of features within an object to make new predictions about how that object will behave?

Moreover, in noisy natural environments infants are often presented with multiple co-occurrences. How do infants know which co-occurrences to attend to and learn from? Social cues may help infants select appropriate information. By the first few months of life, infants engage in joint attention (Butterworth, 2004), elicited by eye gaze, infant-directed speech, initial eye contact, head turn, and gestures (Carpenter, Nagell, & Tomasello, 1998; Senju & Csibra, 2008). Many investigators suggest that this attentional bias helps infants develop their social cognition and competence (e.g., understanding beliefs, desires, goals, and communicative intent, see Carpenter et al., 1998; Csibra & Gergely, 2006; Repacholi & Gopnik, 1997). However, these cues also can help shape basic cognitive development by helping infants *learn what to learn* in a noisy and exciting environment. While the impact of engaging in joint attention on social competence has been studied extensively (for review, see Carpenter et al., 1998), fewer studies investigate how following social cues can shape basic learning. Some studies have focused on word mapping (e.g., Houston-Price, Plunkett, & Duffy, 2006; Pruden, Hirsh-Pasek, Golinkoff, & Hennon, 2006) and learning linguistic structures (Goldstein & Schwade, 2008). Others have shown that such cues can lead to better recognition of an attended object (e.g., Striano, Chen, Cleveland, & Bradshaw, 2006) as well as to encoding an object's featural or spatial information (Yoon, Johnson, & Csibra, 2008). Recently, Wu

and Kirkham (in press) showed that social cues produce better association of audio-visual events than non-social cues (i.e., flashing squares). These findings suggest that following social cues could shape early basic learning. These conclusions, however, require stronger measures of learning than recognition of cued objects or simple matching of audio-visual events.

The present study tested whether infants develop expectations about object integrity based on the co-occurrences of features with and without social attention-directing cues. Binding co-occurring features is an essential skill for developing veridical representations of the visual world. Previous research shows that adults “chunk” co-occurring features into larger perceptual units (e.g., Orbán, Fiser, Aslin, & Lengyel, 2008). These larger units help to identify discrete objects (Baker, Olson, & Behrmann, 2004; Turk-Browne, Isola, Scholl, & Treat, 2008; for review, see Scholl, 2001). Co-occurrences can highlight the integral features of an object, the basis of visual categorization (Palmeri & Gauthier, 2004).

Methods

Experiment 1

We investigated infants’ learning of shape feature co-occurrences and whether those co-occurrences shaped their expectations about the behavior of objects (No Cue condition). Events were presented in a simple spatial layout (Figure 2, top panel), maintaining the same spatial layout between familiarization and test trials.

Participants Eighteen 9-month-old infants (9 females, $M = 9$ months, 1 day, range: 8;14-9;23) participated in this experiment. Three infants were excluded from final analyses due to fussiness (i.e., completing only two out of four blocks). Thirteen infants completed all four blocks; the remaining 5 infants completed 3 blocks. Infants were recruited via local-area advertisements and given t-shirts or bibs to thank them for their participation.

Apparatus Infants’ looks were monitored using a Tobii 1750 eye-tracker (www.tobii.com), and events were presented on a 17” monitor attached to the eye-tracking unit. Stimuli were displayed using Tobii’s ClearView AVI presentation software, and sounds were played through stereo external speakers. An external video camera on top of the screen allowed the experimenter to determine whether the infant was looking at the display. The shape events were created using Macromedia Director MX 2004, and the movie clips were assembled using Final Cut Express HD 3 (Apple Inc, CA).

Stimuli During the familiarization trials, infants watched sequences of looming shapes. Each sequence contained three patterns (Patterns A, B, and C), and each pattern was composed of 3 differently colored component shapes (see Figure 1). Each infant saw one sequence (repeatedly) during

familiarization with a total of 9 shape clusters in each sequence (3 clusters per pattern, 3 patterns per sequence). For each pattern, there was a pair of shapes that were always together and a third shape that varied for each cluster. Each cluster loomed from a minimum of 4.87° to a maximum of 9.72° for 2 seconds. When a cluster grew to its maximum size, it disappeared from the screen, and another cluster appeared. A single sequence appeared in one of two white frames arranged left and right in the lower half of a black screen. Infants viewed the looming pattern while the other frame remained empty.

During the test trials, infants were shown consistent and inconsistent splitting events. Consistent events showed an animation of a cluster breaking into two, with the variable shape moving apart from the other paired shapes. Inconsistent events showed shapes that had been paired together splitting up, where one stayed with the variable shape, and the other moved apart by itself. The same test events were seen by all infants. The events were labeled as consistent or inconsistent according to the pattern that each infant saw during familiarization (i.e., a test event that was a consistent split for Sequence A was inconsistent for Sequence B, and vice versa). Thus, differences in looking time to test events were due to the exposure during familiarization rather than basic perceptual preferences. Each splitting event loomed from a minimum of 4.87° to a maximum of 8.51° for 2 seconds. Then, either a variable or constant shape split off at either a 45° , 180° , or 270° angle (relative to the vertical depending on its position in the cluster) for another 2 seconds until it reached 9.72° . These test events appeared in the same frame as the familiarization events in the lower left or right frame. Consistent and inconsistent test events were shown sequentially in the frame.

Figure 1: Shape cluster stimuli and patterns during familiarization and test trials.

Design and Procedure Infants sat in a car seat 50 cm from the eye-tracker monitor in a small, quiet room, while their caregivers sat out of their view. The caregivers were instructed to refrain from commenting on the movies or interacting with their infant. The experimenter used a 5-

point calibration with a Sesame Street clip on the infants' looks. For the experiment, infants were shown four blocks of trials. Each block consisted of 6 familiarization trials (i.e., two per pattern) that lasted 6 seconds per trial, and two test trials (consistent or inconsistent) that lasted 12 seconds per trial (3 splitting events per trial, one event per pattern). During each familiarization trial, the three shape clusters in a given pattern were presented sequentially. The training sequence (Sequence 1 or 2) and presentation side were counterbalanced across infants. For each infant, the clusters in the test trials were presented in four orders, which were counterbalanced with a Latin Square across all infants. Whether the first test trial displayed an inconsistent or consistent pattern also was counterbalanced across infants. Blocks 3 and 4 repeated all familiarization and test trials from Blocks 1 and 2. Attention getters (still kaleidoscopic circles or squares with either a "bling" or "boing" sound) spliced the familiarization and test trials. The 1-second clip looped until the infants returned their gaze to the screen for approximately 1500 ms.

Coding The Areas of Interest (AOIs) encompassed slightly larger areas than those of the frames to account for noisy infant saccades. For the familiarization trials, total looking time to the AOI containing the target event was calculated with Tobii's ClearView analysis software. For the test trials, a proportional looking time difference score was calculated by subtracting the percentage of looking to the inconsistent events (total looking time to the inconsistent divided by the total looking time to both test stimuli) from that of the consistent. A negative score reflected a preference for the inconsistent splits, and a positive for the consistent.

Results Infants looked at the familiarization sequence an average of 67.15 seconds, ($SE = 4.28$), 46.63% of the entire presentation time. For the test trials, a one-sample t-test revealed that there was a mean preference for the inconsistent splits overall, and that this preference was significantly higher than chance, $t(17) = -2.33$, $p = .03$, two-tailed, $M = -.11$, $SE = .05$.

Discussion Infants displayed an overall preference for the inconsistent split. They were sensitive to the internal statistics of the shapes within each cluster, and when the two co-occurring shapes separated, this attracted their attention. One interpretation is that the infants had represented the co-occurring pair of shapes as a single object, and noticed that object breaking apart. This preference gave us a baseline of learning that allowed us to investigate how learning under more difficult conditions can be influenced by social cues.

Experiment 2

Experiment 2 increased the difficulty of the test events and examined the effect of introducing a social cue during familiarization. At test, splitting events were presented simultaneously (rather than sequentially) in the lower left and right frames. In order to explore how a social cue might

influence infants' learning of the sequences (Figure 2, middle panel), infants were either shown the familiarization sequence by itself (No Cue II condition) or with a face cue that turned down to the patterns (Social Cue condition).

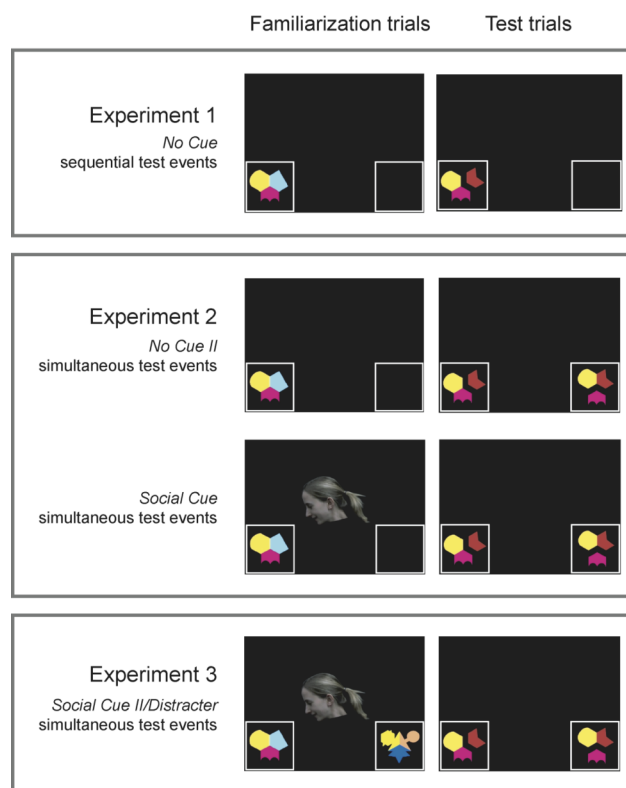

Figure 2. Familiarization and test trials for the four conditions in Experiments 1 to 3.

Stimuli Experiment 2 used the shape stimuli from Experiment 1. The familiarization trials in the No Cue II condition were identical to those from Experiment 1. For the Social Cue condition, before the onset of the shape pattern, a female face appeared in the center of the screen, looked forward, smiled, said "Hi baby, look at this!", and turned to look down at a frame. The pattern then appeared in that frame. The face stayed turned and smiling until the pattern finished (after displaying three clusters sequentially). The pattern disappeared, and the face turned back to the center and changed to a neutral expression as the trial ended. At the beginning of each familiarization trial, the face clip lasted for 5 seconds before the onset of the pattern.

In this experiment, we implemented a preferential looking paradigm by presenting the consistent and inconsistent splits simultaneously in both the right and left locations to increase the complexity of the display. Locations of the splitting events were counterbalanced across infants. To maintain consistency for presentation time and trial numbers, there were two test trials per block that showed the inconsistent and consistent splits simultaneously.

Coding A central AOI was added to the familiarization trials because of the addition of the central face cue. Since

the test trials now included simultaneous consistent and inconsistent splits, the difference score was calculated by subtracting the inconsistent proportional looking time from the consistent for each trial.

Results In addition to the analyses carried out in the previous experiment, we also ran a one-way ANOVA to investigate differences in total looking time during the familiarization trials between the two conditions. For the test trials, we ran a one-way ANOVA (in addition to analyses from Experiment 1) to investigate whether congruency between familiarization and test presentation side (whether infants had to switch sides to look at the inconsistent pattern) affected their preference for the inconsistent event. Infants in the No Cue II condition looked at the familiarization sequence an average of 68.39 seconds ($SE = 5.30$), 47.49% of the entire presentation time, similar to infants in Experiment 1. Infants in the Social Cue condition looked at the pattern for an average of 43.84 seconds, ($SE = 5.53$), 30.44% of the entire presentation time, because these infants split their attention between the face and target shapes. A one-way ANOVA revealed a significant effect of condition on total looking time to the target pattern during familiarization, $F(1, 32) = 10.25$, $p = .003$: Infants looked longer to the shapes in the No Cue II condition than in the Social Cue condition. For the test trials, a one-way ANOVA revealed an effect of condition (Social Cue or No Cue II) on the average difference scores, $F(1, 32) = 4.40$, $p = .04$. Thus, we divided the data set by condition to compare each set of average difference scores to chance: Infants in the Social Cue condition displayed a preference for the inconsistent split, $t(16) = -2.12$, $p = .05$, two-tailed, $M = -.11$, $SE = .05$, while infants in the No Cue II condition did not display a significant preference overall, $t(17) = 1.53$, $p = .15$, two-tailed, $M = .12$, $SE = .09$ (Figure 3).

Figure 3. Difference scores across conditions (mean difference between proportional looking times for consistent minus inconsistent events during test). A negative value reflects a preference for the inconsistent splits. * $p \leq .05$

A one-way ANOVA on switching sides revealed no significant effects of switching on the average difference

score for both the No Cue condition, $F(1, 16) = .78$, $p = .39$, and the Social Cue condition, $F(1, 15) < .01$, $p > .90$.

Discussion With a noisier test layout, but without a social cue during familiarization, infants showed no significant preference for either the consistent or inconsistent splitting event. Infants who saw social cues during familiarization, however, exhibited a preference for the inconsistent split, similar to infants in Experiment 1. This preference discrepancy between the two conditions was not due to gross inattention to the target event. Infants in the No Cue II condition looked *longer* to the patterns during familiarization than infants in the Social Cue condition. Surprisingly, the lesser amount of attention that infants paid to the sequence in the Social Cue condition resulted in clear expectations about the objects.

Experiment 3

The learning challenge became more difficult again in this experiment, as we presented infants with two sequences simultaneously during familiarization (Social Cue II condition, Figure 2, bottom panel). This setup is a little bit closer to the situation an infant encounters in the real world, where there are many potential sources of statistical structure that could be learnt. Moreover, as is also often the case for the infant, there is a social cue present that could direct and shape learning.

Participants Eighteen 9-month-old infants (10 females, $M = 9$ months, 3 day, range: 8;24-9;22) participated in this experiment. Five infants completed 3 blocks, and 13 infants completed all four blocks.

Stimuli The stimuli, design, and procedure in this experiment were the same as those from the Social Cue condition in Experiment 2 except for the addition of a distracter sequence in the frame that was previously empty in Experiment 2. Infants who were directed to look at Sequence 1 had Sequence 2 as the distracter event, and vice versa. Therefore, the sequence that was the target for one infant was the distracter for another. The target and distracter patterns were displayed simultaneously during familiarization.

Coding With the introduction of a distracter during familiarization, we now measured the efficacy of social cues in directing the infants' attention to the target shape. A difference score for the familiarization trials was calculated in the same manner as for the test trials, except for the inclusion of the central AOI (face). During the test trials, the central AOI was disregarded while calculating the difference score, since there was no visual stimulus in the center during test.

Results Infants looked at the cued familiarization pattern an average of 39.14 seconds, ($SE = 4.49$), 27.18% of the entire presentation time and the non-cued pattern an average of

14.40 seconds, ($SE = 1.65$). Difference scores during familiarization indicated that 17 infants (94.44%) followed the cue and looked longer to the cued pattern than the non-cued pattern, $t(17) = 7.67$, $p < .01$, $M = .42$, $SE = .05$. For the test trials, a t-test on the difference score revealed a preference for the inconsistent splitting events compared to chance, $t(17) = -2.48$, $p = .02$, two-tailed, $M = -.09$, $SE = .04$. A one-way ANOVA on the effect of switching sides between familiarization and test trials revealed no significant effects of switching on the average difference score, $F(1, 16) = .55$, $p = .47$.

Discussion Infants in this experiment displayed a preference for the inconsistent split, similar to the preference in Experiment 1 (No Cue condition) and Experiment 2 (Social Cue condition). Interestingly, infants showed this preference despite a) being exposed to an equally salient pattern in the other frame during familiarization, and b) looking for a short amount of time to the target event compared to the other three conditions. These findings suggest that social cues elicit rapid learning in a noisy environment. Infants did not seem to process much of the distracter pattern, as they otherwise would have preferred the opposite event.

General Discussion

We have shown that 9-month-old infants use visual feature co-occurrences to form representations of object integrity, and that with multiple streams of visual information available in their environment, infants will use social cues to select the ones that they learn. First, these findings extend previous work showing that infants recognize visual feature co-occurrences (Fiser & Aslin, 2002) by demonstrating that infants consider co-occurring features as a larger perceptual unit that should remain fused. If this is the case, then infants may consider these larger perceptual units as integral to an object, as is the case with adults (see Scholl, 2001). Therefore, it is plausible that tracking co-occurrences in infants (as in adults) supports essential skills such as object recognition, categorization, and word learning. The fact that statistics are useful for infants in the visual domain echoes findings in the auditory domain and in studies of causal inference. For example, infants use speech segments that are statistically consistent as labels for objects (Graf Estes et al., 2007). Importantly, these findings support the idea that statistical learning is a powerful mechanism that is *useful* and that leads to inferences beyond detection of the statistical pattern itself.

Social attention cues shaped infants' learning about objects, the second finding in our experiments. This effect remained despite the distraction of the face, change in test spatial layout, and additional distracter patterns during familiarization. Again, this finding in the visual domain is similar to those in the auditory domain showing that infant-directed speech and visual face stimulus facilitates word segmentation (Sell & Kaschak, 2009; Thiessen, Hill, & Saffran, 2005). Importantly, this study grounds an emerging literature showing that social cues mediate infants' basic

learning via three key aspects: 1) using a complex measure of learning, 2) comparing learning effects with and without social cues, and 3) investigating such learning with younger, prelinguistic infants. Together, these aspects allow for stronger evidence that social cues mediate learning from the first year.

One could ask whether the social character of the face drove the learning effect or whether a non-social cue would have been equally effective. In this regard, it is noteworthy that the face appeared equidistant from the target and distracter frame during familiarization. Hence, it was not merely the presence of the cue that facilitated learning but the fact that the cue was a face that turned towards one stimulus rather than another. Furthermore, our previous work showed that when cued by flashing squares, 8-month-old infants remember *where* they were cued to rather than *what* they were cued to (Wu & Kirkham, in press). An attention-directing non-social central cue is an interactive stimulus: If a stimulus interacts with the infant and then turns in one clear direction, the infant will follow the object's 'gaze' (e.g., Johnson, Slaughter & Carey, 1998). A recent study, however, showed that 18-month-olds do not map labels onto objects 'gazed' on by an interactive non-social stimulus, only those gazed on by human faces (O'Connell, Poulin-Dubois, Demke, & Guay, 2009), and this interactive stimulus might be argued to itself have social features. In future studies, we intend to find a suitable (and effective) non-social cue for this experimental paradigm. For now, we claim only that social cues facilitate visual statistical learning. We do not claim, however, that social cues are the *only* attention cues that aid learning, nor that they produce better learning than any other attention cue.

In conclusion, our findings suggest that co-occurrence information and social cues inform and direct learning in infancy. In particular, though social cues may temporarily detract attention away from certain learning events in the world, they appear to stimulate infants to display the learning better in complex situations than when infants learn on their own without attention cues. Investigating how infants interact with different cues in the environment (see Goldstein et al., in press) and the developmental trajectory of the use of such cues (e.g., Hollich, Hirsh-Pasek, & Golinkoff, 2000) would clarify the extent to which they shape cognitive development.

Abstract

In adult human brains, the horizontal segment of the intraparietal sulcus plays a large role in representing numeric magnitude. In children and non-human primates, however, frontal cortex may play a larger role. We hypothesized that there is a link between observed developmental changes in locus of representation (frontal to parietal) and type of representation used (logarithmic to linear). Participants were presented with number lines and asked to judge accuracy of linear, logarithmic, or log-linear placements. Consistent with hypotheses, event-related potentials generally revealed greatest parietal N1 amplitudes for linear placements and greatest frontal P3 amplitude for logarithmic placements. Additionally, effects of linear placements on cortical activity were moderated by numerical magnitude: parietal N1 amplitudes decreased with magnitude, whereas frontal P3 amplitudes increased with magnitude. These results suggest adults possess logarithmic and linear representations of number, and when logarithmic representations were elicited, there was greater involvement of frontal cortex.

Keywords: Numerical cognition; representation; brain imaging; event related potentials.

Introduction

Whether a pollster evaluating the sampling process for an election poll, a parishioner telling the time by counting the tolls of a church bell, or a child figuring out how much candy she had received on this Halloween versus a previous one, mental representations of numerical magnitude are important for projecting the future, monitoring the present, and learning from the past. Moreover, this ability to code our experiences numerically must scale consistently regardless of the shape, size, sensory modality or context in which particular numeric magnitudes are presented.

Two prominent brain areas have been implicated in humans' and other animals' representation of numerical magnitudes: the *prefrontal cortex* and the *horizontal segment of the intraparietal Sulcus* (HIPS). Most studies have shown that HIPS plays a major role in numeric representation, with magnitude coded in this area as an abstract, notation-independent representation (Dehaene,

Piazza, Pinel, Cohen, 2003; Dehaene, Dehaene-Lambertz, & Cohen, 1998; Libertus, Woldorff & Brannon, 2007). However, comparative and developmental studies have found HIPS playing a less prominent role. For example, single cell recordings in monkeys (Nieder & Merten, 2007 & Nieder & Miller, 2004) and fMRI studies in children (Ansari et al. 2005; Ansari & Dhital, 2006; Cantlon, Brannon, Carter & Pelphrey, 2006; Cantlon et al., 2009) have shown stronger effects of numerical magnitude on prefrontal cortex than HIPS. Similarly, ERP studies with infants, have also found that nonsymbolic numeric processing generates activity in a parieto-prefrontal network (Izard, Dehaene-Lambertz & Dehaene, 2008; Libertus, Pruitt, Woldorff & Brannon, 2009).

To explain this developmental trend, we propose that: (1) at any given age, the brain represents numeric magnitudes using both a logarithmically-compressed code and a linear code, with the probability of a number being processed by the linear code increasing with age and experience; and (2) logarithmic-coding is predominantly processed in frontal areas, whereas linear coding is predominantly processed in parietal areas. Here we test an implication of this account, namely that large magnitude (low-frequency) numerals are more likely than small magnitude (high-frequency) numerals to be represented in frontal cortex, whereas the reverse is true of parietal cortex.

Development of Numeric Representations

The origin of our developmental hypothesis stems from behavioral studies on development of numeric representations (Booth & Siegler, 2006; Opfer & Siegler, 2007; Opfer & Thompson, 2008; Siegler & Opfer, 2003; Thompson & Opfer, 2008). In these studies, children and adults were asked to estimate the position of numbers on a blank line with the end-points labeled "0" and "100", "0" and "1000", or "0" and "10000". This estimation task is particularly revealing about cognitive representations of numeric value because it transparently reflects the ratio characteristics of the number system. Overall, younger children's estimates typically follow Fechner's Law and

increase logarithmically with actual value, whereas older children's estimates increase linearly. At any given age, however, individual children use both logarithmic and linear representations of number, depending on numerical context. That is, for very large numeric contexts (e.g., on 0-1000 and 0-10000 number lines), children's estimates increase logarithmically; however, the same children will use linear representations when estimating the magnitudes of numbers for small numeric contexts (e.g., on 0-100 number lines). If our developmental hypothesis is correct, it should be possible to identify two different patterns in the brain that are consistent with the type of representation used, thereby providing neural correlates for the logarithmic-to-linear shift hypothesis.

Plausible candidates for these two different patterns of neural activation are provided by the developmental data showing a shift from prefrontal to parietal processing of numerical magnitude (Cantlon, et al., 2009; Rivera, Reiss, Eckert and Menon, 2005). More generally, evidence from perceptual learning has shown that complex conjunctive stimuli are processed by more posterior sites with gains in expertise, both within the visual cortex (Mukai et al., 2007) and between the prefrontal cortex and visual cortex (Eriksson, Larsson, Nyberg, 2008). As a result, information changes from being processed serially and with effort, to being processed in parallel and automatically. Possibly, the same is true for number representation, with the abstract representation that is needed for processing numeric magnitude regardless of shape, size, modality or context originally coming from the prefrontal cortex and gradually shifting to HIPS with gains in expertise.

Present Study

To test our hypothesis, we asked participants to judge whether a number had been accurately marked on a number line, and we evaluated the *Event-Related Potentials* (ERP) generated after participants saw number-line estimates that corresponded or not to a given numeral. By evaluating ERP components related to numeric estimation, we were able to test several predictions derived from our developmental hypothesis. Specifically, we were able to provide a novel test of whether subjects expected positions of numbers on number lines to increase linearly, logarithmically, both, or neither with numeric value, and we were able to test if the topography of those ERP components corresponded to our hypotheses.

Some ERP components can generate diagnostic data about representations of numerical magnitude, even before the subjects' response. Generally, targets that violate subjects' expectations elicit large P3 amplitudes (Donchin, 1981). Thus, numbers marked in non-linear positions would likely generate a higher P3 response than numbers marked in the linear position. Conversely, the N1 component is generally elicited when targets match the subject's orientation of attention (Luck, 2005; Folstein & Van Petten, 2008). Thus, numbers marked in the linear position would be expected to generate higher N1 responses than numbers

marked in the non-linear position. Using this logic, ERP components are capable of early detection of both linear and non-linear representations of number. This provides an important test of our hypothesis because automatic, non-linear representations of number might occur in adults before they have time to provide formally correct, learned responses.

Method

Participants

Participants (N = 21, mean age = 20.5, 8 female) were recruited from an introductory psychology class and were awarded course credit for their participation in the experiment. Nineteen participants were right handed, and all had normal or corrected to normal vision.

Design and Procedure

Each problem presented a blank number line with a width of 255 pixels, labeled with '0' on the left end and '1000' on the right end. The numbers presented appeared on the top of the screen 192 pixels over the line (half point between the top of the screen and the number line). The numbers tested were 5, 78, 150, 606, 725 and 938. These numerosities were selected because they sample the whole length of the line and also maximize the discriminability between linear and logarithmic representations. All stimuli were presented in a dark and sound-attenuated room using DirecRT (Jarvis, 2006).

Participants were instructed to identify if the position of the hatch mark on a number line corresponded to the numeral presented by pressing one key if the position of the hatch mark were correct, and by pressing another if the position of the hatch mark were incorrect (keys were counterbalanced between participants).

At the beginning of each trial, the number line with the marked end points appeared and a fixation was placed where the target numerals were going to be shown for a period of 1 second. Next, the stimulus (i.e. the numeral) replaced the fixation for another 1-second interval. After this period, the hatch mark was placed either in the linear, logarithmic or log-linear position. Once the hatch mark was in place, participants had to decide if the mark was correctly placed and to press the appropriate key (no time limit was imposed on participants' responses). After the response, no feedback was provided and a 2000-ms intertrial stimulus interval (ISI) was used.

Participants were tested on three different sets of trials and the design of the study was all within subjects. Thus, on each block, participants encountered each of the six numerals compared to three possible hatch mark positions (linear, logarithmic, log-linear). The experiment consisted of 16 blocks and presentation of the trials was randomized within each block. This corresponds to a total of 288 trials (96 per trial type condition).

ERP Recording Procedure After attaining informed consent from participants, a NuAmps quick cap with 32 Ag/AgCl electrodes (Compumedics Neuroscan, El Paso, TX, USA) was placed on their heads to record their brain activity. Linked ears served as reference during recording. Before the beginning of the experiment, impedances were held below 40 k Ω ¹. The electroencephalogram (EEG) was amplified with an A/D conversion rate of 1000 and a gain of 250mV. Finally, a recording low-pass filter of 300Hz was used.

Before analysis of the data, the raw EEG data were processed offline using BESA (Version 5.2). Raw data were re-referenced to an average of all electrodes and a digital 0.1 to 30Hz bandpass filter was used. Also, artifact correction (Berg & Scherg, 1994) was used to reduce ocular artifacts and blinks. After artifact correction, an artifact rejection procedure (tailored to each individual) was conducted. After this process, 7 participants – who had less than 85% of the trials accepted – were removed from further analyses. ERP epochs (-200ms to 1000ms) were created for the three trial types (i.e. linear, logarithmic and log-linear), and for hatch mark number size (i.e. hatch marks that corresponded to small numbers and large numbers).

Results

Behavioral Results

Number comparison is typically characterized by effects of distance and size on speed and accuracy of judgments (Moyer & Landauer, 1967). We obtained similar results for judgments of number line placements. Consistent with distance effects, log-linear trials, which were closer to the correct (linear) placements than logarithmic ones, required more time to solve and resulted in the lowest accuracy rates. Consistent with size effects, judging the location of large numbers (i.e. larger than 500) on the number line required more time than judging the location of small numbers (i.e. smaller than 500), with accuracy also being lower for placement of large numbers compared to small numbers. Finally, there was evidence of interactive effects of size and trial type, with larger effects of trial type for small numbers ($\omega^2 = .54$) than for large numbers ($\omega^2 = .32$) on reaction times. This interaction is interesting because it suggests that representations of small numeric magnitudes are more strongly linear and non-logarithmic than representations of large numeric magnitudes, leading to less discriminability between trial types for the large magnitudes.

A potential problem with accuracy measures, such as those reported above is that they can fail to detect systematic response biases. To address this issue, we conducted d' analyses. Because performance of participants was near ceiling, hits and false alarm rates were corrected. Specifically, hit rates were constructed by the formula (hits

+ 1)/(total trials + 2), and false alarm rates were constructed by the formula (false alarms + 1)/(total trials + 2).

As predicted by the size effect, discriminability between the linear, and the logarithmic and log-linear trials declined with numeric size (see Figure 1). This result was confirmed by a one-way repeated measures ANOVA ($F(5,100) = 36.83$, $p < .001$, $\omega^2 = 0.59$). An alternative explanation of this result is that it is due to the distance between the linear and logarithmic trials not being constant throughout the whole range of numbers. Thus, it is possible that the reason why discrimination decreases for the numbers 725 and 938 is because the distances between the linear and logarithmic trials decrease too. To test this alternative hypothesis, we performed a planned comparison between two numbers that differ in size but that have the same distance between the linear and logarithmic hatch mark positions (5 and 725). As predicted by the size effect, even though the distance between the linear and logarithmic trials is equal for these two numbers, discriminability was significantly smaller for 725 ($d' = 2.25$, $SD = 0.78$) than for 5 ($d' = 3.04$, $SD = 0.56$; $p < .001$).

Electrophysiological Results

To understand the temporal characterization of the number line estimation task, average waveforms were computed for the three experimental trials (i.e. linear, logarithmic, log-linear). Additionally, these waveforms were averaged into four different electrode sites with the purpose of reducing experiment-wise error caused by computing multiple statistical comparisons. The frontal left (FL) electrode site was computed by averaging the electrodes FP1, F3, F7, FC3, and FC7. The frontal right (FR) electrode site was computed by averaging the electrodes FP2, F4, F8, FC4, FC8. The parietal left (PL) electrode site was computed by averaging the electrodes CP3, TP7, P3, P7. The parietal right (PR) electrode site was computed by averaging the electrodes CP4, TP8, P4, P8.

¹ Although the impedance threshold for accepting a participant was 40 k Ω , in reality most of the electrodes achieved impedances of 10 to 15 k Ω .

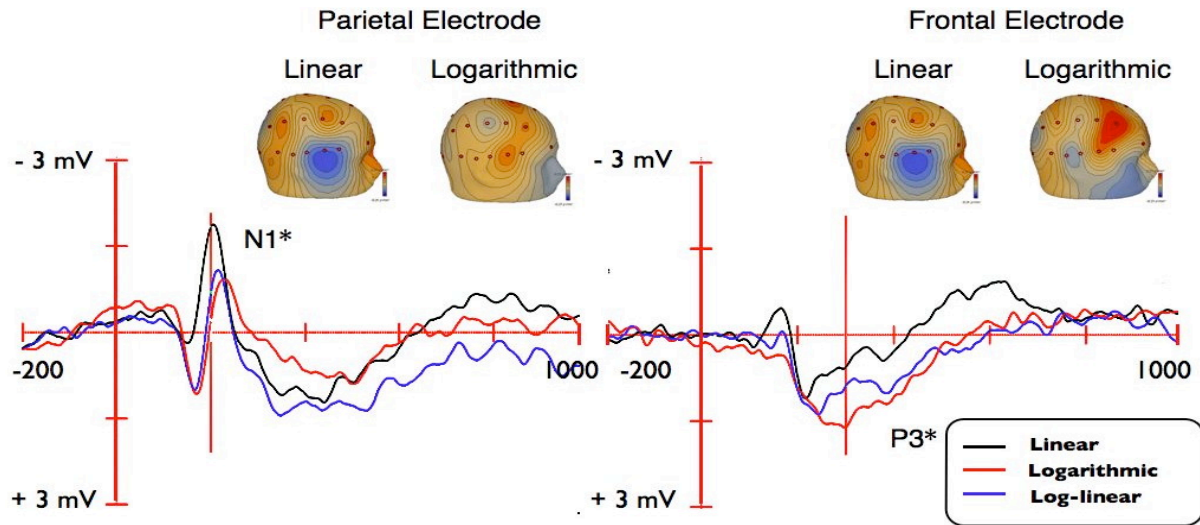

Figure 2: Top: Current source density topographies for linear and logarithmic trial types at 200 ms (left) and at 300 ms (right). Bottom: N1 (140-240 ms) and P3 (260-700 ms) ERP components for linear, logarithmic, and log-linear trials for parietal (left) and frontal (right) electrode sites.

Visual inspection of the waveforms is consistent with the main hypothesis from the study (see Figure 2). First, linear trials generated a greater N1 peak than both the logarithmic and log-linear trials, especially in parietal electrode sites. Moreover, at frontal electrode sites, the logarithmic trials generated a greater P3 peak than the log-linear trials, and in turn, the log-linear trials generated a greater P3 peak than the linear trials. These effects suggest that even before the behavioral response is effectuated, there is a strong recognition of the linear placements of numbers followed by a signal of surprise related to the logarithmic and log-linear placements of numbers.

To test these effects statistically, a 3-way (trial type: linear, logarithmic, log-linear \times electrode site: FL, FR, PL, PR \times component: N1, P3) repeated-measures ANOVA was conducted on the mean amplitudes calculated for the N1 and P3 time windows. All reported p -values are Greenhouse-Geisser corrected for violations of sphericity assumptions. Results indicated a significant component \times electrode interaction, ($F(3,39) = 8.37, p < .001, \eta^2 = 0.39$). This effect is largely due to a larger N1 component in parietal sites compared to frontal sites. Furthermore, as expected, a trial type \times electrode \times component interaction was significant ($F(6,78) = 3.85, p = .033, \eta^2 = 0.23$). This interaction was due to different simple main effects of trial type at the N1 component for the PL ($F(2,26) = 8.07, p = .003, \omega^2 = 0.25$) and PR ($F(2,26) = 14.81, p < .001, \omega^2 = 0.40$) electrode sites versus simple main effects of trial type at the P3 component for the FR ($F(2,26) = 4.69, p = .048, \omega^2 = 0.16$) and PL ($F(2,26) = 18.25, p < .001, \omega^2 = 0.45$) electrode sites.

To explore this more closely, we computed average waveforms for the correct linear trials with hatch marks that corresponded to small numbers (i.e. 5, 78, 150) and to large numbers (i.e. 606, 725, 938). As can be seen in Figure 3,

compared to small numbers, large numbers generated smaller N1 peaks at parietal electrode sites and larger P3 peaks at frontal electrode sites. This pattern of results indicates that small numbers were expected to appear in the linear position, whereas large numbers were not. Thus, even though participants made the correct response for both types of numbers, the brain shows evidence that large numbers and small numbers are processed differently.

To test these results statistically, we conducted a 3-way (Condition: small numbers, large numbers \times Electrode: FL, FR, PL, PR \times Component: N1, P3) repeated measures ANOVA. Results showed a significant electrode \times component interaction ($F(3,39) = 9.14, p < .001, \eta^2 = 0.41$). This effect is largely due to a change in polarity from the N1 to the P3 components in parietal electrodes. Moreover, as expected there was a significant trial condition \times electrode \times component interaction ($F(3,39) = 8.05, p < .001, \eta^2 = 0.38$). Post-hoc analysis revealed that when hatch marks were positioned linearly, a greater N1 component at the PR electrode site ($F(1,13) = 5.67, p = .033, \omega^2 = 0.14$) was elicited by small numbers than by large numbers. Also, at the FL electrode site, linearly positioned hatch marks elicited a greater P3 component ($F(1,13) = 6.31, p = .026, \omega^2 = 0.16$) for large numbers than for small numbers.

DISCUSSION

We aimed to provide a temporal characterization of brain activity evoked by representations of numeric magnitudes. This characterization supported two conclusions: (1) the adult brain continues to represent numeric magnitudes using both a logarithmically-compressed code and a linear code, with the probability of a number being processed by the linear code decreasing with numeric magnitude (and thus frequency and prior experience); and (2) that logarithmic-coding is predominantly processed in frontal areas, whereas

Figure 3: Top: Current source density topographies for correct linear trials divided into small and large numbers at 200 ms (left) and at 300 ms (right). Bottom: N1 (140-240 ms) and P3 (260-700 ms) ERP components for correct linear trials divided into small and large numbers for parietal (left) and frontal (right) electrode sites

linear coding is predominantly processed in parietal areas. These findings are important because they are consistent with our proposed explanation for a key finding in the developmental neuroscience of number representation. Namely, that although it has been found that HIPS is crucial for numeric processing (Dehaene, et al., 2003), studies that test children, have found a greater involvement of the prefrontal cortex (Ansari et al. 2005; Ansari & Dhital, 2006; Cantlon, et al., 2006; Cantlon, et al., 2009; Rivera, Reiss, Eckert and Menon, 2005).

Evidence supporting our first conclusion comes from several findings from this study. Behavioral results indicate that both linear and non-linear positions of numbers were judged as correct, with probability of non-linear positions being judged as correct increasing as numbers increased in size. Electrophysiological results were consistent with this behavioral finding. Small numbers shown in the linear position generated a greater N1 peak than did large numbers shown in the linear position. Similarly, large numbers shown in the linear position generated a greater P3 peak than did smaller numbers. Moreover, these electrophysiological findings held even when subjects' behavior correctly identified locations as linear. Thus, neither behavioral nor electrophysiological results are consistent with the idea that numbers are solely represented linearly or solely non-linearly.

Evidence supporting our second conclusion comes solely from electrophysiological data. As indicated by the N1 component, smaller numbers were more easily identified than large numbers, and this identification was predominantly found in parietal sites (Dehaene, 1996; Libertus et al., 2007). On the other hand, linear trials that corresponded to larger numbers (that are less entrenched) generated a greater surprise response (as indicated by the P3 component) in frontal electrode sites. Likewise, the results for the discrimination between linear and logarithmic

conditions showed that the significant N1 component for linear trials was located in parietal electrodes, while the P3 component for logarithmic trials was located in frontal electrodes.

An alternative hypothesis that could explain the role of prefrontal cortex is that it could be signaling general attentional demands or processes of response selection that become more active for more difficult tasks. However, using habituation paradigms, Cantlon and her collaborators have found greater activity in the prefrontal cortex of children for numeric processing (Cantlon et al., 2006; Cantlon et al., 2009). Therefore, this finding rules out the response selection hypothesis because there was no response needed, and brings doubts about the attentional demands hypothesis because there should not be significant differences in attentional demands between the number and the control tasks used. Furthermore, in our analysis, large numbers have smaller discrepancies between the linear and logarithmic trials. Therefore, if this hypothesis were correct we would expect smaller P3 amplitudes for them. Instead, we found that large numbers elicited larger frontal P3 amplitudes.

In conclusion, this is the first study to provide neural evidence for competing representations of numerical magnitude. By using an ERP paradigm with a number line estimation task, we were able to investigate numeric processing both before participants had reached a final decision about magnitude and a behavior was executed. This paradigm led to the novel finding that not all numbers are represented as linearly positioned on the number line, despite the fact that participants' judgments are very linear at the behavioral level. In this way, our findings are consistent with a novel developmental proposal that can integrate apparently contradictory results regarding the neural representation of numeric magnitude.

The perception of number from long-term memory

Abstract

The perception of numerosity is supported by two systems: an exact system for small quantities, and an approximate system for large quantities. Two properties arise from the combination of these two systems: the accuracy of numerosity judgments changes qualitatively above the capacity limit for exact representations, and the ability to discriminate two quantities depends on the numerical distance between the quantities and the relationship of this distance to the absolute magnitudes. These well-characterized aspects of number cognition have typically been studied in judgments of numerosity based on visual arrays. Across four experiments we demonstrate remarkably similar effects in numerosity judgments based on incidental long-term memory. These results suggest that similar mechanisms and constraints may operate when estimating numerosity from representations of external sensory input and internal representations derived from long-term memory.

Keywords: Numerosity judgments; perception; memory

Introduction

Perception is typically considered a set of processes for analyzing incoming sensory input. Some researchers have argued that the same perceptual and attentional mechanisms can be directed inward during prospection, memory retrieval, and memory search. To what extent are the mechanisms that underlie judgments on the basis of immediate perception similar or constrained in the same way as the mechanisms that underlie judgments derived from internal representations?

One way to answer this question is to examine the relation between numerical judgments on the basis of immediate external visual input and the numerical judgments based on internal representations from long-term memory. In the former case, several features of immediate numerical perception have been discovered. People are very accurate and fast at enumerating small quantities (6 or fewer), a process termed subitizing (Kaufman, Lord, Reese, & Volkman, 1949), while they are subject to capacity limitations with large quantities, a process termed approximation (Mandler & Shebo, 1982; Trick & Pylyshyn, 1994; Feigenson, Dehaene, & Spelke, 2004). Moreover, when discriminating between numerosities, error rates and response times are inversely related to the numerical distance between numbers (Moyer & Landauer, 1967; Dehaene, Dupoux, & Mehler, 1990). When distance is held constant, error rates and response times increase as the absolute sizes or magnitudes of the two numbers increase (Whalen, Gallistel, & Gelman, 1999; Barth, Kanwisher, & Spelke, 2003). Developmental research has also suggested core systems for representations of exact and approximate

quantities (Feigenson et al., 2004; Wood & Spelke, 2005; Opfer & Siegler, 2007).

Numerical judgments from long-term memory have previously been examined in the context of event frequency (Hasher & Zacks, 1979; Hintzman & Block, 1971; Howell, 1973). For instance, according to the strength hypothesis proposed by Hintzman (1969), frequency judgments of an event are determined by the strength or the repetition of the memory trace representing the event. Another view is that frequency judgment is a direct readout of the number of stored traces of an event based on its time lag rather than the strength of a single trace (Hintzman & Block, 1971). More recently, Brown (1995, 1997, 2002) argues that judgments of event frequency depend on context memory in that people rely on enumeration when different contexts produce distinct memory traces.

Here we relate the two areas using tools from studies of immediate numerical perception to focus on how people make numerosity judgments from long-term memory. We investigate the extent to which properties and constraints of numerosity judgments on the basis of long-term memory mirror those of judgments based on immediate perception.

Experiment 1

The purpose of this experiment is to test whether unexpected numerosity judgments from long-term memory are accurate, and whether capacity limitations in subitizing and short-term memory for external visual input also apply for judgments based on retrieved internal representations.

Participants

Twenty students from Princeton University participated in exchange for partial course credit (13 female, mean age 19.2 yrs, $SD = 1.1$).

Materials

Stimuli were chosen from an image set containing 60 distinct object categories. To manipulate numerosity, 50 of these categories were pseudo-randomly assigned to a number between 1 and 10 such that each numerosity level was represented by 5 categories. One exemplar image was chosen from each of these categories, and was presented the corresponding number of times over the course of the first phase of the experiment. For example, if at numerosity level '3' the categories of *dog*, *bear*, *car*, *flower*, and *horse* were chosen, then one exemplar from each category would be presented 3

times throughout the first phase intermixed with images from other numerosity levels. The order of image presentation was randomized for each participant with the constraint that categories could not repeat back-to-back. In addition to the 275 images of interest ($(10 + 9 + 8 + 2 + 1) \times 5$), 20 additional images were selected randomly from the remaining 10 categories with half presented at the beginning and half at the end to control for primacy and recency effects.

Procedure

In the first phase of the experiment, the participant viewed each image and determined whether it corresponded to a *natural* or *artificial* category by pressing one of two keys. This cover task prevents an explicit strategy such as counting, and is orthogonal to the primary manipulation. On each trial, an image appeared on the screen for 2 seconds, followed by an interstimulus interval of one second. The full trial sequence of 295 images lasted about 20 minutes. The participant then completed an unrelated distractor task for 15 minutes.

In the second phase of the experiment, the participant again viewed single images of objects on the screen, and estimated how many times between 1 and 10 they had seen that image in the first part of the experiment by pressing a number key on the keyboard. The 50 exemplar images of interest were presented in a random order. The accuracy and response time for each image were recorded. Filler images were not presented. It is worth noting that participants often expressed surprise when receiving these instructions, and that in post-experiment debriefing no subject reported being aware that their memory for number would be tested in the second part. These responses suggest that any effects we observe reflect incidental encoding of number in long-term memory.

Results

We compared estimated numerosity from the second phase against the objective numerosity from the first phase. At every numerosity level we averaged across the five categories at that level for each participant, and then averaged these mean estimates across participants. These estimates were compared against the objective numerosity by computing differences within participant and averaging these differences across participants. Results are shown in Figure 1.

To quantify performance, estimated numerosities were modeled as a function of objective numerosities using linear regression. Since estimated and objective numerosities were bounded (from 1 to 10), perfect performance would result in a slope of 1 and an intercept of 0. In contrast, chance performance (i.e. guessing) would lead participants to randomly distribute their responses and would result in a slope of 0. If they randomly distributed their estimates across all response options, the expected intercept would be 5.5 ($(10+1)/2$). Thus, we can judge accuracy in estimating numerosity from incidental encoding on a continuum from perfect performance (slope = 1, intercept = 0) to chance performance (slope = 0, intercept = 5.5). The linear regression analysis was performed within each participant. The mean

Figure 1: (A) Mean estimated numerosity plotted against the number of times each image was presented during the first phase (objective numerosity). (B) Mean slope of a linear model applied to the data in Figure 1A over windows of three numerosity levels (e.g. ‘1’ reflects window from 1 to 3 on the x-axis of Figure 1A). (C) Mean intercept of a linear model applied over the same windows. Error bars reflect std. error.

slope across participants was 0.64 ($SD = 0.12$, median = 0.64) and the mean intercept was 1.59 ($SD = 0.71$, median = 1.53).

Prior research has indicated a capacity limitation in highly accurate numerosity judgments of about 4 objects (Mandler & Shebo, 1982; Trick & Pylyshyn, 1994). Thus, despite overall high performance, accuracy may be non-stationary across objective numerosity. In particular, the slope of linear regressions over smaller windows of objective numerosity may approach 0 (with a corresponding increase in intercept). Such a finding would support the existence of capacity limitation in numerosity judgments from long-term memory.

We thus ran a linear regression across all possible windows of 3 contiguous numerosity levels for each participant. That is, separate linear regressions were run on windows [1,3], [2,4]...[8,10]. For each window, the slope and the intercept values were averaged across participants (see Figure 1B). To quantify our results, one way repeated-measures ANOVAs were performed for slopes and intercepts. There were reliable main effects of numerosity on both measures (slope $F[7,145] = 9.4$, $p < .01$; intercept $F[7, 145] = 3.9$, $p < .01$). Post-hoc Tukey HSD tests revealed that the slope values for window [1,3] ($M = 1.08$, $SD = 0.28$) were reliably higher than the rest of the slope values, while the intercept values for the same window ($M = 0.50$, $SD = 0.65$) were reliably lower than the rest of the intercept values.

These results suggest that performance starts off near perfect, and declines steadily as a function of objective numerosity. From inspection of Figure 1B, there appears to be a marked drop in slope and increase in intercept after window [3,5], suggesting a capacity limitation around 4-5 repetitions. To quantify these intuitions, we imposed a mixture of perfect and chance performance on the data in Figure 1A. In particular, we tested a mixed linear model to identify at what point along the objective numerosity line at which participants’ performance started to level off and to decline. In this mixed model, at a given point n on the numerosity line, $y = 1 \times x + 0$ for x in $[0, n]$, and $y = 0 \times x + 5.5$ for x in $[n + 1, 10]$. In other

words, we fit the perfect performance linear model to data up to numerosity n and a chance performance model to data from numerosity $n + 1$ to 10. It should be noted that at numerosity 0 the mixed model becomes a complete chance model and at numerosity 10 it becomes a complete perfect performance model. The average model fits across participants are shown in Figure 2A. SSerror was minimized at n from 4 to 8.

Figure 2: Estimated numerosities in (A) Exp. 1, (B) Exp. 2a, (C) Exp. 2b, tested against the following model: at a given point n on the x-axis, $y = 1 \times x + 0$ for x in $[0, n]$, and $y = 0 \times x + 5.5$ for x in $[n + 1, 10]$. Error bars reflect std. error.

Discussion

The results in Exp. 1 demonstrate that participants can make remarkably accurate numerosity judgments from long-term memory. Moreover, participants were unaware that their memory for number would be tested, and therefore this accuracy reflects incidental/automatic encoding of number in memory. Despite overall high accuracy, estimates of numerosity became less accurate when an image has been presented more than 5 times. To our knowledge, this provides the first demonstration of capacity limitations in judgments operating over internal representations, extending and replicating robust findings of similar limits in short-term memory for external visual input (Xu & Chun, 2006).

Experiment 2a

This putative capacity limit observed in Exp. 1 could reflect the fact that we repeated identical images many times. Such repetition could lead to habituation or reduced attention that would impair further encoding. To test this explanation, here we replicate Exp. 1, but present multiple exemplars of the same category once, rather than the same exemplar multiple times. This increased novelty may improve encoding and may facilitate retrieval.

Participants

Twenty students from Princeton University participated in exchange for partial course credit (14 female, mean age 19.7 yrs, $SD = 1.5$). None had served in the previous experiment.

Materials

The materials were identical to Exp. 1 with one important exception: instead of presenting the same exemplar image from each category n times, n distinct exemplars were randomly

drawn from each category and presented only once. For example, if the category *dog* was assigned to the numerosity level ‘3’, then images of three different dog breeds would each be presented once. This increased the novelty and variance within each category, possibly allowing for more accurate estimates about large numerosity levels.

Procedure

The procedure was identical to Exp. 1 except for one aspect of the second phase: category names (e.g., “dog”) were used to elicit estimates of how many images of that category had been presented in the first phase. Names were used rather than images because there were several possible images to choose from for many of the categories. Thus, 50 category names were presented in a random order.

Results

Data were analyzed in the same manner as Exp. 1. Results are shown in Figure 3. To quantify performance, we modeled estimated numerosities as a function of objective numerosities using linear regression (as in Exp. 1). Surprisingly, the mean slope across participants was 0.33 ($SD = 0.16$, median = 0.34), reliably lower than the mean slope ($M = 0.64$) in Exp. 1 ($t[38] = 6.9$, $p < .01$). The mean intercept across participants was 2.72 ($SD = 1.18$, median = 2.58), reliably larger than the mean intercept ($M = 1.59$) in Exp. 1 ($t[38] = 3.7$, $p < .01$). Contrary to our predictions, these results suggest that performance was worse in Exp. 2a vs. Exp. 1, i.e. farther from perfect performance, and closer to a chance uniform distribution.

Figure 3: (A) Mean estimated numerosity plotted against the number of exemplars of each category from the first phase. (B) Mean slope of a linear model applied to the data in Figure 3A over windows of three numerosity levels. (C) Mean intercept of a linear model applied over the same windows. Error bars reflect std. error.

We again explored the presence of a capacity limit by computing the slopes and intercepts of linear functions over windows of objective numerosity. Despite the relatively poorer performance in this experiment, visual inspection of Figures 3B and 3C revealed a qualitative difference between windows [3,5] and [4,6]. One way repeated-measures ANOVAs revealed a main effect of numerosity on intercept values ($F[7, 145] = 5.6$, $p < .01$). The main effect of numerosity on slope values did not reach significance ($F[7, 145] = 1.5$, $p > .05$).

To further characterize a change in accuracy as a function of numerosity we also tested the same mixed linear models on the data in Figure 3A. The model fits are shown in Figure 2B. Again, across numerosities the data were best represented by a model in which performance was perfect up to 5 exemplars and plateaued for larger numbers.

Discussion

Contrary to our predictions, providing multiple exemplars for number estimation did not improve accuracy. In fact, performance was worse than in Exp. 1, where judgments were based on the number of repetitions of a single stimulus. This suggests that performance in Exp. 1 did not asymptote around 5 presentations because of habituation or diminished attention. The worse performance here could reflect poor encoding of images presented only once, or source confusion during retrieval in response to a category label. For example, “dog” may retrieve more than 3 exemplars, with reduced performance reflecting an inability to distinguish exemplars intruding from prior experience. Regardless, despite overall worse performance, participants nevertheless showed consistent capacity limitations to Exp. 1 of approximately 5 memories.

Experiment 2b

While the worse performance in Exp. 2a vs. Exp. 1 can be due to weaker encoding of number, it remains possible that potentially more accurate judgments were hampered by a less informative retrieval cue. To examine this possibility, here we replicate Exp. 1 with category labels during retrieval.

Participants

Twenty students from Princeton University participated in exchange for partial course credit (12 female, mean age 19.1 yrs, $SD = 1.3$). None had served in previous experiments.

Materials

The stimuli used here were the exactly same as those in Exp. 1. The exemplar image from each category was repeatedly presented depending on the numerosity value.

Procedure

The procedure was identical to Exp. 2a. Participants were cued by a category name (e.g. “dog”) and estimated how many times they had seen an image from that category.

Results

Results are shown in Figure 4. We modeled estimated numerosities as a function of objective numerosities using linear regression. The mean slope across participants was 0.46 ($SD = 0.15$, median = 0.48), reliably higher than the mean slope in Exp. 2a ($M = 0.33$; $t[38] = 2.6$, $p < .01$) but reliably lower than that in Exp. 1 ($M = 0.64$; $t[38] = 4.2$, $p < .01$). The mean intercept across participants was 2.31 ($SD = 0.82$, median = 2.06), which was not statistically smaller than the mean intercept in Exp. 2a ($M = 2.72$; $t[38] = 1.3$, $p > .05$) but was reliably larger than that in Exp. 1 ($M = 1.59$; $t[38] =$

2.9, $p < .01$). Thus, after matching retrieval cues, numerosity judgments from multiple repetitions of the same exemplar remain more accurate than those from multiple exemplars of the same category.

Figure 4: (A) Mean estimated numerosity plotted against the number of exemplars of each category from the first phase. (B) Mean slope of a linear model applied to the data in Figure 4A over windows of three numerosity levels. (D) Mean intercept of a linear model applied over the same windows. Error bars reflect std. error.

To explore possible capacity limitations, we computed slopes and intercepts for linear models over windows of three contiguous numerosities. One way repeated-measures ANOVAs revealed main effects of numerosity on both measures (slope $F[7, 145] = 3.2$, $p < .01$; intercept $F[7, 145] = 4.6$, $p < .01$). Post-hoc Tukey HSD tests revealed that the slope value for window [1,3] ($M = 0.90$, $SD = 0.61$) were reliably higher than the rest of the slope values, while the intercept for the same window ($M = 1.26$, $SD = 1.20$) were reliably lower than the rest of the intercepts.

Moreover, from Fig. 1, 3, and 4 the slope and intercept values for Exp. 2b appear to resemble those in Exp. 1 more than those in Exp. 2a. Collapsing across participants, the mean slope values were highly correlated with those in Exp. 1 ($r = 0.84$, $p < .01$), but not with those in Exp. 2a ($r = 0.51$, $p > .05$). Capacity limitations were examined for each numerosity level where performance plateaued (see Fig. 2C). As in previous experiments, the mixed model fit best at 5.

Discussion

This experiment reveals that judgments of numerosity are more accurate for multiple repetitions of the same exemplar than for single presentations of multiple exemplars of the same category. The category label did somewhat impair performance, but critically, cannot entirely explain the poor performance in Exp.2a. Across three experiments we observed evidence that unexpected judgments of numerosity from past experience are accurate and subject to capacity limitations.

Experiment 3

Capacity limitations are a signature property of perceptual number processing. To further build our case for a similarity between external and internal number estimation, we consider two additional classic effects in the numerosity literature: the *distance effect* and the *magnitude effect*. These

psychophysical effects are evident when two quantities must be discriminated. The distance effect refers to the relative ease with which participants can discriminate two quantities that are farther apart in number space (e.g., 2 vs. 3 compared to 2 vs. 4). The magnitude effect refers to the fact that a given numerical distance can become harder to discriminate at higher magnitudes (e.g., 2 vs. 3 compared to 8 vs. 9). We explore whether these psychophysical effects also occur when discriminating numerosities defined by long-term memory.

Participants

Twenty students from Princeton University participated in exchange for partial course credit (11 female, mean age 19.6 yrs, $SD = 1.6$). None had served in previous experiments.

Materials

The stimuli in Exp. 1 were used. The exemplar image of a category was repeatedly presented depending on the numerosity value.

Procedure

The first phase was identical to Exp. 1, such that all number encoding was incidental. In the second phase, participants judged which of two images they had seen more times during the first phase. Based on numerosity levels, we paired images so as to fully cover the space of possible distances and proportional distances (for the magnitude effect). At distance of 1 we paired an image that was presented n number of times with the one that was presented $n + 1$ number of times. Since numerosity levels range from 1 to 10, there were 9 pairs at the distance of 1 (e.g., 1 vs. 2, 2 vs. 3, etc.). The same pairing method was applied to the distances of 2, 3, 4, and 5, which resulted in 8, 7, 6, and 5 pairs, respectively. Thus, a total of 35 pairs were generated. For each pair, two images were presented side by side on the screen and participants judged which image appeared more times by pressing one of two buttons for left or right. The order of pairs was randomized for each participant and the position on the screen of the image with the larger numerosity was randomized on each trial.

Results

To assess distance effects, we pooled all of the pairs of each distance within participant and computed mean accuracy and RT. To assess magnitude effects, we conditioned every distance on the smaller number of the pair (e.g., 1 vs. 3: distance = $2/\text{base} = 1$). Mean accuracy and RT were again computed within participant for each bin. Results are shown in Fig. 5.

As visible in Fig. 5A and 5B, accuracy increased while response time decreased as a function of distance (the opposite of a speed/accuracy tradeoff). Collapsing across participants, there was a strong correlation between accuracy and distance ($r = 0.98$, $p < .01$) but a weaker correlation between response time and distance ($r = -0.61$, $p > .05$). To test the reliability of these relationships, we correlated accuracy and response time with distance within each participant, transformed the resulting correlation coefficients to Z scores using Fisher's

Figure 5: (A) Mean accuracy as a function of distance. (B) Mean response time as a function of distance. (C) Mean accuracy as a function of the smaller number in a pair and also the distance (e.g. D1 = distance of 1). (D) Mean response time as a function of the smaller number and also the distance. Error bars reflect std. error.

transform, and then compared these values against the null relationship of 0 using a one-sample t-test. Accuracy was positively correlated with distance (mean $z = 0.21$, $t(19) = 5.72$, $p < .01$), and response time was negatively correlated with distance (mean $z = -0.08$, $t(19) = 2.15$, $p < .05$). Thus, participants were able to discriminate between two numerosities in long-term memory, and performed better as a function of the absolute number difference.

To assess the magnitude effect, we performed repeated-measures ANOVAs on accuracy and response time as a function of the base and the distance of each pair. We could not include both the base and distance factors in a two-factor ANOVA because the design was not factorial (e.g., there were no distance = $5/\text{base} = 9$ trials), and thus used separate one-way ANOVAs. There were main effects of base and distance on accuracy (base $F[8, 683] = 18.5$, $p < .01$; distance $F[4, 691] = 50.1$, $p < .01$). There were also main effects of base and distance on response time (base $F[8, 683] = 16.4$, $p < .01$; distance $F[4, 691] = 13.9$, $p < .01$). The robust effect of base demonstrates a magnitude effect in numerosity judgments from memory.

Discussion

When judging which exemplar appeared more times, participants were more accurate and faster when the distance was larger. Holding the distance constant, participants were also more accurate and faster when the base number of presentations was relatively small.

General Discussion

We have found that unexpected numerosity judgments based on long-term memory can be highly accurate, and that this accuracy is maintained for up to a small quantity of retrieved

memories. These findings are largely in agreement with studies of numerical judgments based on immediate visual perception. Moreover, judgments of numerosity were more accurate for multiple repetitions of the same exemplar than for single presentations of multiple exemplars. This rules out the possibility that apparent capacity limitations reflect habituation or reduced attention. The fact that multiple exemplars were in fact *worse* than single exemplars could relate to failures of source monitoring (Dougherty & Franco-Watkins, 2003; Johnson, Hashtroudi, & Lindsay, 1993): when cued by a category, participants may have been unable to screen out extra-experimental memories. Such failures may have been minimized when retrieval was cued by an image rather than a category label, but the effect persisted when retrieval cue was equated. When discriminating between two incidentally encoded numerosities, performance increased with distance but decreased as the magnitude or the absolute size of the numbers increased. These results were again in line with findings on numerosity comparison based on immediate visual perception (Whalen et al., 1999; Barth et al., 2003).

Since numerosity judgments based on long-term memory exhibited similar properties and constraints as compared to immediate perception, our findings are consistent with the existence of a common underlying numerosity mechanism for perception and memory. While our focus has been on drawing this analogy, there may also be important differences between the perception and memory of number information. For example, while the perception of number has been well-characterized by a hard capacity limit on exact judgments, memory for number may be better characterized by a more continuous logarithmic or power law function. Moreover, we do not yet know whether input representations retrieved from long-term memory are the same as those constructed during online perception (e.g., whether numerosity is estimated over a set of retrieved episodes, or directly read out from a symbolic or analog representation of quantity updated during encoding). These are important questions for future research, but our results nevertheless provide initial evidence for a striking symmetry between snap judgments of number from a single sensory stimulus, and delayed (surprise) judgments based purely on long-term memory. In sum, mechanisms that seem to exist in the service of sensory processing may have broader functional roles in cognition, operating similarly over input from internal or external sources.

Mapping number words to approximate magnitudes: associative learning or structure mapping?

Jessica Sullivan (jsulliva@ucsd.edu)

David Barner (barner@ucsd.edu)

Department of Psychology
University of California, San Diego

Abstract

How do we link number words to the magnitudes they represent? We investigated the roles of associative learning and structure mapping in linking the Approximate Number System to number words. Four tasks demonstrated that individuals have strong associative links between magnitudes and number words for relatively small sets, but have weak associative links for larger sets. These results point to multiple mechanisms for the mapping of number words to magnitudes.

Keywords: Language acquisition, approximate magnitudes, word learning, number words

Introduction

How does language represent human numerical knowledge? Are the referents of numerals determined primarily by inference and logical relations between words? Or do we identify the referents of words like *twelve* and *fifty-seven* by associating them, item-by-item, with sets in the world? Humans can represent the approximate numerical magnitude of a set nonverbally using the Approximate Number System (ANS), and previous research has shown that our system of number language is deeply linked to the ANS: adults recruit the ANS when estimating the cardinality of rapidly presented arrays, and judgments about verbally presented numerals show many of the same biases as nonverbal judgments about quantities (Barth, Kanwisher, & Spelke, 2003; Whalen, Gallistel, & Gelman, 1999; Piazza, Izard, Pinel, Le Bihan, & Dehaene, 2004; Holloway & Ansari, 2008; Duncan & McFarland, 1980). We know that mature mathematical thinkers can relate their verbal number system to the nonverbal ANS—but we don't know *how* these systems are mapped onto each other.

By some accounts, number words gain their numerical content in part via a mapping to the ANS (Verguts & Fias, 2006; Piazza, Pinel, Le Bihan, & Dehaene, 2007; Mundy & Gilmore, 2009). However, surprisingly little is known about the nature of this mapping, and descriptions of possible mechanisms are rare in the literature. It is therefore not well understood what roles associative and inferential processes play in relating number words to ANS representations. One possibility is that as humans accumulate experience with number words, they form item-specific associations between individual words (e.g., *ten*) and corresponding magnitudes (e.g., approximately 10 objects). This view, which we will call the associative mapping hypothesis (AM), predicts that the strength of mappings should vary according to how frequently words are used to refer to perceptually available

quantities. Also, it predicts that mappings should be relatively independent of one another, such that a change in one mapping does not automatically impact another mapping. The AM hypothesis is supported by evidence from children's early mappings of small number words: children learn the associations between their first number words and the magnitudes they refer to one at a time, taking nearly two full years to learn the associations between the number words "one" through "four" and the magnitudes they denote (Wynn, 1992).

A problem with the AM hypothesis is that humans may get only limited experience with the denotations of some number words, and no experience at all with others. It seems implausible, for example, that experience with 1 million things would be required to support estimates for sets of this size. Instead, it appears that inferential abilities are required to give meaning to unfamiliar quantities, perhaps on the basis of more familiar amounts. One possibility, for example, is that associative learning about small quantities (e.g., 1 – 10) supports a structure mapping (SM): a linking of representations in one domain to those in another on the basis of their common structure (Izard & Dehaene, 2008; Thompson & Opfer, in press).

One signature of structure mapping is that when a subject's response for a given quantity is changed via feedback (i.e., calibrated), responses for other quantities should shift accordingly. Evidence for this comes from Izard & Dehaene (2008), who showed that mislabeling a visually presented set (e.g., calling a set of 30 dots "twenty-five") led participants to shift their estimates not only for the calibrated quantity, but for all quantities tested. However, this study provided only small amounts of miscalibration, resulting in tiny differences between conditions. For example, even for the most extremely miscalibrated trials, participants mapped the number word "thirty" onto arrays with an average set size between 31.5 and 33.7 (neither of which is perceptually discriminable from 30 for normal adults). As a result, although it appears that SM plays some role in estimation, it remains unclear how malleable estimation behaviors are, and thus what the relative roles of AM and SM are in the mapping of number words to the ANS.

The present study explored the nature of the relationship between the ANS and the count list, and the relative contributions of associative and structural mapping. We hypothesized that neither mechanism, in isolation, could explain how number words are mapped to the ANS.

Whereas AM is limited by the experiences that individuals have with particular magnitudes, in order for a SM to have content, it must be supported by reliable mappings between small number words and magnitudes. Without associative mappings for at least some number words, we submit, no structure mapping could take place. To our knowledge, no previous study has directly tested the contribution of these two mechanisms, and as a result, little is known about their relative contribution to number word mappings. To test our hypothesis, we conducted an experiment with four within-subjects measures that probed for evidence of associative and structural mappings at different numerosities.

In the Calibrated Estimation task, we measured participants' accuracy at labeling sets after they were provided misleading information about the range of set sizes to be presented. We predicted that quantities that have strong associative mappings should be less susceptible to calibration than those with weaker mappings. As in previous studies, we expected that participants' estimates of magnitudes would be influenced by the feedback they received. However, in the present task, we made two critical methodological changes. First, we provided only verbal calibration. While in past studies participants were shown an array and then told that it contained x dots (where x was either an accurate or inaccurate number word label), in the present study we did not mislabel arrays. Instead, we simply stated that "the largest set you will see is x ". In this way, we ensured that any influence of feedback was not because participants constructed new associative mappings, but was due purely to an inference about the structure mapping relation. A second difference was that we provided much more extreme calibration than in previous studies, in order to test the strength of associative mappings throughout the number line. We reasoned that misleading feedback should not influence estimation performance for any magnitude with a strong AM link to the number system, whereas structurally linked magnitudes should be quite susceptible to calibration.

An assumption in our analysis of the estimation task is that a participant's individual estimates act as inputs to a structure mapping, and that each act of estimation therefore constrains later estimates in an experiment. On this view, we predicted that a very similar task in which participants were asked to match a label to one of two visually presented sets would disrupt the structure mapping process. We reasoned that presenting two sets to participants would cause them to experience uncertainty, and thus prevent them from calibrating their mappings across trials. As such, we predicted that performance on this task should suffer for number words that have weak associative mappings to magnitudes. Where stronger AMs exist (e.g., for smaller numbers), performance should not suffer as much, since by our hypothesis the forced choice task relies on the associative strength between the number word and its corresponding magnitude representation. Although past studies have used a forced choice method to test mappings in young children (Lipton & Spelke, 2005; Gilmore &

Mundy, 2009), these studies provided calibration before the study in the form of a familiarization phase. Our study, in contrast, sought to remove all forms of feedback, whether from the experimenter or from trial-to-trial self-calibration, in order to test the strength of associative mappings at different magnitudes.

We conducted two additional tasks as within-subject controls for the Calibrated Estimation and Number Matching tasks. The first was an Uncalibrated Estimation task, which served as a within-subject baseline for the Calibrated Estimation task. The second, a Numerical Discrimination task, used stimuli identical to those in the Number Matching task but asked subjects to judge which of the two sets on each trial was more numerous. This ensured that participants were able to discriminate the quantities used in the Number Matching task, and that any difficulties with the forced choice task were due to their number word mappings and not other stimulus properties.

For both the Number Matching task and the Calibrated Estimation task, we predicted that participants would exhibit strong associative mappings for some number words, resulting in smaller effects of calibration and higher levels of success on the forced choice task. In particular, we predicted that the strength of associative mappings would be strongest for the smallest number words, due to relatively greater experience with these words and their corresponding quantities. Corresponding to this, we also predicted that larger magnitudes would be more susceptible to miscalibration in estimation, and be more difficult to map to number words in the forced choice task.

Materials and Methods

Participants

Thirty adults from the UCSD community participated for course credit. One additional participant was excluded from analyses for failure to complete all tasks.

Procedure

Participants were seated approximately 40 cm from a 27" Mac OSX computer screen and completed 4 computerized tasks. Half of the participants completed the Number Matching task first, and half completed the Discrimination task first. All participants then completed first the Uncalibrated and then the Calibrated Estimation task.

Number Matching: This task evaluated participants' ability to match number words with one of two visually presented sets. Participants heard a number word, saw two arrays of dots flash sequentially on a computer screen, and judged which array best matched the word. Stimuli were sets of red dots on a black screen, and were presented for 400 ms. Trials compared sets that differed in numerical magnitude by either a 1:2 ratio or 3:4 ratio. Sets were matched for density on half of the trials and for total surface area on the other half, and comparisons ranged from small (4 vs. 8) to large (370 vs. 740). For 1/3 of the trials, the smaller of the two sets presented contained fewer than 30

items (Small Number Trials), for 1/3 it contained more than 30 and fewer than 110 (Medium Number Trails), and for the remaining 1/3, it more than 110 items (Large Number Trials).

Numerical Discrimination: This task served as a within-subjects control for the Number Matching task to ensure that participants could discriminate the quantities presented. The stimuli and procedure were identical to the Number Matching task, except that participants indicated which set contained more dots (instead of matching a word with a set).

Calibrated Estimation: This task tested the malleability of participants' numerical estimates. Participants saw sets of dots and estimated their numerosities, recording their estimates using the numeric keypad on a computer keyboard. Although the largest set that participants saw was 350 in all conditions, participants were told that the largest set they would see was either 75 ($N=10$), 375 ($N=10$), or 750 ($N=10$). Critically, this misleading feedback could not be used to alter associative mappings since, because unlike in previous calibration studies, the incorrect number word anchor was not paired with an array, and thus participants could not form new associative mappings between magnitudes and number word labels (e.g., Izard & Dehaene, 2008; Shuman, unpublished thesis). Instead, this feedback could only have influenced participants' notions about the structure and range of magnitudes.

Stimuli were sets of red dots on a black screen. Fifteen numerosities ranging from 8-350 were presented 36 times each. Each numerosity was matched for both density (15 trials) and total occupied area (15 trials) with each other numerosity presented, and non-numerical properties of the sets were otherwise varied for the remaining 6 trials. Participants received 270 of the possible 540 trials in the Calibrated condition, and 270 in the Uncalibrated condition. Trials were presented in random order.

Uncalibrated Estimation: This task served as a within-subjects control for the Calibrated Estimation task to provide a baseline of the participant's Uncalibrated estimates. Stimuli and instructions were identical to those in the Estimation task, except participants were given no information about the largest set they would see.

Results

Number Matching and Discrimination

If participants have associative mappings between individual number words and approximate magnitudes, then they should be able to use these mappings to guide the labeling of sets in the Number Matching task. For example, if the number word *twenty* is associatively mapped to a mental representation of 'about 20 things', then participants should never match the word *twenty* to an array that is discriminably different from 'about 20' (e.g., 40). In other words, for all magnitudes that have associative mappings, participants should perform equally well on the Discrimination and Number Matching tasks, because

discriminably different magnitudes should be mapped to unique number words.

We first explored whether performance differed on the Number Matching task, as compared to the Discrimination task. Qualitatively, every participant performed worse on the Number Matching task than on the Discrimination task, indicating that matching a number word to the correct array is more difficult than judging which array is more numerous. A paired-samples t-test revealed that this trend reached significance (all $p < .05$) for 21/30 participants (binomial probability $p < .01$). This effect was consistent across the range of comparisons presented: participants were significantly less accurate on the Number Matching task than the Discrimination task for Small, Medium, and Large Number Trials (all $p < .01$).

Table 1: Mean accuracy on the Discrimination and Number Matching tasks by magnitude of smaller set

Set Size	Discrimination	Number Matching
Small (<30)	92%	85%
Medium	85%	63%
Large (>110)	82%	70%

To explore in greater detail whether magnitude influenced accuracy on these two tasks, we compared accuracy on the Number Matching task to accuracy on the Discrimination task for each magnitude presented. Interestingly, participants did *not* perform significantly worse on the Number Matching Task than the Discrimination Task for any of the comparisons containing magnitudes smaller than 15 (Dunnett's mean comparison, all $p > .05$)¹. This suggests that participants may have associative mappings for relatively small number words. Consistent with this, accuracy on the Number Matching task was not constant for all magnitudes tested: a regression of accuracy onto set magnitude by ratio revealed an effect of ratio ($F(1,1954)=22.4$, $p < .01$) and an effect of set magnitude ($F(1,1954)=70.5$, $p < .01$), but no interaction ($F(1,1954)=1.4$, *ns*). This pattern of performance indicates that participants had greater difficult matching labels to larger sets relative to smaller ones, and is consistent with the hypothesis that small, but not large, magnitudes are associatively linked to number words.

To explore this trend further, we compared accuracy on the Number Matching task for Small, Medium, and Large Number Trials. Accuracy was significantly different as a function of set magnitude ($F(2,987)=54.3$, $p < .01$), and a post-hoc comparison of mean accuracy revealed that

¹ Accuracy also did not differ between the Number Matching and Discrimination tasks for the four largest comparisons presented. This effect appears to be driven by trials where the larger set was also the correct set: participants may have developed a simple response heuristic for these trials like "when I hear an unusually large number word, I select the larger of the two sets". This is unlikely to be evidence of associative mapping for large sets.

participants performed significantly better on Small Number Trials than either Medium or Large Number Trials (both $p < .01$), but that accuracy on the Medium and Large Number Trials did not differ significantly from each other ($t = -.57$, ns). Participants did not struggle to match number words to magnitudes when the words presented were relatively small, yet accuracy declined rapidly as a function of set magnitude, and remained low for the largest sets.

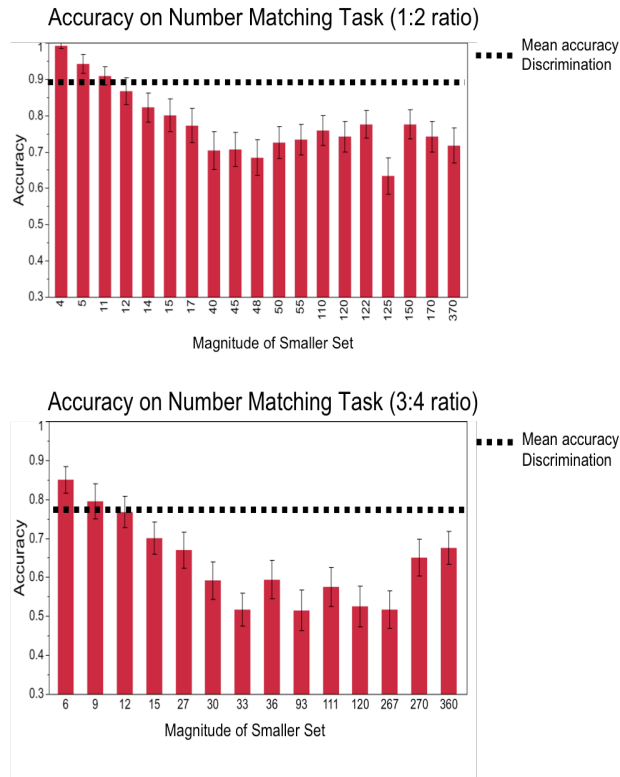

Figure 1: Accuracy on Number Matching task as a function of magnitude of the smaller set being compared

Estimation and Calibrated Estimation

Before completing analyses, we excluded all responses smaller than 2, and all responses more than a factor of 10 larger or smaller than the presented numerosity, as these were likely to be typos. Additionally, we removed outliers on a participant-by-participant basis by excluding all data points more than 3 SD from the mean of each participant's estimate of each presented magnitude (total exclusions: 313/15,450 data points)².

As a group, participants provided estimates that were related to the presented magnitude, and that were influenced by misleading feedback (miscalibration): a regression of estimates onto magnitude by calibration type revealed a significant relationship between set magnitude and estimate

² We also analyzed our data both excluding and including estimates of "75", "375", and "750" to ensure that any effect of calibration was not due to participants' repetition of the number word they had been miscalibrated to. There was no difference at either the group or individual level of analysis.

($F(1,15129) = 3912.5$, $p < .01$), a significant effect of Calibration ($F(1,15129) = 605.3$, $p < .01$), and a significant interaction of Calibration and magnitude ($F(3,15129) = 256.3$, $p < .01$). Participants were influenced by misleading feedback, and the influence of miscalibration differed as a function of magnitude.

To explore the influence of feedback at an individual level, we performed the identical regression on each individual's data. 24/30 participants showed an effect of calibration: 9/10 participants who were calibrated to 75, 8/10 who were calibrated to 375, and 7/10 who were calibrated to 750 (binomial $p < .01$ for each calibration type). Of the 24 participants who were influenced by calibration, 21 demonstrated a significant interaction of Calibration and magnitude of set (binomial $p < .01$), indicating that calibration influenced estimation patterns differently as a function of magnitude. Specifically, participants were less influenced by misleading feedback for smaller magnitudes, and were more influenced for larger magnitudes.

Figure 2: Estimation as a function of calibration

Next, we compared mean estimates for each presented numerosity in the Calibrated vs. Uncalibrated conditions. This isolated the magnitudes for which each participant³ demonstrated the effects of miscalibration (Dunnett's mean, all $p < .05$). Overall, participants were influenced by calibration for relatively small magnitudes: one quarter of all participants provided different estimates for sets containing 8 items in the Calibrated vs. Uncalibrated conditions, and all but four participants were influenced by misleading feedback for at least one magnitude under 100. Participants were more resilient to misleading feedback for small magnitudes than large magnitudes, yet participants incorporated misleading feedback into the full range of estimates, and did not simply alter estimates for the largest sets presented.

Table 2: Smallest magnitude for which participants were influenced by calibration

Calibration	Mean	Median
75	35	61
375	36	42
750	20	45

³ Of the 24 who were influenced by calibration

Discussion

This study provides evidence for at least two mechanisms through which number words are mapped to approximate magnitudes. For the smallest numbers we tested, participants were accurate at matching arrays to number words, and they were resilient to misleading feedback. This suggests that, at least for relatively small and familiar magnitudes, adults may form associative mappings between number words and ANS representations. However, for larger magnitudes, adults struggled to correctly match number words with arrays, and were highly influenced by misleading feedback when estimating, making it unlikely that associative mappings play an important role in relating larger number words to magnitudes.

To our knowledge, this is the first study to demonstrate that adults do not directly link each number word in their count list to an ANS representation of approximately that magnitude. While past studies have shown that adults' estimates can be biased by misleading feedback (e.g., Izard & Dehaene, 2008; Shuman, unpublished thesis), in this previous research, the degree of miscalibration was minimal, and the sets that participants labeled as "thirty" before and after miscalibration were not discriminably different from each other using the ANS: this pattern of performance is consistent with either an associative mapping or structure mapping account. However, in the present study, participants failed to correctly match a number word to one of two discriminably different sets, and consistently provided different estimates of a set's magnitude when provided misleading information than when allowed to estimate without constraints. This suggests that adults do not possess associative mappings between large number words and magnitudes.

We posit a structural mapping hypothesis to account for the mappings adults make between large number words and magnitudes. By this hypothesis, adults recruit associatively mapped information about small numbers in order to map larger number words to magnitudes. We know that even large number words bear some relation to ANS representations of magnitudes, because adults' processing of verbal number words exhibit signatures typical of those found in perceptual judgments of numerosity using the ANS (e.g., Duncan & McFarland, 1980). Because of this, we suggest that structural mappings are constructed and supported by knowledge of associatively mapped magnitudes. This process may recruit more domain-general analogical or comparative mechanisms previously linked to the acquisition and extrapolation of spatial, numerical and categorical information during development (e.g., Gentner & Namy, 2006). As a result, structural links between number words and magnitudes may be based on analogy, proportional reasoning, or an understanding of the ordinality of both the verbal and nonverbal number systems. While each of these possible mechanisms for structure mapping is theoretically plausible and consistent with the current data, the present study cannot disambiguate between them. However, future research manipulating the availability and

content of 'anchor' sets will allow us to construct a precise model of how small-number information is incorporated into structural mappings, by exploring how manipulating the availability of information about small quantities influences judgments about large quantities.

The present study also raises several developmental questions about the acquisition of number language. While much has been learned in recent years about the procedure of number word learning, little is known of the mechanisms that drive this learning. For example, we know that immediately after learning how counting represents sets, many children fail to map larger number words to larger sets in estimation tasks—however, by age 5, most children successfully provide larger estimates for larger magnitudes (Le Corre & Carey, 2008, Barth, Starr, & Sullivan, 2009). Clearly, 5-year olds have learned something about the count system that the 4-year olds have not—but what? The present study demonstrates that it is unlikely that these older children have improved at estimation solely because they have expanded their system of associative mappings between number words and magnitudes: even adults showed little to no evidence of any direct associative link between words like "one hundred" and sets of 100 things. Instead, children who are successful estimators must have learned something about the structural mapping of the count sequence onto magnitudes. What kind of structural relationships have these children learned?

Additionally, if children's structural mappings are constructed early in life, how much of the count sequence must be associatively mapped in order to support adult-like structural mappings? While the present study suggests that adults may have associative mappings for magnitudes as large as 20, we do not know which of these associative mappings are necessary to support a structure mapping. It may be the case that children need only to associatively map the smallest numbers (e.g., 1-10) in their count system in order to have enough information about the number system to develop a rich structural mapping between number words and magnitudes—by this theory, any additional associative mappings gained en route to adulthood (e.g., mappings between 10-20) are simply the result of additional experience with number words and magnitudes, and are not necessary to support structure mappings. However, it is also possible that children must have an adult-like system of associative mappings in order to support a structure mapping system. By this view, children would construct associative mappings between words and magnitudes for the numbers 1-20 *prior* to creating a structure mapping for larger number words. A continuation of the present line of research with children will help distinguish between these two possibilities, and in doing so, shed light on the nature of the inferences that children make about number words as they construct mappings between number language and magnitudes.

A better understanding of the roles of structural and associative mapping in the development of number knowledge may also help to illuminate other poorly

understood developmental phenomena in numerical cognition. For example, one signature of immature estimation ability is a tendency of young children to provide ‘logarithmic’ looking estimates: overestimating small numbers and underestimating large numbers. This tendency largely disappears in the 0-100 range by age 7, and in the 0-1000 range by age 9 (Booth & Siegler, 2006). What new information about the number system do these older children have? Several researchers have posited that the shift from immature-and-logarithmic to mature-and-linear patterns of estimation stems from a change in these children’s underlying numerical representation (Siegler & Opfer, 2003; Booth & Siegler, 2006), or from an increased ability to reason about proportions (Barth & Paladino, 2010). However, the present study leads to an additional (though perhaps not mutually exclusive) hypothesis. Perhaps the shift towards more adult-like estimation can be best explained either by a realignment of structural mappings or to a refinement in the accuracy of the associative mappings that support these structure mappings. These two possible sources of the log-to-linear shift in estimation lead to distinct predictions of how both the younger and older children will reason about small and large numbers.

In conclusion, the present study failed to find evidence of associative links between most number words and magnitudes. Instead, the present study demonstrates that number word meaning is constructed through multiple mechanisms, and not necessarily through associations to real-world exemplars of their referents. By emphasizing the relative roles of associative and structure mappings, we hope to provide a new lens through which to view many of the developmental questions about number language acquisition, and in doing so, to open up new avenues for investigating the kinds of inferences we make about number words.

Analogue Magnitudes and Knower-Levels: Re-Visiting the Variability Argument

James Negen and Barbara W. Sarnecka ({jnegen,sarnecka}@uci.edu)

Department of Cognitive Sciences, 2201 Social & Behavioral Sciences Gateway Building
Irvine, CA, 92697-5100 USA

Abstract

What cognitive system(s) initially provide the numerical content that defines the cardinal number words for young children? Le Corre and Carey (2007) argued that the answer cannot be the analogue magnitude system. Here we re-examine the most powerful of their arguments, which concerned the system's signature *scalar variability* (the standard deviation of answers grows linearly with the mean). Using adult data, we explore a nuance of this signature: that while it is certainly true of the continuous, underlying activation in the brain, it may not always be true of the number-word responses that people produce. With this in mind, we re-examine the aforementioned variability argument; contrary to Le Corre and Carey, we conclude that young children's estimates of small set sizes (up to and including their number-knower-level) *do* show scalar variability.

Keywords: Cognitive Science, Psychology, Cognitive Development, Perception, Bayesian Modeling, Developmental Experimentation, Human Experimentation

How children acquire the meaning of number words is a question of great interest in cognitive development. In infancy, the child can create exact representations only of very small sets (up to 3 items) and can create only approximate representations of larger sets (for review, see Feigenson, Dehaene, & Spelke, 2004). It is from these foundations that the child must build an understanding of integers.

There are at least two families of theories about the role that the analogue magnitude number system plays in number-word learning. One says that (a) the numerical content of number words initially comes from the analogue magnitude system (i.e., the representations of numerosity are only approximate) and (b) number-word meanings are learned in the same way as any other words for antecedently available percepts (e.g., Dehaene, 1997; Gelman & Galistel, 1978; 2004). On this view, the child essentially understands the logic of numbers from the beginning, but must learn the *exactness of number words*. That is, the child must learn that “seven” means exactly 7 – not approximately 5 to 9.

The other family of theories contend that (a) the numerical content initially comes from enriched parallel individuation representations, (which are exact, but cannot go higher than 3 or 4) and (b) number-word meanings are learned one at a time, and in order (e.g., Carey, 2009; Le Corre & Carey, 2007; Sarnecka & Lee, 2009; Lee & Sarnecka 2010). On this view, the child figures out the principle of cardinality and the logic of the integer system

by extrapolating from the first three or four exemplars—the words *one*, *two*, *three* and possibly *four*.

Our proposal takes something from both views. We consider it adequately demonstrated that children do learn the first few cardinal number-word-meanings one at a time, and in order (Carey, 2009; Le Corre, Van de Walle, Brannon & Carey, 2006; Lee & Sarnecka, 2010; Sarnecka & Lee, 2009; Wynn, 1990, 1992). Thus, in this paper we will use the knower-levels framework, wherein a *one-knower* is a child who just knows “one”, a *two-knower* knows “one” and “two”, etc., and a *CP-knower* understands how counting works and what it is used for. Though this view has historically been paired with the view that the numerical content of these words comes exclusively from enriched parallel-individuation representations, that linkage is not logically necessary.

This issue has been examined before by Le Corre and Carey (2007), who made a forceful argument against the analogue magnitude system being involved in number-word learning. The argument was based on variability signatures: Noise in analogue magnitude representations grows at the same rate as the number of objects being estimated. In other words, if you briefly show people 10 dots, and ask them how many are there, they will respond with variability σ . If you then show them 20 dots, they will respond with variability 2σ . More formally, the standard deviation of a person's responses, divided by the mean of their responses, will be a constant (the ‘coefficient of variance’, hereafter COV). This *scalar variability* is a defining characteristic of the analogue magnitude system throughout the lifespan.

Le Corre and Carey (2007) argued that children's estimates of the number of items in a picture did not show scalar variability. Le Corre and Carey used a Give-N task (where children give a certain number of items to the experimenter) as well as a Cards task (where children quickly estimate the number of items on a card). Le Corre and Carey first identified children who were one-, two-, three-, or four-knowers as measured by the Give-N task. Then they analyzed the variability of children's estimates (on the Cards task) for sets of 1, 2, 3 and 4 items. The mean COV grew from 0 (for estimates of 1 item) to 0.4 (for estimates of 4 items), leading Le Corre and Carey to conclude that early on, the cardinal meanings of these words are not defined in terms of the analogue magnitude system.

However, there is a problem with this argument. Logically, scalar variability could be found in two places: in the underlying activations in the brain, or in the distribution of number-word responses. Most studies of the analogue magnitude system in adults treat these as the same. That is, they assume that number-word responses transparently

reveal the underlying activations. This is a reasonable assumption when the numbers involved are large. But with small numbers, the available words (i.e., *one*, *two*, *three* and *four*) may not be sufficient to express the variation in the underlying activations. Below, we describe these ideas in more detail, then support our argument with some new data from adults.

Scalar Variability of Activations versus Responses

Creating and using an analogue magnitude representation is a multi-step process. One place that scalar variability might be found is in the actual number-word responses that people produce. For example, if you show someone 10 and 20 dots in alternation, over and over again, and they say something like: 9, 22, 11, 18, ... their responses could show scalar variability. That is, the standard deviation of the responses could grow linearly with the number of items to be estimated.

Another place you could look for scalar variability would be in a latent, real-valued variable – possibly the logarithm of activation in certain ‘number neurons’ – that describes the person’s perception of how many dots are present. Thus, when shown 10 and 20 dots, the person may experience something like 8.82, 21.58, 11.21 and 18.44 units of activation. But of course, participants do not say that there are 11.21 dots on the screen – they just say “eleven”¹. Scalar variability of the activations means that the standard deviation of this latent variable (as opposed to the responses) grows linearly with the number of dots shown.

For large numbers, these two ideas make almost exactly the same predictions. However, the predictions differ for smaller numbers. Imagine that a person says “four” when shown four dots, on a large number of trials. The variability in responses is zero, but the variability in activations could be much larger. The person might be experiencing anywhere from 3.5 to 4.5 units of activation on each trial. If we add the constraint that activation must be normally distributed, then the continuous standard deviation could be as large as 0.1 while the discrete standard deviation stays very near zero (out to several decimal places).

An analogy may be helpful: Imagine you are about to play a game with a friend. You will see a number of dots on a screen. Your friend has to say how many there are, but can’t see the screen. You have to tell your friend how many dots there are, but you’re not allowed to speak – only to draw a single line on a piece of paper. Your partner can then measure the line accurately with a ruler. Before the game starts, you agree on a simple code: 1 inch = 1 item. It’s easy to see that the average amount of error in your line length will be proportional to the number of items.

Let’s imagine that, when you see 2 items, all of your lines fall between 1.25 and 2.75 inches; you are accurate to $\pm .75$ inches. Now cut that in half for when you see 1 item, and

you are accurate to $\pm .375$ inches. As such, your line lengths show scalar variability. But what about the answers your partner gives? There will be some variation at 2 (when she rounds 2.75 inches to 3, for example) but none at 1 (where all lines fall between .625 and 1.375 inches, and so are rounded to 1). The zero variation in her responses for trials of 1 cannot be half of the above-zero variation for trials of 2.

Thus, the length of your lines can show scalar variability while the number-word answers after measuring do not. This happens whenever the variation is small compared to the minimum distance between values after rounding. In more traditional statistical language, the variation is very fine-grained and the rounding is very coarse-grained, leading to the phenomenon of *heaping*: all of the data gets heaped onto one point.

Le Corre and Carey (2007) argued that one could expect to see scalar variability in the verbal responses all the way down to cards with 1 item. This claim was based on work by Cordes, Gelman, Galistell, and Whalen (2001). In that paper, the experimenters had instructed participants to tap a space bar a certain number of times in a steady rhythm, while saying “the” with each press to suppress counting. Cordes et al. found that participants’ verbal responses showed scalar variability for numbers down to 2. However, they did not test on the number 1, and participants showed a relatively high amount of noise in their answers (a standard deviation of around .4 at minimum). As such, Cordes et al.’s data don’t tell us where the variability was located: at such high levels of noise, the two sources of variability make much the same predictions.

The Present Study

In experiment 1, we examine the two sources of variability by extending the experiment by Cordes et al. (2001). Like them, we showed adult participants a numeral on a screen, and the participants’ task was to tap the space bar that number of times. They had to do this in a steady rhythm while repeating “the” with each tap. We made one modification to reduce the amount of noise in the data: participants’ responses were slowed to 2 Hz by having them tap along with a metronome.

Figure 1: Different behavioral predictions for scalar variability in activations vs. responses.

¹ It may be more satisfying to imagine that this is the center of a confidence distribution. In other words, the participant would experience 11.21 units of activation, and be most confident in the integer 11 (which is closest), followed by 12, then 10, then 13, etc.

The two predictions from the two sources of scalar variability are illustrated in Figure 1. Conveniently, the pattern predicted by scalar variability in the responses is identical to the null hypothesis for a repeated-measures ANOVA.

In Experiment 1, we show that small-number estimation data from adults is consistent with the assumption of scalar variability in the activations. In experiment 2, we develop a simple model that incorporates number-knower-levels and the analogue magnitude system, and we test it using data from children's performance on the Give-N and Cards tasks. We find that the model provides a good fit to these child data, with no problems of variability.

Experiment 1

Methods

Participants Eleven undergraduates were recruited from the University of California, Irvine and successfully completed the task. Two additional participants were excluded because they could not keep a steady rhythm during training trials. Participants were each given a half point of extra credit in an introductory Psychology course.

Procedure On each trial, participants saw a numeral on the screen. They were asked to tap the space bar that many times, along with a 2Hz metronome, saying "the" with each tap to suppress counting. Participants were asked to avoid trying alternate strategies, like chunking, and to just keep tapping until they felt the number had been reached. The numerals used were 1, 2, 3, 4, 5, 6, 9, 12, and 15. For training, there were two trials with each number, and all participants declined the offer to go through training again. For data recording, there were 40 trials with the number 1, and 20 trials with each of the other numbers, for a total of 200 trials. Participants were allowed as many brief breaks as they wanted, though none took more than two. All participants finished the testing session in under 20 minutes.

Results and Discussion

All but two participants were able to keep a steady rhythm throughout the experiment (the two who couldn't were excluded). The mean coefficient of variance (COV) for each stimulus is shown in Figure 2. A repeated-measures ANOVA with the Greenhouse-Geisser correction suggests that the mean COV across stimuli is not constant, $F(2.8, 28.2) = 8.16$, $p = .001$. This discredits the idea of scalar variability in responses: if such variability were true of adult performance, then we should expect the mean COV in responses to be the same for all the numbers we tested.

On the other hand, these data are very consistent with the assumption of scalar variability of activations, with a correlation between prediction and observation of over $r = .8$. There appears to be a section where the rounding-off occurs (numbers 1 to 3), and a section with full observed variance (numbers 5 to 15), as predicted. It's a little surprising that there was so much variability in responses to

1, but this variability comes from only 2 of the participants, representing 3 errors out of 440 trials, and still appears to be lower than the section with full observed variance. It is clear that these data are better explained by scalar variability in the activations than in the responses.

Figure 2: Observed COVs (standard deviation divided by mean) in the responses were lower on average for lower numbers of requested taps, consistent with scalar variability in the activations (but not in the responses).

The amount of variability at numbers 1 to 4 suggests that we were successful in repressing subitization, replicating Cordes et al., 2001. Also, subitizing is usually characterized by a hard limit at 4, but the lowest number where each participant made a mistake ranged from 1 to 6. In addition, if the effect was due to subitizing, we would be able to eliminate it by subtracting out all of the jumps from 4 to 5 (across the limit of what people can subitize). However, this is not the case, $F(7,4) = 7.546$, $p = .035$. Finally, all participants reported that they found it impossible to track individual taps during the task. (Tracking individual taps would show that participants were using the parallel individuation system). All of these facts point away from subitizing as an explanation.

Next, we test these predictions against a corpus of child behavioral data, to re-examine the question of whether the analogue magnitude number system may be involved in early number-word learning.

Experiment 2

We made a simple model of how children would solve the Cards task using the analogue magnitude system. In this task, children are shown a certain number of items on a card and are asked to guess the number of items. This is the same as Le Corre and Carey's (2007) Cards task, but without the time limit. (The purpose of the time limit is to prevent counting, but children who do not yet understand the cardinality principle do not use counting to answer anyway.)

This is how the model works: the child looks at the card once and forms an analogue magnitude representation of the number of items present. This representation could be measured in units of activation. The child then rounds off

this activation level to the nearest positive (non-zero) whole number. If the child knows this number word, she says it. If the child does not know the word for that number, she says a number from among the number words whose meanings she does not know. (For a discussion of how the child chooses *which* undefined number to guess, see Sarnecka & Lee, 2009; Lee & Sarnecka 2010.)

For example, suppose we show a two-knower 2 items on several trials. On the first, she experiences 2.3 units of activation, rounds it to 2, and says “two”. On the second, she experiences .38 units, rounds it to 1, and says “one”. On the third, she experiences 3.3 units, rounds to 3, and picks “six” from among the words that she does not know (“three” and up). These activation levels are being drawn from a normal distribution with a mean of 2.

The computations involved are based on the normal cumulative density function. Say that this child has a COV of α when shown a card with 2 items on it. The chances of saying “one” are $\Phi((1.5-2)/\alpha)$. The chances of saying “two” are $\Phi((2.5-2)/\alpha) - \Phi((1.5-2)/\alpha)$. The chances of saying “three” and up (beyond the knower-level) are proportional to $1 - \Phi((2.5-2)/\alpha)$. The lower α is, the more often the child will be correct.

Figure 3: An example of the model: a two-knower, shown 2 items, draws an activation level from a normal distribution $N(2,1)$ and responds accordingly.

Furthermore, we assume that for each stimulus γ (each number of items shown on the card, up to 4) and knower-level τ , a particular child’s COV is drawn from a normal distribution with mean $\mu_{\gamma,\tau}$ and standard deviation σ . A variable δ describes the constant difference between each μ_γ and the next one up. So $\mu_{2,2} = \mu_{1,2} + \delta$, etc. We planned to use Bayesian inference on these latent variables: if $\delta \neq 0$, then this method of describing variation does not show scalar variability – i.e., a constant COV – and our model is wrong.

It may bother the reader that this model allows for the analogue magnitude system to output a negative number.

However, there is no empirical argument against this—assuming the participant knows to round to the nearest positive whole number. A log-normal distribution may be substituted, which would limit the outputs to positive numbers, but this generally has little effect; having low outputs rounded to 1 accomplishes the same basic goal as making the distribution of outputs stay above zero. Since a normal distribution is symmetric, we assume that the variation to the higher side is sufficient to estimate total variation, e.g., the variation around 1 item is well-represented by the number of times the child says “two” or “three”. Put another way, a two-knower has an equal probability of saying “two” as experiencing between $-.5$ and $.5$ units of activation, when shown 1 item. In any case, the probability of negative activation is often very small.

Methods

These data were taken from a longitudinal study testing children on both the Give-N task and the Cards task. The dataset thus offers a way of independently assessing the child’s knower-level (using Give-N) and then estimating δ (using the Cards task).

Participants A total of 97 monolingual English-speaking children participated. Children were tested once every two weeks for twenty weeks, resulting in a total of 454 sessions. Because little is known about the week-to-week consistency of children’s knower-levels and/or analogue magnitude acuity, each session was modeled as a new child. We included all children who were two-, three-, or four-knowers (as determined by Give-N), and who completed at least 15 trials of both the Give-N and the Cards task. This resulted in a total of 161 sessions (45 sessions with two-knowers, 51 with three-knowers, and 65 with four-knowers).

Give-N The purpose of this task was to determine what number-word meanings each child knew (i.e., to determine the child’s number-knower-level.) The experimenter began the game by bringing out a stuffed animal (e.g., a lion), a plate, and 3 bowls, each containing 15 small identical rubber toys (e.g., toy bananas, approx. 3 cm long). The experimenter said to the child, “In this game, you’re going to give something to the lion, like this [experimenter pantomimes putting an item on the plate and sliding it over to the lion]. I’m going to tell you what to give him.” Instructions were of the form, “Can you give the lion TWO bananas?”

Trials were in pseudorandom order, always starting with a request for one item. There were a total of eighteen trials: six trials each asking for one, two, three, four, six, and eight items. Children were given generalized positive feedback after each trial (e.g., “Thank you!”), regardless of their responses.

The child’s knower-level was estimated using Lee & Sarnecka’s (2010) model. In this model, the child has a prior probability of giving each number of objects: small handfuls are very likely, as is giving the entire bucket. When the

child is asked for a specific number, the response probabilities are updated according to her knower-level. Every child is given a uniform prior chance to be each knower-level, and a posterior distribution is calculated based on the data. We sampled over this posterior distribution with 3 independent chains, 2,000 burn-in samples and 10,000 data collection samples. We then assigned each child's knower-level based on the expected value² from this posterior distribution.

Cards Task This was our comparison task, which provides a set of responses independent from Give-N, so that one can be used to determine knower-level and the other to model the analogue magnitude response. The stimuli were photographs of the same stimuli used in Give-N, on a white background. The difference is that children were asked to label the numerosity instead of generating it. For example, if a child was asked for three red trains in Give-N, she was later shown a picture of three red trains and asked the number on it. As a check that the child was paying attention, trials were thrown out if the child did not produce the correct object name (e.g., trains) along with the number word. Before the first trial, there was a check that the children knew the words for the objects being used, which did not seem to pose a problem for our participants.

Again there were eighteen trials: three trials each for one, two, three, four, six and eight items, in pseudorandom order. We asked children the question “What’s on this card?” because questions that start with “How many ...” are often interpreted as commands to count (Sarnecka & Carey, 2008). Children were given generalized positive feedback after every trial. Order of tasks was counterbalanced across sessions.

Results and Discussion

There were a total of 1,903 usable trials from the Cards Task. We decided to give the model a unit normal prior on effect size δ/σ , as a way to make the prior dimensionless and reasonably vague (Jeffreys, 1961; Rouder, Speckman, Sun, Morey & Iverson, 2009; Wetzels, Raaijmakers, Jakab, & Wagenmakers, in press). We then ran the model with MATLAB and WinBUGS, which uses a form of Gibbs sampling to describe the posterior distribution. We ran five independent chains, with 10,000 burn-in samples and 25,000 collection samples. The within-chain variability matched the between-chain variability, even though the chains were initialized with different effect sizes, which is a good indication of proper convergence.

At the point of the null hypothesis ($\delta = 0$; i.e., the average COV is the same for every number of items shown), there was a prior density of .39. At the same point, there was a posterior density of 5.72, estimated with a normal kernel density method. By the Savage-Dickey Theorem (Dickey &

Lientz, 1970), the Bayes factor is $5.72/.39 = 14.34$, meaning that the data were 14.34 times more likely to be generated by the null hypothesis than the alternate. This is very strong evidence in support of the null hypothesis. In other words, Children *do* show scalar variability in at least one task that taps number-word knowledge – but it is scalar variability of activations, not of responses.

Figure 4: Prior and posterior distributions of δ/σ . There is a great deal of support for the null hypothesis ($\delta = 0$; i.e., the mean COV for every stimulus is the same within each knower-level) in the child data.

General Discussion

In Experiment 1, we showed that scalar variability of adult small-number estimates may be located in the activations, but not in the responses. Our analysis suggests that scalar variability is not always present in the answers that people give when you ask them to estimate a number of items. Instead, scalar variability is present in the latent continuous variable that serves as input, and which gets rounded off in people’s answers. In Experiment 2, we modeled how children respond when asked how many items are on a card. Our model included (a) the use of analogue magnitudes assuming scalar variability in the activations and (b) knower-levels, which are stages of number-word knowledge (e.g., Sarnecka & Lee, 2009). We showed that, contrary to previous reports, there is no problem fitting the well-known signature of scalar variability to real child data. In fact, we found strong evidence that children’s responses *do* show scalar variability, with a Bayes factor of 14.34.

This reverses one of the most powerful arguments against the involvement of the analogue magnitude system in early number-word learning. Scalar variability is a very reliable feature of the analogue magnitude system. We have presented evidence that this signature is found in children’s verbal responses to a small-number estimation task, even before the children have figured out the cardinal principle of counting. The statistical method we used has a very useful feature: it can quantify support for the null hypothesis, rather than simply rejecting or failing to reject it. Thus, we can report positive evidence that children’s responses *do* show scalar variability. This suggests that children do imbue the first few number words (up to and including their

² Another reasonable method would be to take the mode instead of the expected value. This method has high agreement in this case, $r = .992$.

knower-level) with numerical content from the analogue-magnitude system.

Of course, evidence for the involvement of analogue magnitudes is not evidence against the involvement of enriched parallel individuation; it's possible that a parallel-individuation-based model could also be fit sensibly to these data. There are still many reasons to think that parallel individuation is involved. In particular, we do not dispute Le Corre and Carey's finding that new CP-knowers do not connect numbers above 5 to the analogue magnitude system (Le Corre & Carey, 2007; see Sarnecka & Lee, 2009 for a convergent finding). In addition, children seem to become three-knowers or four-knowers, but not five-knowers or six-knowers. The limit after 4 coincides with the set-size limit on the parallel individuation system (e.g., Feigenson & Carey, 2003).

Moving forward, we think tasks that tap more than just the child's number-word knowledge should be part of the debate. For example, there is new interest in the question of whether number-word knowledge is related to estimation acuity, after it was shown that acuity at age 14 retroactively predicts math grades back to first grade (Halberda, Mazocco & Feigenson, 2008). In particular, the present model predicts that estimation acuity should correlate with the number of within-knower-level errors on the Cards task. This kind of argument could be very useful in determining which systems are important to number-word learning and how they contribute.

We hope that this line of work will lead to increasingly accurate descriptions of how children acquire integers, and will help to, resolve debates over the roles of various cognitive systems in number-word learning. The test case of number may then inform more general theories of how new representational resources are acquired.

Acknowledgments

This research was supported by NIH grant R03HD054654 to Barbara W. Sarnecka. We thank the children and families who participated in the study, as well as the teachers and administrators of the following Irvine, California preschools: Jenny Hart Early Education Center, Temple Bat Yahm Preschool, Turtle Rock Preschool, UCI Children's Center, UCI Early Childhood Education Center, UCI Infant and Toddler Center, and University Montessori.

Integrating Reinforcement Learning with Models of Representation Learning

Matt Jones (mcj@colorado.edu) & Fabián Cañas (canas@colorado.edu)

University of Colorado, Department of Psychology & Neuroscience
Boulder, CO 80309 USA

Abstract

Reinforcement learning (RL) shows great promise as a model of learning in complex, dynamic tasks, for both humans and artificial systems. However, the effectiveness of RL models depends strongly on the choice of state representation, because this determines how knowledge is generalized among states. We introduce a framework for integrating psychological mechanisms of representation learning that allows RL to autonomously adapt its representation to suit its needs and thereby speed learning. One such model is formalized, based on learned selective attention among stimulus dimensions. The model significantly outperforms standard RL models and provides a good fit to human data.

Keywords: Reinforcement learning; attention; generalization

Introduction

Most challenging tasks people face are inherently dynamic and interactive. Choices affect not just immediate outcomes but also future events, and hence subsequent decisions that must be made. Normative and descriptive theories of learning in dynamic environments have advanced dramatically in recent years with the development of Reinforcement Learning (RL), a mathematical and computational theory drawing on machine learning, psychology, and neuroscience (e.g., Schultz, Dayan, & Montague, 1997; Sutton & Barto, 1998).

However, RL currently faces a fundamental challenge relating to the issue of knowledge representation. Dynamic tasks tend to be highly complex, with an enormous number of possible states (situations) that can arise. Therefore, efficient learning must rely on generalization from past states that are similar to the current one. Similarity, in turn, depends on how states are represented, including the features by which they are encoded and the relative attention allocated to those features (Medin, Goldstone, & Gentner, 1993). Thus representation is critical to the effectiveness of RL algorithms, because representation determines the pattern of generalization by which past experience is used to make new decisions.

Although there has been little research on representation in the context of RL, representation and representation learning have long been topics of psychological study. Empirical research in a number of domains, including perceptual learning, attention, categorization, object recognition, and analogy, has uncovered principles and mechanisms by which people learn to modify how they encode objects and situations in the service of learning, inference, and decision making. Here we describe a framework for a natural synthesis of these ideas with RL algorithms, which leads to models that learn representations for dynamic tasks. A specific model is presented that is

based on principles of attention learning from the categorization literature (Kruschke, 1992; Nosofsky, 1986). Two sets of simulation studies are reported, which demonstrate both the power and the psychological validity of this approach.

Reinforcement Learning

RL comprises a family of algorithms for learning optimal action in dynamic environments. RL models characterize a task as a Markov Decision Process, in which the environment at any moment exists in one of a set of *states*, each associated with a set of actions available to the learner. The chosen action determines both the immediate reward received, if any, and the state of the environment on the next time step. This general framework encompasses most tasks of psychological interest (Sutton & Barto, 1998).

The key insight behind most RL algorithms is to learn a *value* for each possible state or action. This value represents the total future reward that can be expected starting from that point. Formally, given any state s and action a , the state-action value is defined as

$$Q(s, a) = E \left[\sum_{k=0}^{\infty} \gamma^k r_{t+k} \mid s_t = s, a_t = a \right], \quad (1)$$

where t is the current timestep; s , a , and r are the state, action, and received reward on each step; and $\gamma \in [0, 1]$ is a discount factor representing the relative value of immediate versus delayed rewards. This approach allows action selection to be based directly on the Q -values. Here we use a Luce-choice or Gibbs-sampling rule, with inverse-temperature parameter θ .

$$P(a_t = a) \propto e^{\theta Q(s_t, a)} \quad (2)$$

Once an action is selected, its value is updated according to the immediate reward and the values associated with the state that follows. One of the best-studied algorithms for learning action values, Q -learning (Watkins & Dayan, 1992), uses the update rule

$$\Delta Q(s_t, a_t) = \epsilon_{\text{val}} \cdot \delta, \quad (3)$$

where $\epsilon_{\text{val}} \in (0, 1]$ is a learning rate, and δ is the *temporal-difference (TD) error*, defined as

$$\delta = r_t + \gamma \cdot \max_a \{Q(s_{t+1}, a)\} - Q(s_t, a_t). \quad (4)$$

The TD error represents the difference between the original action-value estimate, $Q(s_t, a_t)$, and a new estimate based on the immediate reward and ensuing state. The expression $\max_a \{Q(s_{t+1}, a)\}$ represents an estimate of the value of the new state, s_{t+1} , based on the best action that could be performed in that state.

The simplest implementations of *Q*-learning and other RL algorithms use a *tabular* (i.e., lookup-table) representation, in which a different set of action values is learned separately for every possible state that can occur. Tabular representations are impractical for most realistic tasks, because the number of states grows exponentially with the number of state variables. Therefore, most implementations of RL utilize some form of *generalization*, whereby knowledge about one state is extended to other, similar states. This approach dramatically speeds learning by reducing the amount of information that must be retained and updated, and by allowing the learner to draw on a richer set of past experiences when making each new decision.

Central to the success of generalization in all learning tasks (not just RL) is the choice of representation. In order for generalization to be effective, states (or stimuli in general) must be encoded so that stimuli that are perceived or treated as similar tend to be associated with similar outcomes or appropriate actions (Shepard, 1987). Such a representation facilitates generalization, and hence learning, because it leads the learner to draw on precisely those past experiences that are most relevant to the current situation.

Unfortunately, the choice of representation is a notoriously difficult problem, and the field of machine learning is far from having automated algorithms that discover useful representations for learning novel tasks. Successful applications of RL have instead tended to rely on hand-coded human knowledge for encoding states. For example, the state representation in Tesauro's (1995) celebrated backgammon program, TD-gammon, was based on complex features (configurations of pieces) suggested by expert human players. Likewise, psychological research in RL generally avoids the problem of representation by using small sets of stimuli with clearly defined features, so that the subject's representation can be confidently assumed by the modeler and is unlikely to change during the course of learning (e.g., Fu & Anderson, 2006). Arguably, representation is where the real challenge often lies, and therefore starting a model with a hand-coded representation, or using experimental stimuli with unambiguous features, presupposes the most difficult and interesting aspects of learning (Schyns, Goldstone, & Thibaut, 1998).

Selective Attention in Category Learning

One behavioral domain in which generalization and representation have been extensively studied is category learning. Much of the research on category learning has aimed to understand the internal representations that humans develop to facilitate classification of objects and inference of unobserved features. All of these models serve, in one way or another, to allow generalization of category knowledge from previously encountered to novel stimuli.

The most direct mechanism for generalization in categorization is embodied by exemplar models (Medin & Schaffer, 1978). In these models, the psychological evidence (*E*) in favor of classifying a stimulus (*s*) into a given category (*c*) is given by summing its similarity to all

previously encountered exemplars (*s'*), weighting each exemplar by its association to *c*.

$$E(s, c) = \sum_{s'} \text{sim}(s, s') \cdot w(s', c) \quad (5)$$

The property of exemplar models most relevant to the current investigation is the similarity function. Rather than being fixed, a large body of evidence indicates that similarity changes during the course of learning as a consequence of shifts of attention among the stimulus dimensions (e.g., Nosofsky, 1986). This flexibility is modeled by expressing similarity as a decreasing function of distance in psychological space, with each stimulus dimension, *i*, scaled by an attention weight, α_i (Nosofsky, 1986). Here we assume an exponential similarity-distance function, in accord with empirical evidence and normative Bayesian analysis (Shepard, 1987).

$$\text{sim}(s, s') = e^{-\sum_i \alpha_i |s_i - s'_i|} \quad (6)$$

The effect of attention on similarity is to alter the pattern of generalization between stimuli so as to fall off more rapidly with differences along dimensions with greater attention weights. When stimuli differ only on unattended dimensions, their differences are unnoticed and hence generalization between them is strong. This adaptation of generalization leads to improved performance when attention is shifted to task-relevant dimensions, because the learner generalizes between stimuli that have common outcomes while discriminating between stimuli that are meaningfully different.

The influence of attention on generalization has extensive support, both theoretically (Medin et al., 1993) and empirically (Jones, Maddox, & Love, 2005; Nosofsky, 1986). An important question suggested by this research is how attention can be learned. One proposal is that attention weights are updated in response to prediction error (Kruschke, 1992). In a classification task, prediction error (δ) is simply the difference between the category evidence, $E(s, c)$, and the actual category membership given as feedback to the learner (e.g., +1 if $s \in c$ and -1 otherwise). The updating rule for attention is then based on gradient descent on this error, squared and summed over categories.

$$\Delta \alpha_i = -\epsilon_{\text{att}} \cdot \frac{\partial}{\partial \alpha_i} \left(\frac{1}{2} \sum_c \delta_c^2 \right). \quad (7)$$

This mechanism for attention learning has been implemented in ALCOVE, a highly successful model of human category learning (Kruschke, 1992). ALCOVE learns to shift attention to stimulus dimensions that are most relevant to predicting category membership and away from dimensions that are non-diagnostic. This leads to adaptation of generalization, which in turn speeds learning.

Attention Learning in RL

Because of the strong empirical support for attention learning in the categorization literature, we believe it is a potentially fruitful topic for study in the context of RL.

Selective attention may be especially relevant in this domain because most interesting RL tasks have complex state spaces of high dimensionality, and learning to distinguish relevant from irrelevant dimensions should be expected to greatly speed learning in such tasks.

The present investigation addresses two questions regarding the relationship between attention learning and RL. The first question is a psychological one, of whether attention learning as observed in supervised tasks such as categorization also operates in the dynamic tasks modeled by RL. This extrapolation is not trivial, because RL relies on TD error, which is an internally generated signal based in part on the learner's own value estimate of the ensuing state (see Eq. 4). It is an empirical question whether this internal signal can drive attention shifts and other forms of representation learning in the same way that external feedback does. A companion paper (Cañas & Jones, 2010) reports a behavioral experiment that supports an affirmative answer to this question, and the data from that experiment are modeled below.

The second question is a computational one, of whether the formal equations that describe RL and attention learning can be coherently integrated, and whether the resulting model will exhibit efficient learning. This normative question is important psychologically because computational power constitutes a significant motivation for expecting attention learning to play a role in human RL. If the two are computationally compatible, then the potential significance of RL is greatly increased, in that RL is capable of autonomously adapting the representations on which it operates.

Comparison of the equations describing Q-learning and attention learning reveals there is indeed a natural, highly complementary integration. The strength of Q-learning, and RL algorithms in general, is in the sophisticated updating signals they compute, which take into account both external reward and internal consistency of value estimates (Eq. 4). The updating itself is fairly trivial, consisting of adjusting the existing estimate by a proportion of the error (Eq. 3). Attention learning, and models of category learning more generally, have the opposite character. Their updating signals are fairly trivial (prediction error relative to external feedback), but the updates themselves are complex, driving adaptation of sophisticated internal representations. This complementary relationship suggests the solution of using the TD error signal from RL to drive representation learning, and in particular to update attention weights.

We refer to the model resulting from this integration as Q-ALCOVE. Q-ALCOVE estimates action values via similarity-based generalization among states, directly analogous to ALCOVE (Eq. 5).

$$Q(s, a) = \sum_{s'} \text{sim}(s, s') \cdot w(s', a) \quad (8)$$

The Q -values are used to generate action probabilities according to the response-selection rule used by both Q-learning and ALCOVE (Eq. 2). The w parameters, which act as pre-generalization action values, are updated

analogously to both Q-learning (Eq. 3) and ALCOVE, using the same TD error signal as in Q-learning (Eq. 4).

$$\Delta w(s_t, a_t) = \varepsilon_{\text{val}} \cdot \delta \quad (9)$$

Similarity between states in Q-ALCOVE is defined identically to stimulus similarity in ALCOVE (Eq. 6), except that a normalization term is included that fixes the total similarity (i.e., the integral of the generalization gradient) to 1. We have found that attention learning in tasks requiring continuous prediction only functions well when normalization is included.

Learning of attention weights follows the same rule as in ALCOVE, except for the critical substitution of classification error with TD error. In addition, we only differentiate δ with respect to $Q(s_t, a_t)$ and not $Q(s_{t+1}, a)$, because the motivation behind Q-learning is to use $Q(s_{t+1}, \cdot)$ to adjust $Q(s_t, \cdot)$. Nevertheless, changing α also affects $Q(s_{t+1}, \cdot)$, and further analytical work is needed to understand the impacts of this fact on model behavior and predictions. The resulting rule for attention learning is

$$\Delta \alpha_i = \varepsilon_{\text{att}} \cdot \delta \cdot \frac{\partial}{\partial \alpha_i} Q(s_t, a_t) \quad (10)$$

The intuition behind attention learning in Q-ALCOVE is that, after feedback, the model adjusts attention weights to reduce generalization from states that contributed to error and to increase generalization from states that suggested more correct predictions. Over the course of experience, attention should shift to those dimensions that are most diagnostic of correct actions and their values.

Simulation Studies

Two sets of simulations were carried out to evaluate the behavior of Q-ALCOVE. The first set was based on Gridworld, a common benchmark task for RL models. These simulations aimed to test whether the attention-learning mechanism in Q-ALCOVE operates as predicted, to shift attention toward relevant dimensions and away from irrelevant dimensions. If so, a second question was whether selective attention leads to significant improvements in learning speed, and how such a potential advantage depends on the dimensionality of the task. The second set of simulations was based on a human behavioral experiment (Cañas & Jones, 2010) designed to test whether humans can learn selective attention using internal value estimates (i.e., TD error) as feedback, as proposed here. These simulations aimed to evaluate Q-ALCOVE's viability as a psychological model.

Directional Gridworld

Gridworld is a class of tasks with a long tradition as a benchmark for RL algorithms (e.g., Sutton & Barto, 1998). The states of a Gridworld task form a rectangular lattice of dimensionality D . We call the present task Directional Gridworld, because it was set up in such a way that one dimension was relevant and the others were irrelevant.

Figure 1. State space for 3-dimensional Directional Gridworld task. Grey states are goal states. Black cloud depicts Q-ALCOVE’s generalization gradient, at the start of learning (left) and after 300 time steps (right).

Figure 1 illustrates the Directional Gridworld task for the case of $D = 3$ (the generalization gradients in the figure are discussed below). Each dimension has 7 levels, for a total of 7^D states. In each state, the learner has $2D$ available actions, corresponding to motion in either direction along any dimension. For simplicity, we assume that actions are deterministic and move the learner by 1 step in the chosen direction. Actions on the boundaries that would take the learner outside the space have no effect.

States are encoded as vectors corresponding to their values on the D dimensions. Other than this, the model has no prior knowledge of the topology of the environment or of the meanings or effects of actions. The spatial interpretation is only a convenient metaphor, and the task is not meant as a model of spatial navigation that might involve specialized psychological mechanisms. The stricter interpretation is as an abstract problem space (e.g., Newell & Simon, 1972).

The highlighted states (Fig. 1) spanning the center of the space are *goal states*. Whenever the learner reaches a goal state, a reward of 10 is provided. On the next step, the learner is taken to a random state maximally distant from the goal region. All actions that do not lead to a goal produce a reward of -1. The learner’s task is to choose actions so as to maximize total temporally discounted reward (Eq. 1, with γ set to .5). Thus, optimal behavior consists of repeatedly moving in a straight line from the boundary to the nearest goal state.

For all values of the dimensionality D , the goal states form a hyperplane through the center of the space. The dimension perpendicular to the goal region is relevant to optimal action selection, as the learner needs to move in opposite directions depending on which side of the goal region it is on. All other dimensions are irrelevant. Indeed, it can easily be shown that the optimal Q -values for any state depend only on the state’s position on the relevant dimension. Therefore, the most efficient generalization strategy for learning Q -values is to average over all states at each level of the relevant dimension but to learn separate values for each level. This strategy can be achieved by strong attention to the relevant dimension and zero attention to all other dimensions. A primary question was whether Q-ALCOVE would learn such an attention distribution.

Figure 2. Learning curves in Directional Gridworld for Q-ALCOVE and version with fixed generalization.

Two models were simulated in addition to Q-ALCOVE. The first was tabular Q-learning, which learns actions values independently for all states. The second was a fixed-generalization model obtained from Q-ALCOVE by setting the attention-learning rate, ϵ_{att} , to 0. Q-ALCOVE was run using $\epsilon_{att} = .01$. All models were run with value-learning rate $\epsilon_{val} = 1$ and choice parameter $\theta = .5$. The models’ value estimates (w or Q) were initialized at 0 at the start of each run. The initial values for attention weights were set to .4 for both Q-ALCOVE and the fixed-generalization model. This value was chosen so as to maximize performance of the fixed-generalization model on 3 dimensions.

Figure 2 shows average learning curves for Q-ALCOVE and the fixed-generalization model for Directional Gridworlds of 3 to 8 dimensions. Performance for tabular Q-learning was poor enough, especially at higher dimensionalities, that it is omitted. Each curve indicates reward rate, smoothed with a rectangular window of 100 time steps, and averaged over 4 separate runs of the model. As can be seen, Q-ALCOVE learns more quickly with attention learning than without, and the magnitude of this advantage grows rapidly with the number of dimensions. This result suggests that attention plays an indispensable role in natural tasks of much higher dimensionality.

Figures 1 and 3 illustrate how Q-ALCOVE’s attention-learning mechanism facilitates learning, in the case of three dimensions. Figure 3 shows the attention weights for a single run, which increase for the relevant dimension and decrease toward 0 for the irrelevant dimensions. This shift of attention leads to the change in the generalization gradient depicted in Figure 1. The initial gradient (left) is spherical, reflecting the model’s lack of knowledge of the dimensions’ predictive validities. After 300 time steps (right), the gradient has been reshaped so that there is strong generalization between states as long as they match on the relevant dimension and very little generalization otherwise. Thus the model has learned the anisotropy of the task, which allows it essentially to estimate a common set of Q -values for all the states at each stratum (as an average over all the w s), while keeping the values for different strata separate.

Figure 3. Dynamics of attention weights for one run of Q-ALCOVE in 3-dimensional Directional Gridworld.

The consequences of all three models' patterns of generalization are illustrated in Figure 4, which shows a two-dimensional slice through the center of the three-dimensional state space. Within each state, the four arrows indicate the model's estimated Q -values for the four actions within the plane. These values are from a single run of each model, after 300 time steps. Darker arrows indicate greater Q -values. The values for tabular Q-learning are irregular, reflecting the fact that they were learned separately for each state. In most states there has not been enough experience to obtain reliable estimates. The Q -values estimated by the fixed-generalization model are more accurate, because each draws on knowledge from neighboring states, so experience is used more efficiently. However, there is still irregularity among states at a given stratum (insufficient generalization across the irrelevant dimension) and too much smoothing (excess generalization) along the relevant dimension. Q-ALCOVE's estimated Q -values are much more accurate, allowing the model to select correct actions more reliably.

The Spores Task

Psychologically, the core assumption of Q-ALCOVE is that attention learning can be driven by internally generated TD-error signals, not just overt feedback. A behavioral experiment, reported by Cañas and Jones (2010), tested this hypothesis using a two-step task, in which Action 1 determined Stimulus 2, but reward was not received until after Action 2. The basic question was whether selective attention to the dimensions of Stimulus 1 could be learned, when the only immediate feedback was the identity of Stimulus 2.

Figure 5 illustrates the design of the task. Stimulus 1 (a cartoon mushroom spore) varied along two dimensions and was sampled from a circular set. This set was probabilistically divided into two regions, which had different consequences for the outcome of Action 1 (two options for how to grow the spore). The border between regions was oriented so that one dimension was more relevant than the other. The second step was designed so that the two possibilities for Stimulus 2 (two colors of mushrooms) each had a different optimal choice for Action 2 (selling the mushrooms to a troll or a goblin). Under these optimal actions, Stimulus 2a led to more reward than Stimulus 2b.

RL models in general predict subjects will learn internal values for Stimuli 2a and 2b (or their pairings with choices of Action 2), and these values will be used to generate internal feedback (TD error) for Action 1. This will in turn

Figure 4. Q -values obtained from all three models after 300 steps in 3-dimensional Directional Gridworld. Shown is a 2-dimensional slice through the center of the state space. Arrows in each state correspond to the four actions within the plane. Darker arrows indicate greater Q -values.

allow subjects to learn to choose Action 1 so as to maximize the probability of obtaining Stimulus 2a (the more valuable mushroom). The key additional prediction of Q-ALCOVE is that TD error will also drive learning of attention to the more relevant dimension of Stimulus 1, to improve the effectiveness of generalization among stimuli.

Results revealed that subjects who learned the first step of the task also learned to selectively attend to the more relevant dimension (see Cañas & Jones, 2010, for details). Simulations of Q-ALCOVE corroborated this conclusion. Q-ALCOVE and the fixed-generalization version of the model were fit to the data of each subject using maximum likelihood. Aggregating over all 150 subjects, Q-ALCOVE fit reliably better, $\chi^2(150) = 1913.8$, $p \approx 0$. The difference between fits of the models was significant at the .05 level for 55 individual subjects. These results support the central hypothesis that attention learning, as embodied by Q-ALCOVE, was involved in learning the task.

Figure 5. Structure of the Spores task.

Conclusions

Despite its computational power and neurological support, the basic principles behind RL are inherently limited by the representations it operates on. We argue here for a tight linkage between RL and mechanisms of representation learning established in other domains of psychology. Specifically, TD error, the engine behind nearly all RL models, can also drive updating of state representations. Representations thereby adapt so the pattern of generalization among states is tuned to the structure of the task, which in turn facilitates learning of optimal actions. RL's capacity to autonomously drive construction of representations that serve its needs greatly increases its power and flexibility, and hence its potential as a model of complex human learning.

The specific model proposed here draws on principles of selective attention from category learning and related domains (Nosofsky, 1986; Sutherland & Mackintosh, 1971). Shifting attention away from irrelevant dimensions allows

the learner to aggregate knowledge over states with similar outcomes, while attention toward relevant dimensions maintains discrimination of meaningful differences. Generalization in any learning task raises a bias-variance dilemma, in that more generalization reduces variance in parameter estimates but increases their bias. Selective generalization as modeled by attention learning is an elegant way of sidestepping this dilemma.

In a companion paper, we report empirical evidence supporting attention learning via TD error as a psychological mechanism (Cañas & Jones, 2010). Here we show how such a mechanism can be formalized in a mathematical model. Attention learning and RL in this model bootstrap off of each other, in that the internal value estimates generated by RL drive shifts of attention, and selective attention in turn improves RL's value estimates. This synergistic relationship, together with the elegance of the integration between the equations of Q-learning (Watkins & Dayan, 1992) and ALCOVE (Kruschke, 1992), suggests that RL and attention learning are similarly tightly coupled in the brain. The simulation studies reported here show that the unified model, Q-ALCOVE, is both computationally powerful and psychologically plausible.

Investigating attention is a useful first step because it acts to modify similarity directly, so that its effects on generalization are transparent. In further work, we plan to explore more complex psychologically supported mechanisms, such as stimulus-dependent attention (Aha & Goldstone, 1992), construction of new conjunctive features (Love, Medin, & Gureckis, 2004), and analogical mapping between structured stimulus representations (Markman & Gentner, 1993).

Psychological models that generalize knowledge based on pairwise similarity are closely related to kernel methods developed in statistics (Jäkel, Schölkopf, & Wichmann, 2007). Kernel methods add considerable flexibility to many learning algorithms, by allowing them to be recast from the raw stimulus space to a mathematical (Hilbert) space of functions (e.g., Cristianini & Shawe-Taylor, 2000). Q-ALCOVE can be viewed as a kernel method applied to RL. Viewed from the perspective of kernel methods, an important contribution of the present research is the proposal for adaptively modifying the kernel (i.e., generalization gradient) to improve learning. Learning the kernel has been a focus of recent research in machine learning (e.g., Micchelli & Pontil, 2007), but results thus far have been largely limited to existence theorems and global-search algorithms that seem psychologically implausible. Here we propose a simpler mechanism based on psychological principles. The mathematical results on kernel learning have been influential in guiding our design of well-behaved models and in inspiring more sophisticated mechanisms. Continuing to exploit this link to statistical and machine-learning techniques, while maintaining grounding in established psychological phenomena, seems promising for advancing the power and flexibility of psychological models.

Attention and Reinforcement Learning: Constructing Representations from Indirect Feedback

Fabián Cañas (canas@colorado.edu) & Matt Jones (mcj@colorado.edu)

University of Colorado, Department of Psychology & Neuroscience
Boulder, CO 80309 USA

Abstract

Reinforcement learning (RL) shows great promise as a theory of learning in complex, dynamic tasks. However, the learning performance of RL models depends strongly on how stimuli are represented, because this determines how knowledge is generalized among stimuli. We propose a mechanism by which RL autonomously constructs representations that suit its needs, using selective attention among stimulus dimensions to bootstrap off of internal value estimates and improve those same estimates, thereby speeding learning. Results of a behavioral experiment support this proposal, by showing people can learn selective attention for actions that do not lead directly to reward, through internally generated feedback. The results are cast in a larger framework for integrating RL with psychological mechanisms of representation learning.

Keywords: Reinforcement Learning; attention; generalization

Introduction

Humans have an incredible capacity to learn new and complex tasks in dynamic environments. In recent years, Reinforcement Learning (RL) has emerged as a theoretical framework that may explain how such powerful learning takes place (e.g., Sutton & Barto, 1998). Reinforcement learning draws on a synthesis of machine learning and neuroscience and offers a set of computational principles for describing learning of dynamic tasks. RL has led to major advances in the ability of machines to learn difficult tasks such as backgammon and autonomous helicopter flight (Tesauro, 1995; Bagnell & Schneider, 2001). RL has also received much interest in neuroscience, based on findings that phasic dopamine signals have similar properties to the internal feedback computed by RL algorithms (Schultz, Dayan, & Montague, 1997). This correspondence suggests that RL offers a useful model of biological learning.

Despite the promise of this framework, the learning performance of RL algorithms strongly depends on the representations on which they operate. RL works by learning which action to perform in each state of a task's environment. In realistically complex tasks with large state spaces, learning about every state individually is impossible, and instead the learner must generalize knowledge among states. Generalization is closely tied to similarity (Shepard, 1987), which in turn depends on how stimuli or situations are represented. Therefore the efficacy of generalization depends on how a task is internally represented. Most often in machine-learning applications, representations are pre-supplied by the modeler based on features that are carefully crafted to capture the most important aspects of the task being learned (e.g., Tesauro, 1995). In psychological contexts, stimuli are chosen so that the subject's representation is transparent, and consequently

the question of how the representation is learned is neglected (Schyns, Goldstone, & Thibaut, 1998).

A great deal of psychological research in domains other than RL focuses on how people learn representations to facilitate learning, inference, and decision-making. The aim of our general research program is to explore how such mechanisms might interact with RL, and in particular how RL can build its own representations to bootstrap learning. In the present paper we focus on selective attention, building on models from the literature on category learning (Kruschke, 1992). In a companion paper (Jones & Cañas, 2010), we provide a formal framework for integrating representation learning with RL and implement a specific computational model based on selective attention. Here, we present a behavioral experiment that support the thesis that RL can drive representational learning. Our results show that the internally generated feedback signals at the core of RL can direct shifts of attention toward those stimulus dimensions that are most diagnostic of optimal action.

The remainder of this paper begins with background on RL and modeling of attention learning in categorization. We then outline our proposal for how RL and attention learning can bootstrap off of each other. We then report the results of a sequential decision-making experiment designed to test this specific proposal. Implications are discussed for the role of attention in more complex and temporally extended tasks, prescriptions for training in such tasks, and interactions between representation learning and declarative memory.

Reinforcement Learning

RL is a computational framework for learning dynamic tasks based on feedback from the environment. RL models represent a task as a set of environmental states together with a set of available actions in each state. The action selected at each step determines the immediate reward as well as the ensuing state. This general framework accommodates nearly any psychological task, from simple conditioning to elaborate planning (Sutton & Barto, 1998).

RL works by estimating values of states and actions, which reflect predictions of total future reward. From any given state, the action with the highest estimated value represents a best guess of the choice that will lead to the highest long-term reward. The key to learning value estimates, which lies at the heart of all RL models, is an internally generated feedback signal known as Temporal Difference (TD) error. TD error represents the discrepancy between the estimated value of an action prior to its execution and a new estimate based

on the immediate reward and the value of the ensuing state.

For the mathematically inclined, TD error is defined as

$$\delta = r_t + \gamma \cdot V(s_{t+1}) - Q(a_t, s_t).$$

Here, s_t represents the current state (at time t), a_t is the action selected, and $Q(a_t, s_t)$ is the estimated value of that action. The immediate reward received is denoted r_t , and $V(s_{t+1})$ is the estimated value of the ensuing state. The temporal discount parameter, γ , represents the degree to which the learner values immediate versus delayed rewards.

A critical question for all RL models concerns the relationship between value estimates (Q or V) for different states. The simplest approach is to learn values for all states independently, but for most realistic tasks with large state spaces this approach is unfeasible. Effective learning therefore requires generalization, or the use of knowledge about one stimulus or situation to make inferences or choose actions for other, similar stimuli. A number of methods have been proposed for implementing generalization in RL, and in all cases, the pattern of generalization depends strongly on the way in which states are represented. Representations relying on different features produce different patterns of similarity and hence different generalization. Learning will be most effective if generalization somehow respects the structure of the task, such that the learner pools knowledge about states with similar consequences but discriminates between states that are meaningfully different.

Representation

The various mechanisms for representation learning that have been identified in cognitive psychology all have potential application to RL as means for speeding learning through enhancing generalization. Our work thus far has focused on principles derived from research on category learning. Much of the literature on human category learning aims to understand how humans develop powerful internal representations that facilitate learning and inference of conceptual knowledge. The mechanisms that have been studied include selective attention (Kruschke, 1992; Nosofsky, 1986); feature discovery (Schyns et al., 1998), prototype formation (Smith & Minda, 1998); hybrid rule-exemplar representations (Erickson & Kruschke, 1998; Nosofsky, Palmeri, & McKinley, 1994); clustering representations that grow with task complexity (Anderson, 1991); mutable representations that evolve among exemplars, prototypes, and rules (Love & Jones, 2006; Love, Medin, & Gureckis, 2004); and conceptual networks based on causal knowledge (Murphy & Medin, 1985). In this paper, we examine the interaction of RL and selective attention.

Though attention has been studied under many guises in psychology, its implications for learning and generalization have been primarily explored in categorization and animal conditioning. In these literatures, attention has been proposed to act by reshaping generalization gradients (Sutherland & Mackintosh, 1971; Nosofsky, 1986). The generalization gra-

dient is an empirical function that describes how strongly subjects generalize between stimuli as a function of how much those stimuli differ. This function is monotonically decreasing, but it decreases more rapidly along attended dimensions than unattended dimensions (Jones, Maddox, & Love, 2005). Thus subjects generalize less between stimuli when they are attending to the dimensions those stimuli differ on. An alternative view is that the generalization gradient is fixed and isotropic, but the perceptual scaling of individual stimulus dimensions is adjustable. Attention to a dimension serves to stretch the perceptual space so that stimuli differing on that dimension are less similar and thus produce less generalization (Nosofsky, 1986).

Theories of selective attention in category learning propose that people learn to reallocate their attention to improve performance. ALCOVE, a model of categorization with learnable selective attention, has an attention weight for each dimension that determines the degree of generalization along that dimension (Kruschke, 1992). The attention weights are learned by gradient descent on classification error, driven by external feedback. This process leads attention to shift to more predictive dimensions, which leads to less generalization along these dimensions and greater generalization along irrelevant dimensions. Selective attention can thus be thought of as a mechanism for representational learning, which facilitates future learning of the task by adapting generalization.

Incorporating Attention into RL

The previous two sections suggest a natural integration between RL and attention learning. RL's major focus is in updating value estimates by computing sophisticated feedback signals from temporal patterns of reward, but current RL models do not address how value estimates are represented. In contrast, theories of category learning focus on how representations are created that allow for effective generalization, but learning is driven by simple updating rules based on external feedback. We propose a natural unification, in which the feedback signals and updating rules from RL drive the representation-learning mechanisms identified in the categorization literature. This integration makes RL significantly more flexible and autonomous, and therefore possibly more aligned with biological learning.

The critical empirical question we explore operationalizes the idea that RL can adapt its own representation through learned selective attention. Specifically, we investigate whether attention learning can be driven by internally generated TD-error signals in the same way that has been observed with explicit external feedback (Nosofsky, 1986). In a companion paper (Jones & Cañas, 2010), we present a formal model that embodies this hypothesis, by synthesizing the learning mechanisms of ALCOVE (Kruschke, 1992) and Q-learning, a well-studied RL model (Watkins & Dayan, 1992). The formalism of the integrated model shows a tight and mathematically elegant synthesis of the two mechanisms, which we believe offers a strong candidate explanation of

how biological RL processes build their own representations. Here we present an experiment that tests that explanation, by assessing the human capacity for attentional learning via internal value and error signals as opposed to direct external feedback.

Experiment

The goal of the present experiment was to determine whether internal TD-error signals can drive attention learning in the absence of any immediate overt reward. The task consisted of a two-step decision process in which the action on the first step probabilistically determined the stimulus on the second step. Only after the second action did the subject receive feedback about reward.

The second stage of the task was a simple decision task with two possible stimuli and two possible actions. A different action was optimal (i.e., maximized reward) for each of these intermediate stimuli. Once this mapping was learned, one intermediate stimulus led to a higher reward than the other. RL predicts that once subjects learned the optimal actions on this second step, they would learn to assign differential values to the two intermediate stimuli. These values would in turn be used for computing a TD-error signal for actions in the first step, thereby allowing subjects to learn an action policy that maximizes the probability of obtaining the higher-valued intermediate stimulus.

The stimulus for the first choice varied on two continuous dimensions, one of which was more predictive of the outcome of the first action (i.e., the intermediate stimulus) and hence of which choice was optimal. The key question was whether learning the first action through TD error would also lead to learning of selective attention between stimulus dimensions, such that subjects would shift attention to the more relevant dimension. The stimulus set of the first step was designed so as to allow assessment of subjects' attentional allocation based on their patterns of errors, as described below.

Methods

150 undergraduate students from the University of Colorado, Boulder served as the experimental subjects in exchange for course credit.

Subjects were instructed they would pretend to be mushroom farmers. On each trial, they were presented with an image of a mushroom spore and asked to choose between two locations for growing the spore, Sun and Shade. This action determined the intermediate stimulus, a pair of blue or orange mushrooms. They were then given the option to sell the mushrooms to either a Troll or a Goblin, who paid them in gold coins. The structure of the task is outlined in Figure 1.

The stimulus in the first stage was a yellow spore shape, consisting of a circular center measuring 2.3 cm in diameter and radial spines arranged evenly around the center. The spines ranged from 8 mm to 260 mm in length and varied in number between 20 and 100. Spores were uniformly sampled from a circular region inscribed within this two-dimensional stimulus space. The spore was presented in the center of

Figure 1: An overview of the task.

an LCD monitor over a black background. The subject selected an action by pressing either S (Sun) or C (Cave) on the keyboard. After this first response was given, the spore disappeared and a pair of cartoon mushrooms appeared in the center of the screen. The subject selected the second action by pressing T (Troll) or G (Goblin). The reward was then presented as stacks of gold coins with a numeric value underneath. The mushrooms and the chosen creature remained on the screen while the reward was displayed.

The transition after each step was animated, lasting 1200 ms between the first response and intermediate stimulus, and 970 ms between the intermediate stimulus and the reward. The reward remained on the screen for 800 ms. A blank screen separated the reward from the beginning of the next trial for 200 ms.

The reward structure for the second step was defined as shown in Table 1. Each mushroom color was associated with a different optimal action. Under these actions, one mushroom (henceforth referred to as the “good” mushroom) afforded a higher reward.

Table 1: Reward Structure of the Second Stage

Mushroom Color	Creature Sold to	
	Goblin	Troll
Blue	[200, 220]	[400 420]
Orange	[300, 320]	[100 120]

Note: Reward on each trial was sampled uniformly from the range shown.

The transition dynamics for the first step were defined as follows. For each action, the probability of one mushroom color versus the other was a logistic function of the dimension values of the spore, given by $p = 1/(1 + \exp(A(30L + 10N)))$, where L and N represent the length and number of the spines, scaled to range from -1 to 1 , and A represents the action on the first step, coded here as ± 1 . The coefficients for L and N were counterbalanced between subjects, so that L was the more relevant dimension for half the subjects and N was more relevant for the other half. The effect of this design was to create an optimal decision bound, at an angle of 18.4° to one of the two axes, such that the action that maximized the probability of obtaining the good mushroom was determined by which side of the boundary each spore lay on.

Subjects were randomly assigned to Length-relevant and

Figure 2: Predictions from selective attention in first step of task. Attention to the more relevant (horizontal) dimension leads to stretching of the stimulus space. Critical stimuli (grey) near ends of optimal decision bound (solid line) are predicted to lead to errors, producing rotation in best fit of linear classifier to subject's responses (dashed line).

Number-relevant conditions, which differed in which spore dimension was more predictive. The roles of the creatures, the colors of the mushrooms, and the labels for the first action were also counterbalanced between subjects. Each subject completed 240 trials (480 total decisions) in blocks of 40.

Predictions and Analysis

Our theory predicts subjects to shift attention to the more relevant spore dimension. Under the view of attention as a transformation of perceptual space, subjects' representations of the set of spores should become stretched along the more relevant dimension and compressed along the less relevant dimension, as shown in Figure 2. Consider the stimuli in the highlighted areas of the figure. Under the attention-altered representation, most of their neighbors lie on the opposite side of the optimal decision bound. Therefore, similarity-based generalization will lead to higher rates of suboptimal actions for these critical stimuli, as compared to matched stimuli on the other side of the optimal bound. The same prediction arises if one assumes subjects learn prototypes for spores associated to the two actions, because each critical stimulus is more similar to the opposite prototype (taken to be the centroid of the region on that side of the optimal bound). Therefore our predictions do not depend on an assumption of exemplar-based generalization.

To test this prediction, we used bivariate logistic regression to fit a linear classifier to each subject's responses. This classifier estimated a linear boundary in stimulus space that best divided the spores the subject chose to grow in the sun from those grown in the shade. To illustrate this analysis, Figure 3 shows the response distribution of a typical subject in the learning group (defined below). Open and closed circles represent stimuli for which the subject selected each of the two actions, the solid line represents the optimal bound, and the dashed line represents the output of the linear classifier. The prediction from selective attention, based on the analysis of expected errors described above, is that the boundary separating each subject's decisions will be rotated relative to the optimal boundary, as shown by the dashed line in Figure 2. Importantly, the estimation of a linear decision bound is a purely descriptive analysis that makes no commitment

Figure 3: Distribution of responses on first step for a typical subject. Solid line shows optimal bound. Dashed line shows fit of linear classifier.

regarding psychological decision processes. In the companion modeling paper (Jones & Cañas, 2010), we fit a process model based on exemplar generalization, and it makes the same predictions.

In the absence of selective attention, the representation of the stimulus space would remain circular, and therefore by symmetry there should be no systematic bias in the subject's estimated decision bound. Therefore, testing for the predicted bias is a diagnostic way to determine whether our postulated attention-learning mechanism is operating.

Results

On average, subjects made the correct action on the second step of the task on 89.4% of trials. Figure 4 shows the distribution, across subjects, of the proportion of good mushrooms obtained following the first step. The histogram shows a clear bimodality, wherein many subjects performed at chance for the first step, but a significant number were able to learn effective actions.

As explained below, we only predict selective attention for subjects who learn the first stage of the task. Therefore we analyzed the responses of subjects who performed above 70% on the first stage. This cutoff was based on a visual inspection of Figure 4 to safely exclude subjects who were performing at chance. A total of 30 subjects performed at or above 70% on the first step of the task, 11 in the Length-relevant condition and 19 in the Number-relevant condition.

Figure 4: Distribution of performance on first step of task.

A linear classifier was fit to the first-step responses of each subject in the learning group. Figure 5 shows the orientations of the resulting decision bounds, indicated by dots on the circumference of the stimulus region. The mean orientation for each group is shown as a dashed line, and the optimal bound as a solid line. The Number-relevant condition is shown in black and the Length-relevant condition in grey. The mean orientation of the decision bound for subjects in the Length-relevant condition was 7.96° from the Number axis. This value was significantly different from the optimal bound (18.4° ; $t_{10} = -2.99, p = .014$) as well as from zero ($t_{10} = 2.29, p = .045$). The mean orientation for the Length-relevant condition was 7.33° from the Number axis. This too was significantly different from the optimal bound ($t_{18} = -3.25, p = .004$) and from zero ($t_{18} = 2.14, p = .046$).

Discussion

The results of the decision-bound analysis confirm that subjects made more errors on the critical stimuli. This prediction follows directly from the assumption of selective attention to the more relevant dimension. Because actions on the first step only led to colored mushrooms and not nominal reward, our results support the proposal that attention learning can be driven by internal value estimates and error signals.

We only predicted selective attention for higher-performing subjects for three reasons. First, our theory only predicts attention to be learned once some amount of learning has taken place in associating stimuli to appropriate actions. Attention learning essentially works as a bootstrapping method operating by altering generalization and thus requires some amount of reliable knowledge to begin with in order for adaptation of generalization to have a useful effect. Second, because our theory predicts a bidirectional relationship between attention and value learning, those subjects

who exhibit more selective attention should perform better on the task. Therefore, performance acts as a cue to indicate which subjects are more likely to exhibit a measurable effect. The third reason is purely methodological, in that the linear classifier requires a systematic set of responses in order to estimate a meaningful decision bound.

An alternative to our proposal of attention learning is that subjects simply disregarded one dimension of the stimulus entirely. This more strategic explanation is still consistent with our general theory of representation learning driven by RL, but the mechanism would be incompatible with continuous adjustment of attention weights. Regardless, the data rule out this explanation. The fact that the mean bound orientations were reliably different from zero (i.e., the less relevant axis) implies that subjects were sensitive to the less relevant dimension (they were just less sensitive to it than to the primary dimension). Another possibility is that some subjects disregarded one dimension and others disregarded the other, with most subjects in each condition disregarding the less relevant dimension. However, this explanation predicts a bimodal distribution of bound orientations at the subject level, which is clearly not present.

General Discussion

We have shown that humans can learn to shift attention in a dynamic task where reward is not given immediately following the decision that attention acts on. This finding tightly aligns with the internal TD-error signals that RL relies on, and it shows that direct external feedback is not required in order to learn selective attention.

At its core, RL uses predictions or knowledge about later states to build predictions and knowledge about prior states. Application of an RL model to our task predicts that after learning the second stage of the task, one mushroom becomes internally represented as more valuable than the other. This internal value in turn acts as a proxy reward that drives learning in the first stage of the task. Our findings support the proposal that this internal proxy reward signal is also capable of driving attention learning.

An alternative to the interpretation that our subjects are using RL-like internal values for the intermediate stimuli is the possibility of an explicit system that learns about both stages of the task simultaneously after the external reward at the end of each trial. Fu and Anderson (2008) found evidence for such a mechanism in a task structurally similar to ours. Explicit learning based on declarative memory is not, however, incompatible with RL. RL as we have discussed thus far, in its most simple form, only updates estimates about the most recent state. However, specific mechanisms, termed eligibility traces, have been explored within RL to maintain information across time steps to facilitate learning (Sutton & Barto, 1998). Eligibility traces permit simultaneous updating of multiple prior eligible states. Declarative memory may play an important role in encoding these eligibility traces, and therefore Fu and Anderson's results do not preclude an underlying RL

mechanism for learning several steps of a task at once.

Furthermore, declarative memory is unlikely to have played a role in the first step of the present experiment. First, in Fu and Anderson's design (2008), there was a direct correlation between the action in the first step and the eventual reward, which could support direct learning of the first action. In our design, only the conjunction of the spore and the action taken on it was directly related to the possible outcomes after the second step. Second, the spores were drawn from a rich set varying on two continuous dimensions, whereas the second stage of the task was very simple. Therefore subjects likely learned values for the intermediate mushrooms, which could then be used as feedback for the first action, well before the relatively weak correlation between spore-action pairs and final reward could be learned. Third, we have shown that subjects' decision bounds were consistently tilted away from unidimensional rules, indicating that subjects learned the first action using implicit information-integration processes not amenable to declarative memory (Ashby & Maddox, 2005). Though our current work does not completely preclude other learning mechanisms, we sought to isolate mechanisms directly related to RL and TD error, and our results show good support for such mechanisms.

Although not tested directly, the behavior of the subjects who did not learn the first stage sufficiently in our task fits well into the learning framework we propose. Before the differential value of the mushrooms is learned, the feedback to all actions of the first step is constant, which drives attention to generalize across the entire spore space. It is possible that by the time some subjects learned the optimal actions for the second step, they may have learned to entirely disattend any variability of the spores. This inattention is self-perpetuating and prevents future learning.

The potential for learned inattention in dynamic tasks has interesting theoretical and practical implications, because it could make aspects of a task far removed from overt reward difficult to learn. From this perspective, it is clear that an understanding of the mechanisms of attention learning could be beneficial in designing human training programs, such as backward chaining to train intermediate value representations before earlier stages are encountered.

The primary question we examined here was whether TD error, and therefore RL, can have an influence not just on learning values of stimuli within a fixed representation, but whether the representation itself can be altered. Shifts in attention alter the similarity structure of a stimulus space and therefore typify the sort of changes in representation we predict RL to effect. That humans exhibited changes in representation in the service of learning a new task involving fine discrimination of stimuli suggests a rich interplay of representation learning and RL.

Abstract

How is reinforcement learning possible in a high-dimensional world? Without making any assumptions about the structure of the state space, the amount of data required to effectively learn a value function grows exponentially with the state space’s dimensionality. However, humans learn to solve high-dimensional problems much more rapidly than would be expected under this scenario. This suggests that humans employ inductive biases to guide (and accelerate) their learning. Here we propose one particular bias—sparsity—that ameliorates the computational challenges posed by high-dimensional state spaces, and present experimental evidence that humans can exploit sparsity information when it is available.

Keywords: reinforcement learning; attention; Bayes.

Introduction

Reinforcement learning (RL) in high-dimensional state spaces is a notoriously difficult problem in machine learning (Sutton & Barto, 1998), primarily because of the *curse of dimensionality*: The number of states grows exponentially with dimensionality (Bellman, 1957), and thus if one were naively to represent a separate value (expected reward) for each state, one would require astronomical amounts of data to effectively learn the value function (and thereby behave adaptively). Nonetheless, humans appear to learn rapidly from small amounts of data. Thus, while substantial evidence has accumulated that human behavior follows the predictions of RL models (Dayan & Niv, 2008), these models may fundamentally underestimate the learning capabilities of humans.
