Figure 3: Percent correct at pretest and posttest for each presentation format.

no diagram) \times 2 (test time: pretest vs. posttest) repeated measures ANOVA on the percent of problems answered correctly yielded a main effect of test time, $F(1, 72) = 5.10$, $p < .05$, $\eta_p^2 = .07$. There was no main effect of presentation format $F(2, 144) = 1.56$, *ns*. However, the interaction between presentation format and test time was significant, $F(2, 144) = 5.25$, $p < .01$, $\eta_p^2 = .07$. To interpret this interaction, we conducted follow-up repeated measures ANOVAs on presentation format, separately for pretest and posttest scores. No significant differences among presentation types were found at pretest $F(2, 144) = 1.91$, *ns*. In contrast, at posttest, a main effect of presentation format was found, $F(2, 144) = 3.95$, $p < .05$, $\eta_p^2 = .05$. Follow-up pairwise comparisons with Bonferroni correction indicated that students scored higher on problems with vertical diagrams than those with no diagrams ($p < .05$). No differences were found between scores on horizontal diagrams problems compared with either of the other presentation formats.

Students solved more vertical problems correctly on the posttest after receiving training on creating and using simpler versions of those diagrams ($t(72) = 2.83$, $p < .01$). Students also improved on horizontal diagrams problems after vertical diagram training ($t(72) = 2.80$, $p < .01$), but no improvement was found on problems that did not contain diagrams ($t(72) < 1$, *ns*). A repeated measures ANOVA on the amount of improvement shown yielded a main effect of presentation type, $F(2, 144) = 5.7$, $p < .05$, $\eta_p^2 = .07$. Follow-up pairwise comparisons with Bonferroni correction indicated that students improved more on problems with vertical diagrams (11%) and horizontal diagrams (10%) than those with no diagrams (both p 's $< .05$). No difference was found between improvement on vertical and horizontal problems.

Error Analysis: The nature of the improvement

To investigate the source of this improvement in scores on the diagrams problems, we conducted a qualitative analysis of the types of errors made by students while solving each type of problem on the pretest and posttest. Four pretest and thirteen posttest problem attempts were found in which students drew diagrams to help them solve

the no diagrams problems; these incidences were thus excluded from the subsequent response and error analysis. One possible source of improvement was that exposure to the diagrams could have made students more comfortable with, and thus more likely to attempt, diagrams problems on the posttest, leading to a higher possible number of diagrams problems answered correctly. To examine this hypothesis, we coded whether students attempted to solve each problem or if they failed to respond to it. We then computed the percentage of each type of problem that was attempted at pretest and posttest. As can be seen in Figure 4, students attempted more problems of each of the three formats at posttest compared with the pretest. This suggests that a higher response rate for diagrams problems is not a viable explanation for the improvement.

A second, more plausible hypothesis was that students better understood the mapping between the diagrams and the stories as a result of instruction. Given that their experience with the Picture Algebra unit trained them to build components of diagrams to represent the information in a story problem, this hypothesis seemed plausible. This improved understanding should lead students to make fewer errors in which they demonstrate failure to make sense of the information in the problem. To test this, we coded student responses in terms of whether they were correct, contained an arithmetic error (e.g., adding $4 + 6$ and getting 9), or contained a conceptual error—one that indicated a misunderstanding of the role of the numbers in the problem (e.g., for the problem pictured in Figure 1, solving the problem as if 7th graders collected 17 fewer cans than 8th graders, instead of 17 more cans). In previous work, adding diagrams to story problems was shown to prevent older, high-achieving students from making common conceptual errors when solving the problems (Booth & Koedinger, 2007), but younger and lower-achieving students did not receive this benefit. Results from the present study indicate that after instruction it appears that fewer horizontal and vertical diagrams problem attempts contained conceptual errors than did at pretest whereas no reduction was apparent for problems without diagrams (see Figure 5).

Discussion

Results from the present study replicated the previous finding that diagrams are not inherently beneficial for solving algebraic word problems. At pretest, no diagrammatic advantage was found for low-achieving pre-algebra students. After instruction, however, the same students experienced a diagrammatic advantage, and there was evidence of transfer of instruction benefits to the non-instructed diagram format. Students made fewer conceptual errors with both types of diagrams after instruction, suggesting that increasing students' skill at mapping between story problems and supplemental diagrams can afford low-achieving students the same benefits as those enjoyed by their higher-achieving peers. Interestingly, no improvement was found for the no diagram condition, suggesting that students' general word problem solving abilities did not increase. Presumably, if students had drawn diagrams to help them solve those problems, as they did in their training, they would have had greater success.

One specific mechanism of the diagrammatic advantage is that it has been shown to increase the likelihood that students will achieve a conceptually sound understanding of a problem, and avoid common conceptually flawed solution paths (Booth & Koedinger, 2007). Consistent with this finding, results from the present study indicated that students reduced the number of conceptual errors made at posttest on transfer problems with diagrams compared to those without diagrams. The likely mechanism by which the diagrammatic advantage emerges is through increased experience coordinating information from two sources, which helps students learn to create appropriate links between the information (e.g., the components of the diagram with the corresponding components of the text). This general ability enables successful mapping between sources in new diagrammatic problems, yielding a sound representation of the overall problem, which leads to fewer critical conceptual mistakes in solution. The process of constructing the diagram facilitated this process by forcing students to make connections explicit; this is consistent with Van Meter & Garner's (2005) assertion that the benefit of diagram construction is that it necessitates integration

between text and diagram. The Picture Algebra lesson provided practice opportunities with feedback for students to gain the general mapping ability, which they were then able to apply successfully to the test problems. Further research is needed to determine whether and how developing students naturally acquire this skill, whether through cognitive maturation (and perhaps the development of more formal reasoning skills), through certain types of experiences that become more prevalent as children age, or some combination thereof.

Results from this study suggest that, while low-achieving students have difficulty interpreting diagrams and using them to their benefit when solving problems, it may not be necessary for students to have specific instruction or experience with a given type of diagram in order to use it effectively. Rather, acquiring more general diagram-parsing skills that facilitate mapping between text and any sort of diagram may be more beneficial. The instruction presented in this study did not just increase comprehension of more complex vertical diagrams; it helped cultivate a broader skill which allowed them to also use complex horizontal diagrams to solve the problem. Future research should investigate the nature of broad diagram-parsing skills and determine how best to teach them to help all students benefit from diagrams and other external representations of instructional information in Algebra.

Why do four- year- olds show poor cross-modal transfer between haptic and vision?

Abstract

Four year olds have difficulty transferring information from the haptic to the visual modality. This difficulty may reflect qualitative differences in haptic and visual object representations or children's inability to obtain the same kinds of perceptual information in the two modalities. Twenty 4-year-olds explored novel objects either haptically or visually, then haptically chose a match from among three test objects that each matched the exemplar on one perceptual dimension. Children chose shape-based matches after visually exploring category exemplars. However, after haptic exemplar exploration, children were equally likely to pick a shape- or texture-based match. Analysis of children's hand movements during haptic exploration showed that certain movements reliably predicted shape-based matches. This finding suggests that children have difficulties in cross-modal transfer because their haptic exploration is not driven by a top-down perceptual focus as it is in adults.

Keywords: Haptic Perception; Cross-modal Transfer; Development

Introduction

The use of perceptual information obtained in one modality - for example, haptics - for use in a task in another modality - for example, a visual task - involves cross-modal information transfer. Cross-modal transfer is important because it allows for inter-sensory predictions. For example, being able to anticipate what an object will look like given that you have only touched it allows for efficient and quick interactions with the world. Adults appear to have no difficulty transferring novel information gathered in one perceptual modality for use in a second modality (e.g., Abravanel, 1971, 1973; Easton, Srinivas, & Greene, 1997; Reales & Ballesteros, 1999). However, there are reports that preschool-aged children have difficulty in cross-modal transfer. In particular, children perform poorly in object recognition tasks requiring the transfer of information from haptics to vision. Two explanations for these findings have been proposed. The first proposal is that there are qualitative differences between the representations that children form from visual and haptic experience, so that translation between the two modalities is hampered. The second proposal is simply that young children have poor haptic perception. The present study explores these two possibilities.

Qualitatively different representations

Bushnell and Baxt (1999) used real-world familiar and novel objects to test 5-year-olds in object recognition requiring either intra- or cross-modal use of haptic or visual information. The children did well in object recognition in intra-modal tasks with both familiar and novel objects, and in cross- modal tasks with familiar objects. Children's performance was markedly poorer, however, with novel objects. Bushnell and Baxt (1999) suggested that "hand-mages" - representations formed entirely from haptic exploration - differ importantly from visual images ("eye-mages"). They proposed that attention during haptic exploration might be focused on material-based properties (texture, mass, rigidity) whereas in vision attention is focused more on shape and color. These differences in perceptual focus would then presumably lead to qualitatively different representations and therefore poorer performance in cross-modal tasks as compared to intra-modal tasks.

Kalagher and Jones (2010) used a novel name extension tasks to test Bushnell and Baxt's (1999) hypothesis that representations formed through experiences in different modalities are qualitatively different. In the standard version of this task (c.f., Landau, Smith, & Jones, 1988), children are visually presented with a novel object (the exemplar) and told its novel name. Children are then visually presented with three test objects; each matches the exemplar on one perceptual dimension - color, texture, or shape - and differs from the other two test objects on the other perceptual dimensions. Children are asked to indicate the object that has the same novel name as the exemplar. Past experiments have shown that children by 2 years of age typically choose shape-based matches predominately over texture- or color-based matches (e.g., Smith, Jones, Landau, Gershkoff-Stowe, & Samuelson, 2002). This "shape-bias" is thought to reflect an acquired attentional bias. Kalagher and Jones (2010) tested children 2 ½ to 5 years of age and adults in a modified version of this task. Children in their experiment explored exemplar objects either haptically or visually. Test objects were then presented visually. All ages in that experiment chose a preponderance of same-shape matches after visual exemplar exploration. However, only 5-year-

olds and adults made shape-based matches after haptic exploration. Children younger than 5- years- old chose test objects at random. Importantly, when older children and adults did choose matches systematically after haptic exploration, they did not make texture matches as Bushnell and Baxt (1999) might predict. Instead, they chose shape-based object matches just as they did after visual exploration. This finding suggests that representations in the two perceptual modalities are not qualitatively different.

Haptic perception

The mature haptic perceptual abilities of adults have been studied extensively. Lederman and Klatzky (1987) studied the hand and finger movements of adults who were attempting to extract information about specific object properties using haptics alone. The researches identified a number of stereotyped manual movements that they called “exploratory procedures” (EPs). EPs are thought to be driven primarily by top-down processes such as task goals but also, to a lesser extent, by bottom-up sensory information. What then is known about young children’s haptic perception? A number of studies have reported poor haptic perception in young children (e.g., Abravanel, 1972; Rose, Blank, & Bridger, 1972). For example, Milner and Bryan (1970) asked 5 to 7 year olds to make same/different judgments about object shape in both intra- and cross-modal conditions. The magnitude of the improvements made between 5 and 7 years of age were comparable in both the intra- and cross-modal conditions. The authors therefore concluded that the developmental change was due to gains in children’s haptic abilities. However, other researchers have found that 5-year-old children’s haptic perception is actually quite advanced, at least when they are asked to explore familiar objects (e.g., Bigelow, 1981). Kalagher and Jones (2010) found mature haptic exploratory behaviors in 5- year- olds but fewer such behaviors in younger children. Their analysis of children’s hand movements during haptic exploration showed that certain movements reliably predicted subsequent shape- or texture-based matches: however, children younger than 5 produced these hand movements at very low frequencies.

In summary, young children’s difficulties with haptic-to-vision information transfer appeared in a previous study to stem from their failure to execute mature hand movements rather than from qualitative differences of object representations in the two modalities. In the present study, we asked whether additional tests of children’s haptic exploratory abilities would point to the same conclusion. More specifically, children in the present study participated in two new conditions: (1) a visual exemplar exploration – to – haptic recognition condition; and (2) a haptic exemplar exploration – to – haptic recognition condition. The visual exemplar exploration – to – haptic recognition condition, like the haptic exemplar exploration - to – visual recognition condition in the previous research, required children to transfer information across perceptual modalities. However,

because children’s attention during visual exploration is consistently biased towards object shape (e.g., Smith et al., 2002), we speculated that children might make more systematic choices using information from vision to make haptic object matches than they had made using information from haptic to make visual matches. In the former case, they would know what they were looking for: that is, their visual explorations would lead them to focus on object shape. A finding that children did not make systematic shape-based matches in this condition would be further evidence against the idea that representations in the two perceptual modalities are qualitatively different and do not translate.

The haptic exemplar exploration – to – haptic recognition condition eliminated the need to transfer perceptual information across modalities. Thus, this condition tested children’s haptic perception only. A finding that children made systematic matches in this condition would indicate that their haptic perceptual abilities were good. Systematic texture matches would support Bushnell and Baxt’s (1999) idea of “hand-mages”. A failure to match objects systematically would suggest that neither shape nor texture had been perceived well enough during object exploration for subsequent use in object recognition in the haptic mode.

Methods

Twenty four- year- old children (range = 46.8 to 56.1 months; *Mean* = 51.65; 10 males) participated in the study. Participants reflected the local community in social class, ethnicity, and racial identity: almost all participants were from white, middle class families.

The stimuli consisted of 16 object sets, each with one exemplar, and three test objects. Exemplars and test objects were 3-dimensional, novel objects constructed from a variety of materials including wood, clay, and cloth. Sizes ranged from 7 to 17 cm. Colors, textures, shapes and masses were widely varied. Each of the test objects shared a different attribute –its color, texture, or shape – with the exemplar, and differed from the exemplar and the other two test objects on the other two dimensions (See Figure 1 for a sample stimulus set).

Figure 1: Sample stimulus set: 1 exemplar object, and 3 test objects, each matching the exemplar on 1 dimension – shape, texture, color – and differing from the exemplar and each other on the other 2 dimensions.

All participants completed two blocks of trials, each consisting of three warm-up trials and eight test trials. In one block of trials, children were limited to visual

exploration of the exemplars (“Visual Exemplar Exploration” condition). In the other block of trials, children were limited to haptic exploration of the exemplars (“Haptic Exemplar Exploration” condition). The order of conditions was counterbalanced across participants. The 16 stimulus sets were divided into two groups and the stimulus groups were counterbalanced within conditions. Thus, half of the participants saw Stimulus Group 1 in the Visual Exemplar Exploration condition, and the other half of the participants saw Stimulus Group 2 in that condition.

Each participant was seated at a table next to his or her parent and across from the Experimenter who explained that they were going to play a “matching game”. The procedure began with three warm-up trials to ensure that participants understood the task. Warm-up trials differed between the two conditions. In each warm-up trial in the Visual Exemplar Exploration condition, participants were simply handed a familiar object and told its name (e.g., “Look, here is a spoon). After three seconds, the Experimenter retrieved the object. In each warm-up trial in the Haptic Exemplar Exploration condition, participants placed their hands and forearms inside a box; a piece of cloth was pulled over their arms to prevent participants from seeing inside the box. The Experimenter put a familiar object into the hands of the participant within the box, identified it by name, and asked the participant whether he or she could feel it (e.g., “This is a spoon. Can you feel the spoon?”). For the test trials in both conditions, participants had their hands and forearms inside the box and a piece of cloth draped over their arms to prevent them from seeing inside the box. On each trial, three test objects were placed inside the box (e.g., a cup, a comb, and a spoon) and the child was asked to pull out the test object with the same name as the exemplar (e.g., “Can you find me the spoon?”).

Test trials followed warm-up trials immediately and were structured in the same way: participants were shown or handed the exemplar from one object set at a time and told its novel name (e.g., “This is a teeka”) then asked to find a haptic match for the exemplar (e.g., “Can you find me another teeka?”) from among the three test items inside the box. Children were given a sticker after each trial regardless of which choice they made. The experiment was digitally recorded, and records were later scored for the test objects – shape match, texture match, or color match – chosen on each trial.

The recordings were also coded for the children’s hand movements while exploring test objects in the Visual Exemplar Exploration condition, and category exemplars and test objects in the Haptic Exemplar Exploration condition.

Results

Object Recognition To determine whether visual or haptic exemplar exploration led predominantly to shape or texture matches, the proportions of shape and texture matches in each condition were calculated. This resulted in 4

categories of scores: (1) visual exemplar exploration resulting in shape match (V->SH), (2) visual exemplar exploration resulting in texture match (V->TX), (3) haptic exemplar exploration resulting in shape match (H->SH), and (4) haptic exemplar exploration resulting in texture match (H->TX). The mean proportions of children’s scores in each category can be found in Table 1.

Table 1. Means and Standard deviations for proportions of shape- and texture- based matching in the Visual Exemplar Exploration and the Haptic Exemplar Exploration conditions.

	Mean	SD
V-SH	0.54	0.27
V-TX	0.32	0.22
H-SH	0.42	0.14
H-TX	0.39	0.13

The proportions were first entered into a 2 Order (Visual Exemplar Exploration first or second) x 2 Gender (male/female) x 2 (Exemplar Exploratory Modality: Haptic/Visual) x 2 (Match Type: Shape/Texture) mixed analysis of variance. There were no between subjects main effects for either Gender ($F_{(1,16)} = 2.67, p = ns$) or Order ($F_{(1,16)} = .17, p = ns$). There was a significant main effect of Match Type ($F_{(1,16)} = 4.5, p < .05$) with more shape-based matches exceeding texture-based matches. We did not find a main effect of Exemplar Exploratory Modality ($F_{(1,16)} = .79, p = ns$). Figure 2 graphs the marginally significant Exploratory Modality by Match Type interaction and illustrates the fact that shape choices dominated choices after visual exploration ($F_{(1,16)} = 3.82, p = .06$).

Figure 2. Match Type by Exploration Modality interaction

The proportions of shape and texture choices shown in Table 1 were also compared to chance (.33) using one-sample t-tests. Children chose same-shape matches at above chance levels in both conditions (H->SH: $t_{(19)} = 2.59, p < .05$; V->SH: $t_{(19)} = 3.46, p < .05$). Their texture-based matches were marginally above chance following haptic exemplar exploration of the exemplar ($t_{(19)} = 2.05, p =$

.054), but not following visual exploration ($t_{(19)} = -.34, p = ns$).

In sum: children showed the previously well-documented bias to preferentially attend to shape in object matching (e.g., Smith et al., 2002) in the Visual Exemplar Exploration condition. However, children in the Haptic Exemplar Exploration condition were equally likely to pick a shape or texture match. Thus, after visual exemplar exploration, children systematically chose shape-based matches suggesting that the representations they formed focused predominately on shape. After haptic exemplar exploration we do not see a similar systematic preference and therefore cannot claim that children's representations formed through haptic experiences are or are not qualitatively different from their representations formed through visual experiences.

We next examined children's hand movements during the test phase in the Visual Exemplar Exploration condition and during both the exemplar exploration and the test phase portions of the Haptic Exemplar Exploration condition.

Hand movements Initially, we attempted to use the taxonomy of exploratory hand movements developed by Lederman and Klatzky (1987) to code children's hand movements while exploring objects in both conditions. However, children in the present study did not produce these movements. Therefore, 5 categories of manual exploratory behavior identified by Kalagher & Jones (2010) in the same age group were used instead. The categories are: (1) "sequential finger movements" (rotating the object around only with fingertips), (2) "fingers palpating" (fingers palpating/ squeezing the object), (3) "static fingers" (fingers placed on object but not moving), (4) "hand grasping" (grasping the object with one hand), and (5) "hand press" (pressing the object between both hands with fingers outstretched).

We also coded instances of children's verbalization specifically recording shape-related verbalizations (e.g., "This feels like the letter 'Z'") and texture-related verbalizations (e.g., "This feels fuzzy"). However, such verbalizations were rare, occurring in fewer than 15% of trials, and were therefore not analyzed.

Hand movements were clearly visible in 108 exemplar exploration trials and 101 test trials in the Haptic Exemplar Exploration condition (H.E.E. and H.E.T.O., respectively) and in 97 test trials in the Visual Exemplar Exploration condition (V.E.E.). Figure 3 shows the frequencies of the 5 kinds of hand movements produced by children in each of these kinds of trials.

Figure 3. Frequencies of exploratory hand movement behaviors.

We then asked whether any of these five behaviors predicted whether children would make a shape-based, texture-based, or color-based (i.e., random) object match. We used multinomial logistic regression to address this question. Multinomial logistic regression is a generalization of the binomial regression and is useful when the dependent variable has more than two discrete choices. In a multinomial logistic regression model, the estimates for the parameter can be identified compared to a baseline category. For our analyses, we used a dependent variable SCORE (1 = shape match, 2 = texture match, and 3 = color match), and independent predictor variables of hand movement patterns. A SCORE value of 3 was specified as the baseline category. The test then estimated the effects of the independent variables on choosing texture or shape matches over making a color-based match.

When the multinomial logistic regression test was carried out on the data the Likelihood Ratio (LR) chi-square test that at least one of the predictors' regression coefficients was not equal to zero yielded significant results, $\chi^2_{(2,14)} = 118.5, p < .0001$. This outcome indicated that particular hand movement behaviors affected subsequent matches (i.e., the participant's score). From the results of the multinomial logistic regression analysis, 2 main effects were significantly predictive of SCORE. The significant main effects were: *sequential finger movements* ($\chi^2_{(2,14)} = 48.22, p < .0001$), and *hand press* ($\chi^2_{(2,14)} = 24.4, p < .0001$). Further chi-square analyses showed that children's use of *sequential finger movements* was predictive of later shape

matches, $\chi^2_{(2,14)} = 73.34, p < .0001$, while the absence of the hand movement pattern *hand press* was also predictive of later shape matches, $\chi^2_{(2,14)} = 30.36, p < .0001$.

The fact that two specific hand movements (i.e., *sequential finger movements*, and *hand press*) during haptic exploration predicted children's subsequent choice of a same-shape match suggests that children were able to obtain shape information and use that information intra and inter-modally.

Item Analysis Individual items were classified into three categories by the extent to which each was matched predominately by shape, texture, or color. These categories and their criteria are as follows: (1) "dominant match" criterion: one feature (shape or texture) is matched more than twice as often as the second more frequently used feature; (2) "selective match" criterion: item is selectively matched but differently by different children (both shape and texture matches separately are chosen at least twice as often as color); (3) "random matches" – remainder. Figure 4 displays the results of applying these criteria to the objects in both conditions.

Figure 4. Frequencies of item analysis match types for the Visual Exemplar Exploration condition (white bar) and the Haptic Exemplar Exploration condition (black bar).

When the 16 category exemplars were explored visually, eight objects were subsequently matched consistently and by different children on one dominant perceptual dimension (shape-6 and texture-2). When those same objects were explored haptically, only 5 were matched on one dominant dimension (shape-3 and texture-2). A chi square analysis found no difference between conditions in the kinds of dominant matches (shape or texture) that children made ($\chi^2_{(1)} = .33, p = ns$).

Discussion

Our primary interest was in whether restricting exemplar exploration to either vision or haptics would have consequences for the kinds of test object that children chose in the haptic modality to match the exemplar objects. When children explored category exemplars visually, they were more likely to pick a same-shape match than if they had

explored the exemplar haptically. This finding is consistent both with Bushnell and Baxt's (1999) suggestion that "eye-mages" represent different perceptual information than "hand-mages", and with the abundant evidence that young children's attentional focus on shape in visual object perception leads to a predominance of shape-based object matches (e.g., Smith, et al., 2002).

When category exemplars were explored haptically, children were equally likely to pick a shape- match or a texture- match. This finding is not consistent with Bushnell and Baxt's (1999) idea that "hand-mages" formed from haptic input predominantly represent object texture, mass, and rigidity. Instead, children in this study appeared to be matching each item on whatever perceptual information gained from exploration of each exemplar object was most salient to them. They do not appear to be using a top-down perceptual focus that would allow them to match objects systematically by either shape or texture.

Overall, we did not find compelling evidence of qualitative differences in the object representations from visual and haptic inputs. Instead, children's use of representations formed through haptic experience seemed to be affected by the most salient properties of the exemplar object (bottom- up), rather than by a particular perceptual focus such as the "shape bias" seen in vision (top-down).

The item analysis provides further support for this last point. When comparing children's consistency in making shape or texture matches in the Visual Exemplar Exploration condition to the children's consistency in making shape or texture matches in the Haptic Exemplar Exploration condition, we did not find a reliable difference in the number or kinds of *dominant matches* made. This result suggests that representations from input in the two modalities are not qualitatively different.

A secondary goal of this experiment was to further examine the status of young children's haptic abilities. Examination of haptic exploratory behavior indicated that when children executed *sequential finger movements* it was likely that they would make a subsequent shape-based match. This finding replicated the results Kalagher and Jones (2010). However, we found no parallel relation between particular hand movements during haptic exploration and children's later choices of texture matches. Again this finding suggests that children's haptic exploratory behavior is not guided by a particular perceptual focus or goal.

Interestingly, the present results show that 4- year -olds can haptically obtain shape information when they have a clear idea of what they are looking for as reflected in the predominance of shape matches in the Visual Exemplar Exploration condition. This predominance suggests that when children visually explored exemplar objects, they formed representations that contained and perhaps emphasized shape information. Guided by these representations, children's haptic abilities were good enough to obtain the shape information needed for a same-shape match. This finding is consistent with previous reports that

found that young children have good haptic perception of familiar objects (Bigelow, 1981; Bushnell & Baxt, 1999; Morrongiello, Humphrey, Timney, Choi, & Rocca, 1994).

In summary, 4 year olds' representations of novel categories experienced haptically do not appear to be focused on either texture or shape. However, the object representations constructed from haptic perceptual input appear to be good enough to support object matches on whichever perceptual dimension is most salient. Thus, the present results indicate that children younger than 5 years of age have functional haptic abilities.

Although haptic perceptual exploration did not appear to be bias towards one kind of perceptual information over another, visual experience of novel categories appeared in this study, as in many previous studies, to lead to the formation of representations focused of shape. A new finding in the present study is evidence that representations built from visual input can transfer, complete with their focus on shape, into the haptic mode. Specifically, the present findings of a predominance of same-shape object matches in the haptic modality given only visual experience of the exemplar object suggests that representations of that visual experience guided the haptic identification of a matching object. Thus, it appears that the shape bias in visual object matching remained intact during the transfer of perceptual information about exemplar objects from the visual into the haptic realm.

Collaborative Sensemaking in the Blogosphere

Richard Alterman (alterman@cs.brandeis.edu)

Johann Larusson (johann@cs.brandeis.edu)

Computer Science Department, Volen Center for Complex Systems
Brandeis University

Abstract

This paper presents a case study of a class of students co-blogging throughout the semester. The students collaboratively made sense of the course material. The class blogosphere became a repository of interpretations, reflections, opinions, monologues and dialogues about the course content. Over the course of the semester there was an aggregation of “sense made” that was “mined” by the students throughout the semester. The data shows that students leverage the contributions of other students when authoring their own posts and later when they write papers.

Keywords: Collaborative sensemaking; Online discourse communities; Co-blogging; Education; Case Study; Field study; Ethnography

Introduction

In a class it is not enough just to remember or retain the information that is presented, it must be “digested” or understood (Dewey, 1964: p. 249): “Of course intellectual learning includes the amassing and retention of information. But information is an undigested burden unless it is understood. It is *knowledge* only as its material is *comprehended*. And understanding, comprehension, means that the various parts of the information acquired are grasped in their relations to one another – a result that is attained only when acquisition is accompanied by constant reflection upon the meaning of what is studied.”

The in-class lecture and discussion provides an explanation of key concepts within the course content and a causal story about how the parts are connected. A student begins to learn the background knowledge, a foundation and framework for understanding the course material. The acquisition of this kind of background knowledge prepares the student for being able to produce causal explanations of key ideas, the relations between issues, and the connections between conclusions drawn from different evidences. Acquiring the background knowledge is a good part of what any course is about.

In itself, the in-class lecture and discussion is not enough to achieve a deeper understanding of the material. Other activities, including carefully reading the course texts, doing homework, and studying for exams, are exercises that help students “digest” material. Finding venues for students to cooperatively verbalize, explain, and discuss undoubtedly has positive educational value. However, finding a time and place for students to meet is a significant barrier for creating collaborative sensemaking opportunities.

This paper explores the value of online co-blogging as a discourse community that provides an arena for the students to work together and collaboratively make sense of the ideas

and concepts taught in the class. The blogosphere is a play space for students to work at “understanding” the course material, even though the students work at different times and in different locations. Activity in the blogosphere is an opportunity to reflect, verbalize, get feedback, read alternate interpretations of the same material, and discuss: the students collectively make sense of the course material. There is a clear boundary between those items which are jointly made sense of in the blogosphere and those that are not.

This paper will present a case study of an interdisciplinary class on Internet & Society where the students co-blogged throughout the semester. The blogosphere provided an intersubjective space in which the students collaboratively worked at making sense of the lecture and course texts. In the blogosphere, the students created *common* and *background knowledge* (Lee, 2001). The data shows that the students drew on the sensemaking of other students that aggregated during the semester in support of their own individual sensemaking.

Co-Blogging

In a student co-blogging community, each student has a *blog*. The blog is composed of multiple *posts* written by the blog owner. Blog posts can summarize the key content of a text that was read for class, or develop an argument on some issue that was discussed during lecture. Students can read each other’s blog posts and *comment* on them. A discussion emerges when a blog attracts a lot of commentary from other students. Blogging on the course material is a learning activity that invites reflection and self-explanation and improves learning. Reading and commenting on each other’s blog posts provides students with other interpretations of the course material and the opportunity to discuss the content of the readings, which also helps learning.

In-class discussions have significant time constraints. Online, students can converse – and (co-)reflect – at their leisure, when they are prepared. Because co-blogging is a text-based community, literal quoting of the text is easier to do: the data shows that in many cases, students literally copied, or paraphrased, a small portion of an assigned reading in order to focus their blog post. Perhaps these kinds of activities occur in an in-class discussion, but since face-to-face discussions are serial there are fewer opportunities for students to present different quotations from the text or alternative viewpoints on the same quote.

The co-blogging community is social and student-owned (Oravec, 2002). Because each student has her own blog, she has full control over the content and can establish personal and intellectual ownership of her work (Fredig & Trammell,

2004). Because co-blogging is Web 2.0 technology, the “buy-in” for students is fairly cheap (Glogoff, 2005; Duffy 2008). Because co-blogging occurs outside the bounds of class time and it is an asynchronous learning activity that does not require the student be collocated, it expands the opportunities for co-reflection and fruitful discussion.

In contrast to discussion forums, in a co-blogging learning activity, students develop individual identities: each student has her own blog. In a discussion forum each discussion has a deep tree structure, and in the blogosphere, the range of discussion is broader with multiple viewpoints, and conversations, emerging. In a discussion forum, because of “the branching structure, the large proportion of messages that terminated branches, and the abstracted nature of student interaction demonstrate an overall incoherence in online discussion. ... Leads to poorly interrelated monologues.” (Thomas, 2002). In the blogosphere discussions develop as smaller chunks of interaction. Where the comments of an individual student can be buried in an extended discussion in a discussion forum, in the blogosphere every student blog attracts a significant amount of attention (Larsson & Alterman, 2009).

When a student writes a blog post she has the opportunity to practice producing a narrative about the significant elements of the course material, making sense of the causal relations among the different elements of the course content (Williams & Jacobs, 2004). Co-blogging creates opportunities to exchange, explore, and present alternate viewpoints (Fredig & Trammell, 2004). It potentially exposes students to alternate ways of “seeing” and “constructing” what is significant and why (Oravec, 2002; Fredig & Trammell, 2004).

When a blog post attracts commentary, it serves to coordinate the students’ work at aligning their views. In this manner, the students can work “through” (Bødker, 1990) a post or discussion together, working at different times in different places to reach a common understanding. Discussions on issues related to the course material naturally emerge, enabling students to collaboratively work through the arguments and trade-offs, weighing and comparing different explanations and justifications (Okada & Simon, 1997), which positively impacts learning (Andriessen, 2006).

The discussions that emerge among the students create a dimension of interactivity. Some students comment (interact) more frequently than others (Rafaeli & Sudweeks, 1998). Each comment can be classified by its level of interactivity. Comments on posts can either elaborate or negotiate (Thomas, 2002). Comments can either be reactive, refer to a prior point in the emerging discussion, or they can be interactive, i.e. “recount the relatedness of earlier messages” (Beuchot & Bullen, 2005; Rafaeli & Sudweeks, 1998).

Case Study

In the Internet & Society course taught in Fall 2008, 25 students collectively blogged throughout the semester. The course was an introductory course. Students in the class were from a variety of disciplines. There were 8 females and 17

males. All of the students were undergraduates. There were 3 science majors and 1 science minor in the class. There were 12 students majoring in the social sciences and 8 minoring in the social sciences. The remainder of the class was either in the humanities or fine arts.

The focus of the analysis presented in this paper is on the co-blogging work that the students did during the time the class read two of the books that were required reading. The students wrote a short paper on each of these books.

Methods

All of the students’ online work was automatically recorded in a transcript, which enabled both quantitative and qualitative analyses. The transcripts can be treated as an event log file and accessed using database queries. Additional tools enable a larger variety of alternate analysis methods, including discourse, conversation, or interaction analysis. One tool replays the transcripts just as if one was viewing a videotape showing the evolution of the blogosphere. Another tool makes it easy for an analyst to systematically annotate, and tag each of the posts and all of the discussions that emerged.

If a student used a newsletter to navigate to the blogosphere, it was possible to determine that the student read the newsletter and also which conversation or post was their destination. If a student’s email client automatically viewed emails in a HTML format, it was possible to track whether a student opened a newsletter even if they did not navigate from the newsletter to the blogosphere. It was not possible to determine which parts of the newsletter were read.

At the end of the semester we distributed a survey, questions were on a 6-point Likert scale (from 1, not useful, to 6, very useful). The survey provided some data on the students’ perception of the academic value of the learning exercise and the functionality and practicality of the collaborative technology. The survey also included open-ended questions.

Metrics

Lectures were presented using slides that summarized the key points of the presentation. At the beginning of each lecture, hard copies of the slides were handed out to support student note taking. PDF versions of the slides were downloadable from the class website.

The lecture slides were used as a basis for identifying the inputs to the blogosphere. For each set of slides, the instructor identified a set of key topics that were covered by the lecture. For each topic a tag was created that was organized into a taxonomy and treated as the potential input to the blogosphere. All posts and comments in the blogosphere were tagged using these topic/tags; this roughly identified the content of each contribution. When the students post on these topics they are reflecting on important course content. One way to measure the impact of a given post is to count the number of comments or reads that it accrued.

Procedure

At the beginning of the semester, an in-class tour and exercise introduced the students to the important features of the co-blogging environment. The students were required to blog at the pace of one post per lecture: there were two lectures per week. A typical post was 1 or 2 paragraphs in length. The students were also required to read and comment on other contributions to the blogosphere. The co-blogging work of each student counted for 35% of his or her grade. Students had the option to opt-out of the study. No student opted-out of the study.

During the semester the students read four books. The students wrote short papers on two of these books. The focus of the analysis presented in this paper is on the co-blogging work that the students did during the time the class read the two books for which they wrote papers.

The Co-Blogging Environment

The co-blogging environment has been developed over a number of years in several different courses following the *design-based research* methodology (Barab, 2006). It is implemented using the Wiki Design Platform (WDP), which is a wiki-based educational platform that supports a variety of collaborative learning activities (Larsson & Alterman, 2009).

In the co-blogging environment, each student has a blog. Each blog post shows a picture of the author, a title, and tag that relates the post to a lecture given in class. At the bottom of a post there is a list of people who read the post. Any threaded discussion that emerges is shown below the relevant post. As a student writes her blog, she can read another student's post on the same topic with a click of the mouse. At the "front entrance" to the blogosphere, there is a list of the ten most recent posts or comments on posts. Each item in the list displays the name of the author of the post or comment and a short excerpt from the contribution. Students can also access the blogs via a word cloud or by searching the content in the blogosphere using keyword(s) or tag(s).

Students receive daily email newsletters that summarize the online co-blogging activity of the class in the previous 24 hours. The newsletter lists the title, author, and first line of all the newly created blog posts, and a list of similar information for any new comment. Students can use the links on the newsletter to directly navigate to any post or comment on the blog site that is of interest.

In the blogosphere there are two ways to be a *primary participant*: author a blog or act as a discussant on another student's blog (Alterman & Larsson, 2009). *Secondary participation* occurs when a student reads either a post or a discussion that has emerged online. A *tertiary participant* reads a brief description of a recent post or a new comment on a post in a newsletter. The students can assume different participant roles at different times. A student can be the author of a post, a contributor to a conversation initiated by a post, a reader of a post or conversation, or an interested party who reads about

the post or conversation in a daily newsletter. Secondary and tertiary participation are more peripheral kinds of participation.

Evaluation

Responses to the survey were positive. When the students were asked to rate the value of their online co-blogging work as a means of giving them first-hand experience with online collaborative learning, the average response was 5.6. In response to the question of whether the students felt the co-blogging community was useful, the average response was 5.3. When queried about the usefulness of the blogosphere for writing papers, the average response was 4.5. When asked as a yes/no question whether re-reading and reusing the blogging text helped the students write their papers, 67% answered in the affirmative.

There were a total of 155 blog posts, 113 comments, and 1010 reading events on the two books that are the focus of this study. There were 31 conversations of length 2, 15 of length 3, 7 of length 4, and 7 of length 5. The average conversation length was 2.85. The length of a conversation is defined as the number of contributions that were made to the discussion. For example, a post that receives one comment is a conversation of length 2.

There was no correlation between the number of tags on a given post and how often it was read; many of the best posts were thoughtful commentaries on a single topic. There was no correlation between the length of a conversation and the number of tags garnered in the conversation. There was, however, a strong positive correlation between the length of a conversation and the number of read events ($r(151) = .061, p < .01$).

Participating in the blogosphere

Students made two kinds of contributions to the blogosphere. As a *blogger*, each student produced an open journal, a monologue about the course content. As a *discussant* each student participated in a dialogue about the content of one or another post.

As a blogger, a student posted her reflections on some part of the course material. A blog post could refer to the text or quote the text; this occurred 75 times during the time the students co-blogged on the two books (roughly 48%). A post could refer to the lecture, an issue that was discussed in class, another blog, or to an outside article, site, or book (26 times; roughly 17% of the time for the two books). Frequently students included personal experiences or anecdotes as part of their post throughout the entire semester (73 times; roughly 14% of the time), and less frequently during the time they co-blogged on the two books (8 times; roughly 5%). Each of these were ways to initiate reflection.

Within the blogosphere, the monologues of the students were published and broadcast to the rest of the class, emerging in an open space, giving students exposure to multiple viewpoints and voices. Students viewed the same material

differently. Their different articulations complemented, regulated, or clashed with one another. All voices could “be heard”. The ratio, the balance, of these voices potentially gave a student a textured view of the course material. By means of *perspective-taking* an intersubjective space emerged (Tomasello et al, 1993).

In addition to authoring posts, students acted as discussants on each other’s posts. Much of the commentary was either an agreement with, or an expatiation of, another student’s point (49 times during co-blogging on the two books; roughly, 43% of the comments). These sorts of confirmations moved the students towards creating a common understanding of a particular interpretation of some portion of a text or lecture. Sometimes a student posed a question or asked for a clarification in her blog or comment, which was answered later by the comment from another student (10 times; roughly, 9% of the comments on posts for the two books). Other responses were more discursive: students frequently disagreed, espousing different viewpoints on the same topic (52 times; 49% of the comments). Comments were linked to other posts (2 times; roughly 2%). Comments either referred to the initial post (102 times; roughly, 90%) or another student’s comment on the post (14 times; roughly, 12%).

Intersubjective space

Participation in the creation and use of information in the blogosphere results in learning and the production of common knowledge. The students work together to “digest” the information that is presented during lecture or in the course texts.

The total number of additions to the blogosphere is a rough measure of the amount of information “digested” by the class while participating in the co-blogging exercise during the semester. One of the topics in the Internet & Society class was the advantages and disadvantages of “working home alone” as opposed to working in an office with your collaborators. Let $x_1, x_2 \dots$ represent the advantages and disadvantages of working home alone. Table 1 shows an idealized representative example sequence of events in the blogosphere that are ordered in time. At times t_1, t_2, t_3 , and t_4 interpretations of content presented in the text or lecture are aggregated: x_1, x_2, x_3 , and x_4 are added to the blogosphere.

Table 1: A sequence of events in the blogosphere.

Time	Event
t_1	Joe posts a blog on “working home alone”, x_1 .
t_2	Mary reads Joe’s post x_1 and posts comment x_2 .
t_3	Mary posts a blog on “working home alone”, x_3 .
t_4	Joe reads Mary’s comment on his post and replies. x_4 .
t_5	Ed reads the conversation between Mary and Joe.
t_6	Ed reads Mary’s post on “collocation”.
t_7	Mary reads Joe’s reply to her comment on x_1 .

What each student learns, how much each student learns, and to what degree the students learn the same things, is all variable. The extent to which students converge on a set of agreed upon factors and arguments concerning some key concept is an open question. The degree to which the students share their beliefs is not clear either.

Common ground is defined in terms of a belief about some proposition p : p is a part of common ground for a set of actors if they all believe p and they believe that the other actors also believe p and that those other actors believe that they believe p and so on (Clark, 1996; Clark & Brennan, 1991). For the sequence shown in Table 1, at no point does it appear that Mary and Joe have attained *common ground* on x_1 (common ground: Clark & Brennan, 1991). At time t_4 , Joe knows Mary read his post. At which point he may or may not believe that she understood his contribution. Suppose Joe believes Mary understood his contribution, he still does not know if Mary believes that he believes she understood his contribution. At time t_7 , were Mary reads Joe’s reply to her comment, even if Mary believes Joe believes she understood his contribution, Joe will not know that.

Lee (2001) makes a distinction between common, shared, and mutual knowledge. Each of these are distinguished by the *certainty of sharedness*. Common knowledge between two individuals is assumed to be held commonly by those individuals because that knowledge is considered to be general background knowledge within a community of which they are both a part. “Shared knowledge, on the other hand, is that information which has been established as shared as a result of interaction and discussion.” Mutual knowledge requires an infinite regress of mutual belief, the certainty of sharedness is 100%. In the case of the sequence of events shown in Table 1, is common or shared or mutual knowledge established?

Lectures and student activity in the blogosphere are good venues for establishing common knowledge (background knowledge). Key points in an assigned reading or a lecture are likely to be common knowledge for the students; only likely because not all students read the assigned material or attend, or listen closely to, lectures. Sharing of knowledge within the blogosphere is asymmetric. When a student writes a post in the blogosphere and another student reads it, the second student believes she has shared knowledge with the first but not vice versa. So, for the sequence of events in Table 1, at time t_2 , Mary believes she shares knowledge of x_1 with Joe, but Joe does not believe he shares knowledge of x_1 with Mary until time t_4 . At time t_5 , Ed may believe he shares knowledge of x_1, x_2 , and x_4 with Joe and Mary, but neither share that with him. And so on.

In a face-to-face interaction, beliefs are grounded from a sequential interaction. In an online community, because all the students are not always together at the same time in the same place, common and shared knowledge emerges intermittently and non-uniformly; it is not clear that mutual knowledge ever emerges from the blogosphere alone. Many of the things the students learn/know as a result of their participation in the blogosphere are beliefs that may be held in common and shared but they are not mutually known.

During the co-blogging activity

Table 2 shows that on average 57% of the topics a student “considered” in the blogosphere were those the student wrote

about in one or another of her posts. On average, the other 43% of the topics that a given student “considered” occurred as a result of commenting or reading in the blogosphere. The variance is high for these numbers because there were a few students who were not very active at all.

Table 2: Learning from other students.

	Average	Median	Stdev
Blogging	57%	55%	22%
Commenting	12%	8%	15%
Reading	31%	28%	20%

These numbers do not reflect the fact that many of the students took advantage of a feature of the blogosphere environment that made it easy for a student writing a blog post to read other posts on the same topic. Over the entire semester, there were 13,408 reading events, 4,693 of them occurred while students were authoring blog posts (roughly 35%). Thus students were able to “mine” other interpretations of the same content even while they were authoring blogs.

While writing papers

Figure 1 shows how activity within the blogosphere exposed students to topics that were later included in one of the two papers they wrote.

1. The y-axis compares the number of topics/tags assigned to each student’s posts and comments (primary participation) to that number for the same student’s topics/tags in his or her paper. A positive number means that more of a student’s paper was composed of topics they contributed initially in the blogosphere. A negative number means that a majority of the content in a student’s paper did not originate in contributions to the blogosphere.
2. The x-axis computes a similar number for reads (secondary participation). A positive number means that more of a student’s paper was composed of topics they read about in blogosphere prior to writing their paper. A negative number means that a majority of the content in a student’s paper did not originate from reading in the blogosphere.

Figure 1: Influence on paper writing.

Consider each of the four quadrants of the graph starting in the upper left-hand quadrant:

Q1: Primary participation provided preparation for writing papers.

Q2: Primary and secondary participation provided preparation for writing papers.

Q3: Secondary participation provided preparation for writing papers.

Q4: Primary and secondary participation provided some help, but most of these papers were derived from work that was not influenced by a student’s activity in the blogosphere.

For 16 of the 25 students, their work in the blogosphere provided background for the majority of the concepts that appeared in their two papers (their data is either positive on the x-axis or y-axis). The largest group of students (Q3) benefited most from the reading. The next largest group (Q2) benefited significantly from both primary and secondary participation in the blogosphere. These data confirm that students were “mining” the blogosphere to support their understanding of the material.

Figure 2 shows the correlations between the preparation for writing papers provided by reading, posting blogs, commenting, or doing all three. The trend line for all three activities combined is significant and positive ($r(23) = 0.485, p < .05$). The trend lines for reading ($r(23) = 0.402, p < .05$) and posting ($r(23) = 0.419, p < .05$) are also significant and positive. The trend line for commenting was not significant.

Discussion

Think of the blogosphere as a play space for students to work at “understanding” the course material. The blogosphere is an opportunity to reflect, verbalize, get feedback, read alternate interpretations of the same material, and discuss. The students are collectively making sense of the course material. The students leverage the aggregate online collaborative sensemaking throughout the semester.

The students produce multiple interpretations of the course material. The students reflect on the meanings of the assigned readings or a lecture given by the instructor in class. Frequently, posts include personal experiences or anecdotes. Comments on posts agreed with, or expatiated upon, another student’s contribution; they also took contrasting views. The students are *many working minds* collaboratively making sense and creating common and shared knowledge; enabling many minds to work together is a significant outcome of Internet technology (Sunstein, 2006).

The blogosphere became a repository of interpretations, reflections, monologues and dialogues about the course content. At various points in the semester the students chose to *mine* the aggregated sensemaking. Because posts and discussions, once created, persist and can be re-considered at a later time, students can increase their common and shared knowledge throughout the semester.

On many occasions, as students composed their own posts, they first sampled another student’s interpretation of the same lecture point or text. Right before a paper deadline, the students did heavy reading in the blogosphere in order to access

Figure 2: How different kinds of participation affect each student's preparation for writing a paper.

and review ideas, arguments, examples that were relevant to the paper they were writing, reproducing, in their own words, the content of relevant posts and discussions found in the blogosphere.

Concluding Remarks

During the semester, common and background knowledge is created by collaborative work in the blogosphere. The individual contribution of each student is an investment, the return on their investment is increased by the collective work of the class. The collective work of the class in the blogosphere produces multiple reflections on the course material. Students enrich their understanding by reading or commenting on the blogs and comments of other students.

The quantitative data from the case study shows that the students *mine* the blogosphere throughout the semester. When students write blog posts, 35% of the time they read other related contributions to the blogosphere first. On average 43% of the topics that a given student wrote about in an assigned paper was presaged by their participation in the blogosphere. The data also shows that for 16 out of the 25 students, the majority of the topics that appeared in their papers were first "played with" in the blogosphere as either a primary or secondary participation; the largest group of students benefited most from reading in the blogosphere. Finally, the data shows that there is a significant positive correlation between preparation for writing papers and a student's reading and posting activities in the blogosphere.

Inflectional Suffix Priming in Czech Verbs and Nouns

Filip Smolík (smolik@praha.psu.cas.cz)

Institute of Psychology, Academy of Sciences of the Czech Republic
Politických vězňů 7, Praha 1, CZ-110 00, Czech Republic

Abstract

Two experiments examined if processing of inflectional affixes is affected by morphological priming, and whether morphological decomposition applies to inflectional morphemes in visual word recognition. Target words with potentially ambiguous suffixes were preceded by primes that contained identical suffixes, homophonous suffixes with different function, or different suffixes. The results partially confirmed the observation that morphological decomposition initially ignores the affix meaning. With verb targets and short stimulus-onset asynchrony (SOA), homophonous suffixes had similar effects as identical suffixes. With noun targets, there was a tendency to respond faster after homophonous targets. With longer SOA in verb targets, the primes with identical suffix resulted in shorter responses than the primes with a homophonous suffix. Similar tendency was observed in some noun targets. The results confirm that it is possible to prime inflectional affixes, but that the mechanisms of morphological analysis may operate differently for different types of affixes.

Keywords: morphological priming, affix priming, word recognition, morphological decomposition, inflection

Introduction

Numerous studies suggested that morphologically complex words are decomposed to individual morphemes during visual word recognition. Most evidence for decomposition comes from priming studies, in which morphologically related words are presented in succession. Repeating the same morpheme in both the first word (prime) and the subsequent word (target) results in faster processing of the targets, as measured for instance by the lexical decision task.

The effects of morphological priming have been established first with words that overlapped in their root morphemes. Words consisting of roots and affixes have been shown to prime their roots (*friendly-friend*), as well other words derived from the same roots (*confession-confessor*, see e.g. Marslen-Wilson, Tyler, Waksler, & Older, 1994). This work established that word roots are accessed during the processing of morphologically complex words. If this is the case, functional morphemes should be accessed as well, and it should be possible to prime the access to these morphemes.

Priming of affixes proved more challenging than priming of word roots. Some studies found priming effects between words sharing prefixes, such as *dislike-disprove*. These effects were stronger than if there was mere orthographic overlap in the word initial segments, e.g. in *uncle-unhappy* (e.g. Chateau, Knudsen, & Jared, 2002; Giraudo & Grainger, 2003). While the findings with prefixes are quite robust, suffix priming has been more difficult to establish. (Marslen-Wilson, Ford, Older, & Zhou, 1996) found evidence for priming between auditory primes and visual targets that shared derivational suffixes (*darkness-toughness*). However, some

research suggested that only prefixes could be primed, but not suffixes (Giraudo & Grainger, 2003).

Recently, Duñabeitia, Perea, and Carreiras (2008) were able to show affix priming in suffixed Spanish words. Their participants processed the suffixed words faster if they were preceded by words with the same suffixes. The effect was also present when the primes contained isolated suffixes only, or suffixes attached to strings of non-letter characters.

The literature thus indicates that affixes can be primed, even though there may be differences between prefixes and suffixes in the susceptibility to priming. However, all research sketched above worked with derivational affixes. It is not clear whether inflectional affixes are susceptible to morphological priming as well. Given that some languages have rich inflectional morphology and that many words in these languages appear with some inflection, the question about affix priming is highly relevant.

Early vs. late decomposition

The available evidence suggests that morphological decomposition of printed words proceeds by first removing all potential affixes and subsequently checks if this decomposition is the correct analysis. So, Rastle, Davis, and New (2004) showed that *brother* can prime *broth*, even though *brother* is not composed of the morphemes *broth+er*. Longtin, Segui, and Halle (2003) speak about *pseudo-derivation* in this context and show that pseudo-derived words may prime words that seem related to them. The meaning-blind early morphological decomposition may be responsible for the difficulties in detecting suffix priming. Duñabeitia et al. (2008) suggested that early decomposition is responsible for the lack of affix priming effects reported by Giraudo and Grainger (2003). Their study compared morphologically related primes (e.g. *fumet-MURET*) or orthographic control primes (*béret-MURET*). It is possible that the orthographic control primes were initially decomposed even though their final segment (*-et*) is not a true suffix. Because of this decomposition, Giraudo and Grainger (2003) did not detect any difference between these conditions. The evidence thus suggests that early stages of morphological decomposition ignore the meaning of affixes. If two homophonous affixes with different function are presented, they should initially have the same impact on the processing of subsequent words.

Current study

The present experiments explored whether the processing inflectional affixes in Czech nouns could be affected by morphological priming. Of particular interest was the issue of homophonous affixes and the process of their interpretation.

Participants saw suffixed target words. These targets were preceded with visual primes. In the two key conditions, the prime words ended in a suffix with the same phonetic form as the suffix in the target words. However, in one of these conditions, this suffix was fully identical to the target suffix, i. e. shared both its phonetic form and its function. In the other condition, the prime word contained a homophonous suffix with a different function.

The basic prediction was that the homophonous morphemes should have similar effects as the identical morphemes in masked priming with short stimulus-onset asynchrony. In unmasked priming, i. e. with longer SOA, suffix with identical function should result in stronger priming effects than the homophonous suffix that merely shares the form but not the function of the target suffix. Experiment 1 tested the prediction for short SOA, Experiment 2 for longer SOA. Each experiment involved two components, one with nouns and one with verbs as target words. The noun component of involved two additional conditions, the baseline, and a condition involving a prime suffix with different form but the same function as the target. The verb component only used primes in the two conditions with homophonous affixes.

Experiment 1

All target words in each component ended with potentially ambiguous suffix. In the noun targets, this was one of the Czech feminine nominative suffixes, *-a*. In the two key conditions, the primes also ended with *-a*. In the identical condition, the primes were feminine nominatives, in the homophone conditions, they were masculine accusatives/genitives. With regard to these two conditions, the prediction was that there would not be no difference between lexical decision times on target nouns. With 50 ms latency, the primes should be decomposed and suffixes identified by the time of target presentation, but the function of the suffixes should not be accessed yet. In order to test whether decomposition occurred at all, a condition with orthographically distinct nominative suffix primes was introduced in the noun component (no such controls were possible for the verbs). Reaction times in this allomorph condition should be slower because the search for the target suffix will not have started until the target is presented. The baseline condition served to establish the processing times for target target words with no primes.

The verb component focused narrowly on the comparison of the identical and homophone suffixes. No differences in the effect of these suffixes were predicted in Experiment 1.

Method

Stimuli The noun component contained 104 experimental items in four conditions summarized in Table 1. Four versions of the protocol were created so that each target word was presented in each condition to approximately the same number of participants. The verb component of the experiment presented 26 target words in two conditions: primes had either the same suffix, or a homophonous suffix. The verb component did not contain the baseline condition, nor

Table 1: Sample stimuli from all conditions

	Condition	Prime	Target
Noun targets	baseline	XXXX	váha
	identical	LÍPA	váha
	homophone	SYNA	váha
	allomorph	VŮLE	váha
Verb targets	identical	BERETE	žijete
	homophone	KUŘETE	žijete

the different-suffix condition. This was mainly because the number of possible stimuli was much smaller. Two versions of the verb component were created and presented to approximately equal number of participants, so that each target word was presented in each condition to equal number of participants. All the experimental conditions were constructed so that the prime and target words had approximately equal frequency, and that in each version of the protocol, the mean frequency of the primes and targets was approximately equal. The primes and targets always had the same number of letters. Primes were presented in uppercase, targets in lowercase letters.

Besides the 140 experimental trials, 123 real word fillers and 270 nonword fillers were presented. The presentation was block-randomized so that trials from different conditions occurred with approximately equal probability during the whole experiment.

Participants Thirty-nine students participated in the experiment as a part of their course requirement. All were native speakers of Czech.

Procedure The experiment was presented on a laptop computer using DMDX (Forster & Forster, 2003) as the presentation and response-collection software. Each trial started with a fixation cross presented for 500 ms. Then, the prime word was presented for 50 ms, followed by the subsequent presentation of the target word. The target word was shown until response was made or until 1500 ms from the onset. If no response was made within 1500 ms, the no response was recorded and the computer proceeded to the next trial.

Analysis The data were analyzed using linear mixed models with random effects for persons and items. This procedure replaces the separate ANOVA analyses by subjects and items (cf. Baayen, Davidson, & Bates, 2008). Post-hoc pairwise comparisons used the Tukey method as implemented in the `multcomp` package for R (R development core team, 2003).

Results

Results are summarized in Table 2. The initial analysis compared the reaction times in the experimental conditions to the baseline using planned contrasts. Compared to the baseline, reaction times were significantly longer in the nominative allomorph (*-e*) condition ($t = 3.55$, $p < 0.001$). In the identical (nominative *-a*) condition, the times were also slower and

Table 2: Top: baseline reaction times and the effects in experimental conditions. Bottom: pairwise comparisons of reaction times in experimental conditions. *** $p < 0.001$, ** $p < 0.01$, * $p < 0.05$

	SOA	
	50 ms	150 ms
Baseline	664	667
Nom. -a (identical)	*10	*13
Acc. -a (homophone)	2	***20
Nom -e (allomorph)	**17	*12

	50 ms	150 ms
Identical – homophone	8	7
Identical – allomorph	-7	-1
Homophone – allomorph	*15	-8

the difference was significant ($t = 2.01$, $p = 0.048$). There was no significant difference between the baseline and the incongruent homophonous (accusative -a) suffix condition ($t = 0.46$, $p = 0.67$). Post-hoc analysis using Tukey contrasts revealed a significant difference between the accusative homophonous condition and the nominative allomorph condition ($p = 0.01$). There was no significant difference between the congruent condition and the incongruent or allomorph condition.

The prediction for the experiment was that there should be no difference between the congruent and incongruent condition. This is in line with the results. However, both these conditions should be faster than the allomorph condition. This is only true about the incongruent condition. In order to examine this discrepancy, an analysis was performed that divided the items according to their length. It may be the case that the shorter prime words were processed to a larger extent than the longer primes. If there are any differences between shorter and longer words, the original prediction should be valid for the longer words, that were presumably processed to a lesser extent. In shorter words, differences between the two key conditions may surface because the prime suffix has been processed enough so that its function is being accessed.

Two analyses were performed separately for two groups. One group consisted of stimuli with 4-, 5- and 6-letter words (57 trials), the other group of stimuli with 7-letter words (47 trials). Results are summarized in Table 3. In longer words, the pattern of results seemed to fit the expectations: there was only a small difference between the identical and homophonous condition, but the allomorph condition appeared slower and was significantly slower than the baseline ($t = 2.17$, $p = 0.03$). However, the pairwise comparisons revealed only a marginally significant difference between the homophonous and allomorph condition ($p = 0.05$). There was no significant pairwise difference between the identical condition and the allomorph condition. In the group of shorter words, responses in the identical and the allomorph condition were slower than the baseline ($t = 2.58$, $p = 0.01$ for identi-

cal, $t = 2.94$, $p < 0.01$ for allomorph). In post-hoc analysis, there were no significant differences between conditions.

In trials with verb targets, there were only two conditions. Reaction times were 14 ms slower in the homophonous condition than in the identical condition. This difference approached statistical significance ($t = 1.71$, $p = 0.08$). Because the observed difference conflicted with the prediction, the analysis was repeated for shorter and longer words, with the expectation that the results for shorter words would fit the original prediction. In the 24 trials with 7- and 8-letter-long words, the responses were 8 ms slower in the homophonous condition, a nonsignificant difference ($t = 0.77$, $p = 0.44$). In the 12 6-letter trials, there was a significant 28 ms effect ($t = 2.06$, $p = 0.04$) with faster reactions in the identical condition.

Discussion

The predictions for Experiment 1 were only partially confirmed. No significant difference between the priming effects of homophonous suffixes was found, which was in line with the predictions. However, the reaction times in the identical condition were significantly slower than the baseline, while those in the homophone condition were very close to the baseline. The two conditions with the -a suffix in the primes may thus have differing priming effects, which was not expected. The allomorph condition resulted in the slowest reaction times, being significantly slower than both the baseline and the homophone condition.

The differences between the identical and allomorph condition might be due to differences in the progress of processing in prime words of different lengths. The subsequent analysis supported this view to a certain extent. The difference between the effects of identical and homophone primes was weaker in long words, which were presumably processed to a lesser extent. However, even here, the two critical conditions did not pattern in a completely identical manner and only the homophone condition showed a marginally significant advan-

Table 4: Top: overall reaction times and the condition effects in verbs. Bottom: reaction times and effects from Experiment 1, separately for long and short words. $**p < 0.01$, $*p < 0.05$, $\dagger p < 0.10$

tage over the allomorph condition. In longer words, there were no significant pairwise differences between the conditions, but the identical and allomorph conditions were significantly slower than the baseline, while the homophone condition was not.

The analysis of the verb component showed a marginally significant effect of condition, with homophonous targets showing a tendency to slower responses. The subsequent analyses for longer and shorter words suggested that the marginal effect could be attributed to short words, which showed significantly longer reactions in the homophone condition. Apparently, 50 ms is enough time for the word processing system to start accessing the function of a suffix at least in shorter words.

Some of the findings are surprising, especially the relative effects of the identical and homophone condition in nouns and verbs. The pattern in verbs was in line with intuition: if there is any difference between conditions, the homophone condition should be slower, since the suffix on the homophone primes only shares its form, but not its function with the target suffix. In shorter verbs, there was indeed a significant difference in this direction. However, the pattern in nouns appears to be opposite. There was a tendency in the identical condition towards slower reaction times than in the homophone condition. This was especially apparent in the group of shorter nouns, where the identical condition, but not the homophone condition, was significantly slower than the baseline. Possible reasons for this pattern are addressed in the general discussion below.

Experiment 2

Experiment 2 presented the same stimuli with longer SOA. Under these conditions, it was expected that the homophonous condition will elicit slower reaction times than the identical condition. If the function of the suffix is accessed within the chosen SOA (150 ms), the effect of the identical and allomorph suffix should be identical, or at least their difference should be smaller than in the homophonous condition.

Method

Design, procedure, participants Experiment 2 used the same design, stimuli and procedure as Experiment 1. The only difference was in the stimulus onset asynchrony. The primes were presented for 150 ms. Responses were collected from 38 students who volunteered or participated in exchange for course credit. None of the students participated in Experiment 1.

Results

The results are summarized in Tables 2, 3, and 4, along with the results from Experiment 1. In the noun component, the reaction times in all three experimental conditions were significantly slower than in the baseline condition (identical: $t = 2.57$, $p = 0.01$; homophone: $t = 3.93$, $p < 0.001$; allomorph: $t = 2.23$, $p = 0.03$). Pairwise post-hoc analysis revealed no significant differences between the individual levels. The direction of the differences was in line with the expectations, with the longest reaction times in the homophone condition, and the allomorph and identical condition eliciting similar responses. However, none of the pairwise differences between the experimental conditions were significant.

In order to examine the results more closely, the stimulus set was again split, and the groups of short and long words were analyzed. In the shorter words, there was a significant difference between the baseline and the homophone condition ($t = 2.41$, $p = 0.02$), as well as the allomorph condition ($t = 2.67$, $p = 0.01$). This would suggest an advantage for the stimuli primed with the identical suffix. However, post-hoc pairwise comparisons have not revealed any significant difference between the experimental conditions. Therefore, even though there seems to be an advantage for the identical condition, the prediction is not supported.

In the group of long words, the pattern of results is different. Compared to the baseline, the reaction times were significantly slower in the identical condition ($t = 2.42$, $p = 0.02$) and in the homophone condition ($t = 3.14$, $p < 0.01$). Pairwise comparisons revealed a significant difference between the allomorph and homophone condition, with homophone condition significantly slower than the allomorph condition ($z = 2.62$, $p = 0.04$).

In the verb targets, the reaction times in the homophone condition were significantly slower than in the identical condition ($t = 2.88$, $p < 0.01$). The results from the verb component are in line with the predictions.

Discussion

In Experiment 2, the predictions were again confirmed only partially. In the verb component, the homophone condition was slower than the identical condition, which is in line with the expectations. However, the expected differences in the more complex, noun component of the study have not materialized completely. Overall, there was a nonsignificant tendency for the reaction times to be longer in the homophone condition (20 ms effect against baseline) than in the identical or allomorph condition (13 and 12 ms effect, respectively).

This would be in line with the expectations. However, separate analyses for shorter and longer words complicated the picture. In the group of shorter words, more thorough processing of the primes is expected. The results should be in line with the predicted pattern. However, the homophone condition, predicted to be the slowest, has practically identical effects as the allomorph condition. These two conditions are significantly slower than the baseline. While this is not in line with the prediction, it is understandable under the assumption that the effects of orthography and function are about equally strong at 150 ms SOA. In the homophone condition, the response is inhibited by the difference in the morpheme function (accusative instead of a nominative marker). In the allomorph condition, the function is the same, but processing is inhibited by the difference in orthography. In any case, there was no significant pairwise difference between the identical condition and the two slower conditions, so the effects should be understood as a mere tendency.

In longer nouns, the pattern of results was more intriguing. Responses in the identical and homophone conditions were significantly slower than the baseline. Pairwise comparisons showed a significant advantage of the allomorph condition over the homophone condition. This appears to suggest that in these words, the function of the suffix is more influential than its orthographic form, since the condition with the different-function suffix is significantly slowed down. However, in such a case, the identical condition should be even faster than the allomorph condition. Another surprising aspect of the results is the fast response in the allomorph condition. The longer words are presumably processed to a lesser extent than the shorter words discussed above. Yet, the inhibiting effect of orthography against the baseline is present in the shorter, more completely processed words, and not in the longer words. This goes against the assumption that the orthographic form is accessed first and the function later. Moreover, it goes against other aspects of the present data. The allomorph condition was slower than the baseline both in Experiment 1, where the primes were presumably processed to a lesser extent, as well as in the short words in Experiment 2, where the processing of the primes progressed more than in the long words.

General discussion

The experiments examined the effects of morphological priming on word recognition. While the phenomenon has been well established with derivational morphemes, little research is available for inflectional morphemes. The results show that inflectional affixes can exert priming effects similar to those reported by Duñabeitia et al. (2008) and others for derivational affixes. However, the evidence is unequivocal only for the 2nd person plural verb suffixes at 150 ms SOA. For nominal suffixes, the results show a more complex pattern.

In verb targets in Experiment 2, the presentation of a noun prime with homophonous suffix inhibited word recognition compared to verb primes with identical suffix. This means

that after 150 ms from the prime onset, the processing of the suffix moved beyond the level orthography, and words ending with homophonous suffixes inhibited the processing of target words. In Experiment 1, no such difference was predicted. It was expected that mere orthographic overlap between the prime and target suffix would initially affect the targets equally strongly as the repeated presentation of an identical suffix in the prime and target. However, it appears that in short words, the ending is recognized even within the 50 ms window, resulting in a morphological priming effect exceeding the effects of orthography.

The results from nouns require more detailed discussion. There was no significant difference between the two key conditions (identical and homophone) in Experiment 1, which was predicted. However, it was predicted that these two conditions would result in significantly faster responses than in the allomorph condition. This was true only for the homophone trials. Trials with identical suffix primes had longer reaction times than the homophone trials, and were not significantly different from the allomorph trials. This should not occur if the initial decomposition is blind to the function of the prime ending. Moreover, the difference between the homophone and identical trials, though nonsignificant, goes in the unexpected direction and contradicts the findings from the verb component.

It is useful to summarize the results from the two key conditions based on the presumed amount of processing performed on the primes. On longer words with shorter SOA, i.e. after the least amount of processing, none of these conditions is faster than the baseline. In shorter words and short SOA, the identical condition is slower than the baseline. In longer words with 150 ms SOA, both identical and homophone conditions are slower than the baseline. Finally, with longer SOA and shorter words, only the homophone condition is slower than the baseline. This result is in line with the prediction that in the later stages of processing, the functional aspect of the affixes will play stronger role than their orthographic form. However, it is not clear why the primes with identical and homophone suffixes result in slower processing of long words in Experiment 2, and why identical suffixes inhibit processing of short word targets in Experiment 1.

One possible explanation is that morphological decomposition does not occur in frequent nominative forms. In this view, the processing system attempts morphological decomposition unless it can recognize the whole word form as a whole. If decomposition is attempted, the function morpheme is initially identified regardless of its function. If it is not attempted, there is nothing that would exert priming effect on the targets. If this view is correct, the accusative homophone primes in this experiment were decomposed. The *-a* suffix was initially not identified as accusative but activated all possible meanings, including nominative. For this reason, it facilitated the processing of the nominative target words. The nominative primes were not decomposed and thus could not exert the priming effects. This would explain the tendency

towards slower responses in the identical condition in Experiment 1, as well as the absence of the difference between identical and homophone primes in longer words in Experiment 2. In these longer words with 150 ms SOA, the homophone prefix presumably started to develop an inhibitory effect due to the functional difference between primes and targets. At the same time, the lack of priming due to the lack of nominative prime decomposition still inhibited processing after the identical primes.

This view may seem paradoxical. If nominatives are not decomposed, why should the decomposed *-a* affix from the accusative primes temporarily activate the nominative interpretation? The possibility must exist that a low-frequency word or a novel word will be analyzed as nominative. For this reason, separating the *-a* suffix activates the nominative interpretation, even though nominatives are not regularly decomposed. Another question that arises is why nominative targets should be facilitated if they are not decomposed. But it is not necessary to assume that facilitation of target processing operates on the suffix. The activation of nominative *-a* suffix on the prime may activate the whole corresponding declensional class of nouns (paradigm “žena”). There is independent evidence that declensional class of nouns is represented in an abstract manner (Bordag & Pechmann, 2009). This way, the target nouns could be primed even if not morphologically decomposed.

The reason why nominatives would not be decomposed lies in the fact that they function as the base and default form. Nominatives are considered the citation form of nouns, and they are the most frequent case form (Jelínek, Bečka, & Těšitelová, 1961). It has been proposed that only low-frequency words undergo morphological decomposition (Baayen, Dijkstra, & Schreuder, 1997; Baayen & Schreuder, 1999). Even though there is evidence that all suffixes, including pseudo-suffixes, are decomposed, the decomposition of nominatives may be slower than direct retrieval. In that case, nominatives would not be decomposed.

This proposed explanation might explain many aspects of the results reported here. Some aspects remain unexplained, especially the fast responses in the allomorph condition on long words in Experiment 2. In any case, the processes of morphological decomposition of inflectional suffixes deserve closer scrutiny. In particular, further research needs to test whether nominative words undergo morphological decomposition.

To summarize, findings from Experiment 1 suggest that the purely orthographic, function-blind stage of morphological decomposition may be over in less than 50 ms, at least in shorter words. At the same time, results from the noun targets in both experiments suggest the possibility that nominative forms do not undergo morphological decomposition.

Restructuring Causal Concepts

Eric G. Taylor (etaylor4@illinois.edu)
Department of Psychology, 603 East Daniel St.
Champaign, IL 61820 USA

Abstract

Typical studies of concept learning in adults address the learning of novel concepts, but much of learning involves the updating and restructuring of familiar conceptual domains. Research on conceptual change explores this issue directly but differs greatly from the formal approach of the adult learning studies. This paper bridges these two areas to advance our knowledge of the mechanisms underlying concept restructuring. The main idea behind this approach is that concepts are structured by causal-explanatory knowledge, and hence, models of causal induction may help to clarify the mechanisms of the restructuring process. A new learning paradigm is presented to study the learning *and revising* of causal networks. Results show that some behaviors indicative of conceptual change arise from basic causal learning mechanisms. Results also support models of causal induction that assume inhibition between competing causes.

Keywords: knowledge restructuring, conceptual change, belief revision, causal induction, concept learning.

Concept learning is an incremental process. We learn a concept for the first time only once, and often our initial understanding is flawed. The remainder of learning involves the updating, revising, and restructuring of previous conceptual knowledge. The critical implication—that most concept learning is actually the refinement of familiar concepts—runs counter to the traditional approach in the study of concept learning in adults, which has focused on the learning of entirely novel concepts (Murphy, 2002). Many open questions remain on the nature of concept restructuring.

The goal of this work is to better understand the basic mechanisms of concept restructuring by forging a connection between traditional work on concept learning and the literature on *conceptual change*. Although these two areas differ greatly (in everything from goals to dependent measures), this paper builds on recent work that highlights their commonalities.

Studies of conceptual change typically outline the process of knowledge restructuring in broad strokes: e.g., by showing that it often occurs abruptly (Kuhn, 1962), that people are highly resistant to giving up their prior beliefs (Chinn & Brewer, 1993), and that novice concepts appear to “differentiate” and “coalesce” over the course of development (Carey, 1985). To support these claims, authors have focused on specific real world domains and the shifts in knowledge therein, such as children’s learning of biological concepts (Carey, 1985) and young adults’ learning of physics (diSessa & Sherin, 1998).

These studies differ dramatically from the traditional research on concept learning in adults, despite great overlap in interests. The adult work has primarily used domain-general laboratory paradigms and formal models to assess the specific representations and processes underlying basic conceptual tasks like classification, inference, and category-based induction (Murphy, 2002).

A complete understanding of concept learning and restructuring requires explanations from both levels of analysis. This paper suggests that recent work developing the *theory view* of concept representation (Gopnik et al., 2004; Murphy & Medin, 1985; Wellman & Gelman, 1992) serves as a linkage between these levels. The theory view states that concepts are built upon networks of causal-explanatory knowledge. This knowledge affects performance in laboratory-based learning tasks (Murphy, 2002) and plays a role in the learning and development of real world concepts where conceptual change effects are typically demonstrated (Vosniadou, 2008). Assuming that concept learning amounts, in large part, to the learning of causal relations, then models of causal reasoning (Kim & Ahn, 2002; Rehder, 2003) provide the requisite theoretical tools for understanding the basic mechanisms of concept learning and potentially also conceptual change.

Few previous studies address this linkage to concept restructuring, however. Murphy’s work (e.g., Kaplan & Murphy, 2000) has examined cases where prior causal knowledge is invoked when learning later concepts, but in these studies the prior concepts are not revised. Work on order effects in causal induction suggests that what is learned from the first half of a set of contingency data may be overwritten by later contingencies (Ahn & Marsh, 2006), but the initial learning (and hence, what is restructured) is not typically evaluated. A developmental study by Schulz, Bonawitz, and Griffiths (2007) showed that 4 to 5-year old children inferred causal relations from evidence that ran contrary to their prior beliefs. However, their evidence for belief revision, as measured by transfer performance, was mixed. This study is perhaps the strongest empirical evidence linking studies of causal induction to concept restructuring.

Other findings bearing directly on concept restructuring are less tied to the formal approach. Chinn & Brewer (1993) documented the many ways that people react to anomalous data, only one of which (the least common) was genuine concept revision. Chinn & Brewer (2001) also proposed a set of mental models for interpreting people’s verbal evaluations of anomalous data and patterns of belief change,

but these were not formalized at the level specified in the causal induction models.

To directly address the linkage between concept learning research in the theory view tradition and studies of concept restructuring, I developed a task in which individuals would learn and then *revise* their hypothesized causal relations for a novel conceptual domain. The task was inspired by causal structure learning in real world domains, where one often develops a naïve, incorrect view of the underlying causal structure, and then with the accumulation of knowledge and evidence, restructures their original beliefs.

Figure 1: Diagrams of a hypothetical learner's causal representations en route to learning a common cause relation. The prior link remains in the target concept, though reduced, signifying a possible residual belief in that link.

The “common cause” scenario is one of many ways a learner may develop a prior, naïve concept and then need to restructure that concept based on new knowledge and evidence. See Figure 1 for an example. In this scenario, two variables—A and B—will appear correlated, and without further scrutiny, one may assume these variables share a direct causal relation. In fact, both A and B are caused by a third variable, the common cause. When the common cause becomes known, learners can track the relations it shares with variables A and B, and rule out the direct causal relation initially hypothesized.

This paper uses an empirical study based on the common cause scenario as a starting point to understanding the mechanisms underlying shifts in causal knowledge. Given that we currently know much about the initial learning of causal relations (i.e., the learning of the initial A causes B link), this study asks how that initial learning affects the process of concept restructuring. In particular, how does the belief in the prior concept affect later learning where one views contingency data in favor of the target explanation?

Consider the possible effects the prior concept may have on inferring the target structure. First, the prior concept may serve as an anchor, or bias, such that people show commitment to the A.B link (A.B means “A causes B”) and later learning of alternative causes is more difficult. Previous work shows that prior beliefs are difficult to give up, especially when they figure centrally in other causal explanations (Chinn & Brewer, 1993).

Second, the acquisition of the prior belief may actually benefit later learning. In particular, evidence suggesting the lack of a correlation between other nodes in the system (between C&A and C&B) might draw resources away from

those nodes and facilitate later search for the correct causal mechanism. This is especially true in Figure 1 since an alternative explanation for the A&B correlation is a mediating causal pathway, A.C.B. To the extent that one can rule out this “mediating cause” explanation, they might rule in the common cause explanation.

Third, both previous effects may occur. That is, learning the prior might increase one's belief in the A.B link, and independently, guide learners away from the wrong links and toward the right ones. If learners infer both the common cause and maintain a belief in the direct cause, they will have “over-explained” the occurrence of event B. Although previous work shows that people prefer simple explanations with fewer causal links (Lombrozo, 2007) and that competing causal hypotheses are considered in opposition (Lu et al., 2008), none have examined a case where learners are committed to a prior alternative conceptual structure, as is typically found in studies of conceptual change. In this case, people might over-explain to retain both possible causal pathways.

Experiment

The goal of the experiment was to determine how previously learned causal relations affect continued learning and concept revision. I created an experimental paradigm analogous to Figure 1. One group, the *change* condition, was verbally instructed on a prior structure with three nodes where A directly causes B, then in a second phase, was shown a fourth node (D) and had to infer the correct causal structure from contingency data. The control group, the *no-change* condition did not learn the prior structure and immediately attempted to infer the correct structure from contingency data with nodes A-D. The question is: How does the learning of the prior concept in the change condition affect the learning of the target concept, relative to that of the no-change condition?

Two dependent measures assessed learners' knowledge of the causal system. First, after the prior and target learning phases, participants rated the likelihood of each possible configuration of the system (e.g., A/~B/C for the prior phase, A/~B/~C/D for the target phase). These were used to infer participants “implicit” causal models of the system via model fitting, with the idea that some predictions offered above might not hold if participants were asked directly about their beliefs in the causal links (due to experimenter demands). Second, participants were asked at regular intervals during the target learning phase which of a set of possible links they believed were true. These judgments correspond to participants “explicit” beliefs about the causal system, similar to typical causal induction measures.

Method

Participants Forty-eight University of Illinois students participated in exchange for course credit.

Materials Participants learned about a fictitious ecosystem composed of four observable properties. Each property varied probabilistically during learning, taking one of two binary values (see Figure 2 for “on” values). The first property was the population size of a new fish biologists call “tespula”: **above average** or **normal**. The second property was the color of a new type of algae called “plemocyn”: **very green** or **normal**. The third property was the chemical composition of barium contained in the ecosystem’s water: **crystallized** or **not crystallized**. The fourth property was the cloudiness of the water: **cloudy** or **not cloudy**. I refer to the first mentioned values as the “on” values.

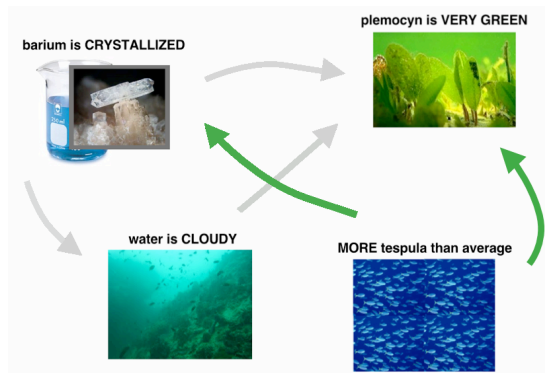

Figure 2. The causal structure of the ecosystem. Darkened links indicate that properties share a generative causal relation with causal power 0.85.

During covariation trials, the property values on each trial were determined by a causal system displayed in Figure 2. When the tespula population is more than average (base rate equal to 0.6), this will cause the barium to be crystallized with probability 0.85, and independently, the plemocyn to be green with probability 0.85. The water will be cloudy with probability 0.6. When the tespula population is average (depicted by a less colorful picture not shown in Figure 2), all other properties will be “on” with probability 0.6.

Covariation trials appeared like Figure 2, except that the property values varied probabilistically and all arrows appeared in grey. During the test phases, participants viewed all “on/off” combinations of the four properties and told to rate their likelihood (see *Procedure* section). In this phase, the arrows were completely absent.

Design Participants were divided into two groups: *change* and *no-change*, corresponding to those given a prior belief regarding the properties’ causal relations and those who were not, respectively. Each group was subdivided into four counterbalance conditions, controlling for which properties were assigned to the roles in the causal system.

Procedure Prior to the experiment, participants read and signed a consent form. Participants then read instructions and completed all tasks on a computer.

Change condition: The instructions stated that the purpose of the task was to learn about a new oceanic ecosystem. Specifically, the task was to help a group of biologists to understand how the properties of the ecosystems cause one another. Three properties of that ecosystem were described—the top two properties from Figure 2 (A and B) and the bottom left property (C). The fourth property was absent during this phase. Participants were told that the biologists’ current understanding was that property A causes property B (and told nothing else about C). They were also shown a picture with properties A-C and a green arrow connecting A to B. To ensure understanding, participants answered a multiple-choice question asking which properties were related and in what way. If they answered incorrectly, they repeated the instructions and retook the question until they were correct.

Next, participants entered the *prior learning phase* where they viewed a sequence of 30 “snapshots” of the ecosystem. Each snapshot depicted a particular on/off configuration of properties A-C. Each snapshot appeared with a frequency proportional to its likelihood, which was determined using the probabilities given in the *Materials* section. To compute the probability of a particular snapshot, one computes the probability of each node taking its presented on/off value (conditional on the parent nodes) and then takes the product. Rehder (2003) describes this procedure building on Cheng’s (1997) causal power theory, showing that the probability of node N being “on” is $1 - (1 - b_N) \prod (1 - m_{CN})^{Con}$, where b_N is the probability of some unobserved background cause leading to the presence of node N , m_{CN} is the probability that node C generates the presence of N , and Con is an indicator variable equal to 1 when feature C is “on” and 0 otherwise. The snapshot frequencies were identical for all participants, but the order was random and different for each. Note that the causal system from Figure 2 creates a correlation between properties A and B, which supports the belief that A causes B when the status of property D is not visible.

After the 30 snapshots, participants entered the *prior likelihood rating phase* where they viewed each possible snapshot and were told to rate how likely the ecosystem is to look like the snapshot. They were also told, “when making the judgments, be sure to keep in mind the fact that the biologists think that [property A] causes [property B].” Ratings were given by moving a vertical bar up and down a scale, where the highest position indicated “VERY likely” and the lowest indicated “NOT likely.”

Then, participants entered the *target learning phase*. They were told that the biologists discovered an important new aspect of the ecosystem, property D, and now they are wondering if their previous belief that A causes B was “wrong or perhaps missing something.” They viewed a diagram similar to Figure 2 except with no links darkened, and were told their next task was to help the biologists figure out which of the shown potential causal relationships were true. Participants would learn which causes were true by viewing snapshots like those in the prior learning phase. The instructions also clarified that each property may occur

without being caused by another observed property (i.e., even if X causes Y, Y may appear in the absence of X) and that the links were not necessarily deterministic (e.g., if X causes Y, Y is simply more likely to appear in the presence of X). Finally, they were told that in addition to viewing the snapshots, they would sometimes be making predictions about which of the causes are true. Later during learning, the computer would give feedback about whether their hypotheses were close to or far from the true structure.

After every 10 snapshots participants were asked to guess which of the possible links were true. They were shown the picture in Figure 2 but with no links darkened, and told to click on the links to make their guess. Links darkened when selected. To assist with learning, participants were given indirect feedback regarding their link choices starting on their 4th hypothesis trial (after 40 snapshots)¹. They were never told the status of any particular link choice (e.g., that the A.B link was right or wrong). Instead, they were told that the hypothesis was VERY GOOD, GOOD, WEAK, or VERY WEAK, indicating that 5, 4, [3 or 2], [1 or 0] links were correct, respectively. Participants were not told the correspondences between the feedback and number of accurate links. On the final hypothesis, participants were told, “This is your LAST PREDICTION. On the next trial, make your best guess as to what causes what.”

Finally, in the *target likelihood rating phase*, participants again rated the likelihood of all possible snapshots of the ecosystem but this time with nodes A-D.

No-change condition: The no-change condition was identical to the change condition, but the prior learning phase and the prior likelihood ratings phase were excluded. The instructions immediately introduced participants to all four aspects of the ecosystem and the five possible links. Participants then began the target learning phase.

Results and Discussion

Hypotheses First, I present the results from the hypotheses participants made during the target learning phase. Each link was analyzed separately. Hierarchical logistic regression was used to evaluate the effects of condition and hypothesis trial on link choice. The “hierarchical” component refers to a random intercept term, which was used to model the between-participant variability in overall response tendency.

Results are plotted in Figure 3. To reduce inter-trial variability, I blocked the trials, except for the final trial: 1-4 (without feedback), 5-11 (feedback 1st half), 12-17 (feedback 2nd half), and 18 (the final trial). Main effects and interactions were assessed using Wald tests and likelihood

ratio comparisons, but only Wald tests are reported. Likelihood tests led to similar interpretations.

The main effect of block on choosing the A.B link was significant, $\chi^2(1)=10.23$, $p<0.01$, suggesting that learning did occur, as participants selected this incorrect link less over time. The main effect of condition was marginally significant, $\chi^2(1)=3.44$, $p=0.06$, revealing an early and late bias in the change condition to select the prior link. The interaction was marginally significant, $\chi^2(1)=3.33$, $p=0.07$.

Figure 3. The probability of a participant including a link in their hypotheses during the target learning phase. Error bars are standard errors (binomial variance for final block).

Because the difference in conditions for the A.B link was non-monotonic over blocks, two separate regressions were fit to blocks 1-3 and blocks 3-4. The interaction between trial and condition was significant for blocks 1-3, $\chi^2(1)=9.36$, $p<0.01$, and for blocks 3-4, $\chi^2(1)=6.81$, $p<0.01$. Finally, the difference in conditions on just the final hypothesis was assessed using Fisher’s exact test, which did not reach significance, $p>0.1$.

The interactions between trial and condition for the A.B link have two implications. First, although the change condition began selecting A.B more than the no-change condition, this difference went away by the third block as both conditions learned to not select A.B. Second, the difference in conditions increased from blocks 3 to 4.

¹ Feedback was added to improve learning based on the results of a pilot study and previous work showing poor learning for 3-4 node structures given only covariation data (e.g., Lagnado & Sloman, 2004; Steyvers et al., 2003). Feedback is natural in real world learning and is usually provided by confirming or disconfirming predictions made on the basis of hypothesized causal relations. The feedback in this task can be viewed as a proxy for the outcome of multiple such predictions.

Relative to the no-change condition, the change condition was more likely to retain a belief in the prior concept in their final judgment, despite both groups having chosen this link equally often during the final block of feedback.

The incorrect links A.C and C.B were analyzed together. The interaction between block and condition was not significant, $\chi^2(1) < 1$. The main effect of block was significant, $\chi^2(1) = 23.02$, $p < 0.01$. The main effect of condition was also significant, $\chi^2(1) = 4.49$, $p < 0.05$, even when considering only the final hypothesis (Fisher's exact test, both $ps < 0.01$). This advantage for the change condition is sensible; they are likely attributable to the extra learning in the change group during the prior learning phase. The scientists' tentative theory regarding the ecosystem implied no causal relation between node C and either A or B. Further, the 30 covariation trials suggested little correlation between these nodes, corroborating the scientists' view.

The correct links D.A and D.B were also analyzed together. The interaction between block and condition was not significant, $\chi^2(1) = 2.63$, $p = 0.10$. The main effect of block was significant, $\chi^2(1) = 15.74$, $p < 0.01$. The main effect of condition was not significant, $\chi^2(1) = 1.34$, $p > 0.10$, though there was a tendency for to change condition to choose these links more often.

Likelihoods judgments Likelihoods judgments were used to infer participants' latent causal representations via model fitting. Causal model theory (CMT; Rehder, 2003) and a version of causal support (Griffiths & Tenenbaum, 2005) were fit to each individual's data. Only the results from CMT are presented here, since they were very similar to the results from causal support.

Causal model theory fits were obtained via maximum likelihood estimation. Each fit yields an estimate of nine free parameters: the strength of each potential causal relation in Figure 2, plus an estimate of the probability that some unobserved background node causes each feature. The fitting routine worked by assuming that the participants' likelihood judgments were guesses about the relative frequency of the snapshots, should they be sampled again. Thus, 100 new snapshots were created with frequencies proportional to the normalized likelihood judgments of each participant. The MLE parameter values were those that maximized the likelihood of the snapshots.

The fits to CMT are presented in Table 1. Fitted background probabilities did not differ between the groups, but estimates of causal strength were different, and in the same direction as the differences present in the hypotheses data. First, the difference for link A.B was significant, $t(46) = 2.39$, $p < 0.05$, reinforcing the non-significant trend in the hypotheses data. This implies that the change condition represents the prior link stronger than the no-change condition, and this difference is robust for the more implicit measure, the likelihoods, where causal strength is not queried directly.

The conditions did not differ significantly in their representation of the incorrect links A.C and C.B, but the

differences in the correct links were marginally significant: the change condition represented the D.A link more strongly, $t(46) = 1.82$, $p = 0.06$, as well as the D.B link, $t(46) = 1.93$, $p = 0.08$. In addition, when averaging the strength of the correct links, the difference in conditions was reliable, $t(46) = 2.32$, $p < 0.05$.

Table 1. Average causal strengths (standard deviations).

	No change	Change	p-values
Link A.B	0.06 (0.08)	0.14 (0.14)	0.02
Link A.C	0.10 (0.11)	0.06 (0.08)	0.12
Link C.B	0.07 (0.12)	0.05 (0.06)	0.50
Link D.A	0.20 (0.15)	0.28 (0.16)	0.08
Link D.B	0.25 (0.16)	0.35 (0.20)	0.06
Average of D links	0.22 (0.13)	0.31 (0.14)	0.02

The latter result is in line with a predictions stated earlier that the change group may benefit from the prior learning phase by observing the lack of a correlation between nodes A&C and between nodes C&B. Recall that links A.C and C.B constitute an alternative explanation of the A/B correlation; i.e., that A causes C causes B. Put simply, this set of links may be considered in opposition to the common cause links D.A and D.B in order to avoid over-explaining node B. If so, a reduced belief in the former may increase one's belief in the latter.

The idea that alternative causes compete or inhibit one another has empirical backing (Rehder & Milovanovic, 2007) and is made explicit in recent models of causal induction (Lu et al., 2008). In the current study, to evaluate the relation between choices of links involving the two explanations, I used a hierarchical linear regression with number of correct links chosen as the dependent variable and number of incorrect links as the predictor. The predictor variable was separated into two parts: the participant-level effect (the average number of A.C and C.B links chosen by a participant) and the within-participant effect (the number of links chosen on a given hypothesis minus the participant's average). These variables address different questions: the former asks whether participants who choose more incorrect links on average tend to choose more correct links; the latter asks whether on a given trial the number of incorrect links chosen affects the number of correct links chosen.

The effects of the two predictors were evaluated via model comparison. A model excluding the between-participant effect did not fit worse than a model including both effects, $\chi^2(1) = 0.26$, $p > 0.10$. However, a model excluding the within-participants effect did fit worse than the model with both effects, $\chi^2(1) = 52.03$, $p < 0.01$, suggesting that causal links involved in competing explanations inhibit one another on a trial-by-trial basis. To my knowledge this is the first evidence showing that competition occurs at the level of entire explanations (i.e., sets of causes), beyond simply individual causal relations.

Conclusion

The goal of this paper was to show that some aspects of concept restructuring might result from basic causal learning mechanisms, thus bridging the formal approach to concept learning with the conceptual change literature. In a novel learning task, participants first developed a prior conceptual belief and were then prompted to revise that concept through contingency learning. Results showed that the prior learning phase led participants to retain their original belief despite evidence against it but also led to enhanced learning of the target causal structure. That is, despite learning of the target, individuals retained the belief in the prior at the cost of over-explaining. Further evidence showed that when revising one's beliefs, alternative causal explanations are considered in opposition, building on the predictions of recent models for simpler causal structures.

Conceptual change surely involves many processes and representations, only some of which are the learning and revising of causal structures (and within that, only some of which are learning from contingency data; Ahn et al., 1995). For example, people also revise their taxonomic hierarchies (Thagard, 1992) and accrue domain-specific knowledge (Carey, 1985). In addition, full-blown conceptual change presumably requires the restructuring of numerous causal hypotheses and may result in emergent representations inherently unlike the prior beliefs. However, current models incorporate powerful learning mechanisms that are capable of such large-scale changes (Kemp & Tenenbaum, 2008). The hope is that improved cross-talk between formal, empirical, and developmental studies will help to build an integrated view of concept learning and conceptual change.

Abstract

In a laboratory experiment, 13 participants reproduced from memory the position of a sphere relative to a second landmark sphere located on the viewing axis of the observer. The relative location of the second sphere varied both laterally and in depth. The stimuli were generated on a stereoscopic display. The paper focuses on the analysis of the structure of the noise in the reproduced object locations, this structure reflecting the mental representation of the stored spatial relations. The results showed that the spatial location of the landmark sphere affects the variability of the reproduced object locations. In particular, the variability in the frontoparallel plane increases with the length of the depth component of the spatial relation. This finding can be interpreted in two ways. First, spatial acuity in perception decreases, or second, participants encode sensory information by transforming it into a mental spherical coordinate system. Both interpretations are discussed.

Introduction

McNamara (2003) proposed that locations are memorized in egocentric and allocentric coordinate systems. Allocentric coordinate systems define locations with respect to objects in the environment. We believe that shifts of attention between several locations in space define the reference axes and planes of local allocentric coordinate systems within which the spatial relations are encoded. This assumption is consistent with the idea that locations are encoded by intrinsic frames of references (Mou & McNamara 2002; Schmidt 2004). These intrinsic reference frames would result naturally from salient landmarks of the scene that attract attention. The structure of the variability in the reproduced locations provides essential information about the nature of the allocentric reference systems and reveals the dimensions in which attributes of the location had been encoded. Only a few reports in the literature have provided a systematic investigation of the dispersion of locations recalled from memory. The most frequently cited work in this field is by Huttenlocher, Hedges, and Duncan S. (1993),

who conducted an experiment in which the participants had to reproduce locations within a circle, the observed distribution of which was consistent with encoding the locations relative to the center of the circle in terms of the distance from the center and the polar angle. Furthermore, they found systematic distortions of the reproduced polar angles for locations near the virtual horizontal and vertical lines that divide the circle into quadrants. The participants misplaced the locations toward a central location in each quadrant. Huttenlocher et al. proposed a stochastic model based on hypothesized probability density functions for the recall of the locations from memory. Based on these findings Werner & Diedrichsen (2002) investigated the time course of the memory distortions for the location of a dot in relation to two horizontally aligned landmarks. These works and the work of McNamara (2003) complemented each another, if the recall of locations from memory is described by probability density functions according to the dimensions of the allocentric reference systems.

The aims of the experiment described in this paper are twofold. First to confirm basic parameters of the noise in the mental representation reported in the literature, which we have already used to model phenomena in memorizing object locations in graphical structures (Winkelholz & Schlick 2007a) and for symmetry detection (Winkelholz & Schlick 2007b). Second to gain insight into the structure of the probability distribution of basic three dimensional spatial relations reproduced from memory. Especially, we are interested if subjects encode the stimuli on the basis of values of the perceived attributes or if they transform the perceived attributes into a mental coordinate system.

Experiment

Within the experiment participants reproduced random virtual object locations on three predefined frontoparallel planes. If the object location is represented mentally by a distance and a solid angle relative to a landmark location, then the variability in the lateral coordinates of the

reproduced object locations should increase with their relative distance in depth from the landmark location. If the variability is independent of the reproduced location, the latter's mental representation might simply be its perceived projection on the screen and a relative distance in depth that is perceived by disparity and the visual angle of the circumference. In general, an increase in the variability of the lateral coordinates might be just the result of visual perception. When the visual system focuses on a location in three-dimensional space through convergence, only the points contained inside Panum's fusional area near the horopter are fused into a single image. Therefore, outside of Panum's fusional area oculomotoric sensor information will additionally be used by the visual system to determine the spatial relation. Accommodation should have no effect on spatial acuity, since the stereoscopic stimuli were generated synthetically on a display at a fixed distance from the observer.

Method

Participants

Thirteen volunteers (11 male, 2 female, average age 27), who were recruited from the staff of our institute, took part in the experiment. All participants had normal or corrected-to-normal vision.

Apparatus and Stimuli

The experimental task environment was generated on a Windows workstation equipped with a NVIDIA Quadro graphics card. The subjects used a spacemouse and the standard keyboard to provide input information. The spacemouse, a three-dimensional interaction device with six degrees of freedom, contains a controller cap that can be pushed, pulled and twisted in any direction. The subjects used the spacemouse to control the spatial movement of the object during the response stage. The stereoscopic images were rendered at 120 Hz on a 21" CRT monitor and a resolution of 1280×1024 pixels. The images for the left and right eyes were separated by shutter glasses, which meant that the frame rate per eye was 60 Hz. The scene was rendered using antialiasing (16 times provided by the driver) to increase the visual spatial resolution and thereby enhance perception of the disparity. The monitor screen was located 60 cm in front of the subject. The spheres were displayed using the user-centric projection method that is commonly employed in virtual environments such as caves and workbenches (Cruz-Neira, Sandin & DeFanti 1993). Points in object space are projected onto the screen according to the positions of the user's eyes. Each eye perceives the points on the surface of a virtual object from the correct solid angle as if the object was actually present. In other words, the disparity of the displayed objects on the screen and the viewing angle of the projected size of the spheres were the same as if real spheres had been placed at these coordinates.

Fig. 1: Illustration of the experimental setup. The lower part of the figure shows two cross-sections of the display setup, the first from the side and the second from above.

To accomplish this, subjects were advised to sit in an appropriate position so that their head was within the range of the parameters used in the projection model. In the following, the stimulus parameters are reported in virtual coordinates according to this user-centric projection model. All spheres were displayed to appear on one of three virtual planes. The screen is defined to be at $z = -60 \text{ cm}^1$. The first plane was -1.5 cm [$z = -58.5 \text{ cm}$] in front of the screen, and the second and third planes were located 1.5 cm [$z = -61.5 \text{ cm}$] and 4.5 cm [$z = -64.5 \text{ cm}$] behind the screen, respectively. Hence, the disparities shown on the display were $-9.5'$ for $z = -58.5 \text{ cm}$, $9.1'$ for $z = -61.5 \text{ cm}$, and $26'$ for $z = -64.5 \text{ cm}$. The diameter of the spheres was 1 cm and the corresponding visual angles of the displayed size were $58.8'$, $55.9'$ and $53.3'$, respectively. The landmark sphere was always displayed on the z axis. The sphere whose location had to be memorized was positioned at two distinct distances from the center axis. The radii of the circles were chosen so that the viewing angle of the distance to the center was constant across different virtual planes. The visual angle, $\alpha_{xy} = \tan^{-1}(\sqrt{x^2 + y^2} / z)$, of the lateral distance was 2.9° for the inner circle and 4.8° for the outer circle. The associated distances of the projected locations on the screen from the center were 3.0 cm for the inner circle and 5.0 cm for the outer circle. This procedure was used to ensure that effects in the xy -component of reproduced spatial relations did not result simply from different distances on the retina, which would make reasoning about the effects more difficult. On the other hand, this procedure makes it more difficult to analyze the effects in the displayed, virtual, three-dimensional space. However, variation in the radii of the test stimuli in virtual space was quite small and only resulted in additional noise that was identical for each factor level of Δz and therefore did not affect the main effects. In the virtual space, the range of the radii was $[2.8 \text{ cm}, 3.1 \text{ cm}]$ for the inner circle and $[4.9 \text{ cm}, 5.4 \text{ cm}]$ for the outer circle.

¹ The x , y , and z axes form a right-handed coordinate system.

Fig. 2: (a) Absolute deviation of e_x and e_y as functions of $|\Delta z|$.
(b) Absolute deviation of e_{xy} as a function of $|\Delta z|$ parameterized by the distance to the center axis.

Procedure

In each experiment the subject's task was to reproduce the location of one sphere relative to a second sphere. All participants performed training sessions to familiarize themselves with the stereoscopic information display and the spacemouse. Each experiment used a $3 \times 3 \times 2$ within-participants design. The first factor was the virtual frontoparallel plane on which the landmark sphere was located. The second and third factors indicated the virtual frontoparallel plane and the eccentricity of the location that had to be memorized, respectively. The polar angle of the location on the circle in question was randomized by a uniform distribution. All object configurations were tested in a randomized order. At the beginning of each trial, both spheres were displayed for one second, followed by a blank screen shown for two seconds. Finally, the landmark sphere was displayed at its previous location and a second sphere was shown at the default location, the origin. This second sphere had to be moved to the memorized location using the spacemouse. When the subject was confident that the second sphere was located at its remembered location he/she confirmed the location by pressing the spacebar on the keyboard. After a blank screen had been displayed for a short time, a new trial containing new locations for the spheres followed. For movement of the sphere, the translation of the controller cap was modeled as a three-dimensional Cartesian vector. Because the controller cap can be moved along all dimensions simultaneously, this Cartesian vector can point in any direction and has no preferred movement along a particular axis. The sphere moved in the virtual display space in the direction of this vector with a speed proportional to the vector norm.

Dependent Variables

In the following, the triplet (x_0, y_0, z_0) represents the coordinates of the landmark location, (x, y, z) are the coordinates of the location that had to be memorized, and (x', y', z') are the coordinates of the location that was reproduced by a subject. In this study, the relative distances

of the locations to the landmark location are of major interest: $\vec{v} = (x - x_0, y - y_0, z - z_0)^T$, $\vec{v}' = (x' - x_0, y' - y_0, z' - z_0)^T$. To test the hypothesis that relative depth is encoded independently of relative lateral location, we first investigated the response errors, $\vec{e} = \vec{v}' - \vec{v}$, in Cartesian coordinates. The reliability of the memorized location is reflected in the variability of the responses. By itself, the error vector reflects systematic distortions in the mental representation. Without a systematic component of distortion in the mental representation, the mean error equals zero. The variability of the errors is identical to the variability of the responses. We used the average absolute deviation to measure variability and the median to measure central tendency.

Results and Discussion

All trials on which the distance between the reproduced location and the correct location was larger than the distance between the correct location and the landmark location were considered as outliers. Since the exclusion of outliers resulted in empty cells for two of the participants, their data were excluded from further analysis. There were 6.9% outliers in the remaining group of 11 participants.

Cartesian coordinate system

For each factor level, the mean response error, \vec{e} , was determined. Using these means, the absolute deviations of each component, x and y , of the response error were calculated. The absolute deviation was analyzed using a repeated measures ANOVA with $|\Delta z| = |z - z_0|$ (0 cm, 3 cm, 6 cm), the visual angle of the lateral distance, α_{xy} , (2.9° , 4.8°) and component (horizontal (x), vertical (y)) as the within-subject factors. The ANOVA results showed that the absolute deviation varied systematically with $|\Delta z|$ ($F(2,20) = 5.88$, $p < .01$, $\eta_p^2 = .37$), its value being smaller for $|\Delta z| = 0$ cm ($Mean = .36$ cm, $SEM = .04$ cm) than for $|\Delta z| = 3$ cm ($Mean = .44$ cm, $SEM = .03$ cm) and $|\Delta z| = 6$ cm ($Mean = .47$ cm, $SEM = .06$ cm). No significant difference was found between $|\Delta z| = 3$ cm and $|\Delta z| = 6$ cm. The analysis revealed neither a main effect of the component type ($F(1,10) = .60$,

$p = .46$) nor an interaction effect of component type and $|\Delta z|$ ($F(2,20) = 1.00$, $p = .38$). The absolute deviation of e_{xy} , parameterized with α_{xy} , is plotted in Fig. 2b. The absolute deviation varied systematically with α_{xy} ($F(1,10) = 19.5$, $p < .001$, $\eta_p^2 = .66$), and the interaction of $|\Delta z|$ and α_{xy} was not significant ($p > .5$). The absolute deviation was smaller for $\alpha_{xy} = 2.9^\circ$ ($Mean = .37$ cm, $SEM = .04$ cm) than for $\alpha_{xy} = 4.8^\circ$ ($Mean = .48$ cm, $SEM = .04$ cm).

Spherical coordinate system

To analyze the variability of the responses using a spherical coordinate system, both the length and the zenith angle were calculated for all spatial relations that had been analyzed. Since it was assumed that the reference axis points in the same direction as the spatial relation, the zenith angle only varied from 0° to 90° . Based on the grouping of these two values, factor levels were defined for the zenith angle and the lengths of the tested spatial relation. The defined factor levels are shown in Fig. 3.

Fig. 3: Factor levels of the stimuli used for the analysis.

The factor levels with different lengths for a single zenith angle are of special interest. This is the case for $\theta_{42^\circ} \approx 42^\circ$ and $\theta_{90^\circ} = 90^\circ$. Therefore, if the response errors are examined in spherical coordinates, the absolute deviations of the angles should be identical for different lengths of the spatial relation. To verify this, the absolute deviations of the zenith and azimuth angle for each response were calculated. A three-way repeated-measures ANOVA was conducted using Euclidean length and zenith angle of the tested spatial relation and the angular component of the reproduced spatial relation as within-subject factors.

There was no significant effect of the length of the tested spatial relation on the absolute response deviation ($F(1,10) = 1.52$, $p = .246$). Therefore, the absolute deviation of the reproduced spherical angles was also calculated for θ_{25° and θ_{60° . In Fig. 4a, the absolute deviations of the reproduced angles are plotted for all zenith angles under study. The absolute deviations of the reproduced zenith angles increased for smaller zenith angles of the tested spatial relation, whereas this dependence seemed to be weaker for the reproduced azimuth angle.

A two-way repeated-measures ANOVA showed significant effects for the angular component ($F(1,10) = 15.30$, $p < .005$, $\eta_p^2 = .54$) and the zenith angle of the tested spatial relation ($F(3,30) = 6.46$, $p < .01$, $\eta_p^2 = .39$). The interaction of these two factors was not significant ($F(3,30) = 2.13$, $p = .12$, $\eta_p^2 = .18$). The increase in the absolute deviation of the reproduced azimuth angle was smaller (θ_{90° : $Mean = 5.14^\circ$, $SEM = .85$; θ_{25° : $Mean = 7.12^\circ$, $SEM = .97$) than the increase in absolute deviation of the reproduced zenith angle (θ_{90° : $Mean = 9.15^\circ$, $SEM = .79$; θ_{25° : $Mean = 15.53^\circ$, $SEM = 1.96$). The strong dependence of the absolute deviations in the reproduced zenith angles on the tested zenith angle contradicts the predictions of a pure spherical geometry for the mental representation. Therefore, as a next step the absolute deviation of the reproduced length of the spatial relation was analyzed. For each defined factor group, the tested lengths have a given absolute deviation, which need to be considered in the analysis. For a spherical geometry it must be expected that the absolute deviations of the reproduced lengths increase linearly. In contrast, the analysis showed a disordered picture for the reproduced lengths, the mean of the reproduced length being smaller for d_5 than for d_4 (Fig 4b). A one-way repeated-measures ANOVA revealed no significant difference for these two groups ($F(1,10) = 2.93$, $p = .12$, $\eta_p^2 = .23$).

Therefore, the mean of the reproduced length for d_5 ($Mean = 5.45$ cm, $SEM = .19$ cm) was at least equal to or possibly smaller than that for d_4 ($Mean = 5.73$ cm, $SEM = .13$ cm). However, groups d_4 and d_5 also differed in zenith angle for the tested spatial relation. In d_4 , the mean zenith angle was 42° , whereas for d_5 the mean zenith angle was 90° . For d_5 , the spatial relation had no depth component, and the absolute deviations did not increase with the length of the tested spatial relation.

The absolute deviation for the tested length for d_3 was significantly smaller than that for d_2 ($F(1,10) = 13.6$, $p < .005$, $\eta_p^2 = .58$). Again, both groups also differed in zenith angle (d_2 : $\theta = 20^\circ$, d_3 : $\theta = 42^\circ$), and consequently by the fraction of the depth component. These findings suggest an independent analysis of the depth and lateral components of the length of a spatial relation. Therefore, the data are grouped by $|\Delta z|$ and the length of the xy -component of the tested spatial relations. The absolute deviations increased with the length of the related length. A one-way repeated-measures ANOVA showed that this effect was significant for the z -component ($F(2,20) = 35.1$, $p < .001$, $\eta_p^2 = .78$) and the xy -component ($F(1,10) = 20.3$, $p < .001$, $\eta_p^2 = .67$). Since the absolute deviations from the given spatial relations also increased itself for the xy -component, an additional two-way repeated-measures ANOVA was performed on pooled data from the tested spatial relations and the reproduced spatial relations. This analysis, which included reproduced vs. original spatial relations as an additional factor, revealed a significant interaction between reproduced vs. original spatial relation and length ($F(1,10) = 6.59$, $p = .028$, $\eta_p^2 = .39$). This interaction indicated that an additional increase in the absolute deviation results from the

Fig. 4: (a) Absolute deviation of the reproduced spherical angular components as a function of the zenith angle of the tested spatial relation. The multiple measure points at θ_{42° and θ_{90° show the absolute deviations for the corresponding distance groups. (b) Mean and absolute deviation of the reproduced and tested Euclidean distances as a function of the corresponding mean.

mental representation. Notably, the absolute deviations of the z-component appeared to increase linearly with $|\Delta z|$ for the tested spatial relation but not with the reproduced length. Furthermore, the z-component shrinks in memory. The strengths of the growth and shrinkage depended on $|\Delta z|$. A more detailed analysis is out of the scope of this paper

General Discussion

The results of the experiment showed that the variability of a location reproduced from visual spatial memory is influenced by the relative distance in depth to a landmark. With increasing distance in depth, not only did the variability of the reproduced depth component of the distance increase, but the variability of the reproduced lateral location also increased. The effect of landmarks on locations reproduced from memory generally indicates that participants include spatial relations between the location and the landmark in the encoded location. The structure of the variability of the reproduced locations provides insight into the mental representation. For an analysis a detailed model should describe the actual information processing steps that transform sensory information into a cognitive representation and then into a reproduction. Such a model can be greatly simplified if noise contained in the mental representation is much greater than the noise contained in visual sensory information. In this case, the noise from sensory information can be neglected. For two dimensional stimuli, visual acuity was much higher than the variability of the reproduced locations. For example, the visual acuity at an eccentricity of 5° is about $3''$. Under the assumption that the landmark location can be assessed with a resolution of $1''$, the lateral direction of a location relative to the landmark location should be discriminated by $2 \cdot \tan(5^\circ/(4''/2)) \approx 0.08^\circ$, which is much lower than the usually obtained variability of directions reproduced from memory. Similar arguments apply for the reproduced lateral distance to the landmark location. The lateral noise parameter σ_φ and $\sigma_{\alpha_{xy}}$ determined from the data can be

compared to values reported in literature. Huttenlocher et al. (1991) reported $\sigma_\varphi = 10^\circ$, which is somewhat higher than the value of $\sigma_\varphi = 6.3^\circ$ found in our data. In contrast, we found $\sigma'_{f_a} = 0.11^2$ for the standard deviation to reproduce radial distance, which is larger than $\sigma_{f_a} = 0.025$, the value reported by Huttenlocher et al. (1991). This difference may be caused by the fact that participants in the experiments of Huttenlocher et al. had to estimate locations within a circle. To do so, initially they had to estimate the center of the surrounding circle as the landmark location, which adds noise to the direction, whereas the radial component could be estimated more efficiently by using more than one landmark located on the circumference of the circle. For three dimensional stimuli, the assessment of sensory acuity is much more complex than it is for two dimensional stimuli. There are several sources of sensory information that can be exploited by the visual system to deduce information about depth: disparity, accommodation, and vergence. To the best of our knowledge, the quantity representing the effect of an increase in disparity on lateral spatial resolution has not been described in the depth perception literature. In contrast, the dimensions of Panum's fusional area have been well studied (Kenneth & Ogle 1952). Additional studies have focused on the dependence of the stereo acuity on eccentricity (Rawlings & Shipley 1969) and the effect of object size on stereoscopic spatial depth acuity (Schlesinger & Yeshurun 1998). A decrease in spatial acuity in the lateral dimensions due to increasing disparity is to be expected, because double images are perceived outside Panum's fusional area. However, we believe that the additional noise from disparity is less than the increase in noise that was found in the data. Furthermore, because the stimuli had horizontal disparity, this noise should only affect the horizontal component of the

² To be compliant to Weber-Fechner-Law the standard deviation of reproduced eccentricity scales linear with the eccentricity of the actual memorized visual angle α_{xy} is given by: $\sigma_{\alpha_{xy}} = \sigma_{f_a} \alpha_{xy}$

lateral location and not the noise in the vertical component, which surprisingly increased by similar amounts. Nevertheless, the analysis of the absolute deviation of the reproduced distances as a function of the distances examined in the experiment showed that the depth component of distance was crucial, since the variability was much greater in depth than it was in the lateral dimensions. This is consistent with the findings of Norman et al. (1996), who observed that participants are highly sensitive to small differences in the length of lines presented in the frontoparallel plane, while the sensitivity decreases by an order of magnitude when the line segments are presented at random orientations in depth. In case of a mental representation of the spatial relation in a spherical coordinate system a model should include this noise in the perception of depth, while the zenith angle is deduced from this noisy depth component. The dependence of noise in the depth component on eccentricity, where landmark location and the to-be-reproduced location are in the same frontoparallel plane ($\theta = 90^\circ$), was similar to values reported in the literature. It is known that stereoscopic acuity is a decreasing function of eccentricity. Rawlings and Shipley (1969) reported a stereo acuity of 21" at the point of focus and 155" at an eccentricity of 4° . If 25% is assumed to be the threshold of the just-noticeable difference, an interpolation of the data reported in this paper will predict a stereo acuity of 221" at an eccentricity of 4° . On the one hand, this finding does not deliver a new argument that spatial relations are mentally represented in a spherical coordinate system, since the additional noise might simply be the result of the subject's carelessness when adjusting the stimulus to the remembered location. Yet on the other hand, this finding does not contradict the argument that the noise contained in the mental representation results from noisy perception. A model assuming a mental representation in a spherical coordinate system would explain both effects—the increase in depth variability with eccentricity and the increase of lateral variability with relative distance in depth—using only one noise parameter for the zenith angle σ_θ , whereas a model considering independent dimensions for the depth and the lateral location needed two parameters: one noise parameter for the lateral projected distance in dependence on the depth component ($\sigma_{f_a}(\Delta z)$), and a second noise parameter for the noise in the depth component in dependence on the eccentricity of the spatial relation ($\sigma_{\Delta z}(\alpha_{xy})$). In future research the mathematical modeling of human performance variability using probability density functions would clarify the underlying assumptions regarding dependencies between spatial attributes. The resulting parameterized models could be used to describe the recollection of locations from memory. The distortions at categorical boundaries emerged naturally at the boundaries of the probability density functions. Furthermore, the results of this study should be generalized. In the current experiment, the viewing axis was a natural

choice for the polar axis of the spherical coordinate system, since there was only one landmark sphere present. If there are two landmark spheres, we suggest that the line connecting the two spheres serve as the polar axis of the mental representation.

Abstract

Asocial learning is a mechanism by which innovations develop, and social learning is a mechanism by which innovations spread. Penetration of an innovative behavior through a population is measured by the proportion of the population that possesses the innovation. Via agent-based modeling, we examine innovation diffusion with agents learning and interacting in space. Simulations show that innovation spread systematically deviates from differential equations of the proportion of the population that has the innovation. Mediation analysis confirms that boundary surface length of groups having the innovation accounts for these spatial effects. Proportion of asocial innovative learners increases surface length which, in turn, increases social imitative learning.

Keywords: Social learning; asocial learning; imitation; innovation; spatial simulation; surface length; mediation analysis; agent-based modeling.

Introduction

Since Darwin's theory of evolution, researchers have sought to understand how organisms adapt to their environment to maximize their reproductive potential. In addition to biological evolution, some lasting adaptations manifest themselves through animal phenotypes with no genetic changes. Innovative behaviors allow relatively quick adaptation to rapidly changing environments, and can spread and persevere (Laland, Boyd, & Richerson, 1996; Reader & Laland, 2003). For our purposes, *innovation* refers to an adaptive behavior pattern with relative novelty.

Innovative behaviors can be acquired through either asocial or social learning. In asocial learning, an innovation is acquired through individual experience. In social learning, an innovation is acquired from a conspecific demonstrator (Heyes, 1994). Because individual discoveries are costly, they may occur in only a few key individuals through asocial learning and then diffuse through a population via social learning (Laland, Boyd, & Richerson, 1996). The dynamics of innovation diffusion and imitation are an important aspect of collective social cognition and behavior, and thus relevant to integrative cognitive science (Goldstone & Gureckis, 2009).

However, patterns of sequential spread in a population resembling those predicted by some models of social learning can result from asocial processes alone. It is not always clear which type of learning drives innovative acquisitions, so it is thus important to disentangle social

from asocial learning. One useful method is diffusion curve analysis, or DCA (Reader, 2004; Franz & Nunn, 2009). Diffusion is the change in frequency of an innovative behavior in a population over time. In DCA, the shape of the curve is used to infer whether social or asocial learning is the mechanism of diffusion.

Our purpose is to simulate the spatial diffusion of innovation and compare the results to DCA predictions. Although there is a rich literature on learning in laboratory experiments, understanding of how social learning occurs in the wild is limited.

S-shaped logistic curves are predicted by DCA to characterize social learning. If the amount of social learning at a given time step is proportional to both the number of possible demonstrators and the number of possible learners, then it can be obtained as the product of the proportion of the population that knows the innovation and the proportion of the population that does not know the innovation (Laland, Boyd, & Richerson, 1996). This corresponds mathematically to the differential equation:

$$\Delta u = R_s u(1 - u) \quad (1)$$

where R_s is a constant rate of social learning, and u is the variable proportion of the population with the innovation.

In a population of only innovators, assuming no social learning, the following differential equation applies:

$$\Delta u = R_i (1 - u) \quad (2)$$

where R_i is the rate of innovation. As more innovators learn, the number of naïve innovators decreases in a decelerating curve (Franz & Nunn, 2009).

Social and asocial learning are not mutually exclusive. In an analysis of data from research by Hinde and Fisher (1949) on innovation spread in birds, Lefebvre (1995) concludes that milk-bottle-opening likely spread by some form of social learning from many unique points of origin. This is supported by evidence that some birds open bottles spontaneously without any prior experience with bottles or demonstrators (Sherry & Galef, 1984). Thus, asocial learning can occur alongside social learning, and Equations 1 and 2 can be summed to accommodate this:

$$\Delta u = R_s u(1 - u) + R_i (1 - u) \quad (3)$$

Equation 3, however, applies only to a population where every member is capable of being an innovator and a social learner. It may be more realistic to assume that only a certain proportion of the population is capable of either of

these things. No explanatory power is lost in making this assumption as these proportions can be set to 1, and the resulting model is only slightly less parsimonious. To accommodate this variation in ability, Equation 3 can be modified by multiplying the innovation and social learning parts of the equation by their corresponding proportions, I and S , respectively:

$$\Delta u = SR_s u(1-u) + IR_I(1-u) \quad (4)$$

We refer to Equation 4 as the DCA equation. Based on the proportion of social learning compared to asocial learning, this differential equation generates a curve with either a logistic shape (greater social learning) or a decelerating shape (greater asocial learning). The DCA equation has been applied in various experimental contexts, including the diffusion of innovations in humans from peer and media influences (Lekvall & Wahlbin, 1973) and bystander effects in the diffusion of foraging techniques in pigeons (Laland, Boyd, & Richerson, 1996).

The DCA equation relies on one key variable: the proportion of the population that knows the innovation. This proportion thus serves as both the dependent and independent variable in the differential equation. Here we test the results of spatial simulations against the predictions of the DCA equation. The diffusion of innovation is in part a spatial process, a fact captured by the simulations, but not by the DCA equation. We answer several questions. What are the essential differences between asocial and social learning and how can these two types of learning be identified in wild populations? Does the DCA equation account for all aspects of these issues, or are other approaches required? Are these features realistic, or are they artifacts of abstract simulations?

To explore the spatial diffusion of an innovation, our simulations create a two-dimensional space containing agents. Depending on their genotype, agents can be innovators and/or social learners. Parameters of the simulation include the proportions of innovators and social learners, just as the DCA equation uses these factors as variables. Comparing the rate of learning in the simulation to the rate of learning predicted by the DCA equation could provide insight into any potential spatial factors affecting innovation diffusion.

Methods

The simulation is set on a torus, a 25 by 25 lattice in which each edge touches the opposite edge. Each of the 625 tiles contains one agent with on/off genes for innovation and social learning.

Agents with an activated innovation allele can spontaneously discover the innovation at a fixed innovation rate of .025. Agents with an activated social-learning allele can copy the innovation from their neighbors: for every adjacent neighbor that knows the innovation, a social learner's chance of learning the innovation increases by .25. The ten-fold difference between the success of social and asocial learning is based on an assumption of differential learning costs: if asocial learning has a greater cost and

requires more resources than social learning, it should occur at a slower rate than social learning. The simulation experiment assigns genes to individual agents probabilistically depending on the proportion of social and asocial learners specified in simulation parameters. The simulation runs for 80 learning cycles, recording agent behavior, the times at which agents learn, and the neighbors from whom they learn if the learning is social.

The effect of number of innovators was investigated in simulations with the proportion of innovators ranging from .05 to 1.0, holding the proportion of social learners at 1.0. The effect of number of social learners was studied with simulations varying proportion of social learners ranging from 0 to 1.0, holding the proportion of innovators at 1.0.

Results

Figures 1-6 plot the change in the proportion of the population that knows the innovation over time, averaged across five runs. Figures 1 and 2 depict the results from varying the proportion of the population with the asocial learning allele when the whole population has the social learning allele. Figure 1 shows predictions of the DCA equation, and Figure 2 presents simulation results.

Figure 1: Diffusion curves predicted by DCA equation with asocial learning rate = .025, social learning rate = .25, proportion of social learners = 1, and the proportion of asocial learners varying from .05 to 1.

Figure 2: Simulations with asocial learning rate = .025, social learning rate = .25, proportion of social learners = 1, and proportion of asocial learners varying from .05 to 1.

These results reveal subtle but noticeable differences between the DCA equation and the simulations. For Figures 1 and 2, the whole population is capable of social learning;

what changes across curves is the proportion of the population capable of asocial learning. In Figure 1, the curves determined by the DCA equation appear more parallel than they do in the simulation results of Figure 2.

We can understand these differences by considering the DCA equation itself. This equation (4) has a social learning component (left half) and an asocial learning component (right half). Recall that the DCA equation's key variable is the proportion of the population that knows the innovation. At the beginning, the innovative behavior is introduced into the population by asocial learning, so the proportion of the population that can do asocial learning has a large effect as seen in Figure 1. Because this proportion of asocial learners is different in every curve, the curves differentiate quickly. However, as the proportion of the population that knows the innovation increases, the social learning component of the DCA equation has a greater effect. Because all of the curves in Figure 1 have the same social learning settings, with the proportion of social learners S set to 1 and the rate of social learning R_S set to .25, their learning rates are very similar after this original differentiation, causing the observed parallelism. Thus, the parallel nature of the equation-produced curves in Figure 1 is a direct consequence of using the proportion of the population that knows the innovation as the key independent variable.

The lack of parallelism in simulation curves can be quantified by examining the maximum learning slope for each curve, which represents the amount of learning when u , the proportion of the population that knows the innovation, equals .5. This is the point that maximizes the product $u(1-u)$ and thus also maximizes innovation spread according to the DCA equation. Figure 3 presents mean maximum slopes of diffusion curves as a function of the proportion of the population with the innovation allele.

Figure 3: Maximum slope of curves (where $u = .5$) from the DCA equation and the simulations.

Figure 3 indicates that the maximum slope of each curve from the DCA equation is relatively stable across variation in number of innovators, consistent with a constant social learning component in the DCA equation. The corresponding simulations, however, do not follow this pattern; rather than being stable, the maximum slope increases with the proportion of innovators.

As Figure 6 indicates, there is no discrepancy between the asocial learning component of the DCA equation and

asocial learning in simulations. Thus we can infer that this increase in maximum slope across number of innovators is due to social learning. This implies that increasing the proportion of the population with the asocial learning allele speeds innovation spread in the simulation, which is exactly what we see in Figures 1 and 2.

Analogously, Figures 4 and 5 depict results from adjusting the proportion of the population with the social learning allele when the whole population has the asocial learning allele. Figure 4 shows predictions of the DCA equation while Figure 5 presents simulation results. Again, the curves produced from the simulations have a greater maximum learning slope than the curves predicted by the DCA equation, and these discrepancies increase with the proportion of the population that is capable of social learning.

Figure 4: Diffusion curves predicted by DCA equation with asocial learning rate = .025, social learning rate = .25, and proportion of social learners varying from 0 to 1.

Figure 5: Simulations with asocial learning rate = .025, social learning rate = .25, proportion of social learners varying from 0 to 1, and proportion of asocial learners = 1.

With purely asocial learning ($S = 0$), the DCA equation closely tracks simulation results. The absolute differences between the equation and simulations averaged below .01 across all time steps. The lowest navy blue curves in Figures 4 and 5 are nearly identical. These two curves are re-plotted in Figure 6 to emphasize the overlap. This is the only simulation curve that the DCA equation successfully predicts. This predictive success makes sense because asocial learning in the simulation occurs as a random event based on a fixed probability, just as in the equation. Therefore, discrepancies between all other DCA and

simulation curves must result from social learning or possible interactions between social and asocial learning.

A possible cause of the increase in social learning as the proportion of innovators increases (Figure 3) is boundary surface length, the length of the perimeter surrounding groups of agents that know the innovation. These boundaries mark the area where naïve agents can learn the innovation. Thus, increasing this area should increase the speed of innovation spread.

Figure 6: Diffusion curve predicted by the DCA equation compared to simulation results. Asocial learning rate = .025 and proportion of asocial learners = 1.

According to this analysis of the simulations, the spatial distribution of the agents that know the innovation affects social learning. Consider each innovator as a start point for an island of social learners. There will be more such islands when there are more initial innovators. More innovation islands generate more surface length and therefore more

social learning. This suggests an interaction effect with the proportion of innovators in the population: when there are multiple initial innovators, there is a higher likelihood that more social learning will occur as a result of greater surface length. When there are fewer initial innovators, less social learning will occur as a result of less surface length.

Figure 7 shows two plots from simulations exemplifying this argument. These two tori present simulation outputs, each depicting the point where one-half the population possesses the innovation. In 7A, where the proportion of innovators = .05, there are two islands, resulting from a few early innovators. In 7B, where the proportion of innovators = 1, there are upwards of nine islands due to more innovators. Although the proportion of the population possessing the innovation is the same in both worlds, surface length is much greater for the simulation that was initialized with a higher proportion of innovators.

Thus, an explanation for the discrepancies between the predictions of the DCA equation and the simulation results is that asocial learning increases the number of start points for social learning, and therefore the emerging amount of surface length. Because surface length determines the amount of social learning that can take place, social learning and innovation spread increase substantially as surface length increases. Thus, increasing asocial learning increases social learning in the simulation (Figure 2) but not in the DCA equation (Figure 1; see Figure 3 for direct comparison). This explanation can be further validated by a mediation analysis (MacKinnon et al, 2007).

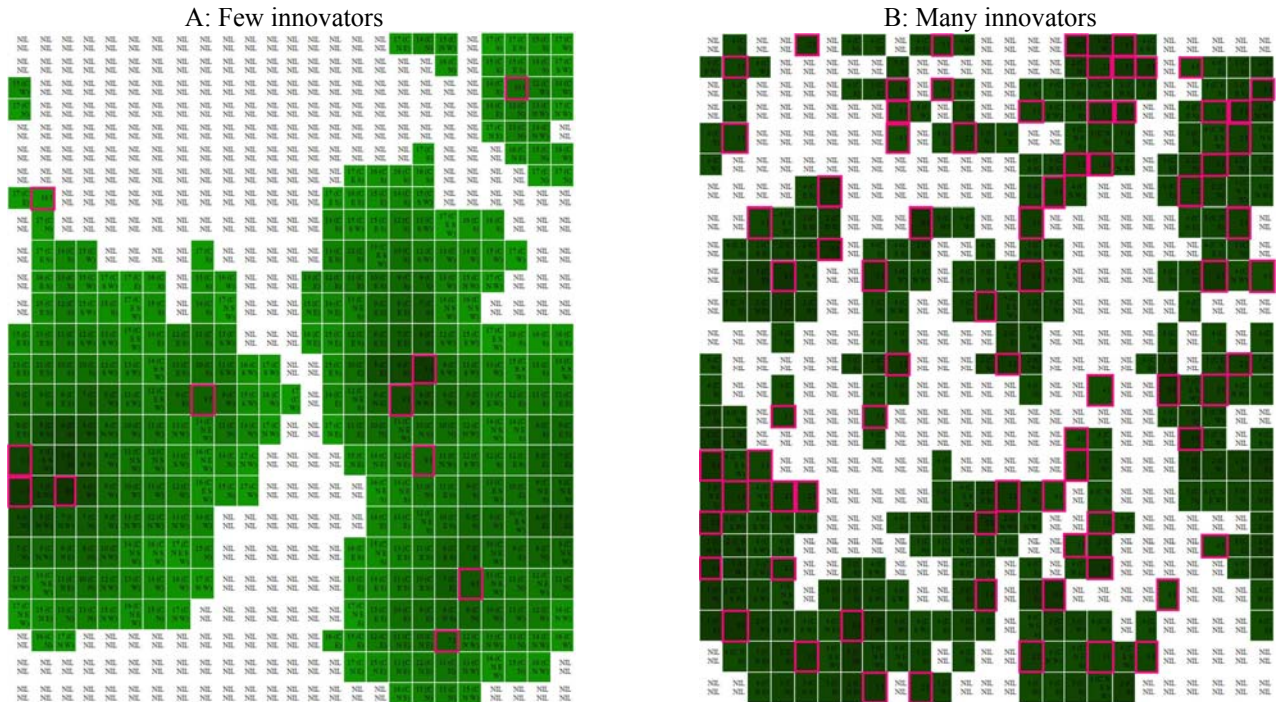

Figure 7: Two worlds with innovator proportions of .05 (A) and 1.0 (B). Time of acquisition is indicated by color saturation. Innovators are outlined in pink.

Mediation analysis is a type of linear regression that evaluates the relative effects of an independent variable (here, proportion of asocial learners) and a mediating variable (here, surface length) on a dependent variable (here, amount of social learning). The idea is that the independent variable affects the dependent variable, not only directly, but also indirectly via a mediating variable.

A mediation analysis of the simulation data across the six increasing proportions of asocial learners shows that 90.2 percent of the variance in the amount of social learning caused by variance in the proportion of asocial learners is mediated by surface length (total effect = 19.233 [$\beta = .945$], mediation effect = 17.351 [$\beta = .912 * .934 = .852$], $p < 0.0001$). As shown in Figure 8, the direct effect of the proportion of asocial learners on the amount of social learning becomes non-significant after controlling for the mediating variable of surface length, implying full mediation. This mediation analysis lends statistical support to the idea that surface length is the mechanism through which asocial learning causes social learning to speed up.

Figure 8: Standardized regression (beta) coefficients for mediational analysis. The path from X to Y falls to non-significance after controlling for the mediating variable of surface length (as indicated by the small coefficient in parentheses).

In summary, the simulations indicate that increasing social learning by adding more asocial learners increases surface length, and therefore increases the speed of social learning. This goes beyond the DCA equation which takes only the proportion of the population that knows the innovation as its independent variable. Also, speed of innovation spread is reduced as the number of agents with the social learning allele decreases.

Discussion

Our results show a difference between the DCA equation and the simulations, and this difference derives from the spatial factor of surface length. In the simulation, surface length is causally related to both social and asocial learning. Asocial learning increases surface length and surface length, in turn, increases social learning. The DCA equation, whose only independent variable is the proportion of the population that knows the innovation, does not capture this spatial factor. It is possible that the DCA equation could be

improved on by a more sophisticated mathematical model that incorporates surface length.

A fundamental question is whether or not these results apply to the real world. After all, the results are a consequence of the design of the simulations. There is a high viscosity in the design, meaning that agents can only learn from their directly adjacent neighbors. This characteristic is presumably the cause of the spatial effect. If an agent could learn from any other randomly-selected agent, then the spatial arrangement of agents would have no bearing on the results. Therefore, the results are only applicable to real-world scenarios where social learning depends highly on spatial proximity. With tools like the telephone and internet, which allow social learning to take place across oceans, these results may not apply to diffusion of innovation for many human populations. This is not to say that diffusion in humans is random, but rather that these present simulations may be too constrained to model it. However, the current results do seem applicable to populations where social learning is heavily dependent on proximity, which would include a lot of human learning based on face-to-face interactions.

This consideration points to a distinction between *geographic* and *social-network* analysis. The simulations we present here are examples of geographic analysis, with agents learning from their immediate neighbors. Social networks can transcend spatial proximity by using communication technologies to cover great distances. This difference is not just one of viscosity but also of structural complexity, because social networks are often more complicated than geographic relationships.

Franz and Nunn (2009) developed a method of social network analysis called network-based diffusion analysis, or NBDA. NBDA uses the social network of a population and the times at which they learn innovations to probabilistically determine whether the learning mechanism is social or asocial. Their method of social network analysis seems promising, although it requires the researcher to determine the social network of a population. Such specification may not be feasible in excessively large populations. There are also cases where a geographic analysis may be more appropriate because some environments are in fact viscous (e.g., Lefebvre, 1995).

Also, Franz and Nunn's main interest was in detecting social or asocial learning when one such learning method was exclusively present. In contrast, our research used various, systematic combinations of these two learning mechanisms. Model sensitivity to such combinations of social and asocial learning is more interesting and important than detection of pure cases. Studying such combinations is critical to discovering interactions between social and asocial learning, as highlighted in our results.

A lattice structure permitting interaction only between immediately adjacent neighbors is actually a special case of a network that provides only those links (or edges). Thus, a generalization of our results would entail testing whether an analog of surface length would facilitate information

diffusion in networks of various topologies. Such an analogy might be the number of directed links between agents who possess, and agents who lack, an innovation. If such links indicate direction of causal influence, then it would be important to count the links from knowledgeable to naïve agents; if links indicate friendship choice, then count the links from naïve to knowledgeable agents, because agents are likely to be influenced by those they consider to be friends.

The original aim of this project was to look for ways to disentangle social learning from asocial learning through a spatial analysis of the diffusion of innovative behavior. The results suggest that a greater proportion of asocial learners results in more innovation islands and greater surface length. Although it may be difficult to determine surface length in wild populations, counting islands in a topographic analysis of observations of innovative behavior would seem feasible.

The spatial effect of surface length provides a mechanism to disentangle social and asocial learning that is not available in diffusion curve analysis. This kind of spatial analysis could become another valuable tool to measure and understand the differences between social and asocial learning. One next step is to apply the ideas developed from this simulation to real biological data. In doing so, we may be able to contribute new understanding of how adaptive innovations spread and how they interact with evolution. Another planned thrust is to study how evolution selects the best proportions of social and asocial learning alleles under different environmental conditions (Laland et al., 1996; Shultz, Hartshorn, & Hammond, 2008; Shultz, Hartshorn, & Kaznatcheev, 2009). In such research, faster learning cycles can be nested within slower evolutionary cycles.

Abstract

The Raven's Progressive Matrices intelligence test is widely used as a measure of Spearman's general intelligence factor g . Although Raven's problems resemble geometric analogies, prior computational accounts of solving the test have been propositional. Studies of both typical and atypical human behavior suggest the possible existence of visual strategies; for example, neuroimaging data indicates that individuals with autism may preferentially recruit visual processing brain regions when solving the test. We present two different algorithms that use visual representations to solve Raven's problems. These algorithms yield performances on the Standard Progressive Matrices test at levels equivalent to typically developing 9.5- and 10.5- year-olds. We find that these algorithms perform most strongly on problems identified from factor-analytic human studies as requiring gestalt or visuospatial operations, and less so on problems requiring verbal reasoning. We discuss implications of this work for understanding the computational nature of Raven's and visual analogy in problem solving.

Keywords: Analogy; intelligence tests; knowledge representations; mental imagery; Raven's Progressive Matrices; visual reasoning.

Introduction

The Raven's Progressive Matrices tests (Raven, Raven, & Court, 1998) are a collection of standardized intelligence tests that consist of geometric analogy problems in which a matrix of geometric figures is presented with one entry missing, and the correct missing entry must be selected from a set of answer choices. Figure 1 shows an example of a 2x2 matrix problem that is similar to one in the Standard Progressive Matrices (SPM); other problems contain 3x3 matrices. The entire SPM consists of 60 problems divided into five sets of 12 problems each (sets A, B, C, D & E), roughly increasing in difficulty both within and across sets.

Although the Raven's tests are supposed to measure only educative ability, or the ability to extract and understand information from a complex situation (Raven, Raven, & Court 1998), their high level of correlation with other multi-domain intelligence tests have given them a position of centrality in the space of psychometric measures (e.g. Snow, Kyllonen, & Marshalek 1984), and as a result, they are often used as tests of general intelligence in clinical, educational, vocational, and scientific settings.

Computational accounts of problem solving on the Raven's tests have, with the exception of Hunt (1974), assumed that visual inputs are translated into propositions,

over which various kinds of reasoning then take place. In this paper, we provide evidence from two different methods that Raven's problems can be solved visually, without first converting problem inputs into propositional descriptions.

Existing Computational Accounts

Carpenter, Just, and Shell (1990) used a production system that took hand-coded symbolic descriptions of problems from the Advanced Progressive Matrices (APM) test and then selected an appropriate rule to solve each problem. The rules were generated by the authors from *a priori* inspection of the APM and were validated in experimental studies of subjects taking the test with verbal reporting protocols. Bringsjord and Schimanski (2003) used a theorem-prover to solve selected Raven's problems stated in first-order logic.

Lovett, Forbus, and Usher (2007) combined automated sketch understanding with the structure-mapping analogy technique to solve problems from the Standard Progressive Matrices (SPM) test. Their system took as inputs problem entries sketched in Powerpoint as segmented shape objects and then automatically translated these shapes into propositional descriptions. A two-stage structure-mapping process was then used to select the answer that most closely fulfilled inferred analogical relations from the matrix.

In contrast to these propositional approaches, Hunt (1974) proposed the existence of two qualitatively different strategies: "Gestalt," which used visual representations and perceptual operations like continuation and superposition,

Figure 1: Example problem similar to one from the Standard Progressive Matrices (SPM) test.

and “Analytic,” which used propositional representations and logical operations. The Analytic algorithm is similar to that of Carpenter, Just, and Shell (1990) in that it applied rules to lists of features representing each matrix entry. The Gestalt algorithm is similar to our methods in that it used visual operations over imagistic problem inputs, but it differs in that it operated on the entire problem matrix as a single image, whereas our methods treat each matrix entry as a separate image. While Hunt’s algorithms provide an intuitively appealing account of solving Raven’s problems, neither algorithm was actually implemented.

Behavioral Evidence for Multiple Strategies

Studies of human behavior suggest that qualitatively distinct problem solving strategies can be used to solve Raven’s problems. Factor analyses of both the SPM (Lynn, Allik, & Irving, 2004; van der Ven & Ellis, 2000) and the APM (Dillon, Pohlmann, & Lohman, 1981; Mackintosh & Bennett, 2005; Vigneau & Bors, 2005) have identified multiple factors underlying these tests, which often divide test problems into two categories: those solvable using visuospatial or gestalt operations and those solvable using verbal reasoning. In support of this dichotomy, DeShon, Chan, and Weissbein (1995) found that simultaneously performing a verbal overshadowing protocol differentially impaired accuracy on about half of APM problems.

These studies of typically developing individuals have generally focused on within-individuals differences in solution strategies, i.e. a particular individual using different strategies on different portions of the test in a single sitting. Recent evidence from autism offers evidence of between-individuals strategy differences as well: individuals with autism do not show the same correlations between Raven’s scores and other cognitive measures that are robustly demonstrated by typically developing individuals (Dawson, Soulières, Gernsbacher, & Mottron, 2007).

Even more striking are recent neuroimaging data that show increased brain activation in visual regions for individuals with autism solving the SPM than controls (Soulières et al., 2009). This study also found significant differences in reaction time as a function of problem type, with problems classified as “figural” or “analytic” based on previously published factor-analytic studies. The results from this study are highly suggestive of individuals with autism using a visual strategy that contrasts with the strategy used by controls. Evidence for a visual strategy preference in autism is found across several other cognitive task domains as well (Kunda & Goel, 2008).

Our approach

We hypothesize that Raven’s problems can be solved computationally using purely visual representations. To test this hypothesis, we have developed two different algorithms that in this paper we will call the “affine” method and the “fractal” method. Both methods use image transformations to solve Raven’s problems *without* converting the input images into any kinds of propositions. Below, we describe

each of these algorithms, followed by an analysis of their performance on all 60 problems from the Raven’s Standard Progressive Matrices (SPM) test.

Visual Methods for the Raven’s Test

Similitude Transformations

At the core of each of our algorithms are image operations that fall under the category of affine transformations, and in particular similarity-preserving or “similitude” transforms. Similitude transforms can be represented as compositions of dilation (i.e. scaling), orthonormal transformation, and translation. Our implementations presently examine the identity transform, horizontal and vertical reflections, and 90°, 180°, and 270° orthonormal rotations, composed with various translations. The affine method restricts dilation to a value of one, i.e. no scaling, whereas the fractal method uses a short sequence of progressively smaller dilation values, i.e. its similitude transformations are contractive.

There is evidence that human visual processing can apply some of these types of transformations to mental images, or at least operations that are computationally isomorphic in some sense. In the theory of mental imagery proposed by Kosslyn, Thompson, and Ganis (2006), transformations of mental images include scanning (i.e. translation), zooming (i.e. scaling), and rotation, among others.

A Model of Similarity

Similarity lies at the core of both of our accounts of visual problem solving on the Raven’s test. We calculate visual similarity using the ratio model (Tversky, 1977):

$$\text{similarity}(A, B) = \frac{f(A \cap B)}{f(A \cap B) + \alpha f(A - B) + \beta f(B - A)} \quad (1)$$

In this equation, f represents some function over features in each of the specified sets; for instance, f might simply be a count of features. The constants α and β are used as weights for the non-intersecting portions of the sets A and B . If α and β are both set to one, then this equation becomes:

$$\text{similarity}(A, B) = \frac{f(A \cap B)}{f(A \cup B)} \quad (2)$$

Equation (2) is used in both the affine and fractal methods, and it yields maximal similarity for sets in which A is equal to B . In contrast, if α is set to one and β is set to zero, it yields maximal similarity for sets in which A is a proper subset of B . If α is set to zero and β is set to one, then the opposite holds, and maximal similarity is found for sets in which B is a proper subset of A . These two variants are used in the affine method to capture notions of image composition, i.e. image addition and subtraction.

In the affine method, each feature is defined as a pixel, and intersection, union, and subtraction operations are defined as the product, maximum, and difference of RGB pixel values, respectively. The fractal method uses features derived from different combinations of elements from the fractal encoding (McGregor, Kunda, & Goel, 2010).

The Affine Method

The affine method assumes that elements within a row or column in a Raven's problem matrix are related by similitude transformations. It tries to discover which similitude transformation best fits any of the complete rows or columns in the matrix, and then applies this transform to the last row/column to generate a guess for the answer. Then, it compares this guess to each of the answer choices, and chooses the answer that is most similar.

Each similitude transformation is represented as the combination of three image operations: a base transform, a translation, and a composition. Algorithm 1 shows how, for a pair of images A and B, these three components of the "best-fit" similitude transformation are found. Given a Raven's problem, then, the affine method seeks to discover the best-fit similitude transform over various combinations of the matrix entries. In particular, the algorithm assumes that certain analogical relationships exist based on the spatial arrangement of the entries. Similitude transforms are calculated for those combinations of entries that would yield an analogical mapping to solve for the missing entry. The specific base transforms and analogical relationships used by the affine algorithm are shown in Table 1, divided into those used for 2x2 and for 3x3 matrix problems.

Once the relationship and transformation are found that maximize similarity, the transformation is applied to the first entry or entries in the last row or column, as listed in Table 1. The resulting image represents the algorithm's best guess as to the missing entry. This image is compared to the answer choices, using Equation (2), and the best match is chosen as the final answer.

For each base transform T:

Apply T to Image A.

Find translation (tx, ty) which yields best match between T(A) and B, using Eq. (2).

Find image composition operand X as follows:

Calculate similarity using Eq. (1) with:

1) $\alpha = 1, \beta = 1$

2) $\alpha = 1, \beta = 0$

3) $\alpha = 0, \beta = 1$

Choose maximum similarity value.

If maximum is (1), then $X = 0$.

If maximum is (2), then $X = B - A$,

and \oplus refers to image addition.

If maximum is (3), then $X = A - B$,

and \oplus refers to image subtraction.

The best-fit similitude transformation can then be specified as:

$$[T_{\max} + (tx, ty)](A) \oplus X = B$$

Algorithm 1. Affine method for calculating best-fit similitude transformation for a pair of images A and B. For three-element transforms, T is applied to images A and B, and the result is compared, as above, to image C.

Table 1: Base transforms and matrix relationships used by the affine algorithm.

Transforms	2x2:		3x3:		
	A B C ?		A B C D E F G H ?		
Two-element transforms & relations	Identity		BC→H? DG→F?		
	Mirror		AC→G? AG→C?		
	Flip	AB→C?	EF→H? EH→F?		
	Rotate90	AC→B?	DF→G? BH→C?		
	Rotate180		GH→H? CF→F?		
	Rotate270				
Three-element transforms & relations	Union		ABC→GH?		
	Intersection	n/a	DEF→GH?		
	XOR		ADG→CF?		
			BEH→CF?		

For example, take the problem given in Figure 1. The similarity scores calculated for the various transforms and relationships are shown in Table 2. The best-fit similitude transformation is found to be a mirror (or reflection about the vertical axis) for the relationship AB, using an addition image composition (i.e. maximal similarity found using $\alpha = 1, \beta = 0$). Therefore, the answer image "?" is obtained using the analogous relationship of $A:B :: C?$. C is mirrored, translated by the (tx, ty) that was found in the search, and the composition operand of $B - A$ (which in this case is mostly a blank image) is added on to the result. Finally, this "guess" image is compared to each of the six answer choices using Equation (2), and the best match is chosen as the final answer, which in this case is answer #5.

Table 2: Calculation of best-fit similitude transform and resulting answer guess for the problem shown in Figure 1.

Relation	Transform	$\alpha = 1$ $\beta = 1$	$\alpha = 1$ $\beta = 0$	$\alpha = 0$ $\beta = 1$
AB	Identity	0.475	0.644	0.644
	Mirror	0.963	0.981	0.981
	Flip	0.337	0.504	0.504
	Rotate90	0.341	0.508	0.508
	Rotate180	0.453	0.624	0.624
	Rotate270	0.947	0.973	0.973
AC	Identity	0.256	0.764	0.277
	Mirror	0.252	0.759	0.274
	Flip	0.335	0.951	0.341
	Rotate90	0.331	0.941	0.338
	Rotate180	0.257	0.771	0.279
	Rotate270	0.250	0.752	0.273

The Fractal Method

The fractal method proceeds in a manner which at once resembles and yet differs from the affine method. Like the affine method, the fractal method seeks to find a re-representation of the images within a Raven's problem as a set of similitude transformations. Unlike the affine method, the fractal method seeks these representations at a significantly finer partitioning of the images, and uses these representations (and more precisely, features derived from these representations) to determine similarity for each possible answer, simultaneously, across the bulk of relationships present in the problem.

The mathematical derivation for the process of fractal image representation expressly depends upon the notion of real world images, i.e. images that are two dimensional and continuous (Barnsley & Hurd, 1992). Two key observations are that all naturally occurring images we perceive appear to have similar, repeating patterns, and, no matter how closely we examine the real world, we find instances of similar structures and repeating patterns. These observations suggest that it is possible to describe the real world in terms other than those of shapes or traditional graphical elements—in particular, terms that capture the observed similarity and repetition alone. Computationally, determining the fractal representation of an image requires the use of the fractal encoding algorithm, which, given an image D , seeks to discover the set of transformations T that can transform any source image into D .

Decompose D into a set of N smaller images $\{d_1, d_2, d_3, \dots, d_n\}$. These individual images are sets of points.

For each image d_i :

Examine the entire source image S for an equivalent image s_i such that a similitude transformation of s_i will result in d_i . This transformation will be a 3×3 matrix, as the points within s_i and d_i under consideration can be represented as the 3D vector $\langle x, y, c \rangle$ where c is the (grayscale) color of the 2D point $\langle x, y \rangle$.

Collect all such transforms into a set of candidates C .

Select from C the transform which most minimally achieves its work, according to some predetermined, consistent metric.

Let T_i be the representation of the chosen affine transformation of s_i into d_i .

The set $T = \{T_1, T_2, T_3, \dots, T_n\}$ is the fractal encoding of the image D .

Algorithm 1. Fractal encoding algorithm for determining the fractal representation of an image D .

This algorithm, shown in Algorithm 2, is considered “fractal” for two reasons: first, the transformations chosen are generally contractive, which leads to convergence, and second, the convergence of S into D can be shown to be the mathematical equivalent of considering D to be an attractor (Barnsley & Hurd, 1992).

Once fractal representations have been calculated for each pair of images in a Raven's problem, the metric shown in Equation (2) is used to calculate similarity between all of the pairwise relationships present in the matrix and those calculated with the given answer choices, using features derived from the fractal encodings. Whichever answer choice yields the most similar fractal representations across all pairwise relationships is chosen as the final answer. The fractal method is described in more detail in McGreggor, Kunda, and Goel (2010).

Results

We tested both the affine and fractal algorithms on all 60 problems from the Raven's Standard Progressive Matrices (SPM) test. To obtain visual inputs for the algorithms, we first scanned a paper copy of the SPM, aligned each page to lie squarely along horizontal and vertical axes, and then divided each problem into separate image files representing each of the matrix entries and answer choices. No further image processing was performed on these input images. As a result, these images were fairly noisy; they contained numerous misalignments and pixel-level artifacts from the scanning and subdividing processes.

Then, after answers for all 60 SPM problems were obtained from each algorithm, we scored each method according to standard protocols for the SPM. In particular, we looked at three different measures of performance:

- 1) The total score from the SPM summarizes the test-taker's overall level of performance.
- 2) This total score can be compared to national age-group norms to determine a percentile ranking.
- 3) A “consistency” measure is obtained by comparing performance on each of the five sets within the SPM, A through E, with the expected scores for each set given the same total score, which are obtained from normative data (Raven, Raven, & Court, 1998).

In addition, we conducted a separate analysis of results according to problem type, looking at accuracy as a function of three problems classifications: “gestalt continuation,” “visuospatial,” and “verbal-analytic,” which we obtained from a published factor analytic study of the SPM (Lynn, Allik, & Irving, 2004).

Affine Results

The affine algorithm correctly solved 35 of the 60 problems on the SPM. For children in the U.S., this total score corresponds to the 75th percentile for 9-year-olds, the 50th percentile for 10½-year-olds, and the 25th percentile for 13-year-olds (Raven, Raven, & Court 1998).

The breakdown of this total score across sets is shown in Figure 2, along with the expected score composition for this

Figure 2: Breakdown of affine (left) and fractal (right) results across sets in the SPM. Also shown is the expected score breakdown for total scores of 35 and 32, from normative human data (Raven, Raven, & Court, 1998).

same total score. Scoring instructions for the SPM indicate that, if the score for any set deviates from the expected score for that set by more than two, the overall test results cannot necessarily be interpreted as a measure of general cognitive function (Raven, Raven, & Court, 1998). This check is intended to detect scores affected by a poor understanding of test instructions, random guessing strategies, or other departures from the intended test-taking framework. As shown in Figure 2, the affine scores deviate by more than ± 2 from the expected scores on sets B and D. In particular, the affine algorithm does too well on Set B and not well enough on Set D to match typical human norms.

Fractal Results

The fractal algorithm correctly solved 32 of the 60 problems on the SPM. For children in the U.S., this total score

corresponds to the 75th percentile for 8-year-olds, the 50th percentile for 9½-year-olds, and the 25th percentile for 11½-year-olds (Raven, Raven, & Court 1998).

The breakdown of this total score across sets is shown in Figure 2, along with the expected score composition for this same total score. The fractal scores fall within ± 2 of the expected scores for each set, indicating that the fractal results are “consistent” with normative SPM scores.

Results by Problem Type

The final analysis we performed looked at the performance of both algorithms as a function of problem type on the SPM. Factor-analytic studies have often found evidence for multiple factors underlying problem solving on the SPM (e.g. van Der Ven & Ellis, 2000); we used the breakdown obtained by one such study to divide problems into those

Figure 3: Breakdown of affine and fractal algorithm results on the SPM by problem type. Problem breakdowns were obtained from a factor-analytic study of human performance (Lynn, Allik, & Irving, 2004).

that loaded on “gestalt continuation,” “visuospatial,” or “verbal-analytic” factors (Lynn, Allik, & Irving, 2004).

Figure 3 shows the performance of both the affine and fractal algorithms on problems from the SPM which load on different combinations of these factors. Both the affine and fractal methods perform most strongly on gestalt problems, slightly less so visuospatial problems, and significantly less so on problems requiring verbal-analytic reasoning, though the relative difficulties of each of these problem types could represent a potential confound for these results.

Discussion

We have presented two different algorithms that use purely visual representations and transformations to solve more than half of the problems on the Raven’s SPM test. Our results align strongly with evidence from typical human behavior suggesting that multiple cognitive factors underlie problem solving on the SPM, and in particular, that some of these factors appear based on visual operations. Whether these algorithms behave on the SPM similarly to individuals with autism, who may demonstrate a cognitive preference for solving the test visually, remains to be determined.

That purely visual methods can achieve such significant results on a standardized intelligence test is a little surprising to us, especially as the input images for both algorithms were taken “as is,” from raw scans of a paper copy of the test. This robust level of performance calls attention to the visual processing substrate shared by the affine and fractal algorithms: similitude transforms as a mechanism for image manipulation, and the ratio model of similarity as a mechanism for image comparison. Of course, there are many other types of visual processing that may or may not be important for accounts of visual analogy, such as non-similitude shape transformations or image convolutions, which certainly bear further investigation.

While it has been shown (Davies, Yaner, & Goel, 2008) that visuospatial knowledge alone may be sufficient for addressing many analogy problems, the representations used in that work were still propositional. In contrast, the methods described here use only visual representations in the form of image similitude transformations. We believe the visual methods we have presented for solving the SPM can be generalized to visual analogy in other domains, such as other standardized tests (e.g. the Miller’s Geometric Analogies test). We conjecture that these methods may provide insight into general visual recognition and recall.

Abstract

How much are people's responsibility attributions affected by intended versus actual contributions in group contexts? A novel experimental-game paradigm dissociated intended from actual contributions: good intentions could result in bad outcomes and bad intentions in good ones. Participants acted as external judges and attributed responsibility to computer players engaging in a repeated game. On each round, three players formed a group and each chose to roll one of three dice that differed in terms of price and probability distribution. The team won if the sum exceeded a certain threshold. The results showed that both intended contribution, reflected in the choice of die, and actual contribution, reflected in the outcome of rolling the die, were determinants of participants' responsibility attributions. However, contrary to previous evidence (Cushman, Dreber, Wang, & Costa, 2009), more participants based their attributions on the intention rather than the outcome.

Keywords: responsibility; attribution; intentionality; outcome bias; experimental game.

Introduction

At the beginning of the movie "Naked Gun 2 1/2" the police officer Frank Drebin is honoured at the presidential dinner for his recent achievement of having eliminated his 1000th drug dealer. In response to this, Mr Drebin admits that he had run over the last two men with his car. Luckily, it turned out that they were wanted drug dealers. Cases of "moral luck" have drawn the attention of philosophers (Williams, 1981), legal scholars (Hart, 1985), and psychologists (Mitchell & Kalb, 1981). These situations are characterized by the fact that the outcome of an action influences its moral evaluation retrospectively, even if this outcome was to a large extent beyond the control of the agent. Mr Drebin, for example, receives praise for his reckless driving only because the men he ran over happened to be drug dealers: a circumstance which was clearly beyond his control.

That people are influenced by outcome knowledge is a well established psychological finding (Baron & Hershey, 1988; Fischhoff, 1975). Fischhoff (1975) showed that people are prone to a hindsight bias: knowledge about the real outcome influences the perceived likelihood of different possible outcomes. Furthermore, people appear to be unaware of the influence that outcome knowledge exerts on their judgments and are, hence, unable to control for its effect. Baron and Hershey (1988) showed that outcome knowledge influences how people evaluate decisions made under uncertainty. Even when participants had all information relevant to the decision,

including the probabilities of each possible outcome, knowledge of the actual outcome nevertheless influenced their judgments of the competence of the decision-maker. Interestingly, when asked whether they *should* take the outcome into account, most participants answered in the negative.

Differential evaluations of identical decisions or actions are also reflected in the Law's differential treatment of negligence versus negligence that leads to harm, as well as cases of attempted murder versus murder. The latter cases share the fact that the person had the intention to kill; however, only in the case of murder did the intended event come about. Recently, experimental philosophers have put forward the claim that the folk notion of intention is deeply intertwined with the (moral) evaluation of the potential outcomes (Knobe, 2003). Whether a behaviour is thought to have been performed intentionally depends crucially on the outcome of that action. An identical action is judged by more participants as intentional when its outcome is blameworthy as opposed to praiseworthy.

Psychologists have also shown that intentions play a significant role when it comes to attributions of responsibility (Lagnado & Channon, 2008) and intentionality thus constitutes an important building block of psychological frameworks of responsibility attribution (Alicke, 2000; Shaver, 1985). Shaver's (1985) theory of blame assumes a linear process starting from considerations about causality, intentionality, foreseeability and potential justifications and leading to judgments of blame or praise. In contrast, Alicke's (2000) account acknowledges the possibility of that process being reversed. The valence of the outcome can trigger spontaneous moral or emotional evaluations which influence the perception of the antecedents of the outcome. This includes judgments about the causal impact of an agent, whether the action was performed intentionally as well as whether the agent should have foreseen the outcome.

The importance of the concept of intentionality has also been recognized by economists. Variations of classic economic games, like the ultimatum game, have been employed to investigate the effects of outcome versus intention on people's perception of fairness. In the ultimatum game (Güth, Schmittberger, & Schwarze, 1982), a first player is allocated a certain amount of money. She can then decide how much of that money to give to a second player, who can either accept or reject the offer. If he refuses, both players get nothing.

Two main findings with respect to the influence of intentions on the behaviour of the second player are worth mentioning. First, if the allocation of the first player is determined by a computer and hence cannot be ascribed an intention, the rejection rates for “unfair” offers are significantly lower (Falk, Fehr, & Fischbacher, 2008). Second, the rejection rates of unequal offers strongly depend on the allocator’s set of possible alternatives (McCabe, Rigdon, & Smith, 2003). The acceptability of an action is hence evaluated with respect to the choice set and an unequal offer more readily accepted if the allocator could not have been kinder. In order to accommodate these findings, economists have moved from fairness theories that only considered outcomes (Fehr & Schmidt, 1999) to theories based on intentions (Dufwenberg & Kirchsteiger, 2004) and theories incorporating both intentions and outcomes (Falk et al., 2008).

As demonstrated by the moral luck example in “Naked Gun”, there is another factor beyond intentions and outcomes that is relevant when it comes to considerations about fairness or attributions of responsibility: the control an agent has over the outcomes he brings about. Our environment is fundamentally noisy and, most of the time, we only have partial control over the effects of our actions. While it is true that the valence of intention and outcome are correlated in everyday life, this relationship is imperfect. Good intentions can sometimes lead to bad outcomes and bad intentions to good ones. For example, a careful driver might cause the death of a careless child. In order to understand the complex relationship between intentions, outcomes and control it is necessary to create experimental situations in which these factors can be dissociated.

In a recent study, Cushman et al. (2009) investigated the effects of intention versus outcome on perceived fairness in a two-player, allocator-responder game. Similar to the ultimatum game, the allocator proposed how a pot of \$10 should be shared. Allocations were either stingy (player 1: \$10, player 2: \$0), fair (\$5, \$5) or generous (\$0, \$10). The responder could punish or reward the allocation of player 1 by subtracting or adding up to \$9 to her account. Importantly, in one condition of the experiment, the allocator only had partial control over the outcome. She had to choose which one of three possible dice she wanted to roll. These dice differed in terms of the probability with which they led to stingy, fair or generous outcomes. Following a strategy format, responders had to indicate for each of the 9 possible combinations (e.g. generous die, stingy outcome) how much money they wanted to add or subtract from the allocator. The results revealed that participants were much more influenced by actual outcomes than by intentions. Responders tended to subtract money for selfish outcomes for all three dice, whereas they added money for fair and generous outcomes. The choice of die exerted only a small effect on this general pattern. Surprisingly, the results of a condition in which the allocator had perfect control were virtually identical. Hence, the study provides further support for the finding that people can be so sensitive to outcomes

that they sometimes disregard the underlying intention that lead to that outcome. However, Cushman et al. (2009) admit that methodological limitations might have contributed to their findings. Importantly, since the responder is part of the game it is the outcome and not the intention that is the most relevant to him. In order to validate their findings, it is important to investigate how an independent judge would have decided.

The current experiment addressed this limitation. We created a setting in which an external observer evaluated the behaviour of agents participating in an experimental game. The following scenario helps to exemplify the main components of our experiment: Sarah is running for the position of student representative. Three friends are helping her campaign by distributing flyers. Tom puts in a lot of effort and distributes 100 flyers. John puts slightly less effort into the campaign and only distributes 50. Finally, Alex thinks that Tom’s and John’s contributions are probably already enough to win the campaign and he only distributes 30 flyers. As it turns out, 20 of Tom’s, 20 of John’s and 25 of the people who received their flyer from Alex voted for Sarah. As a result, Sarah won the election. Assuming that Sarah knows about both the number of distributed flyers and the votes she received, how much is she going to praise each of her three friends for their contribution to her win?

Two aspects of the outlined scenario are important with respect to the current study. First, it shows how intention and outcome can sometimes mismatch in situations over which agents exercise only partial control. Despite Tom’s good intention and effort he contributed no more to the collective outcome than John and even less than Alex. Second, the scenario entails a component that is characteristic of social dilemmas (see e.g. Hardin, 1968). Each individual agent has to weigh the cost of the effortful process of distributing flyers with the potential gain of an election won. Alex’s thought process indicates each person’s motivation to free-ride on the effort of the others. Assuming the spoils of a victory are equally shared, the person who put in the least effort will have the highest net benefit.

The current study investigated the effects of intended and actual contributions on responsibility attribution in a group context in which agents had only partial control over their contributions. How well can intended contributions, actual contributions, or their combination explain participants’ responsibility attributions?

Experiment

The aim of the experiment was to generate a situation in which intended versus actual contributions could dissociate. Participants took the perspective of an external observer and judged the behaviour of computer players engaging in an experimental game (see Figure 1). Hence, participants did not actively engage in the game themselves. In each round of the game, three computer players were randomly selected to form a group. Each player chose one of three available dice to roll. The dice differed in terms of their underlying probabil-

Figure 1: Screenshot of the game depicting a won round.

ity distributions (see top part of Figure 1). The white die had a higher probability of smaller values, the grey die was fair, and the black die was skewed towards higher values (in the experiment, the colours were bronze, silver and gold). The group of players won a round if the sum of their outcomes was greater than 10. If the group won a round, 30 pence were equally distributed between the players. If the group lost, no money was distributed. Importantly, the players had to pay different amounts for the dice before they rolled them. The white die cost 1 pence, the grey die 3 pence, and the black 5 pence. Each individual player's payoff was a function of the group's result, that is, whether they won or lost, and the money he had to pay for the die of his choice. The task of the participants as independent judges was to indicate how much they thought each player was responsible for the group's result in each round.

The computer players chose each of the dice with an equal probability. The chosen payoff function created a social dilemma. The overall probability of winning was 50%. The probabilities of winning given that a player had chosen the white, grey or black die were 33%, 50% and 68%, respectively. This led to an expected payoff of 2.3 pence per round for the white die ($33\% \times 9 - 67\% \times 1 = 2.3$). The expected payoffs for the grey and black die were 2 and 1.8 pence. Hence, there was an incentive for each player individually to choose the white die. However, if all of the players chose that die, the probability of the team winning was only 2%, and the expected payoff -0.8 pence.

Figure 2 shows the underlying structure of the experiment. The choice of die reflected the *intended* contributions of the players while the team's result was a function of the *actual* contributions. We predicted a main effect of intention: the same outcome of roll will elicit different responsibility attributions dependent on the choice of die. We also predicted a main effect of outcome: responsibility attributions for a given die will vary with the outcome of rolling this die. Finally, previous research suggested that outcomes will affect participants' responsibility ratings more strongly than intentions (Cushman et al., 2009).

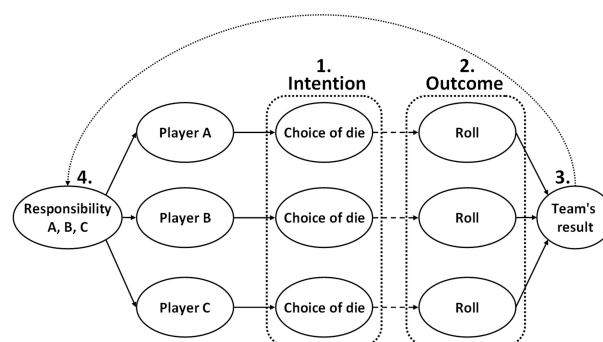

Figure 2: Underlying structure of the paradigm. Numbers 1. - 4. indicate the different components of each round.

Method

Participants and Materials 80 participants from the UCL subject pool participated for the chance of winning one of six amazon vouchers worth £150 in total. 55 participants were female and the mean age was 23.2 (5.94). With the second part of the experiment added at a later stage (see Procedure), 35 participants performed only the first part of the experiment, whereas the remaining 45 participants performed both. The study was conducted online and programmed with Adobe Flash.

Procedure Participants were informed that the experiment would take 20 minutes and that their task was to evaluate the behaviour of players engaged in an experimental game by attributing credit for wins and blame for losses. Participants read a description of the three dice which made it clear that they differed in terms of both probability distribution and price. A practice round served to familiarize participants with the structure of the game. After the practice round, participants had to answer questions to ensure that they had understood the rules of the game correctly. The game was then played for 20 rounds.

On each round, participants saw a table that showed for each player which die she had chosen, the outcome of having rolled that die and the amount won or lost in that round. In Figure 1, Player C chose the grey die and rolled a 5. Her payoff was 7p since she paid 3p for rolling the grey die and each player received 10p for winning this round. Players were indicated by capital letters which changed in each round. This was done to prevent participants from forming an overall impression about individual players. The header above the table showed the sum of points and changed its colour from green to red according to whether the round was won or lost. For each player, participants attributed blame for losses or credit for wins, by moving a slider ranging over a scale from 0-10. Its endpoints were labelled 'low' and 'high'. In line with the result of the round (loss/win), the label (blame/credit), color (red/green) and position of sliders (middle to left/ middle to right) of the last column changed.

45 of the 80 participants also completed a second stage of the experiment. Those participants were informed after the 20th round that they would see 14 novel situations that could

Figure 3: Mean responsibility ratings for each combination of die and outcome for both losses and wins. Lines represent the different dice and values on the x-axes indicate the outcome of rolling each die.

have occurred in the game and which were of special interest to the researchers. As explained below, the test cases were chosen so as to enable a fine assessment of the weight assigned to intentions and outcomes. The order of these test cases was randomized. Finally, participants were asked to indicate in a textbox whether they had focused on the choice of die, the outcome, or both.

Results

Mean Responsibility Ratings

In order to evaluate the effects of choice of die and outcome of roll for the first stage of the experiment, we ran separate 3 (Die) x 6 (Roll) ANOVAs for both wins and losses. Figure 3 shows the mean responsibility attributions as a function of choice of die and outcome of roll. For wins, there was a significant main effect of Die $F(2, 2472) = 87.10, p < .001, \eta^2 = .066$ and of Roll $F(5, 2472) = 9.53, p < .001, \eta^2 = .019$, as well as an interaction effect $F(10, 2472) = 1.91, p < .05, \eta^2 = .008$. For losses, there was a significant main effect of Die $F(2, 2327) = 31.62, p < .001, \eta^2 = .027$ and of Roll $F(5, 2327) = 15.31, p < .001, \eta^2 = .032$, but no interaction effect ($p > .05$).

To qualify these results, we ran linear contrasts on Die and Roll for both wins and losses. For wins, there was a significant positive linear trend of Die as well as for Roll. For losses, there was a significant negative linear trend of both Die and Roll (all p 's $< .001$).

These analyses show that overall, both the choice of die and the outcome of its rolling influenced participants' responsibility ratings. However, the results cannot reveal how individual participants weighted these two factors. To find out, we conducted individual regression analyses, and report them below.

Regression Analysis

First, we ran the following three separate regression analyses based on the overall data (80 participants x 20 rounds x 3

Figure 4: Scatterplot of correlations with outcome-based model and intention-based model. Black circles indicate participants classified as intention-based ($N = 29$), white circles indicate participants classified as outcome-based ($N = 16$).

ratings data points):

$$\text{intention-based model: } \text{responsibility} = \beta_0 + \beta_1 \text{ die} \quad (1)$$

$$\text{outcome-based model: } \text{responsibility} = \beta_0 + \beta_1 \text{ roll} \quad (2)$$

$$\text{mixture model: } \text{responsibility} = \beta_0 + \beta_1 \text{ die} + \beta_2 \text{ roll} \quad (3)$$

All three regression models accounted for a significant amount of the variance in the data (see Table 1).

Evaluation of Test Cases

To break the results down even further, we ran the regression models for each individual participant. Based on the magnitude of the correlation with the intention-based regression model versus the outcome-based regression model, we grouped the 45 participants who completed the second stage of the experiment in two groups. We used this grouping to predict how participants would attribute responsibility for the chosen test cases (described below). Figure 4 shows how well the behaviour of the classified participants was predicted for the test cases.

The test cases were constructed to enable a fine analysis of the relative weights assigned by participants to intentions versus outcomes. It should be noted that in the first 20 rounds of the experiment the choice of die and outcome of roll were highly correlated due to the chosen probability distributions ($r = .68, p < .001$). In contrast, for the test cases the choice of die and outcome of roll were uncorrelated ($r = 0$). This shows that these test cases indeed created situations that could

Table 1: Results of overall regression analyses.

Model	R^2	F	$p <$	β	t	$p <$
intention-based	.268	1757.70	.001	0.518 ^a	41.93	.001
outcome-based	.219	1346.33	.001	0.468 ^b	36.69	.001
mixture	.303	1042.31	.001	0.370 ^a	24.02	.001
				0.238 ^b	15.48	.001

$$a = \beta_{\text{die}}, b = \beta_{\text{roll}}$$

be used to distinguish between intention-based and outcome-based participants.

Figure 5 shows how the 29 intention-based participants attributed responsibility in the test cases. Figure 6 shows the responsibility attributions for the 16 participants who had been classified as outcome-based. The test cases can be categorized into 4 groups: a) different dice, same roll; b) same dice, different rolls; c) congruent; d) incongruent. ‘Congruent’ means that the quality of die and outcome of roll corresponded (i.e. the expensive die led to a high and the cheap die to a low outcome); ‘incongruent’ means that the quality of die and the outcome of roll mismatched.

Inspection of the graphs validates the original partition. First, in the congruent test cases (‘c’) - which serve as a manipulation check - both groups show the same pattern of attributions, with that for the intention group being steeper than that for the outcome group. For the intention test cases (‘a’), the differences in attributions are large for participants in the intention group and small for participants in the outcome group. An opposite pattern of attributions is evident with the outcome test cases (‘b’): there the intention group exhibits small differences and the outcome group exhibits large differences. Finally, and most interesting, the pattern of attributions reverses in the incongruent cases (‘d’). Despite the fact that in these situations the expensive die led to the lowest outcome, the intention-based participants attribute the least blame to this player for the loss (Figure 5, top) and the most credit for the win (bottom). In contrast, the attributions of the outcome-based participants for these cases closely follows the number rolled, independent of the choice of die (Figure 6).

Discussion

The current study investigated the influence of intended versus actual contribution on the attribution of responsibility in a group context. We found that both intention and outcome exerted a significant influence on participants’ attributions. Fur-

Figure 6: Mean responsibility ratings of *outcome-based* participants.

thermore, we provided evidence that individuals differ in the extent to which they base their attributions on intentions or outcomes.

Our experimental procedure allowed us to dissociate intentions from outcomes and created a situation in which participants played the role of an external judge. We found that the majority of participants were better explained as having focused on intended rather than actual contributions. Methodologically, the current experiment shows that it is important to analyse the data on the level of individual participants. While on an aggregate level, it seems that participants are weighting both choice of die and outcome of roll to determine their responsibility attribution (see Figure 3), more careful analyses reveal that most participants actually tend to either focus on the intention or the outcome (see Figure 4).

At this point, we can only speculate about the factors driving these interindividual differences. Different interpretations of the notion of responsibility could have influenced participants’ behaviour. Outcome-based participants might have endorsed a *causal* conception of responsibility. Accordingly, players that rolled high numbers were credited higher since their contributions caused the win. Intention-based participants, on the other hand, might have used a *moral* conception of responsibility. Hence, players were judged for their choice of die which reflected their underlying attitude towards the team. Alternatively, the results could reflect interindividual differences in the ability or motivation to mentalize. We would assume that people who find it hard to take another person’s perspective are more likely to focus on the actual outcome rather than the underlying intention. We are planning to use a simplified version of the employed paradigm to test this hypothesis on a patient group. Finally, outcome-based participants’ ratings might have been influenced by beliefs about the gambling-competence of players. On this view, rolling a high number with the cheap die reflects a special ability deserving credit. Some of the participants’ written comments confirm the influence of such arguably non-normative considerations.

Why did we find a relatively stronger effect of intentions when previous studies postulated the existence of an outcome bias (Cushman et al., 2009)? Several differences between studies that draw their conclusions from economic games, such as the ultimatum game, and our study could potentially explain these divergent results. First of all, most of the studies in the economic literature were interested in exploring perceived fairness and not directly in responsibility attributions. Although we presume that these notions are tightly linked, it might be that considerations about fairness and responsibility can lead to different results. Second, the participants in those studies directly experienced the outcomes, while inferring the intentions of the other player was not incentivised. In our study, in contrast, participants acted as independent external judges. It is, hence, less likely that their attention was biased towards outcomes. In a future study, we aim to explore how the patterns of attribution change when participants actively take part in the game.

An important feature of the employed experimental paradigm is its potential to explore different combination functions between the individuals in the group. Gerstenberg and Lagnado (2010) have shown that the way in which individual contributions are translated into group outcomes significantly influences people's responsibility attributions. Accordingly, an identical individual contribution can lead to very different responsibility attributions as a function of the group context. While the current experiment used an additive combination function for the contributing players, we will investigate in future experiments how attributions change when the rule of the game reflects a minimum function (i.e., the group wins if no player rolls a 1) or a maximum function (i.e., the group wins if at least one player rolls a 6). Are participants more likely to focus on the actual rather than the intended contribution when the combination function is non-compensatory?

Finally, our paradigm can be used to explore how uncertainty affects responsibility attributions. In everyday life, we do not have direct access to other people's intentions. Rather, we try to infer the intention from a person's behaviour. Our paradigm allows us to model this situation. Instead of revealing all the information to the participant, we will only show the outcomes of rolling the dice but not which dice the players have chosen. We can then compare participant's ability to infer the underlying intentions from observed outcomes with an ideal Bayesian learner and evaluate in how far their attributions can be explained by their knowledge about the players.

In conclusion, the current study explored the influences of intentions versus outcomes on responsibility attributions in a group context. We found that a majority of our participants focussed on the intention rather than on the outcome. We introduced a novel experimental paradigm which is flexible enough to lend itself to the investigation of future questions that will help to disentangle the complex relationship between control, intention, outcome and responsibility attributions.

Abstract

Complex tasks with a visually rich component, like diagnosing seizures based on patient video cases, not only require the acquisition of conceptual but also of perceptual skills. Medical education has found that besides biomedical knowledge (knowledge of scientific facts) clinical knowledge (actual experience with patients) is crucial. One important aspect of clinical knowledge that medical education has hardly focused on, yet, are perceptual skills, like visually searching, detecting, and interpreting relevant features. Research on instructional design has shown that in a visually rich, but simple classification task perceptual skills could be conveyed by means of showing the eye movements of a didactically behaving expert. The current study applied this method to medical education in a complex task. This was done by example video cases, which were verbally explained by an expert. In addition the experimental groups saw a display of the expert's eye movements recorded, while he performed the task. Results show that blurring non-attended areas of the expert enhances diagnostic performance of epileptic seizures by medical students in contrast to displaying attended areas as a circle and to a control group without attention guidance. These findings show that attention guidance fosters learning of perceptual aspects of clinical knowledge, if implemented in a spotlight manner.

Keywords: example-based learning; eye tracking; expertise; attention; medical education

With progressing technical development, complex visualizations are increasingly in use for tasks, such as interpreting weather maps (Canham & Hegarty, 2010), classifying fish locomotion (Jarodzka, Scheiter, Gerjets, & Van Gog, 2010), driving (Underwood, Chapman, Brocklehurst, Underwood, & Crundall, 2003), or air traffic control (Helleberg & Wickens, 2003), to name just a few diverse examples. Dealing with such tasks requires not only knowledge about facts in this domain (i.e., conceptual knowledge), but also substantial visual search (i.e., perceptual skills). Sophisticated perceptual skills enable people in these professions to rapidly perceive the relevant out of the irrelevant and interpret it correctly. A large body of research has already shown that experts exceed novices in those skills (e.g., Antes & Kristjansson, 1991; Canham & Hegarty, 2010; Charness, Reingold, Pomplun, & Stampe, 2001; Jarodzka et al., 2010; Underwood et al., 2003; Van Gog, Paas, & Van Merriënboer, 2005; Vogt & Magnussen, 2007).

Perceptual Skills in Medical Education

The extensive presence of visually rich tasks and thus, the importance of sophisticated perceptual skills is especially true for the medical domain. Many medical imaging techniques

developed only recent (like fMRI, CT, 3D displays). The task to diagnose medical images can also be seen as a visually complex task. In particular, since research could already show expertise differences on a perceptual level (e.g., Krupinski, 2005; Krupinski et al., 2006; Kundel, Nodine, Krupinski, & Mello-Thoms, 2008; Lesgold et al., 1988; Nodine, Kundel, Lauver, & Toto, 1996). However, not only diagnosing medical images is difficult from a perceptual perspective. Also the diagnosis in real-life situations of diseases that manifest in occasionally occurring behavioral patterns, like seizures, is difficult on a perceptual level (Balslev et al., in preparation). In the case of diagnosing seizures it is crucial to recognize the important features, which distinguish the seizure from normal behavior. Those features, however, might be short-term, subtle, time-sensitive, and not salient compared to other features.

Little children display many different movements. In rare cases some of these movements may be symptoms of diseases. In particular for small children that cannot be questioned it is important to carefully observe their movements for diagnosing certain diseases. The example we focus on are epileptic seizures. Epileptic seizures can be distinguished according to whether they involve one or both hemispheres of the brain ("International Classification of Mental and Behavioural Disorders (ICD-10)", 2006): if only one brain hemisphere is involved they are classified as partial seizures whereas if both hemispheres are involved they are classified as general seizures (here: spasms). Both seizure types have a normal behavior counterpart (i.e., differential diagnosis) with which they can easily be confused: epileptic seizures are easily confused with benign sleep myoclonus (BSM; Egger, Grossmann, & Auchterlonie, 2003), whereas spasms are easily confused with infantile masturbation (IM; Hansen & Balslev, 2009). A *general seizure* (spasm) is characterized by bilateral movements that can be spasmic or jerky, the face is affected, the infant briefly loses consciousness / awareness, and the movements are not stopped by touching the child. BSM is also characterized by bilateral, jerky movements, however, the face is not involved, the child is asleep, and the movements may rather worsen by touching the child. A *partial seizure* is characterized by lateral movements that can be spasmic or jerky, the face is affected, the infant loses briefly consciousness / awareness, and the movements are not stopped by touching the child. IM is also characterized by lateral, rather tension movements, however, the face is not in-

volved, the child is awake and conscious, and the movements stop by touching the child.

In order to convey diagnostic skills, medical education focused in its beginnings on the role of biomedical knowledge (Feltovich & Barrows, 1984; Kuipers & Kassirer, 1984; Lesgold et al., 1988). Biomedical knowledge is the knowledge contributing to the understanding of the functioning and dysfunctioning of the human body and gained during textbook or lecture study. It is composed of conceptual or factual knowledge. Thus, biomedical knowledge may be described as “inert knowledge”. Knowledge is inert, if it is learnt in a formal setting and can be expressed by the student as facts without the ability to apply it in a real world situation (Whitehead, 1929). The focus on conveying inert knowledge in education has been extensively criticized by educational psychologists (e.g., Pozzi, Noss, & Hoyles, 1998).

In line with those findings, current research on medical education emphasizes that besides biomedical knowledge, also clinical knowledge is important (Boshuizen & Schmidt, 1992; Patel, Evans, & Groen, 1989a, 1989b; Patel & Kaufman, 1995; Schmidt & Boshuizen, 1992, 1993). Clinical knowledge is composed of manifestations, classifications, and treatments of diseases and it is gained during clinical praxis. One important aspect of clinical knowledge may be seen as being of perceptual nature (Manning, Gale, & Krupinski, 2005). As described above, novices have severe deficiencies on this level. However, there is little research so far, focusing on this aspect of clinical knowledge (Chen, Gale, & Evans, 2009; Jarodzka, Gog, Dorr, Scheiter, & Gerjets, in preparation; Litchfield, Ball, Donovan, Manning, & Crawford, 2008). Thus, the aim of the current study is to enhance the perceptual part of information-processing as part of medical expertise.

Conveying Perceptual Skills by Modeling Examples

An approach that has recently been developed to foster perceptual skills are eye movement modeling examples (Jarodzka et al., in preparation; Van Gog, Jarodzka, Scheiter, Gerjets, & Paas, 2009). To develop such modeling examples an expert model is recorded while performing a task. In addition, the model explains hers/his actions and hers/his eye movements are recorded. In a second step, those recordings are replayed to a student as an educational video. Those videos can be seen in the tradition of example-based learning and modeling. Example-based learning has been shown to be a powerful instructional method in early skill acquisition. Examples demonstrate a problem solution to students, either by providing them with a written, worked-out problem solution to study (i.e., worked examples; see, Atkinson, Derry, Renkl, & Wortham, 2000; Sweller, Van Merriënboer, & Paas, 1998) or by allowing them to observe an expert performing the task live or on video (i.e., modeling examples; Bandura, 1977; Collins, Brown, & Newman, 1989). For cognitive tasks, modeling examples require the model to verbalize his/her cognitive actions while performing the task (e.g., Wouters, Paas, & Merriënboer, 2008).

For cognitive tasks that require the processing of complex visual information, it is crucial that the student not only hears the expert's verbal explanations, but can also see the material the expert is looking at. However, this may not suffice. As Bandura (1977) noted, to learn from modeling examples students have to attend to the important features of the modeled behavior. The verbal explanations of the expert can only guide the students' attention to the important features of the material when students know exactly what the expert is referring to. However, the chance that they simultaneously attend to the same features is very small, as was shown by the eye tracking research described above. Thus, when learning from modeling examples that involve complex visual material, novices might need attention guidance to those task aspects that the expert is attending to. Otherwise, especially on dynamic tasks, they may miss important information relevant for understanding and learning from the example.

Although several studies exist on attention guidance via cueing instructional material (for a review: Koning, Tabbers, Rikers, & Paas, 2009), the decision concerning which information will be highlighted and when often remains arbitrary. In particular, since research has shown that experts cannot estimate the knowledge level of novices appropriately (Hinds, 1999). Thus, it is very unlikely that they would be able to estimate appropriately, where to place a cue for a novice. On the other hand, research has shown that choosing a cue based on eye movements of successful problem solvers, enhances the probability for correctly solving an insight problem (Grant & Spivey, 2003). The question remains, however, whether attention guidance based on eye movements, not only as a single cue but the entire perceptual process of the expert, cannot just influence insight problem performance on the task at hand, but also enhance learning. Learning refers to the resilient change in a person's knowledge about a task that enables him or her to independently perform that task after practice (Simon, 1983).

In an earlier study, we could show that students' attention can be guided directly by the eye movements of an expert and that this influences learning (Jarodzka et al., in preparation). We developed modeling examples for a classification task in which an expert's eye movements and verbal explanations were recorded while he was performing this task. Participants who studied examples in which the expert's eye movements were displayed either as a dot on the fixated area or by blurring non-fixated areas (spotlight display), closely followed the expert's gazes during example study. The spotlight display led to significant improvements in learning in terms of visual search during the test, and the dot display led to enhanced classification performance on the test. These findings showed that guiding students' attention can go beyond guiding thought, to guiding learning.

Still, two open questions remain. First, since none of the displays was optimal, the current study aimed at improving both types of display. The dot display partially occluded relevant problem features. Thus, instead of a solid dot, the ex-

pert's gazes are displayed as a circle. For the spotlight display, we decided to use a less intrusive blurring so that a holistic impression of the overall scene can be gained. This was done by compressing the video on non-attended areas. This procedure has shown to be well accepted by viewers (Nyström & Holmqvist, 2007). Second, although the classification task in the study described above was visually rich, the task in itself was simple. For this reason the benefit of this instructional approach might not have fully unfolded, because the task itself was too easy. Thus, the current study uses a medical diagnosis task based on video cases, which is not only a visually rich task, but is also composed of a complex underlying decision tree.

Research Question - Hypothesis

In line with prior research, we hypothesize that attention-guidance based on expert's eye movements will foster learning of perceptual skills not only in a simple classification task, but also in medical diagnosis. Since both ways of display were improved, we assume learning to enhance in terms of a better diagnostic performance.

Method

Participants and Design

Participants were 60 medical students in their final year of the University of Aarhus (age: $M = 26.57$ years, $SD = 2.03$; 41 female), who had no prior knowledge on the task and had normal or corrected-to normal vision. They had been randomly assigned to one of three conditions ($n = 20$ each): (1) control condition with no attentional guidance, (2) attentional guidance by a circle on fixated areas based on the model's eye movements (circle display), (3) attentional guidance by blurring non-attended areas and leaving fixated areas sharply displayed (spotlight display).

Apparatus and Materials

Eye tracking equipment The expert model's eye movements were recorded with a SMI High Speed eye tracking system with a temporal resolution of 240 Hz and the iView X 2.2 software. These eye tracking data were edited with BeGaze 2.3 software (www.smivision.com) and self-programmed MatLab algorithms. All video material was presented to the participants via Experiment Center 2.2. The questionnaire in the testing was presented via e-prime 2.0 software.

Modeling examples The modeling examples for the control group consisted of four digital videos (.avi format), sized 720×576 pixels and presented in fullscreen on a 1280×1024 pixels resolution (corresponding to 17.07×13.65 inches). Each video depicted a single infant (between 4 hours and 8 months old), whereby two infants deployed behavioral patterns corresponding to a focal seizure and two infants deployed different types of normal behavior (benign sleep myoclonus, infantile masturbation). The original sound was removed from the videos, because parents and clinical staff

were talking, which would disturb the use of verbal explanations. The duration of the videos was between 71 and 103 seconds. All videos included a spoken description and diagnosis of the behavior by the expert model. The expert was a physician of pediatric neurology, with extensive experience in diagnosing epileptic seizures. Rather than using the expert's natural performance of these tasks as an example we decided to instruct the expert to behave didactically, that is, to explain to novice students what the relevant aspects of the behavioral pattern shown in each video are. Each recording was replayed to the expert so that he could self-evaluate the replay data based on a number of statements (e.g., for a novice student, the disease is explained in enough detail, in comprehensible terms, et cetera; cf. Jucks, Schulte-Löbber, & Bromme, 2007), and if necessary, he could re-record it. This was done, because a prior study had shown that experts use knowledge-based shortcuts in verbal and eye tracking data due to automated processes as well as using many technical terms that a novice student would not understand (shortcuts in this domain, cf. Balslev et al., in preparation).

In the circle display condition, participants received the same examples as the control group but those additionally included the expert's eye movements. These were created using the manufacturer rendered "fixation scanpath display function". The saccadic definition was set at a peak velocity threshold of 40/s. The fixations were displayed as yellow circles with a line thickness of one pixel and a gaze trail for a temporal window of 1 sec. In the spotlight display condition, potentially distracting features in the unattended areas were filtered out. That is, the focus of the expert's attention (with a radius of 32 pixels) was visible as usual, whereas the areas surrounding it were blurred' by off-line foveation via video compression on non-attended areas (Nyström & Holmqvist, 2007). Figure 1 shows a screen shot from each of the three conditions.

Tests Participants were shown six new realistic videos for a mean duration of 31.00 seconds ($SD = 18.35$) of different children displaying different types of behavior ($3 \times$ seizures and $3 \times$ normal behavior). The duration of the testing video depended on the duration of the seizure / normal behavior. Afterwards, their diagnostic performance was assessed by answering multiple-choice questions on those videos: (1) indicating from a list of body parts, which was moving, (2) indicating from a list the type of the movement, (3) indicating, whether the face was involved and whether or not this was important for the diagnosis, (4) indicating the level of consciousness of the child, (5) indicating, whether awaking the child would change the movement, if child was asleep, and (6) indicating, whether touching the child changes the movement.

Procedure

The recording ran in individual sessions of approximately 45 minutes each. At the beginning, participants filled in a questionnaire on their prior knowledge in this task and their de-

Table 1: Screenshots from the three conditions used in the study.

mographic data. Then, they received a short introduction to the topic, stating very general information on seizures and the importance to distinguish them from normal behavior. Then, the learning phase started. Participants were told that they will subsequently receive videos of the to-be-learned disease, where an expert explains the according movements and behavioral pattern. Depending on the condition, they were told that they will additionally see where the expert's attention was attracted to on the video. Before watching the learning videos, participants received the age, gender, and a short problem description of the patient.

In the testing phase the testing videos were replayed once. Afterwards, each video disappeared, resulting in a blank screen. Then, the participants had to answer the multiple-choice questions in an arbitrary order. This procedure was repeated for six new patient video cases.

Data Analysis

Test performance The construction and scoring of the performance measure was derived from a task analysis and by the help of domain experts. Accordingly, to diagnose a focal seizure, the following guidelines should be applied: (1) correctly stating which part of the body is involved in the movement, (2) correctly stating how this part moves, (3) correctly stating, whether the face was involved and whether or not this is important for the diagnosis, (4) correctly indicating the child's level of consciousness, (5) correctly indicating, whether awaking the child would change the movement, if child was asleep, and (6) correctly indicating, whether touching the child would change the movements. Hence, participants could receive a maximum of six points per video (1 point for each category).

Results

For all statistical tests reported here, a significance level of .05 is used. Means and standard deviations for each condition are given in Table 2.

Table 2: Means (and SD) for Testing Performance for Diagnosing Seizures and Differential Diagnoses.

		Control group	Circle display group	Spotlight display group
Testing	Seizure diagnosis	3.25 (0.47)	3.38 (0.41)	3.90 (0.62)
	Differential diagnosis	3.78 (0.59)	3.48 (0.81)	3.57 (0.69)

Seizure Diagnosis

An ANOVA showed significant differences between conditions in performance on the multiple choice test, $F(1, 59) = 9.13, p < .01, \eta_p^2 = .24$. Bonferroni post-hoc tests indicated that the spotlight display condition outperformed the circle display condition ($p < .01$) and the control condition ($p < .01$), while the control condition and the circle condition did not differ significantly.

Differential Diagnosis

An ANOVA showed no significant differences between conditions, $F < 1$.

Discussion

This experiment showed that attention guidance based on displaying expert's eye movements in video-based modeling examples fostered learning in terms of improved diagnostic skills. Participants in the spotlight display group outperformed the control and the circle display group in diagnosing epileptic seizures. No differences were found in diagnosing normal behavior.

These findings leave us with two questions: (1) Why did both types of eye movement displays result in such differential effects and (2) why does this effect occur for diagnosing seizures, but not for diagnosing the differential diagnosis?

Considering the first question, the fact that the circle display did not enhance learning is surprising. Although, one study found a negative effect on learning by displaying the model's eye movements based on the manufacturers' gaze replay functions (Van Gog et al., 2009), three others found a positive effect of a comparable visualization (Chen et al., 2009; Litchfield et al., 2008; Jarodzka et al., in preparation). However, only the latter three studies used visually rich learning tasks. Adding information to a display in terms of eye movements, might only be a benefit for visually rich tasks. In this study, a visually rich task was also used, but what differed was the fact that the display was not a solid dot, as for the remaining three studies, but a fully translucent circle. Might it be that the total translucence in terms of a circle reversed the positive learning effect? This might be tested in future studies by investigating the students' ability or willingness to follow the circle during learning. Another possibility is that the circle display increased mental effort due to a noisy type of display? Van Gog et al. (2009) found a higher mental effort in their study for this display, which lead to detrimental effects on learning. This should be investigated in future research by assessing mental effort in the learning and the testing phase. In contrast, the spotlight display, which was rather an unintrusive guidance, might have enabled the students to infer the element behind the cue and thus, lead to a holistic impression of the behavioral pattern.

The second question, about the different effects for seizure and differential diagnosis, has two competing answers. First, it might be that detecting the symptoms of a seizure, strongly relies on interpreting the perceptual input. Whereas detecting the symptoms of types of normal behavior requires more conceptual knowledge. This type of knowledge, however, was not varied between the groups in the current study. Second, it might be that the lack of an effect for the differential diagnosis is due to the type of material used in this study. One type of normal behavior (benign sleep myoclonus) was quite easy to detect, because both children in training and in testing were asleep. Neither of the others was asleep. Thus, this cases might have been too easy. The other normal behavior (infantile masturbation) was trained with an older child, whereas the testing occurred with younger children. Thus, thus testing might have been too difficult. Both possible reasons should be investigated in future research with more cases.

In sum, the current study provided an interesting, first approach to train perceptual skills in medical diagnosis. Still many research questions remain. Not only the above mentioned issues should be further investigated, but also additional improvements of the training are conceivable. We trained the students in this case only for a short time and only within individual learning. Training students in longer sessions that allow them to re-view the cases and discuss them with peers might further improve the training. On the other hand, the training effects should be also investigated in a more direct manner via detailed analyses of potential influences on participants' eye movements.

Structure Awareness in Action-Outcome Learning Eradicates the Detrimental Effect of Reinforcement Delays

Abstract

Many studies of Action-Outcome Learning have demonstrated that reinforcement delays exert a detrimental influence on learning performance. Different theoretical perspectives offer varying explanations for this effect. A rational perspective suggests that as long as action-outcome pairings can be clearly recognized, delays should not interfere with the inductive process. Here we tested this idea by manipulating whether action-outcome contingencies were clearly identifiable as such by providing structural information in real time. In the absence of such information, we replicated the familiar detrimental effects of delay. Providing structural markers, and thus allowing easy identification of action-outcome pairings, eradicated this effect. Importantly, two additional experiments indicate that these results cannot be attributed to alternative explanations involving outcome salience or better awareness of timing. We conclude that when the environment allows Action-Outcome Learning to be conceptualized as a contingency learning task, learners are capable of covariation computation and immune to variations of response-outcome timing.

Keywords: Causality, Contiguity, Reinforcement, Structure, Computation

Introduction

The detrimental effect of a cause-effect delay on the learning of a causal relation is well established. However, the precise reason for this effect is still the subject of some debate. While it seems fairly intuitive that delayed causal relations might be more difficult to detect, and judged as weaker, compared to more immediate relations, this raises the question of how we ever manage to infer delayed causal relations of more than a few seconds. Yet we manage to do so routinely in day-to-day life. At the same time, laboratory experiments using basic stimuli have demonstrated that delayed causal relations of more than a few seconds could not be distinguished from non-contingent alternatives (Shanks, Pearson, & Dickinson, 1989). It therefore follows that in real-world causal induction, some other tangible source of information must be brought to bear that enables us to correctly identify delayed causal relations.

There have been a plethora of studies investigating the ability of humans to judge event contingencies (e.g. Shanks, 1987; Wasserman, Chatlosh, & Neunaber, 1983). A long-standing paradigm is the instrumental free-operant procedure (FOP), whereby participants evaluate the effectiveness of their responding (for instance pressing a key on a keyboard) in producing an outcome (such as a flash or a tone). These experiments are typically

programmed with an invisible underlying trial structure, whereby the condition timeline is divided into several temporal segments. If a response is made during a particular segment, then an outcome will be scheduled to occur (with a certain probability) at the end of that segment. A key consideration that is often overlooked in such experimental designs is whether this trial structure is apparent. This may play a critical role in the mediation of empirical cues such as delay.

Several potential explanations for the effect of delay have been offered stemming from different theoretical motivations. Traditional associative accounts argue that causal induction is simply an extension of associative learning, and is as a consequence governed by the same principles as other forms of learning such as Pavlovian and instrumental conditioning. This perspective adopts the Humean assertion that temporal contiguity is necessary for learning to occur. Degradation of this contiguity leads to weaker increments of associative strength and thus universally attenuates learning.

Cognitive perspectives on causal learning, on the other hand, tend to focus on event contingencies. Most proponents of this view agree that the sensory input available to us, in the form of presence or absence of events, is computed to provide an assessment of the covariation between candidate causes and effects. In the simplest terms, the possible event combinations are as follows: Both cause and effect occur (c,e), the cause occurs without the effect (c~e), the effect occurs without the cause absent (~c,e), and neither cause nor effect occur (~c,~e). These event frequencies are often represented in a 2x2 contingency matrix, and form the basis for many different computational models of learning (see, e.g., Hammond & Paynter, 1983). Provided that this information can be discerned from the available evidence, contiguity is not essential.

The role of contiguity from this perspective is instead limited to determining whether or not events are classed as contingent. Longer intervals increase the likelihood of intervening events to occur between action and outcome, which compete for explanatory strength and place greater demands on processing and memory resources. Accordingly, where there is some temporal separation between cause and effect, the crucial decision revolves around deciding whether this constitutes a case of c,e, or separate cases of c,~e and ~c,e. The greater the delay, the more likely the latter becomes, and the effect will not be attributed to the cause. This is therefore known as the *attribution shift* hypothesis (Buehner & May, 2009).

Experiments by Buehner & May showed that by appealing to higher level knowledge, the detrimental effect of delay can be modulated (2002) and abolished completely (2004). Participants were presented with action-outcome learning tasks in different thematic scenarios. By manipulating the context using cover-stories, a delay between cause and effect was made to seem plausible by providing explicit information regarding the expected timeframe of the causal mechanism. In a scenario where participants evaluated the effectiveness of pressing a switch on the illumination of a lightbulb, one group of participants were told that the bulb was an ordinary bulb that should light up right away, while another group of participants was instructed that the bulb was an energy-saving bulb that lights up after a delay. For this latter group there was no decline in ratings with delay; delayed and immediate causal relations were judged as equally effective.

These findings were consistent with the knowledge-mediation hypothesis (Einhorn & Hogarth, 1986): reasoners have pre-existing ideas about specific mechanisms by which causes produce their effects, which in turn enables flexible interpretation of incoming evidence, including appraisal of delayed causal relations. However, a problem with this approach is circularity: if causal learning is governed by top-down assumptions regarding causal mechanisms, where does this knowledge come from in the first place?

Perhaps some causal knowledge is innate. Stimulus selectivity in rats (Garcia & Koelling, 1966) demonstrates that animals indeed have pre-existing conceptions about the types of stimuli that can elicit particular physiological reactions. It is therefore not unreasonable to suggest that animals (including humans) may likewise have some prior expectation about certain potential mechanisms, which may well include non-contiguous causal relations. Nevertheless, it seems appropriate to search for other means by which the connection between a proximal candidate cause and a distal effect may be bridged. Are there cues that can mitigate the impact of delay without recourse to knowledge of mechanism?

Our goal here was to create a paradigm by which the underlying trial structure could be made evident without appealing to prior knowledge, or manipulation of expectations using cover stories or thematic contexts. Instead, we aimed to convey this information using stimuli that are directly observable in the learning environment and thus demonstrate that empirical cues can be used to infer delayed causal relations without any prior cognitive bases. This was achieved by using a brief auditory tone to signal the end of each trial. This tone occurred regardless of whether an effect occurred or not, and if an effect was scheduled it occurred simultaneously with the tone. The tone thus marked the point at which an effect could potentially occur.

Our hypothesis represents a convergence of two traditionally opposing perspectives on causal learning. In accordance with associative learning theory, we predict a decline in causal ratings as delay increases and no additional

information is provided. However, when the tone is introduced, providing markers that effectively reveal the delineation into trials, then contiguity becomes unimportant. The task will reduce to a simple contingency judgment, and we should see no delay-induced decline in ratings, as predicted by a computational account of causal learning.

Experiment 1

Method

Participants

33 undergraduate students from Cardiff University were recruited via an online participation panel. Participants included both males and females, with a modal age of 19 years. Either course credit or £3 payment was awarded for completion of the experiment. One participant failed to make any responses during two of the experimental conditions and thus was dropped from the analysis.

Design

The factors *trial length* (2s/5s) and *trial structure* (*apparent* vs. *not*) combined to produce four experimental conditions. Previous studies have found manipulation of trial length as an effective determinant of action-outcome delay, thus 2s and 5s were classed as *short delay* and *long delay* conditions respectively. For the *apparent* conditions, the end of each trial was signaled by an auditory tone, with the commencement of the next trial coinciding with tone offset. Meanwhile no additional cues were provided for the *not apparent* condition. Effectively, each trial ran seamlessly into the next, with no markers delineating one trial from the next (other than the occurrence of an effect). All participants experienced all four conditions, providing a 2x2 within-subjects design. The conditions were blocked such that the two *apparent* conditions were always presented one after the other, likewise for the two *not apparent* conditions. The order of which *apparent* or *not apparent* condition was presented first, or whether the *apparent* or *not apparent* block was presented first, was counterbalanced. At the end of each condition, participants were presented with the following question: "Please enter a rating from 100 to -100 to indicate the effect you think the button had on the triangle's behavior. 0 means it had no effect, +100 means it always made it light up, and -100 means it always prevented it from lighting up." The rating provided by participants constituted the dependent measure.

Apparatus, Materials & Procedure:

The experiment was conducted on an Apple "Mac Mini" computer running Microsoft Windows XP and Python 2.4.1, with a 17" LCD display, with standard headphones used to deliver the auditory stimulus. The stimuli consisted of an outline of an equilateral triangle and an image of a red circular button situated directly beneath it. Participants were free to click on this button with the mouse at any point. On doing so, the button stimulus 'depressed' for 500ms.

An effect constituted the triangle 'lighting up' (the transparent background became bright yellow and a 'glow' effect appeared around the triangle border) for 500ms. The

occurrence of the effect was determined probabilistically. If a response was made during the trial, $P(e|c)$ was 0.7; if no response was made, $P(e|\sim c)$ was 0.2. Only the first response in each trial altered the probability from 0.2 to 0.7, with subsequent responses having no influence.

For the apparent conditions, at the end of each trial, an auditory tone of 1000Hz was played for 500ms. This tone signaled the end of the trial, with the next trial beginning on termination of the tone. If an effect was scheduled, it occurred at this point of the trial to coincide precisely with the tone. For not apparent conditions, an equivalent 500ms was added to the end of each trial and the effect (if scheduled) occurred during this period. This ensured identical trial lengths and reinforcement delays between apparent and not apparent conditions. Each condition comprised 60 consecutive trials; total condition lengths were thus 150s and 330s for 2s and 5s conditions.

Participants were instructed to determine to what extent pressing the button caused or prevented the triangle from lighting up. Apparent conditions included the following additional instructions: "Each problem is divided into a series of trials. The end of each trial is marked by a beep. The triangle can only light up once per trial, and if it does so, it will light up at the end of the trial (i.e. to coincide with the beep)."

Results & Discussion

Causal Ratings

All analyses adopted a significance level of 0.05. One participant failed to make any responses during two of the experimental conditions and thus was dropped from the analysis altogether. One additional data point which was more than two standard deviations from the mean was also removed from the analysis for causal ratings. Figure 1 shows that ratings fell sharply in the *not apparent* conditions as trial length (and resultant action-outcome delay) was increased. However, a corresponding decline is not seen for the apparent conditions; there appears to be no difference between 2s and 5s. This suggests that the provision of trial structure information nullified the deleterious impact of delay.

A 2x2 within-subjects ANOVA corroborated these impressions, finding significant main effects of delay ($F_{(1,31)} = 7.276$), trial structure ($F_{(1,31)} = 4.322$), and a significant delay x structure interaction ($F_{(1,31)} = 4.719$). This supports the original hypothesis. However we must exercise caution in the interpretation of these results. Because we employed a free-operant paradigm, it is possible that participants' response behavior differed between conditions, resulting in different objective response-outcome contingencies (cf. Buehner & May, 2003). If any such differences occurred were between the *apparent* and *not apparent* conditions, then manipulation of trial structure would be confounded with contingency and our results compromised. In addition, because participants were free to respond at any given time, there is no guarantee that increasing trial length will produce a concomitant increase in the action-outcome delay. A

participant could respond at any point during the trial and therefore it is perfectly possible that contiguous cause-effect pairings will be experienced in both the 2s and 5s conditions. A closer inspection of the behavioral data is therefore warranted.

Behavioral Data

Response rate was calculated as the total number of responses, both reinforced and unreinforced, produced by participants across the entire duration of the condition and including all responses made during each trial. Mean action-outcome interval was calculated as the time between the first response in a given trial and the subsequent effect (if one occurred). If the response was unreinforced then this was not included in the calculation.

An analysis of behavioral data using 2x2 within-subjects ANOVAs on response rate and action-outcome interval revealed that, as expected, action-outcome intervals were significantly longer for trials of 5s length than for 2s ($F_{(1,32)} = 84.942$) confirming that controlling trial length was effective in manipulating reinforcement delay. We also found an effect of trial length on response rate ($F_{(1,32)} = 28.437$), which replicates earlier findings (e.g. Buehner & May, 2003). The important comparisons, however, were those involving trial structure. Specifically, if action-outcome intervals were significantly shorter for *apparent* than *not apparent* conditions, then our case for structural insight would be weakened by a mediation through experienced delay. Likewise, differences in response rate would entail different objective contingencies experienced across these conditions.

However, there was no significant main effect of trial structure on either response rate ($F_{(1,32)} = 0.814$) or action-outcome interval ($F_{(1,32)} = 1.495$); neither was there significant interaction between trial length and trial structure for response rate ($F_{(1,32)} = 0.026$) or action-outcome interval ($F_{(1,32)} = 0.033$). We can thus have confidence that our results concerning causal ratings are purely driven by structure information, and are not mediated by behavioral differences.

Figure 1: Mean causal ratings for Experiment 1. Error bars show standard error.

This finding suggests that causal learning in real time can, under certain conditions, be approached as a contingency learning task. When trial structure is apparent, contingency information can easily be discerned, and events accurately assigned to the cells of the contingency matrix. Under such circumstances, delays do not interfere with learning, as predicted by contingency-based or covariational models. Indeed in this case, judgments closely matched actual ΔP . Reinforcement delays thus are only detrimental to causal learning when they introduce ambiguity concerning response-outcome pairings.

It is important to note that our structural manipulation presented a tone simultaneously with the outcome. The tone therefore cannot act as a signal, bridging the temporal gap (Reed, 1992). There are however some other potential alternative explanations that must be ruled out.

Experiment 2A

Research in classical conditioning has demonstrated that increasing outcome salience increases the associative strength gained on each successive trial (e.g. Rescorla & Wagner, 1972). It could be argued that the tones marking the end of trials in the apparent conditions served to increase the saliency of the outcome, which coincided with them. If the causal learning process is subject to this property of associative learning, it might be responsible for alleviating the effect of delay. It could therefore be that our results are in fact driven by salience rather than structural insight.

To explore the effect of outcome salience, we modified the original paradigm such that under one set of conditions, outcome salience was increased, but without providing trial structure information. Accordingly, in one set of conditions, the triangle flash was accompanied by the same auditory tone used to provide structural markers in Experiment 1, adding to the salience of the outcome. The crucial distinction between this and the first experiment was that that here, the tone did not sound on occasions where there was no outcome, and thus did not convey trial structure information.

Method

Participants

32 participants, recruited as those in Experiment 1, completed the experiment to receive either £3 payment or course credit.

Design

Trial Length was either 2s or 5s as in the previous experiment, and Salience was either standard (no tone) or enhanced (tone present). Accordingly this gave four conditions which were presented in a blocked counterbalanced design as in the previous experiment.

Apparatus, materials & procedure

As before, except that in the *enhanced* conditions, the outcome was accompanied by the auditory tone, and participants received the following extra instructions: "When the triangle flashes, it will be accompanied by a tone." The *standard* conditions were identical to the *not*

apparent conditions in the previous experiment. This and the following experiment were conducted in a small computer lab using Windows XP machines, and testing multiple participants at once. Partitions between machines and use of headphones ensured that each participant could focus exclusively on their own task.

Results & Discussion

Causal Ratings

Two data points which were more than two standard deviations from the mean were removed from the analysis. Figure 2 shows that causal ratings declined as trial length increased from 2s to 5s for both standard and enhanced conditions. There also appeared to be a slight positive influence of enhanced outcome salience. Most importantly there appeared to be little difference between 5s-salient and 5s-standard conditions, suggesting that increasing outcome salience alone cannot replicate the observed effect from Experiment 1.

A 2x2 within-subjects ANOVA found the expected significant main effect of delay ($F_{(1,30)} = 5.634$). There was no significant effect of salience ($F_{(1,30)} = 1.705$) nor was the salience x delay interaction significant ($F_{(1,30)} = 0.036$).

Behavioral Data

We found the expected main effects of delay on both response rate ($F_{(1,32)} = 33.512$) and action-outcome interval ($F_{(1,32)} = 355.372$). The effect of salience was non-significant on both response rate ($F_{(1,32)} = 0.199$) and action-outcome interval ($F_{(1,32)} = 1.361$). The interaction between salience and delay was non-significant for both response rate ($F_{(1,32)} = 1.779$) and action-outcome interval ($F_{(1,32)} = 1.643$).

The non-effect of increasing outcome salience was not wholly anticipated; the literature suggests that this manipulation might have enhanced learning (although such a trend, albeit non-significant, was seen). More importantly however, the decline from 2s and 5s remains for the salient condition, while there is no real difference between the 5s-

Figure 2: Mean causal ratings for Experiment 2A. Error bars show standard error.

salient and the 5s-standard conditions. We can thus rule out increased outcome salience as an alternative explanation for the effects observed in Experiment 1. We turn next to examine another potential confound, the presence of an auditory pulse.

Experiment 2B

In Experiment 1, the tone sounding at regular intervals (at the end of each trial) effectively produced a metronomic pulse that might have influenced participants' perception of time. In Experiment 1, the meter of this auditory pulse changed in line with trial length, such that there was either a relatively quick pulse occurring every 2s, or a slower pulse every 5s. Importantly, although trial length was different, there was one beat per trial in each case, so the marking of the passage of time was consistent for both conditions. Thus there was an imposed degree of perceptual similarity which could have accounted for the lack of difference between 2s and 5s when the tone was present.

To test this alternative explanation, we modified Experiment 1 in a fairly simple manner that would retain the auditory pulse, without necessarily providing information regarding trial structure. The tone was thus moved so that it did not occur at the end of each trial, thus demarcating one trial from the next, but rather occurred midway through each trial. Each tone was separated by the exact same interval, thus still providing a regular pulse, but was now no longer contiguous with the end (or beginning) of each trial, and therefore did not convey (useful) trial structure information.

Method

Participants

34 psychology students from Cardiff University received either £3 payment or course credit for participation.

Design

As for the previous experiments, four experimental conditions were produced by combining the factors *Trial Length* (2s or 5s) and *Pulse* (present/not present) and presented in a blocked counterbalanced design.

Apparatus, Materials & Procedure:

The apparatus, location and procedure was identical to the previous experiment, except that participants in the pulse conditions received the following extra instructions: "You will hear a tone sounding at regular intervals. This is a pulse to help you keep track of time."

Results & Discussion

Causal Ratings

Figure 3 suggests that the auditory pulse did not alleviate the effect of delay. Interestingly however, it does seem that the presence of the pulse did improve judgments of causality across the board; both for 2s and 5s, although it did not noticeably improve judgments at 5s relative to 2s. This general effect could be due to a slowing down of the internal pacemaker by the auditory pulse. Studies have provided evidence that human time perception is determined

by a temporal oscillator, the frequency of which can be altered by interference from an imposed rhythm (Treisman, Faulkner, Naish & Brogan, 1990). Slowing the frequency means time seems to pass more quickly and the subjective duration of intervals is shortened. As a result, the perceived delay between cause and effect could have been decreased by the presence of the auditory pulse.

A within-subjects ANOVA found significant main effects of both pulse ($F_{(1,31)} = 4.413$) and delay ($F_{(1,31)} = 5.523$), but importantly no significant pulse \times delay interaction ($F_{(1,31)} = 0.988$). These results suggest that the effect in Experiment 1 is not attributable to the presence of the auditory pulse alone, and is due to our manipulation of trial structure information. However, one has to be cautious in the interpretation of a null result. While the interaction indeed falls considerably short of significance, one can notice from Figure 3 that the slope from 2s to 5s for the *pulse* condition is less steep than that for the *no pulse* condition. One might therefore suggest that a more powerful experiment may also have elicited a significant interaction.

These slight concerns can be alleviated by an inspection of the behavioral data. The bisection of the trial by the tone had the potential to induce a change in the behavior of participants. Some significance may have been attached to the tone, for instance being perceived as marking the start of the trial, or a point at which they should respond. Participants may therefore only have responded at or after the tone, and by doing so, effectively cutting the trial in half, and significantly reducing the action-outcome delay. This would account for the increase of 5s relative to 2s – if trial length is indeed truncated in this fashion, it will have been shortened by approximately 2.5s compared to 1s.

Behavioral Data

An analysis of the behavioral data reflected these suspicions. While the main effect of pulse on response rate was non-significant ($F_{(1,34)} = 2.760$), there was indeed a significant effect of pulse on action-outcome interval ($F_{(1,34)} = 25.983$). Mean action-outcome intervals where no pulse

Figure 3: Mean causal ratings for Experiment 2B. Error bars show standard error.

was present were 1.38s and 3.46s at trial lengths of 2s and 5s respectively; with the inclusion of the pulse, these were shortened to 1.11s and 2.78s. This can explain both the main effect of pulse, through the overall reduction in delay, and also the smaller decline in ratings from 2s to 5s (when the pulse was present) as there is a smaller discrepancy in delay. Consistent with the previous experiments, we also found the expected main effects of trial length on both response rate ($F_{(1,34)} = 13.819$) and action-outcome interval ($F_{(1,34)} = 546.072$). The interaction between pulse and trial length was significant for action-outcome interval ($F_{(1,34)} = 5.477$) but not for response rate ($F_{(1,34)} = 1.054$).

We can therefore be confident in our assessment that auditory pulse is not the determinant of the interaction observed in Experiment 1; when trial structure was present, 5s conditions received significantly higher ratings than when it was not, despite a lack of difference in actual action-outcome interval. If this effect were driven by the pulse, then in the present experiment, coupled with the behavioral shift, a significant interaction should have been even more likely, yet was not obtained.

General Discussion

This paper has demonstrated that by providing structural information in a real-time causal judgment task, the detrimental effect of temporal separation between action and outcome can be abolished. When cause and effect pairings are clearly delineated, the learning process appears to reduce to a simple contingency assessment which is unaffected by delay. Two follow-up studies ruled out potential alternative explanations for this effect, thus we can have confidence in the validity of the trial-structure manipulation.

These findings are consistent with a rational perspective on causal induction and could be regarded as a step towards overcoming the problem of circularity that hampers the causal mechanism view. It may well be that in the absence of clear structural information, other sources of knowledge (such as expectations based on previously acquired mechanistic beliefs) serve to divide the event stream into meaningful patterns of event co-occurrence. Importantly, we have shown that such beliefs are not necessary when structural information is apparent in the input, and furthermore, that such information serves to overcome the well-established detrimental effects of reinforcement delay.

Abstract

Probability-matching is a well-documented suboptimal behavior that arises in simple prediction tasks. We identify two distinct, local choice strategies that both give rise to probability-matching behavior on a global level. Using a dual-task paradigm, we evaluate the hypothesis that these qualitatively different strategies exhibit different demands on individuals' central executive resources. We find that participants placed under a concurrent working memory are driven away from the one-trial-back strategy—utilized by participants without a working memory load—and towards a strategy that integrates a longer window of past outcomes into the current prediction. In other words, the demands of the concurrent task appeared to shift the prediction strategies used by decision-makers in our study.

Keywords: Decision-making; Prediction; Win-Stay-Lose-Shift; Working Memory; Dual Task; Heuristics

Introduction

One decision-making anomaly of great interest is the tendency for humans to match their responses to outcome probabilities in the prediction of binary outcomes. For example consider a laboratory task in which people need to repeatedly predict which of two outcomes (say Event A and Event B) will occur next. If Event A occurs at a base rate of $p = .65$, Event B occurs at a base rate of $p = .35$ and each outcome is conditionally independent of the last outcome, the optimal prediction strategy would be to always predict that Event A will occur next, which is called *maximizing*. However, a large body of empirical work suggests that people appear to predict events in proportion to their frequency of occurrence, known as *probability matching* (Estes, 1961; Vulkan, 2000). Under probability matching, a person would predict Event A 65% of the time and Event B 35% of the time. It is easy to see that this strategy produces an expected overall accuracy of 54.5% (calculated as $.65 \times .65 + .35 \times .35$), which is inferior to that produced by *maximizing*—which produces an expected overall prediction accuracy of 65%. In the present study, we examine strategies that be may underlying probability matching in random sequences of events.

The psychological mechanisms that give rise to probability matching behavior are unclear and are a matter of ongoing debate. One hypothesis posits that probability matching arises from the use of a suboptimal cognitive shortcut in which individuals allocates their responses according to an assessment of the observed outcome probabilities (e.g., Koehler & James, 2009). Under this strategy, termed *expectation matching* (EM), the decision-maker's responses are the

result of integrating a moving window of past outcome information (Sugrue, Corrado, & Newsome, 2004). To generate a response, the individual stochastically and independently generates predictions in accordance with this historical assessment of outcome probabilities. Assuming a sufficiently long historical window, a decision-maker utilizing the EM strategy in the example above would stochastically allocate 65% of their predictions to Event A and 35% of their predictions to Event B.

Another proposal suggests that probability matching behavior seen at a more global level is the byproduct of a local decision process called *win-stay lose-shift* (WSLS; Herrnstein, Rachlin, & Laibson, 2000). Under WSLS, an individual persists with predicting one event, say Event A, until they make an incorrect prediction, at which point they shift responses and persist with predicting Event B until they are incorrect. While under certain task circumstances WSLS is an optimal choice strategy (Shimp, 1976), it is a suboptimal prediction strategy in the task outlined above. It can be shown that WSLS produces overall response rates (and hence, accuracy rates) equivalent to probability matching (Unturbe & Corominas, 2007). Further, there is evidence that people utilize WSLS in the simple binary prediction task described above (Gaissmaier & Schooler, 2008). Unlike the EM strategy, which involves integrating a comparatively long historical window of outcomes, WSLS requires that the decision-maker maintain a short-term memory for only the most recent response and outcome.

In the present study, we examined the cognitive demands imposed by the WSLS and EM strategies, with the idea that decision makers may utilize both strategies, but under different circumstances. While both strategies result in equivalent behavior at a global level—probability matching—they make different behavioral predictions at a local, trial-by-trial level. It is well documented that the working memory demands of a secondary task deplete mental resources that could otherwise be used to accomplish a primary task (Pashler, 1994). For example, Zeithamova and Maddox (2006) found that working memory load disrupts learning of explicit, rule-based categories and drives participants towards the use of an implicit, information-integration strategy. Here, we place decision-makers under a concurrent working memory load and find that they exhibit the same global tendency to probability match as decision-makers without a working memory

load. Using simple models, we demonstrate that different local strategies result in global probability matching. The distinction between these two matching strategies is theoretically significant because recent contributions to the probability matching literature (e.g., Gaissmaier & Schooler, 2008; Koehler & James, 2009) fail to find common ground on a) which strategies may give rise to probability matching behavior, and b) to what extent these strategies place demands on executive function.

Method

Participants One-hundred and sixty undergraduates at the University of Texas at Austin participated in this study, randomly assigned to one of two conditions: Dual-Task (DT) and Single-Task (ST). Participants were paid a small cash bonus of one cent per correct prediction.

Design and Procedure The experiment stimuli and instructions were displayed on 17-inch monitors. The participants were told that their goal was to predict repeatedly whether a red square would appear above a fixation cross or a green square below the fixation cross, using the up and down arrows respectively (see Figure 1 for a task screenshot). Like other studies (e.g., Koehler & James, 2009), the sequence of events was serially independent. The probability of the more common event was $p = .65$. The assignment of the high-probability event to the outcomes was counterbalanced across subjects. Subjects completed 10 practice trials in order to familiarize themselves with the response procedure, followed by 320 trials divided into 8 blocks of 40 trials each.

Figure 1: Example task screenshot of response and outcome for a correct prediction.

In order to accommodate the dual-task manipulation, the prediction task used a deadline procedure to ensure that a fixed amount of time elapsed each trial. At the start of each trial, the subject saw the word “PREDICT” and had two seconds to make a response. This response window lasted two seconds regardless of the timing of the response, and was followed by the actual outcome along with feedback indicating whether their prediction was correct (“CORRECT”) or incorrect (“INCORRECT”). The outcome and feedback were displayed for one second, and was followed by a one second inter-trial interval. If a subject failed to respond within the response window, the message “TOO SLOW” was displayed

along with the outcome. The timing of response windows and outcomes was the same for both the ST and DT conditions.

Blocks in the DT condition consisted of a secondary tone-counting task in addition to the prediction task. The design of the secondary task follows that of Foerde et al. (2007). Two types of tones, high-pitched (1000 Hz) and low-pitched (500 Hz) were played during each trial in the DT condition. Each three-second trial was divided into 12 intervals of 250 ms, with the tones occurring in intervals 3-10 (500-2,500 ms after trial onset). The number of tones presented each trial varied uniformly between 1 and 3 and occurred randomly within intervals 3-10. The pitch of each tone varied randomly, with the base rate of high tones varying uniformly from .3 to .7 each block. The subjects were instructed to maintain a running count of the number of high tones while ignoring the low-pitched tones. Note that the secondary task persisted during both the response window and the outcome. At the end of each 40-trial block, the subjects reported their running count using the keyboard and were instructed to restart their count at zero.

After subjects had completed 320 trials, they completed a questionnaire in which they were asked to provide estimates of the overall frequency of the red and green events. They were also given five prediction strategies to evaluate. These strategies included an expectation matching strategy (“Predict GREEN 65% of the time regardless of what happened during the last outcome”), a maximizing strategy, (“Always predict GREEN, regardless of what happened during the last outcome”), and a WSLS strategy (“Stick with predicting one outcome, and then change your prediction if you were incorrect on the last trial”). Subjects were instructed to rank these five strategies from 1 (“the best possible strategy”) to 5 (“the worst possible strategy”), using each ranking only once.

Results

We removed data from 12 ST and 26 DT participants whose prediction behavior differed non-significantly from equiprobable responding (Binomial test at the $p = .05$ level of significance). We also removed the data of eleven participants who failed to respond before deadline more than 20 times during the experiment. One hundred and eleven participants (48 DT and 63 ST participants) remained in the analysis that follows.

Overall Prediction Performance Figure 2 depicts the subjects’ accuracy, by condition, in predicting outcomes over the 320 trials. The dashed line depicts the level of accuracy expected under probability matching probability—that is, if participants allocated their 65% of their responses to the more frequent outcome. A 2 (task condition) \times 2 (trial block) ANOVA revealed neither a significant main effect of task condition, $F(1,107) = .55$, $p = .46$, nor a significant interaction between condition and trial block, $F(1,107) = 0.27$, $p = .61$. There was a significant main effect of trial block, $F(1,107) = 25.51$, $p < .001$. Again, the lack of effect of task condition suggests that the dual task manipulation did not hinder subjects’ overall accuracy, but rather, may have shifted the

Figure 2: Left panel: mean prediction accuracy, by task condition and trial block. ST = Single-task condition, DT=dual-task condition. Error bars represent standard error of the mean.

prediction strategies that subjects employed.

Overall Deviation from Matching Recall that our main goal was to determine whether matching behavior results from different strategies across the ST and DT conditions. Before comparing strategy usage, we first determine that both groups were in fact predominantly matching—and to the same degree. Specifically, we determined whether the secondary task manipulation affected the degree to which subjects deviated significantly from matching behavior (that is, allocating 65% of one’s responses to the more frequent event). For each of the 8 blocks, we calculated the proportion of subjects whose response allocations deviated significantly from a response allocation that matched the observed outcome frequency. The proportion of subjects in each condition, by block, that deviated significantly from probability matching behavior (under a Binomial test at the $p = .05$ level significance) are shown in Figure 3. We conducted a logistic regression with each subject’s classification (deviating significantly or not) as the criterion and task condition and trial block as predictors, observing no significant coefficients for task condition ($Beta = -.83$, $p = .44$) or the interaction between task condition and trial block ($Beta = .08$, $p = .53$). Trial block did have a significant coefficient ($Beta = .5$, $p < .001$). The apparent null effect of task condition suggests that ST and DT subjects were engaging in prediction behavior that appears similar at a coarse level of analysis.

Exponentially-Weighted Averaging Model Analysis At least two distinct response strategies can manifest themselves as probability matching. Under WSLs, the decision-maker repeats the previous trial’s response after a correct prediction and switches their response after an incorrect prediction. Thus responses under WSLs are determined by the outcome

Figure 3: Proportion of Subjects Deviating Significantly from Matching (by Binomial test), by task condition and trial block. ST = Single-task condition, DT=dual-task condition. Error bars represent standard error of proportion.

on the only the most recent trial. In contrast, EM requires that the decision-maker integrate a much longer window of previous outcomes, which in turn informs the decision-maker’s response probabilities. By fitting a simple exponentially-weighted averaging model model to participants’ responses, we identified the degree to which participants’ predictions were dependent on recent outcomes. The probability $P(t)$ of the decision-maker predicting the green event at time t is determined by:

$$P(t) = recency * outcome(t-1) + (1-recency) * P(t-1),$$

where $outcome(t-1)$ is the outcome on the previous trial, $P(t-1)$ is the model’s estimate of the rate at which the green outcome occurs, and $recency$ is a parameter that determines how much recent outcomes are weighted in updating $P(t)$. When the recency parameter is large, $P(t)$ is based only on the most recent trial’s outcome, and when the recency parameter is small, the model’s predicated response on the next trial $P(t)$ is based on a long window of previous outcomes. We fit this model to each participants’ responses using maximum likelihood estimation, assuming separate parameter values across blocks. As shown in Figure 4, ST participants had larger estimated learning weights than DT participants, indicating that prediction strategies employed by ST participants were influenced more by recent outcomes. A 2 (task condition) x 2 (trial block) ANOVA revealed a significant main effect of task condition, $F(1,107) = 4.13$, $p < .05$, a significant main effect of block, $F(1,107) = 21.38$, $p < 0.001$, and a significant interaction between condition and trial block, $F(1,107) = 6.34$, $p < .05$. The effect of condition suggests that ST participants exhibited choice behavior characteristic of WSLs—dependence on only the most recent trials—while DT participants used a strategy characteristic of the EM strategy—involving integration of a long window of past outcomes.

Figure 4: Average best-fitting recency parameter values for exponentially-weighted averaging model, by task condition and block. ST = Single-task condition, DT=dual-task condition. Error bars represent standard error of the mean.

Models of the Two Prediction Strategies To more directly address usage of these strategies, we compared the relative goodness-of-fit of two models that instantiated the WLS and EM strategies. To examine participants' WLS usage, we fit a simple WLS model to participants' choices, hypothesizing that ST participants would be better fit by this model than DT participants. This one-parameter model constrains the probability of a switching responses after an incorrect prediction (or a "loss") to the probability of persisting with the same response after a correct response (or a "win"). This model follows the WLS implementation described by Steyvers, Lee, and Wagenmakers (2009). To examine usage of the EM strategy, we fit a simple stochastic response model, which we call the fixed response probability (FR) model, to participants' data. Under this model, a single parameter determines the base rate of predicting the green event. This model—which we use a proxy measure for EM strategy use—assumes that responses are determined stochastically and independently. One crucial difference between these two models is the dependence of the response on trial t to the outcome on trial $t-1$. We fit both models to each participants' choice data using maximum likelihood estimation allowing parameter values to vary across blocks.

We predicted that ST subjects would be better described by the WLS model and that DT subjects would be better described by the FR model. Figure 5 depicts the relative goodness-of-fit (expressed as a log-likelihood ratio) between the two models, for each condition across the 8 blocks. Indeed, the likelihood ratios reveal that ST participants were better described by the WLS model than the responses of DT participants, and conversely, DT participants were better described by the FR model—our proxy for the EM strategy. A 2 (task condition) x 2 (trial block) ANOVA revealed a significant main effect of task condition, $F(1,107) = 5.28, p < .05$,

Figure 5: Comparison of model goodness-of-fit between WLS and EM models. Average likelihood ratios using best-fitting parameter values for each block of each subject. Error bars represent standard error of the mean. ST = Single-task condition, DT=dual-task condition. Error bars represent standard error of the mean.

a main effect of trial block, $F(1,107) = 19.18, p < .001$, and no significant interaction between task condition and trial block, $F(1,107) = 1.14, p = .29$. The main effect of task condition suggests that the concurrent working memory load influenced the local prediction strategies utilized by decision-makers.

Offline Reported Event Probabilities We hypothesized that the secondary task would impair DT participants' ability to explicitly encode information about outcome frequencies. To test this, we calculated absolute deviations between participants' offline reported outcome probabilities and true empirical base rates. The average absolute deviations are shown in Figure 6. We found that DT participants' reported outcome probabilities deviated significantly more from observed base rates than ST participants, $t(107) = 2.82, p < .01$. Taken in conjunction with the similar overall accuracy profiles of the two groups, this result suggests that the two groups may have been using qualitatively different strategies to make predictions.

Strategy Self-Reports We assessed participants' offline endorsement of the strategies that were described in the questionnaire. To do this, we compared participants' relative preference for the WLS over EM by their subtracting their ranking of the WLS strategy from their ranking of the EM strategy, yielding a measure of endorsement of WLS (note that this measure is equally informative about preference for EM). We found that ST participants' endorsement of WLS significantly correlated with their overall WLS model goodness-of-fit, $r(107) = .35, p < .01$, suggesting that ST participants had some explicit awareness of the strategies they employed. In contrast, DT participants' strategy endorsements did not significantly correlate with their average goodness-of-fit mea-

Figure 6: Mean absolute deviation from observed (empirical) base rate, by task condition. Error bars represent standard error of the mean.

tures for either model, suggesting the concurrent working memory load impaired decision-makers' ability to explicitly report the strategies they employed [WSLS model: $r(107) = .15$, $p = .28$, FR model: $r(107) = -.02$, $p = .82$].

Discussion

In this experiment, we investigated the effect of a concurrent working memory task on probability-matching behavior in a random, sequentially independent prediction task. To do so, we imposed a secondary working memory task on subjects, which was believed to deplete working memory resources that could have been used on the primary prediction task (Pashler, 1994). In the DT condition, subjects needed to both make responses in the prediction task and update their count of auditory tones, while in the ST condition, subjects needed only to make predictions. Although most subjects in both conditions demonstrated probability matching, subjects in the ST condition relied more on a WSLS strategy, which requires memory for the previous prediction and outcome. This finding suggests that while both ST and DT subjects appear to be using suboptimal strategies with similar base rates at a molar level, the two groups may actually be using different prediction strategies.

Our results are interesting in the context of previous dual-task studies of human learning. For example, Foerde et al., (2007) found that a concurrent working memory load during probabilistic classification learning impaired subjects' acquisition of explicit associations between perceptual cues and outcomes, although these subjects evidenced implicit learning of cue-outcome contingencies. Further, they were unable to flexibly apply knowledge about cues in an offline evaluation. Zeithamova and Maddox (2006) found that a concurrent working memory load disrupts learning of explicit, rule-based categories and instead drives subjects towards the use of an implicit, information integration strategy. Both of these studies point to the possibility that concurrent working memory load engenders the use of implicit learning systems. In our study, utilization of the EM strategy may be indicative of the operation of an implicit system.

Another possibility raised in the literature is that probabil-

ity matching arises out of peoples' search for regularities in the event sequences (Gaissmaier & Schooler, 2008). Even when laboratory prediction tasks are probabilistic and outcomes sequences are conditionally independent, people may search for deterministic patterns in an attempt to achieve prediction accuracy above that of maximizing. Thus, if an individual believes that the event sequence contains structure, he or she will try to improve their accuracy by searching for patterns. Gaissmaier & Schooler's result suggests that that some individuals in the present study who appear to be probability matching—rather than maximizing—are more adept at detecting deterministic patterns when they are later introduced into the sequence of events.

One possibility in the present study is that subjects in the ST condition may have begun a search for deterministic patterns and abandoned the search given the very low likelihood of a pattern repeating itself in the random sequence, reverting later to a suboptimal WSLS strategy. Supporting evidence comes from the fact that over 60% of the ST condition's responses are consistent with WSLS and that this percentage increases over time. This hypothesis will be the subject of investigation in future studies.

Abstract

There is much debate over the degree to which language learning is governed by innate language-specific biases, or acquired through cognition-general principles. Here we examine the probabilistic language acquisition hypothesis on three levels: We outline a theoretical result showing that probabilistic learning in the limit is possible for a very general class of languages. We then describe a practical computational framework, which can be used to quantify natural language learnability of a wide variety of linguistic constructions. Finally, we present an experiment which tests the learnability predictions for a variety of linguistic constructions, for which learnability has been much debated. We find that our results support the possibility that these linguistic constructions are acquired probabilistically from cognition-general principles.

Keywords: child language acquisition; Gold's theorem; poverty of the stimulus; probabilistic learning; simplicity principle; adult grammar judgments; natural language

Introduction

A central debate in cognitive science revolves around how children acquire their first language. A significant portion of this debate centers on how children learn complex linguistic structures, such as restrictions to general rules. An example restriction-rule can be seen in the contraction of 'going to': 'I'm gonna leave' is grammatical whereas 'I'm gonna the store' is ungrammatical. Language communication requires the speaker to generalize from previously heard input. However, research shows children rarely receive feedback when they produce an over-general, ungrammatical sentence. Children also aren't explicitly told which generalizations are allowed and which are not (Bowerman, 1988). These observations evoke the question: how do children learn that certain overgeneralizations are ungrammatical without explicitly being told?

Traditionally, linguists have claimed that such learning is impossible without the aid of innate language-specific knowledge (Chomsky, 1975; Crain, 1991; Pinker, 1989; Theakston, 2004). However, recently, researchers have shown that statistical models are capable of learning restrictions to general rules from positive evidence only (Dowman, 2007; Foraker, Regier, Khetarpal, Perfors, &

Tenenbaum, 2009; Grünwald, 1994; Perfors, Regier, & Tenenbaum, 2006; Regier & Gahl, 2004).

Here we examine language acquisition from a probabilistic perspective on a theoretical, computational and experimental level. We first revisit Gold's theorem and show that language identification *is* possible from a probabilistic perspective. Next we mention a recently proposed, general framework which can quantify learnability of constructions in natural language. This flexible framework allows for predictions to be made concerning the natural language learnability of a wide variety of linguistic rules. Finally, we experimentally test the learnability predictions obtained from this framework by comparing these predictions with adult grammaticality judgments for a wide range of linguistic constructions.

Gold revisited: probabilistic language acquisition with a simplicity prior

Inherent in a simplicity-based approach to language acquisition is the trade-off between simpler vs. more complex grammars: Simpler, over-general grammars are easier to learn. However, because they are less accurate descriptions of actual language statistics, they result in inefficient encoding of language input, i.e. the language is represented using longer code lengths. More complex grammars (which enumerate linguistic restrictions) are more difficult to learn, but they better describe the language and result in a more efficient encoding of the language, i.e., language can be represented using shorter code lengths. Under simplicity models, language learning can be viewed in analogy to investments in energy-efficient, money-saving appliances. By investing in a more complicated grammar, e.g. one which contains a restriction on a construction, the language speaker obtains encoding savings every time the construction occurs. This is analogous to investing in an expensive but efficient appliance that saves money with each use. A linguistic restriction is learned when the relevant linguistic context occurs often enough that the accumulated savings makes the more complicated grammar worthwhile. Because complex grammars become worth while as linguistic constructions appear more often,

simplicity models are able to learn restrictions based on positive evidence alone (See Figure 1).

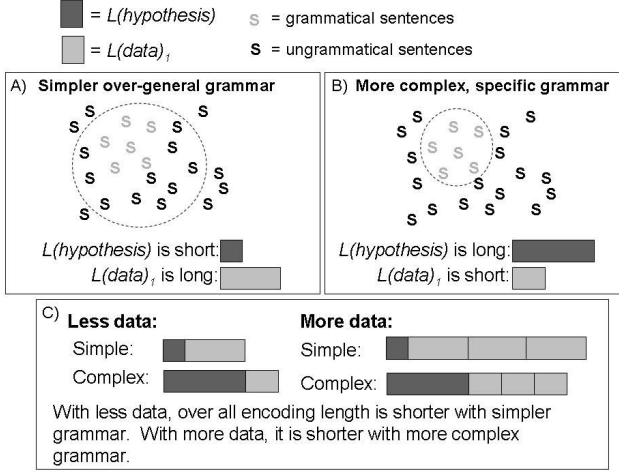

Figure 1: MDL simple grammar vs. efficient language encoding trade off. A) A simpler grammar is often over-general, i.e., allows for ungrammatical sentences as well as grammatical ones. Such an over-general grammar may be easy to describe (i.e., short grammar encoding length), but results in less efficient (longer) encoding of the language data. B) A more complex grammar may capture the language more accurately, i.e., allows only for grammatical sentences and doesn't allow for ungrammatical sentences. This more complex grammar may be more difficult to describe (i.e., longer grammar encoding length), but will provide a shorter encoding of language data. C) Initially, with limited language data, the shorter grammar yields a shorter coding length over-all, and is preferred under MDL. However, with more language input data, the savings accumulated from having a more efficient encoding of language data correctly favour the more complex grammar.

A central theoretical question is: given sufficient exposure to the language, can the learner recover a perfectly accurate description of that language? Gold (1967) famously showed that, under certain assumptions, this is not possible. However, a range of more positive results have since been derived, e.g., (J. A. Feldman et al 1969; Chater & Vitányi 2007). Here we show that under a simplicity-based probabilistic formulation, a new and strong positive result can be derived.

Suppose that the learner encounters sentences, s , which are independently sampled generated from a computable probability distribution, $C_P(s)$, which has Kolmogorov complexity $K(C_P)$. Here we will define learning a language as the process of identifying this distribution. $C_P(s)$ generates a corpus $S_n = s_1, s_2, \dots, s_n, \dots$ which continues indefinitely. We assume that $C_P(s)$ allows all and only grammatical sentences in language L . That is, the probability of generating all sentences s , that are grammatical in L , is greater than zero, $C_P(s) > 0$; and

conversely, if the probability of a sentence being generated is greater than zero, then it is grammatical according to L .

There is one additional mild constraint that we need to impose: that $C_P(s)$ has a finite entropy, i.e.,

$$H(C_P) \propto \sum_{j=1}^{\infty} C_P(s_j) \log \left(\frac{1}{C_P(s_j)} \right) < \infty$$

This is a modest constraint, because it follows from the assumption that the mean sentence length under distribution $C_P(s)$ is finite, which is clearly true for natural language.

The learning problem proceeds as follows: A learner is given an initial sample of the corpus S_n . The question then is: how should the learner assign probabilities to the various possible computable distributions C_Q that might have generated the corpus? This is equivalent to learning: $Pr(C_Q|S_n) \propto Pr(S_n|C_Q)Pr(C_Q)$

Also, we ask how these probabilities change as the corpus grows arbitrarily long, i.e., as n tends to infinity? In particular, can the learner identify the true probability distribution, C_P , in the limit?

Intriguingly, it turns out that this is possible – and indeed that an ideal learner (Chater & Vitányi 2007)) will ‘converge’ on the true probability distribution, C_P , with probability of measure 1, given a sufficiently large corpus. Suppose, for concreteness, that the learner “announces” its current most probable generating distribution each time a new sentence i arrives, based on the i sentences that he has received so far $S_i = \{s_1, s_2, \dots, s_i\}$. More formally, the following theorem holds: Consider any computable probability distribution C_P , from which samples, s_i , are drawn independently to generate a semi-infinite corpus S . Let m' be the number of initial items of S so that $S_{m'}$ is a “prefix” of S (i.e., a corpus consisting of the first m' items of s). With probability greater than $1-\epsilon$, for any $\epsilon > 0$, there is an m such that, under the simplicity principle, for all $m \geq m'$, the most probable C_Q , given $S_{m'}$ is the generating distribution C_P , i.e., $\text{argmax}(Pr(C_Q|S_{m'})) = C_P$.

Why is this true? A full proof is beyond the scope of this paper (see Chater & Hsu, in preparation); but the essence of the argument is the following. We know that almost all random samples from P will be incompressible (i.e., n sentences generated by the true generative model P will have no shorter description than the entropy $nH(P)$). This implies that, for *typical* data generated by P (which have summed probability arbitrarily close to 1), $K(P) + nH(P) \geq K(S_n) \geq nH(P)$. Now for each S_n , consider the set of probability distributions Q which satisfy this criterion: $K(Q) + nH(Q) \geq K(S_n) \geq nH(Q)$. For each n , there will be finitely many such Q ; and, by our argument above, these will include the true distribution P . Now, for each n , the learner “announces” the simplest Q' , i.e., the Q' such that for all Q , $K(Q) \geq K(Q')$. We know that P will always be in this set, by the argument above. However, there are only finitely many Q that are simpler than P . Once these simpler Q have been eliminated, then P will be the shortest element in the set, and will be announced indefinitely thereafter. We know that each of this finite set will be eliminated for

sufficiently large n , because the expected excess cost of encoding data generated by P with distribution Q is $nD(Q||P)$, where $D(Q||P) > 0$ unless $Q=P$; this excess cost tends to infinity as n tends to infinity. Hence, for some $n' > n$, after all probability distributions Q with shorter codes than P have been eliminated, P will be announced indefinitely.

Practical framework for quantifying learnability

The positive learnability results indicate that the probabilistic approach can be practically applied to the problem of language acquisition. Recently, researchers have used probabilistic models to show that many complex linguistic rules can be acquired by directly learning the probability distribution of grammatical sentence structures in language. These models learn this probability distribution under a cognition general prior for simplicity (Dowman, 2007; Foraker et al., 2009; Grünwald, 1994; Perfors et al., 2006; Regier & Gahl, 2004). Many of these studies used restricted language sets. In the context of natural language, a few studies have addressed specific linguistic cases such as anaphoric one (Foraker et al., 2009) and hierarchical phrase structure (Perfors et al., 2006).

Recently, a *general quantitative framework* has been proposed which can be used to assess the learnability of any given *specific linguistic restriction* in the context of real language, using positive evidence and language statistics alone (Hsu & Chater, 2010). This framework built upon previous probabilistic modeling approaches to develop a method that is generally applicable to any given construction in natural language. This new tool can be used to explicitly explore the learnability in a corpus relative to well-known information theoretic principles given a grammatical description. When using this framework to analyze learnability of a linguistic construction, there are two main assumptions: 1) The description of the grammatical rule for the construction to be learned. 2) The choice of corpus which approximates the learner's input. Given these two assumptions, the framework provides a method for evaluating whether a construction is present with adequate frequency to make it learnable from language statistics. The framework allows for comparison of different learnability results which arise from varying these two main assumptions. By making these assumptions explicit, a common forum is provided for quantifying and discussing language learnability.

Minimum Description Length hypothesis

Because this framework is detailed elsewhere (Hsu & Chater 2010), we will only provide a brief overview here. Learnability evaluations under a simplicity prior can be instantiated through the principle of minimum description length (MDL). MDL is a computational tool that can be used to quantify the information available in the input to an idealized statistical learner of language as well as of general cognitive domains (Jacob Feldman, 2000). When MDL is

applied to language, grammars can be represented as a set of rules, such as that of a probabilistic context free grammar (PCFG) (Grünwald, 1994). An information-theoretic cost can then be assigned to encoding the grammar rules as well as to encoding the language under those rules.

Hsu & Chater (2010) used an instantiation known as 2-part MDL, which we will refer to as just MDL for brevity. In the context of language acquisition, the first part of MDL uses probabilistic grammatical rules to define a probability distribution over linguistic constructions, which combine to form sentences. Note that these probabilities are not necessarily the real probabilities of sentences in language, but the probabilities as specified under the current hypothesized grammar. The second part of MDL consists of the encoded representation of all the sentences that a child has heard so far. MDL selects the grammar that minimizes the *total* encoding length (measured in bits) of both the grammatical description and the encoded language length¹.

According to information theory, the most efficient encoding occurs when each data element is assigned a code of length equal to the smallest integer greater than or equal to $-\log_2(p_n)$ bits, where p_n is the probability of the n th element in the data. For our purposes, these elements are different grammar rules. The probabilities of these grammar rules are defined by the grammatical description in the first part of MDL. Because efficient encoding results from knowing the correct probabilities of occurrence, the more accurately the probabilities defined in the grammar match the actual probabilities in language, the more efficient this grammar will be.

Under MDL, the grammatical description is updated to be the most efficient one each time more data input is obtained. Savings occur because certain grammatical descriptions result in a more efficient (shorter) encoding of the language data. In general, more complex (i.e., more expensive) grammatical descriptions allow for more efficient encoding of the language data. Because savings accumulate as constructions appear more often, more complex grammars are learned (i.e., become worth investing in) when constructions occur often enough to accumulate a sufficient amount of savings. If there is little language data (i.e., a person has not been exposed to much language) a more efficient encoding of the language does not produce a big increase in savings. Thus, when there is less language data, it is better to make a cheaper investment in a simpler grammar as there is not as much savings to be made. When there is more language data, investment in a more costly, complicated grammar becomes worthwhile. This characteristic of MDL learning can explain the early overgeneralizations followed by retreat to the correct

¹ The MDL framework can also be expressed as a corresponding Bayesian model with a particular prior (Chater, 1996; MacKay, 2003; Vitányi & Li, 2000). Here, code length of the model (i.e., grammar) and code length of data under the model (i.e., the encoded language) in MDL correspond to prior probabilities and likelihood terms respectively in the Bayesian framework.

Table 1: Grammatical and ungrammatical sentences used in experiment.

Construction	Grammatical usage	Ungrammatical usage
is	She's as tall as he is.	She is as tall as he's.
arrive	The train arrived.	He arrived the train.
come	The train came.	I came the train.
donate	He donated some money to the charity.	He donated the charity some money.
fall	The ornament fell.	He fell the ornament.
disappear	The rabbit disappeared.	He disappeared the rabbit.
what is	What's it for?	What's it?
shout	I shouted the news to her.	I shouted her the news.
pour	I poured the pebbles into the tank.	I poured the tank with pebbles.
vanish	The rabbit vanished.	He vanished the rabbit.
whisper	I whispered the secret to her.	I whispered her the secret.
create	I created a sculpture for her.	I created her a sculpture.
who is	Who's it for?	Who's it?
going to	I'm gonna faint.	I'm gonna the store.
suggest	I suggested the idea to her.	I suggested her the idea.
that	Who do you think that she called?	Who do you think that called her?
want to	Which team do you wanna beat?	Which team do you wanna win?

grammar that has been observed in children's speech (Bowerman, 1988). The output of the framework described in Hsu & Chater (2010) results in an estimated number of occurrences needed for a specific linguistic rule to be learned and corpus analysis is then used to assess how many years on average are needed for the sufficient number of occurrences. The general applicability of this framework and its ability to produce clear learnability predictions allow us to take the crucial next step in addressing the language acquisition problem: experimentally assessing whether language might actually be probabilistically acquired.

Testing learnability predictions

Hsu & Chater (2010) used the above framework to assess language learnability of constructions, whose learnability have been commonly debated. These all involve restrictions on a general linguistic rule, which was described using PCFG's. Predictions for learnability in terms of years needed was made for constructions whose learnability have been commonly debated in the language acquisition field. These included restrictions on the following 17 constructions²: contractions of *want to*, *going to*, *is*, *what is* and *who is*; the optionality of *that* reduction; dative alternation for the verbs *donate*, *whisper*, *shout*, *suggest*, *create*, *pour*; transitivity for the verbs, *disappear*, *vanish*, *arrive*, *come*, *fall*. See Hsu & Chater (2010) for the explicit grammar descriptions of linguistic rules to be learned. The

² Hsu & Chater (2010) also included analysis of two more linguistic rules concerning the necessary transitivity of the verbs *hit* and *strike*. Though these verbs are traditionally known to be transitive, in colloquial speech they have evolved to have a ambitransitive usage: e.g. *The storm hit. Lightning struck*. In COCA there are 3678 and 1961 intransitive occurrences of *hit* and *strike* respectively. Thus we did not assess rules regarding the intransitivity of these verbs in our experiment.

results showed a large spread in learnability. Some constructions appeared readily learnable within just a few years whereas other constructions required years that far outnumbered human life spans. Hsu & Chater (2010) compared predicted MDL learnability with child grammar judgments of constructions for which there was data collected from previous experimental work (Ambridge, Pine, Rowland, & Young, 2008; Theakston, 2004). It was found that child grammar judgments for the constructions were more correlated with learnability than frequency counts (the entrenchment hypothesis (Theakston, 2004)).

Figure 2: Estimated years required to learn construction. The constructions are sorted according to learnability: 1) *is* 2) *arrive* 3) *come* 4) *donate* 5) *fall* 6) *disappear* 7) *what is* 8) *shout* 9) *pour* 10) *vanish* 11) *whisper* 12) *create* 13) *who is* 14) *going to* 15) *suggest* 16) *that* 17) **want to*. *Predicted years for learning *want to* is 3,800years.

Here we propose that construction learnability should also correlate with adult grammaticality judgments: The more difficult a construction is to learn, the greater the difference

should be between judgments of the ungrammatical vs. grammatical uses of the construction.

Model Predictions

We conducted our learnability analysis using the full Corpus of Contemporary American English (COCA), which contains 385 million words (90% written, 10% spoken). We believe this is a reasonable representation of the distributional language information that native English language speakers receive. Learnability results using the British National Corpus were similar to that from COCA (Hsu & Chater, 2010). Figure 2 shows the estimated number years required to learn the 17 constructions. We quantified learnability as $\log(1/N_{\text{years}})$, where N_{years} was the number of estimated years needed to learn a construction (Hsu & Chater, 2010).

Learnability vs. entrenchment To verify that our experimental results are not also trivially explained by a simpler hypothesis, we will also compare experimental results with the predictions of entrenchment theory. Entrenchment is the hypothesis that the likelihood of a child over-generalizing a construction is related to the construction's input occurrence frequency. There is some relation between learnability and entrenchment predictions because high construction occurrence frequencies do aid learnability. However, learnability differs from mere frequency counts because MDL also takes into account the complexity of the grammatical rule that governs the construction to be learned. Additionally, learnability is influenced by whether the restricted form would be commonly or uncommonly expected, if it were grammatically allowed. Here, we propose that under entrenchment hypothesis, the relative grammar judgment difference should be related to the construction's input occurrence frequency. (Frequencies estimated from COCA).

Experimental method

Participants 105 participants were recruited for an online grammar judgment study (age range: 16-75 years, mean=34 years). Results were included in the analysis only for participants who answered that they were native English speakers (97 out of 105 participants). The majority (74%) of our participants learned English in the United States. Other countries included the UK (14%), Canada (5%), Australia (4%). The rest learned English in either Ireland or New Zealand.

Procedure Participants were asked to rate the grammaticality of grammatical and ungrammatical sentences using the 17 constructions whose learnability were quantified above. These sentences (34 total) are shown in Table 1. Grammar judgments ranged from 1-5: 1) Sounds completely fine (Definitely grammatical) 2) Probably grammatical (Sounds mostly fine) 3) Sounds barely passable (Neutral) 4) Sounds kind of odd (probably

ungrammatical) 5) Sounds extremely odd (Definitely ungrammatical).

Results

Results show a strong correlation between averaged relative grammaticality vs. log learnability as predicted by MDL, $r=.35$; $p=.0045$ (see Figure 3). Relative grammaticality for a given linguistic construction is the grammatical rating for the ungrammatical sentence subtracted by the rating for the grammatical sentence. Note that 4 is the maximum possible relative grammaticality because the lowest ungrammatical rating is 5 and the highest grammatical rating is 1. In contrast, there is no correlation between relative grammaticality and construction occurrence frequency, as would be predicted by entrenchment (see Figure 4).

Figure 3: Human grammar judgments vs. learnability analysis. Learnability is log of the inverse of the number of estimated years needed to learn the construction. Correlation values: $r=.35$; $p=.0045$

Figure 4: Human grammar judgments vs. log of occurrence frequency. Frequencies were estimated using Corpus of Contemporary American English.

Summary and Conclusions

This presented work helps evaluate how much of first language is probabilistically acquired from exposure. We show that, despite Gold's theorem, language is identifiable with a cognition general prior of simplicity under fairly general assumptions. We then describe a recently formulated framework which allows probabilistic learnability to be quantified in the context of natural language. This framework makes concrete predictions in terms of years needed to learn particular linguistic rules, given an assumed formulation of the rules to be learned and the corpus which represents a learner's language input.

There has now been a substantial body of work showing that probabilistic language learning *is theoretically and computationally possible*. The important next step in research on language acquisition is to assess whether probabilistic learning actually occurs in practice. Here we make the supposition that if language is probabilistically acquired, then there should be evidence of this in adult grammar judgments. There is a subtle leap of logic in this supposition. MDL learnability assumes that a grammar is learned in an absolute sense: once a grammar is chosen under MDL, that is the one used and there is no gradation of knowledge. However, here we are conjecturing that learnability should not only correlate with how long it takes for linguistic rule to be acquired, but also with how certain is one's knowledge of that rule. The more certain one is of a grammatical rule, the greater the difference should be one's acceptability rating of the ungrammatical form relative to the grammatical form. Experimental results show that predicted learnability correlates well with relative grammar judgments for the 17 constructions analyzed, chosen as controversial cases from the literature. Our experimental results support the possibility that many linguistic constructions that have been argued to be innately acquired may instead be acquired by probabilistic learning.

Our learnability predictions were calculated using a large corpus (COCA) to represent the distributional language input that native English speakers receive. This assumes that the distributional information estimated from this corpus is representative of that which influenced the language acquisition process in our adult participants. It also allows for the possibility that a speaker's certainty about different linguistic rules is updated through adulthood using probabilistic learning. If so, older adults might more certain in their grammar judgments, is a direction for future work.

Abstract

Modeling how concepts are learned from experience is an important challenge for cognitive science. In cognitive psychology, progressive alignment, i.e., comparing highly similar examples, has been shown to lead to rapid learning. In AI, providing very similar negative examples (*near-misses*) has been proposed as another way to accelerate learning. This paper describes a model of concept learning that combines these two ideas, using sketched input to automatically encode data and reduce tailorability. SAGE, which models analogical generalization, is used to implement progressive alignment. Near-miss analysis is modeled by using the Structure Mapping Engine to hypothesize classification criteria based on differences. This is performed both on labeled negative examples provided as input, and by using analogical retrieval to find near-miss examples when positive examples are provided. We use a corpus of sketches to show that the model can learn concepts based on sketches and that incorporating near-miss analysis improves learning.

Keywords: Concept learning; analogy; generalization.

Introduction

How concepts are learned from experience is a central question in cognitive science. It is well-known that some concepts can be viewed as analytic, having compact necessary and sufficient defining criteria (e.g., *grandparent* or *triangle*), whereas others are based on similarity or typicality (e.g., *chair*, *bachelor*). Prior work has explored analogical generalization as an explanation for learning similarity-based categories. The SAGE model of analogical generalization, an evolutionary improvement over SEQL (Kuehne *et al* 2000a) has been used to model learning of perceptual stimuli (Kuehne *et al* 2000b), stories (Kuehne *et al* 2000a), spatial prepositions (Lockwood *et al* 2008) and causal models (Friedman & Forbus, 2008; Friedman & Forbus, 2009). SAGE's ability to construct probabilistic generalizations provides a model of typicality, i.e., high-probability relationships and attributes are more typical. SAGE has been used to model *progressive alignment* (Gentner *et al* 2007), where sequences of highly similar exemplars lead to more rapid learning (Kuehne *et al* 2000a). Progressive alignment alone may suffice to generate rule-like concepts (e.g., Gentner & Medina, 1998), but another possibility is to use negative examples to sharpen criteria for concepts. Winston (1970) proposed the idea of a *near-miss*, a labeled negative example that differs from the intended

concept in only one way. A near miss exemplar should be highly alignable with some instances of a concept¹.

This paper describes a model of concept learning that combines analogical generalization and near-miss analysis to capture both similarity-based and analytic aspects of concepts. Its inputs are labeled positive or negative examples of concepts. It uses SAGE to construct generalizations for each concept, thus capturing similarity-based aspects of concepts (and typicality, via probability). When a positive example is provided, the corresponding concept is updated. When a negative example is provided, analogical retrieval is used to find the closest prior positive example or generalization, and analogical matching is used to construct and update hypotheses about inclusion and

Figure 1: An example of the *skeletal arm* concept drawn in CogSketch.

exclusion criteria for that concept. Near-miss analysis is also attempted when a positive example is provided, using analogical retrieval over negative examples to look for a candidate near-miss. (Using analogical retrieval to find positive concepts and near-misses is a significant advance over Winston's model, which used hand-coded representations, a single abstract description for concepts and required a teacher to supply all negative examples.) To test the model, we use sketches to describe concepts, which are automatically encoded by a sketch understanding system. We show that the model can indeed learn concepts from sketches, and that including near-miss analysis improves learning. Our simulation is implemented using the Companions cognitive architecture (Forbus *et al*, 2009), which integrates analogical processing and sketching.

¹ For disjunctive concepts, some exemplars will not be similar.

The next section summarizes the simulations of analogical processing and sketch understanding that our model is built upon. We describe our model next, followed by a description of our experiments. We close with related and future work.

Simulation Components

Analogical processing

Our system uses three cognitive models as components to learn concepts and categorize examples. Similarity-based retrieval is used to find similar examples across conceptual boundaries. Analogical comparison is used to compare examples and generate classification hypotheses. Finally, analogical generalization is used to generalize examples. We use the Structure Mapping Engine (SME) (Falkenhainer et al, 1989) to model analogical matching, MAC/FAC (Forbus et al, 1995) to model retrieval, and SAGE (Keuhne et al, 2000) to model analogical generalization.

SME is based on Gentner's (1983) structure-mapping theory of analogy. Given two relational representations, a base and a target, SME computes *mappings* which represent how they can be aligned. A mapping consists of correspondences which describe "what goes with what" in the two representations and a numerical score indicating their degree of similarity. SME also computes *candidate inferences* from the base to the target and from the target to the base. Candidate inferences suggest possible relations that can be transferred across representations, using the correspondences in the mapping as support.

Given a probe case and case library, MAC/FAC efficiently retrieves a case from the case library that is similar to the probe. For scalability, its first stage estimates similarity via dot products on vectors automatically produced from the structured, relational representations used as cases. At most three descriptions are passed to the second stage, which uses SME to compare their full relational versions to the probe, in parallel, to find the best case, or up to three cases if they are very close to the best.

Our model uses SAGE for generalization. Each concept has its own *generalization context*, which SAGE uses to maintain a list of generalizations and ungeneralized examples. Given a new example, it is first compared against each generalization in the context, using SME. If the SME similarity score is over the *assimilation threshold*, the example is merged to update the generalization. Otherwise, the new example is compared with the ungeneralized examples in the context. Again, if the score is over threshold, the two examples are then combined to form a new generalization in the context. Otherwise, the example is added to the context's list of ungeneralized examples. Figure 2 depicts generalization contexts for concepts *Arch* and *Triangle*.

CogSketch

CogSketch² (Forbus et al, 2008) is an open-domain sketch understanding system. The ink that a user draws to represent an entity is called a *glyph*, which can be labeled with concepts from an OpenCyc³-derived knowledge base. For example, in the sketch shown in Figure 1, each bone is labeled a *Bone-BodyPart*, which is stored as an attribute for each of the individual entities.

CogSketch automatically computes qualitative spatial relations (e.g., *above*, *rightOf*, *touchesDirectly*) between glyphs. In the knowledge representation that is produced by CogSketch, these relations are automatically applied to the entities that the glyphs represent. CogSketch also computes candidate *visual/conceptual relations* (again, from the OpenCyc-derived knowledge base) for pairs of sketched entities based on the visual relationships that hold between them the conceptual labels they have been assigned, and the genre and pose of the sketch. For example, the fact that the glyphs depicting the carpus and metacarpus in Figure 1 touch suggests that the objects they depict might be touching or connected in some way. The list of candidate visual/conceptual relations for these objects is further constrained by the *Bone-BodyPart* concept labels they have been assigned, as well as the *Physical*

Figure 2: SAGE generalization contexts for *Arch* and *Triangle* concepts, with associated inclusion and exclusion hypotheses (h_i and h_e , respectively).

genre and *from-side* pose of the sketch. The user can browse the candidate relationships and select those which are accurate. In our input stimuli, correct visual/conceptual relationship candidates were always included.

CogSketch is based on the observation that people talk when they sketch, providing verbal labels for what they are drawing, and using language to express functional relationships (e.g. that two parts can rotate, or that one supports another) that the sketch alone cannot convey. The conceptual labels described above, which are applied by a simple menu system, model the effect of verbal labeling. The possible visual/conceptual relationships described above, which are computed automatically and are available

² <http://www.qrg.northwestern.edu/software/cogsketch/>

³ www.opencyc.org

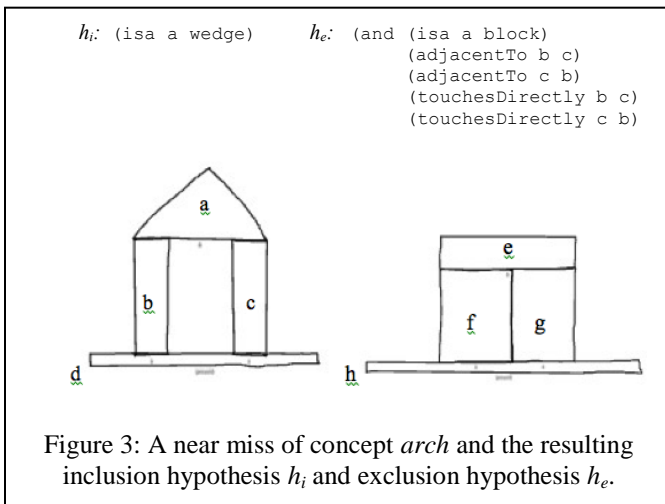

for the user to choose or not, model the effect of providing functional information via language. This makes the input process much closer to what happens in human-to-human sketching. The user draws ink, which CogSketch's visual system analyzes, producing visual and spatial relationships. The user-supplied conceptual labels plus the visual/spatial analysis enables CogSketch to automatically compute visual/conceptual relationship candidates, from which the user can select, if they choose. (In the experiments reported here, correct visual/conceptual relationships were always chosen, thereby providing some functional information about the concept.)

Similarity & near-miss concept learning

Our model takes as input a stream of labeled sketches. There are two kinds of labels: A positive label indicates that the example is an instance of a concept, e.g., an arch. A negative label indicates that, whatever it is, it is not an example of that concept (e.g. not an arch). Currently the model assumes that concepts are mutually exclusive. When the first positive example for a new concept is provided, a generalization context is created for that concept. Positive examples are added to the appropriate generalization context, invoking SAGE on it. MAC/FAC is used to find a negative example similar to the positive example. If a sufficiently similar exemplar from a different concept is found, near-miss analysis is invoked. Similarly, when a negative example is provided, MAC/FAC is used to retrieve the closest positive exemplar or generalization, which is then used for near-miss analysis.

When given an example to categorize, the model uses MAC/FAC to generate a reminding from each concept's context. The system tests the new example against the classification criteria for each concept. Of the concepts whose criteria are satisfied, the one with the most similar reminding is chosen as the category of the new example.

In explaining our model, we use as a running example learning the concept of an *arch*, which was first used by Winston (1970), who used hand-generated representations.

Near-miss analysis. Winston argued for the importance of *near misses* in learning concepts. A near miss consists of a positive example e_1 (e.g. Figure 3, left) and a negative example e_2 (e.g. Figure 3, right) that differ only slightly.. In analogical reasoning terms, e_1 and e_2 are highly alignable, enabling a learner to conjecture that differences between them could be useful criteria for classification. Two kinds of hypotheses are computed to enhance concept discrimination. *Inclusion hypotheses* represent potential necessary conditions for something to be an instance of the concept. *Exclusion hypotheses* represent potential negative conditions that are sufficient to prevent something from being classified as an instance of that concept.

Near-miss analysis starts with a positive and a negative example. As noted above, one of these examples is a new learning example, while the other is a previous example retrieved via MAC/FAC. A similarity threshold of 0.75 is used for their comparison, to ensure high alignability.

Figure 3 shows a near miss that was processed by our simulation. The positive example is used as the base whereas the negative example is used as the target, and they are compared via SME. SME aligns a with e, b with f, c with g, and the grounds d with h. The conjunction of positive→negative candidate inferences in the mapping becomes a new inclusion hypothesis (Figure 3, h_i) designating criteria that might be necessary for concept membership. Similarly, the conjunction of all negative→positive candidate inferences is becomes a new exclusion hypothesis (Figure 3, h_e) designating criteria that might prevent concept membership. Here the attribute (isa a wedge) is the sole forward candidate inference, so it becomes the inclusion hypothesis h_i . Similarly, the block attribute, touchesDirectly relations, and adjacentTo relations comprise the conjunctive exclusion hypothesis h_e .

Inclusion and exclusion hypotheses are associated with the positive example in the near miss, as shown in Figure 2. Consequently, when MAC/FAC retrieves more than one near miss for a given positive example, the system computes more than one inclusion and exclusion hypothesis about the example, and must combine them. Inclusion hypotheses pertaining to the same example are combined via set union, since all necessary facts must hold for positive classification. Conversely, any exclusion hypothesis suffices to rule out that concept, so they are kept separate.

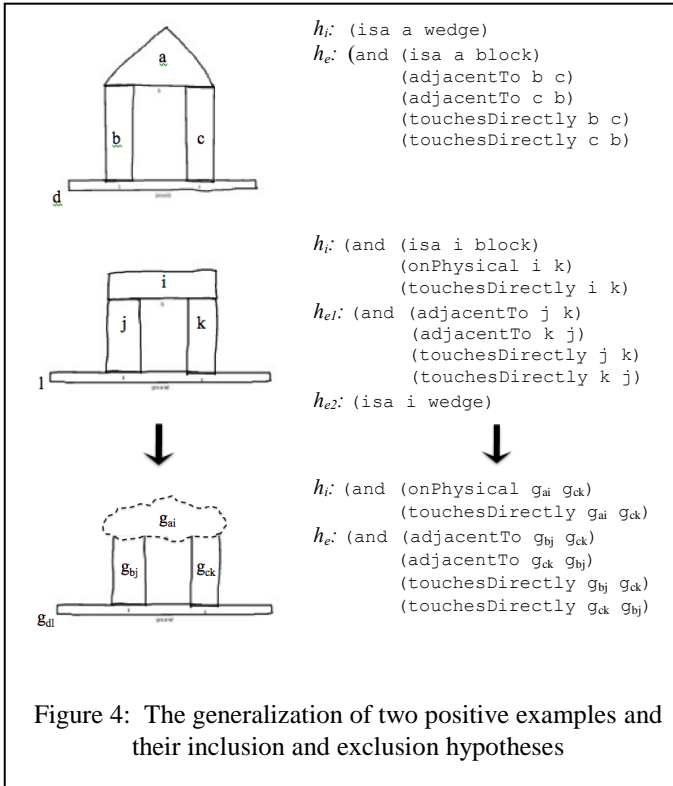

In Figure 3, the inclusion hypothesis h_i generated by the system erroneously asserts that all arches have wedges as their top. This error reflects one learning bias of the model, which is the immediate assumption that all differences detected in the near miss of a concept are important to the definition of the concept. Such errors can be removed during analogical generalization, which we discuss next.

Analogical generalization. During training, our learning system incrementally develops a disjunctive model of a concept through the observation of positive and negative examples. As positive examples are observed, they are added to a SAGE generalization context for the concept, where they are generalized with sufficiently similar

examples. When an example is generalized, resulting in new or larger generalizations (shown in Figure 2) the system revises the near-miss hypotheses associated with the generalization constituents.

Across generalizations, the near-miss hypotheses can be considered disjunctive hypotheses about the concept. For example, suspension bridges may be different enough from beam bridges that the classification hypotheses required of them differ. We can capture this distinction if suspension bridge examples and beam bridge examples form separate generalizations when added to the generalization context for the concept *bridge*. During classification, we may claim that an example is a bridge if it is similar enough to the *suspension bridge* generalization and satisfies the conditions for *suspension bridge*, or if it is similar enough to the *beam bridge* generalization and satisfies the conditions for *beam bridge*. The construction of disjunctive hypotheses based on similarity introduces another learning bias of the model, which assumes that similar examples of a concept are subject to the same rules for membership.

After an observed positive example is generalized with an existing generalization or ungeneralized example, their hypotheses are generalized. Figure 4 shows how a new example (top) and a previously ungeneralized example (middle) are merged into a new generalization with revised hypotheses (bottom).

The first step in generalizing inclusion hypotheses is mapping the hypotheses from their respective generalized examples to the newly created generalization. This involves replacing the names of entities with the names of corresponding entities in the generalization. Next, inclusion hypotheses are pruned by removing any assertions that do

not hold on the new generalization. In Figure 4, the facts $(isa\ a\ wedge)$ and $(isa\ i\ block)$ are pruned from the inclusion hypotheses of the constituent examples because they are not true of the resulting generalization, i.e., the corresponding generalized entity g_{ai} is not known to be either *wedge* or *block*. After pruning, the facts of the two inclusion hypotheses are unioned to create a conjunctive hypothesis associated with the new generalization.

Next, the system uses the generalization operation to identify and discard erroneous exclusion hypotheses. In Figure 4, exclusion hypothesis $(isa\ i\ wedge)$ of the middle example is erroneous because it shares a generalization with the topmost example whose corresponding entity *a* is a *wedge*. Consequently, the exclusion hypothesis is discarded. Remaining exclusion hypotheses are mapped onto the resulting generalization. Finally, the system discards exclusion hypotheses of the resulting generalization that are more specific than other associated hypotheses (i.e., for every exclusion hypothesis composed of fact set *f*, any hypothesis of fact set *f'* such that $f \subseteq f'$ is eliminated). In Figure 4, hypothesis h_e of the topmost example is discarded for this reason.

Classification

Given a new testing example e_{new} , our model decides whether it is an instance of one of its learned concepts. The model decides this using similarity-based retrieval and by testing the hypotheses created during learning.

For each learned concept, the system uses MAC/FAC to retrieve the most similar generalization or ungeneralized example of the concept e_c from the concept's generalization context. The inclusion and exclusion hypotheses associated with e_c (as shown in Figure 2) are used as criteria for classifying e_{new} .

The inclusion and exclusion hypotheses associated with e_c are represented in terms of the entities in e_c , which typically do not exist in e_{new} . Consequently, structural alignment is used to perform the analogical equivalent of rule application. SME is used to find entity correspondences between e_c and e_{new} , and the entities of e_c are substituted with the corresponding entities in e_{new} in each hypothesis.

Testing the classification criteria is the final step in classification. If an inclusion hypothesis does not hold in e_{new} , or if an exclusion hypothesis does hold in e_{new} , it is not an instance of the concept. Otherwise, e_{new} is an instance of the concept. If e_{new} is a viable instance of multiple concepts, given the exclusion and inclusion criteria, the system chooses the concept whose MAC/FAC reminding similarity score was higher. Thus our model of concepts combines both rule-based and similarity-based aspects.

Experiment

We created a series of 44 sketches representing six concepts for learning and categorization, summarized in Table 1. The *false arches*, *false triangles*, and *false squares* sketches are all highly alignable with examples of their associated concept, but are not positive examples themselves.

Table 1: Sketched examples for simulation.

Arches:	8	Triangles:	4
False arches:	8	False triangles:	4
Bridges:	4	Squares:	4
Skeletal arms:	4	False squares:	4
Skeletal legs:	4		

Our experiment follows a four-fold cross validation format covering all 44 sketches. The sketches were randomly assigned to four groups (folds) of 11 sketches each, with the constraint that all groups had the same distribution of sketches from the categories in Table 1 (two arches, two false arches, one bridge, one skeletal arm, etc). The system trained on three 11-example groups, for a total of 33 examples for learning. The remaining group of 11 examples is used for classification testing. We repeat this four times, so each group of 11 examples is used once for testing, resulting in 44 classifications total.

We tested our simulation under two conditions: The *full* condition uses the entire model, while in the *similarity-only* condition, near-miss analysis is turned off. In similarity-only, the system classifies a new example by using MAC/FAC to retrieve a similar representation from the concept context, and asserts concept membership if the normalized SME similarity score is above a threshold of 0.85. We expected that, based on prior experiments (Kuehne *et al* 2000b), similarity-only will learn quite well with only a handful of examples. However, we also expect that it will show false positives due to misleadingly similar negative examples, which near-miss analysis should prevent.

Figure 5: Effectiveness of using structural similarity alone for classification, as a function of similarity threshold.

In the similarity-only condition, 79% correct classification is achieved with a similarity threshold of 0.75 (Figure 5), well above chance ($p < 0.001$). Inspection of the results revealed that almost all of the 20% error can be attributed to false positives. One such false positive is the rightmost example in Figure 3, which shares considerable relational structure with other arches.

With near-miss analysis turned on, 86% correct classification was achieved, which is better than chance with

$p < 0.001$. The number of false positives decreased from eight to two but the number of false negatives increased from one to four due to overly restrictive hypotheses. The rightmost example in Figure 3 was among the negative examples correctly classified. Just as with similarity-only, the model determined that this example was sufficiently similar to a generalization of the concept *arch*. However, it reported a failure to meet classification conditions due to a satisfied exclusion hypothesis,

```
(TheSet (adjacentTo f g)
(touchesDirectly g f))
```

which expresses the justification “This is not an arch because f is adjacent to g and g touches f directly.”

Discussion & Future Work

We have described a model that extends analogical generalization with near-miss analysis to learn concepts from sketches. We have generalized the notion of near-miss that Winston (1970) used in two important ways. First, Winston assumed that near-misses were always provided by a teacher. We have shown that near misses can also naturally arise from the process of similarity-based retrieval, thereby providing more self-direction in learning. Second, Winston’s system had one description of the target concept it was learning, and hence did not capture the possibility of disjunctive concepts and finding the appropriate conceptual representation, which we do via a combination of SAGE and MAC/FAC. A version of the model without near-misses, using similarity alone, performs well over chance. However, similarity alone leads to a pattern of misclassification errors, which is partially corrected by near-miss analysis. The incorporation of classification criteria enables the model to make more expressive justifications for its classification decisions, as in the case of the negative example from Figure 3. We also believe that near-miss analysis will allow the model to more readily benefit from a larger training set, as hypotheses from new near-misses will add potentially valuable criteria to reduce false positives and hypothesis generalization will alleviate over-restrictiveness, which accounted for all but one of the false negatives. We expect the similarity-only classifier to gain less from additional training, since the examples it misclassifies are mostly negative examples that bear high relational similarity to positive examples. Thus near-miss analysis provides an important extension to similarity-based concept learning.

Our concept learning model learns several concepts simultaneously, with relatively few examples. It requires orders of magnitude fewer examples than existing connectionist models of concept learning (e.g., Krushke, 1992; Regier 1996; Elman 1999), and unlike such models, uses automatically encoded relational stimuli, to reduce tailorability. We believe our model makes more realistic demands, although it could be argued that our model learns too quickly. One reason that we see such rapid learning in simulation experiments is that our system, unlike people, has many fewer distracters. Everyday life does not always afford closely packed sequences of similar concept

instances, and human perception may contain more attributes and relations than CogSketch currently computes. However studies such Gentner *et al* (2009) suggest that people can learn spatial concepts quickly with highly alignable near-misses, which our model captures nicely.

Winston (1982, 1986) also explored learning rules from analogies, using simplified English inputs. His system generalized based on one example, rather than several, and produced logical quantified rules, while ours uses analogical matching to apply hypotheses to new examples. His if-then rules and censors are functionally similar to our inclusion and exclusion hypotheses, respectively.

There are several aspects of concept learning that our model does not currently capture. For example, our sketched input does not include causal relationships or goals (Lombrozo, 2009; Rehder & Kim, 2006). Based on prior work (Falkenhainer, 1987; Friedman & Forbus, 2009) we believe our model will handle such information if it is included in the initial encoding, since it basically adds relational structure that influences similarity judgments, and hence classification, in our model. Other factors, such as ontological structure (Medin & Smith, 1984) and centrality and mutability of properties (Sloman, Love, & Ahn, 1998) we believe can be handled by further exploiting the statistical information gathered via SAGE in cross-concept analyses. We plan to explore both of these issues in future work.

Inferring Multitasking Breakpoints from Single-Task Data

Abstract

Recent research has shown that computer users placed in a deferrable multitasking situation generally postpone secondary-task interruptions until points of low mental workload in the primary task. Studies examining this phenomenon have relied on empirical data that explicitly show user switch points in the course of multitask performance. This paper addresses a related question: Can these same switch points, found empirically in a multitasking context, be inferred solely from single-task data? We investigate this question and propose an approach that analyzes a particular behavioral signature in single-task data—outliers in the distributions of time between task actions—to infer multitasking breakpoints. We evaluate this approach using behavioral data from a user-interface task, showing how the proposed method’s inferences from single-task data match well to the real switch points observed during multitask performance.

Keywords: Multitasking; task analysis; data analysis.

Introduction

Multitasking is a concept that is familiar to most computer users. It is not uncommon for a user to switch computing tasks every few minutes. In many cases switching is initiated by an interruption of the current task. For example, a notification of a newly received email may appear on the screen prompting a user to stop what he is doing and look at his email before continuing his previous task. Research has shown that interruptions can increase the overall time spent on a single task. One important source of this increase is the *resumption lag*, or time required to switch back to the task and resume after the interruption has been addressed (Trafton, Altmann, Brock, & Mintz, 2003; Monk, Boehm-Davis, Mason, & Trafton, 2004). Recently it has been shown that it is more beneficial to interrupt at certain points than at others (Adamczyk & Bailey, 2004; Bailey & Konstan, 2006; Cutrell, Czerwinski, & Horvitz, 2000). One particularly strong result states that the performance loss associated with interruption is reduced when interruptions occur at points of low mental workload (Iqbal & Bailey, 2005). This result has obvious importance when considering *forced interruptions* in which the user is required to address the interruption immediately before moving on with the primary task.

The relationship between mental workload and interruptibility has been strengthened in further studies of *deferrable interruptions* (Salvucci & Taatgen, 2010) in which a user is notified of a secondary task but the user can defer processing of this task until a later (presumably more comfortable) time. For example, it has been shown (Salvucci & Bogunovich,

2010) that in this situation users tend to defer switching tasks until a point where there is a drop in mental workload. As exemplified by these studies, a detailed analysis of when users switch tasks is critical to a deeper understanding of human multitasking behavior. A particular goal in this line of research involves the prediction of breakpoints, the points in a task sequence where the user can most conveniently switch tasks.

One approach to breakpoint prediction combines expert coding, feature detection and model prediction (Iqbal & Bailey, 2007). This approach begins by observing users in some natural multitasking environment. An expert manually examines user actions and identifies specific features which appear to signal breakpoints. A statistical model is then developed based on these features. Promising results have been obtained with this method, however it requires the human coders to identify the perceived breakpoints and features, and does not necessarily make use of the relationship between cognitive load and interruptibility. A successful related approach that makes use of mental workload is to examine the typical execution structure of an action in advance and use this structure to estimate opportune breakpoints (Bailey, Adamczyk, Chang, & Chilson, 2006). This method still requires expert analysis and it may fail when variation in strategy is introduced.

There exists a well-known relationship between cognitive load and pupil dilation (Beatty, 1982). Researchers have made use of this link in another approach to breakpoint detection (Bailey & Iqbal, 2008). In this approach, pupil dilation data is recorded as users perform a task, and subtask boundaries, where there is an assumed drop in cognitive load, are estimated by changes in dilation. The result is a more general and more automatic estimation of good potential breakpoints that relies less on pre-computed models or experts. Despite these findings, it may not be possible to obtain pupil-dilation in practice for many tasks.

In this paper we attempt to infer multitasking breakpoints in a automatic, data-driven manner. In this respect our approach is most similar to (Bailey & Iqbal, 2008), but instead of relying on typically inaccessible equipment like eye-trackers, our goal is to come up with the good estimates using only data logs of system events generated by users performing a single primary task. Our analysis focuses on the distributions of elapsed time between recorded event pairs, using single-task data collected for a customer-support task

(Salvucci & Bogunovich, 2010). From our analysis of the recorded data, and particularly the estimation of observed outliers in distribution tails, we were able to infer breakpoints that closely mirror actual deferred user breakpoints as they arose in a multitasking context.

Task and Data

The task that we analyzed is taken from a recent experiment in which users performed a mail-based customer-support primary task while occasionally being interrupted by chat (instant-message) questions. The primary task simulated a typical customer-service scenario where a user receives email inquiries for the prices of a variety of products. The simulation was comprised of a simulated email program and a browser window used for looking up product prices, shown in Figure 1. Each email in the inbox contained a request for the price of a single product. Once the user read the email and became aware of the request, he or she had to look up the product in the browser to obtain the correct price. Each product consisted of a real manufacturer name and a fictitious model identifier (for example, “Canon H-44”, or “Sony M-76”). To find the price of a product, the user had to first click on the proper manufacturer name from the top-level of the browser, and then click on the proper model identifier from a secondary browser level. The user could have at any time returned to the top level of the browser by clicking “home” button. Once the price of the product in question had been located, the user sent a reply email containing the requested information. The users were also asked to manually move the replied to emails to a “replied” bin by clicking and dragging.

In the multitasking setting a secondary chat task was introduced which simulated a typical instant messenger conversation. A chat window was included in which the users were occasionally asked questions about recent films by a simulated interlocutor. The users were notified of a new question by having the chat window flash, but it was up to the users to decide when to break from the primary mail task to address the questions once the notification was received.

It is important to note that in both the single mail task and dual mail and chat task situations, the simulation windows were arranged so that only the window that was currently being focused on could be seen. For example, while looking up a product price in the browser window, the name of the product given in the email window was obscured. This required the users to commit sub-task relevant information to memory.

For our analysis, we look specifically at single mail task data collected from six participants in this experiment. This data was collected in a session where the chat simulation was not present. In particular, our goal is to analyze the single-task data, infer and estimate breakpoints from these data, and then evaluate our estimates by comparing the results to the also collected multitask data. The data recorded for the mail task (both single- and dual-task contexts) comprises a sequence of time-stamped events occurring in the task. Table 1 lists and describes these events. The full data recorded

<i>mail-select:</i>	Select (click on) an email from a list.
<i>mail-move:</i>	Move (drag) an email to the “Replied” bin.
<i>browser-focus:</i>	Change focus to browser window.
<i>browser-home:</i>	Press “browser home” button.
<i>mfr-link:</i>	Click on “product manufacturer” link.
<i>model-link:</i>	Click on “product model” link.
<i>reply-button:</i>	Press “Reply” button to open a new window to compose response.
<i>reply-type:</i>	Type characters in a response email.
<i>reply-send:</i>	Press the “Send” button to send response email.
<i>reply-focus:</i>	Change focus to an opened response window.

Table 1: User events in the mail customer-support task.

for a single event includes the event type, as given in Table 1, the time of the event, and any auxiliary information about the event (for example, which character was typed, or which product link was clicked); we use only the event type and time information here.

Analysis of Recorded Event Data

Starting with the recorded single-task data, we tried several theoretically-motivated approaches for analyzing the data and inferring multitasking breakpoints. In the following sections we discuss several of the approaches that we took. Motivations and limitations associated with each approach are given.

Frequency of Sequences

When relying solely on the frequencies of occurrence of given event sequences, perhaps the most naive hypothesis is that good locations for breakpoints are found between pairs of consecutive events that were observed infrequently. The motivation is that sequences which appear frequently consist of events that are strongly linked together, and thus switching tasks between the events is less desirable or at least less likely.

Problems with this hypothesis arise immediately, however, in noting that it is extremely unlikely or impossible for many pairs of events to occur consecutively. For instance, in the mail task, it is not possible for to observe the event “*model-link*” followed immediately by the event “*mfr-link*” due to the design of the task interface. Other pairs of consecutive events are unlikely due not to the design of the simulation, but simply because they make little sense for any user attempting to complete the mail goal. For example, the sequence “*mfr-link* → *browser-home*” is not useful in looking up a product price, since the price is not obtained until the “*model-link*” event. Any occurrences of “*mfr-link* → *browser-home*” are likely due to an error by the user and there is little reason to believe that this is a good place to switch tasks.

While it is clear that pairs of events with no or few occurrences do not necessarily represent good breakpoints, it still

Figure 1: The customer service mail simulation.

seems possible that pairs of consecutive events with high frequency represent strongly linked events and that task switching should not occur between them. This argument is supported when we compile a list of the most frequent consecutive event pairs and observe that one of the highest frequency consecutive event pairs is “*mfr-link* → *model-link*”. It makes sense that we should link together these actions as they are the ordered steps required to look up a product’s price. There should not be a drop in cognitive load after the “*mfr-link*” event since the model number is still required for the following “*model-link*” event and we should not expect task switching here. On the other hand, another high frequency consecutive event pair is “*reply-send* → *mail-select*”. While these events appear to be strongly linked together, this pair actually does present a reasonable breakpoint. The “*reply-send*” event signals that a response email has been sent and a customer inquiry is completed. Handling a new customer inquiry is always marked by selecting a new mail from the list, or a “*mail-select*” event. It follows that the pair “*reply-send* → *mail-select*” is a task boundary and a drop in cognitive load should accompany it, making this a good breakpoint.

Mean Elapsed Time

A second attempt at identifying breakpoints involves considering the mean elapsed time between events. The hypothesis is similar to the frequency hypothesis: A low mean elapsed time between two events signals a strong link between them that should not be broken, while a large mean elapsed time between events indicates a weak link that may be broken when an interruption occurs.

For a given pair of events such as “*A*” and “*B*”, it is not im-

mediately clear how to construct the frequency distribution. We could look at all occurrences of “*A*” followed by a “*B*” any time thereafter, with the possibility of some events in between. This approach is appealing since it introduces some robustness to “noisy” user errors in the recorded events. We see some positive evidence supporting this choice in the distributions shown in Figure 2(a) and Figure 2(b). In both of these distributions, the mean of the histogram is indicated by a red (lighter) bar. The distribution shown in Figure 2(a) corresponds to the event pair “*mfr-link* → *model-link*”, which as a sequence makes sense in a goal strategy and does not represent an expected boundary of cognitive subtasks. The mean of this distribution is about 1.56 seconds elapsed between the occurrence of the two events. The distribution shown in Figure 2(b) corresponds to the event pair “*model-link* → *reply-button*”, which occurs when the user has completed the task of looking up the price of a product and is about to begin the process of responding to the inquiry. The mean of this distribution is 4.29 seconds of elapsed time between events. The larger mean found here supports the hypothesis, since this pair of events should straddle a subtask boundary and a drop in cognitive load should accompany it.

The idea of considering all occurrences of “*A*” followed some time later by “*B*” begins to break down, however, when we consider the distribution shown in Figure 2(c). This distribution corresponds to the elapsed time between the events “*mail-select*” and “*reply-button*”. The mean elapsed time is 5.66 seconds, which seems to indicate that the events are not strongly linked. The problem with this assessment becomes clear when we take into consideration the variations in task strategies taken by different users. The consequence

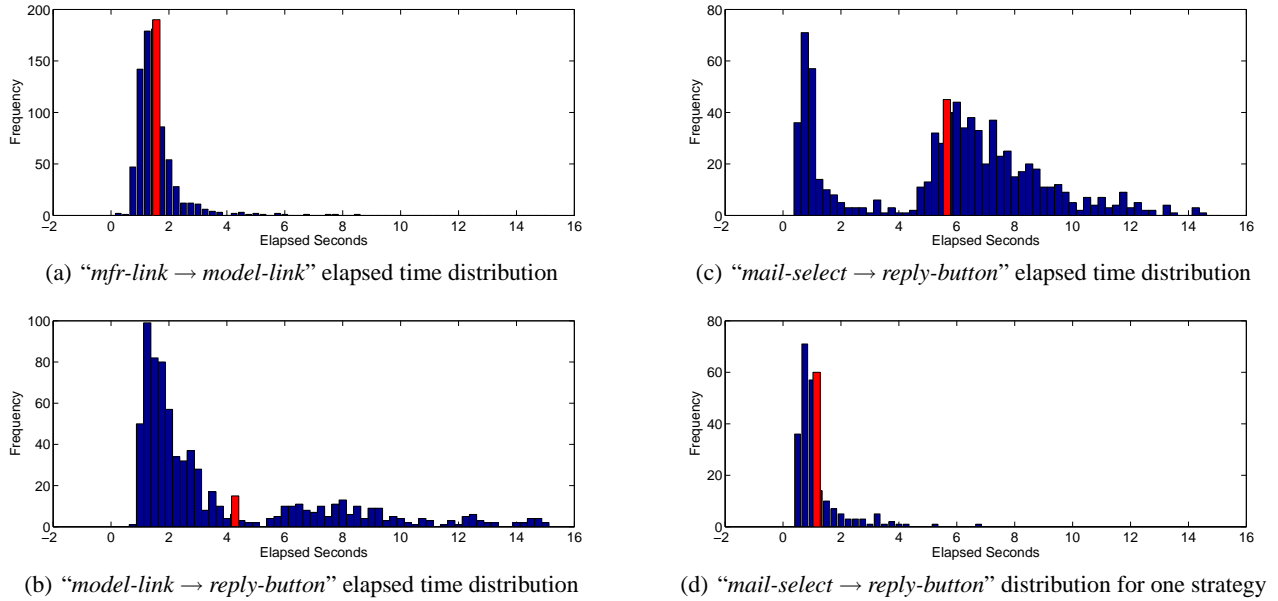

Figure 2: Distributions of elapsed time between pairs of events. The locations of the means are indicated by a red (lighter) bar.

of this is that the sequence “mail-select → reply-button” is strongly linked together in several task strategies, but it is not found in all of them. This explains the two peaks seen in the histogram. The first peak (and the surrounding bins) correspond to the instances of the strategies which make use of the “mail-select → reply-button” sequence, while the second peak corresponds to the remaining strategies. Analyzing this sequence simply based on the mean of all of the possible occurrences does not provide a clear understanding of the data.

Addressing Multiple Strategies

Regardless of the usefulness of the mean elapsed time in indicating the breakpoints, the observation concerning the multiple strategies needs to be addressed in any analysis of distributions. It seems that our distributions represent a classic example of a mixture distribution, which should lead us to consider a method such as expectation maximization (EM) (Moon, 1996) to fit a mixture model to the histogram. Once we’ve found a mixture model, we could then perform clustering to obtain only the instances of event sequences which should correspond to a single strategy. Another approach would be to use the T-Patterns method for identifying the critical interval (Magnusson, 2000) of elapsed time that we should consider acceptable for a given event pair. Both of these approaches present advantages and disadvantages for our data, and are likely to prove both useful and necessary in analyzing tasks containing variation in general.

We decided to use a much simpler approach to identifying the valid instances of a sequence. Based on the task that was assigned, we note that each task trial—the processing of a single email—must begin with a “mail-select” event to view the email. Furthermore, that once a new email has been selected, another “mail-select” event is very unlikely before this first

email has been completely addressed. Following these assumptions, we can segment our raw event data stream into individual mail task instances by using each “mail-select” event as a boundary and consider unique sequences separately. This method is supported by Figure 2(d), where only the instances of the sequence “mail-select → reply-button” which are part of a strategy using those consecutive events are considered in the distribution. When compared to Figure 2(c) we now see a single a peak with a mean of 1.30 seconds versus two peaks and a mean of 5.66 seconds.

By considering instances of consecutive event pairs which are part of a particular observed task strategy, a lot of unexpected behavior in the elapsed time distributions is removed, but not enough to make the mean elapsed time a completely useful indicator of cognitive load or interruptibility. One reason for this lies in the simple nature of the data that was recorded. By comparing just the elapsed time between events “A” and “B”, the analysis does not have at its disposal vital information about possible subtasks being performed. Consider once again the “mfr-link → model-link” sequence. Generally this sequence is observed when the user is looking up the price of a product for a customer inquiry. For one strategy which uses this sequence (actually all strategies must use this), we get a mean of 1.49 and a relatively large st. dev. of 0.59. Based on our hypothesis we should expect both a small mean and variance for such a strongly linked pair of events, but in fact we see a relatively large variance. This contradiction is explained when we consider that after a “mfr-link” event, a user completing this action is required to perform the relatively time-consuming task of reading through the list of model numbers to find the link for the model in question, before the “model-link” event can occur. A similar statement could be made about any event preceding the “mfr-link”

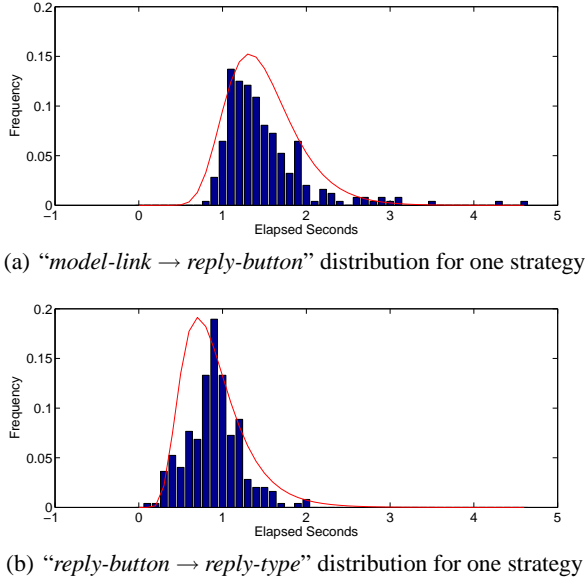

Figure 3: Distributions for instances of pairs found in one strategy. The histograms are shown with a fitted log-normal distribution curve. Note that in 3(a) more of the mass falls in the far right end of its tail than in 3(b).

event. (More detailed data, such as eye-movement recordings, would further inform such an analysis—but again, such detailed data are not available in the general case.)

Tail Mass of Elapsed Time Distributions

Since basic statistics of our elapsed time distributions do provide an adequate signature with respect to multitasking breakpoints, we decided to take a closer look at the form of the distributions. When we compare the histogram distributions for different pairs of events, it becomes clear that certain histograms appear to have longer tails than others. To obtain a better picture of this, we could look at the amount of the histogram mass that falls several standard deviations to the right of the mean. We can also observe modeling the histogram with a normal distribution may not be the best choice, since there can be no negative elapsed times and typically the distributions exhibit an early peak followed by a right end tail. The log-normal distribution has these properties and we can easily find a maximum likelihood log-normal distribution to fit to our observations. Figure 3 shows two pair histograms that have been fitted with log-normal distributions. Figure 3(a) shows the distribution for the pair “model-link → reply-button”, which corresponds to the boundary between the price lookup task and the email reply task and is a reasonable breakpoint. Figure 3(b) shows the distribution for the pair “reply-button → reply-type”, which form consecutive events in the mail reply task and probably is not a good breakpoint. Notice that a significantly larger portion of the total observed mass in Figure 3(a) appears in the far right tail of the fitted distribution than does the mass in Fig-

ure 3(b). Another way to put it is that the “model-link → reply-button” distribution contains significantly more outliers than the “reply-button → reply-type” distribution.

The hypothesis resulting from this analysis is that the amount of observed mass in the far end of the tails (outliers) of distributions of elapsed time between event pairs is a good indicator of the interruptibility between the events. We suspect that the underlying reason relates to people taking short mental breaks between these task steps: by resting for a short time (up to a few seconds) between actions, a person can mentally regroup for the next component of the task. It seems reasonable that such a mental regrouping would occur at higher-level task boundaries, or equivalently at places of low mental workload. Whatever the underlying reason, the tails of the distributions seem to serve as a good signature for multitasking breakpoints, as we detail in the next section.

To identify the outlier observations, we can simply fit the model to our observations and see how many observations fall n standard deviations to the right of the mean. Since we are specifically interested in outliers in the far right end of the tail, we should set n to be large, possibly $n = 3$ or 4. This simple method will certainly identify some outliers, but we can improve the method by performing it iteratively. In the iterative approach, we first fit the model, find the estimated std. dev., remove outliers n standard deviations from the mean from the distribution, and repeat. At each iteration the estimated mean will shift slightly to the left and we will consider more observations to be outliers. For large fixed n the estimates converge after a few iterations (i.e., no new outliers are found). At that point we have a good estimate of the percentage of the total observations which can be considered outliers.

Results

To evaluate the outlier-based inference of multitasking breakpoints, we selected the events corresponding to the most frequently observed mail task strategy that we obtained from our data segmentation procedure. The complete sequence has the form: *mail-select*, *browser-focus*, *browser-home*, *mfr-link*, *model-link*, *reply-button*, *reply-type*, *reply-send*, *mail-select*. We calculated the outliers for each pair of consecutive events, and formed a normalized histogram of breakpoint likelihoods where the frequency of each bin is based on the number of outliers that were found. Our results were obtained using a log-normal distribution to fit our elapsed time distributions and a value of $n = 3.75$ standard deviations for the identifying outliers. Using the accompanying multitasking (mail and chat task) data, we also constructed a similar histogram of the actual deferred breakpoints that we taken by users while employing this strategy.

Both of the resulting histograms are shown in Figure 4. The inferred results match reasonably well to the observed breakpoints, $R = 0.83$. We obtained similar but not as good results using the normal distribution, and for several observed secondary strategy sequences.

(a) Observed Proportions of Breakpoints while Multitasking

(b) Proportions of Breakpoints Inferred from Single-Task Data

Figure 4: Comparison of actual breakpoints taken in (Salvucci & Bogunovich, 2010) with the outlier inferred breakpoints for the most frequent strategy: (1) *mail-select*, (2) *browser-focus*, (3) *browser-home*, (4) *mfr-link*, (5) *model-link*, (6) *reply-button*, (7) *reply-type*, (8) *reply-send*, (9) *mail-select*.

Discussion

To summarize, we found that the outliers (tails) of the distributions of time between task actions in a single task setting served as a good indicator of multitask breakpoints, were a secondary task to be introduced: The presence (or lack) of outliers in the tails of the distributions correlated well with people's tendency to switch away from a task between two given actions. These conclusions build on the results of (Bailey & Iqbal, 2008) which showed that users produce evidence of potential interruptibility in a single-task setting, but the proposed method was able to identify similar evidence using solely time and event data (rather than pupil-dilation or other data that may be more difficult to obtain). Our results suggest that when performing a task, users may occasionally take a short breaks (up to a few seconds) when a cognitive subtask is completed and before beginning a new subtask. Analysis based on this idea agrees well with multitask data from (Salvucci & Bogunovich, 2010) and hints at a strong relationship between distribution outliers and boundaries of cognitive subtasks.

Abstract

Intelligent Tutoring Systems are often modeled after human tutors; however, the effectiveness of this strategy is yet to be determined. Research on media interactions suggests that behaviors with humans are similar to those with computers. Intelligent Tutoring System studies have said the opposite. In this study we compared a human-human and a human-computer tutoring system in terms of metacognitive, social, and nonsense statements to dig deeper into these interactions. We discovered that the interactions were quite different between human-human and human-computer tutoring. With a human, participants expressed more positive metacognitive statements and social statements. When interacting with a computer tutor, students were more likely to make negative metacognitive statements and social statements. In addition, the interpretation of these results differed between the two corpora. In human-human tutoring, the more often a participant made positive metacognitive statements, the worse their learning gain. Their social dialogue had no impact on learning gain. In human-computer tutoring, the more negative and positive metacognitive statements and the more negative social statements they gave the worse their learning gain. It is clear from this study that students do not act the same with a human tutor as they do with a computer tutor. Therefore, designers of ITS systems should not just blindly model their systems after human tutors. The differences in human and computer interactions should also be considered.

Keywords: Human Computer Interaction (HCI), Intelligent Tutoring Systems (ITS), Metacognition, Social dialogue, Tutorial dialogue

Introduction

Over the years, Intelligent Tutoring Systems (ITSs) have become popular learning and teaching tools. Thus, their design is becoming more sophisticated. One approach to creating ITSs is to model them after a human tutor because human tutoring has been said to be the most effective form of teaching (Bloom, 1984). However, it has not yet been

determined that this is a good strategy. Two unresolved questions are whether you will find the same kinds of dialogue when a student is interacting with a human and a computer tutor (ITS) and whether those types of dialogue can be interpreted in the same way with regards to the learning that is occurring.

Research on media interactions has stated that people interact socially and naturally with media (to include computers) as they do humans (Reeves & Nass, 1996). The researchers suggest that people follow rules of social relationships when interacting with media and that this occurs naturally and unconsciously. For example, media has been shown to induce emotions such as frustration and politeness.

Similarly, studies examining interactions with virtual humans have shown that people react in the same manner to these entities as they do with other humans (Zanbaka, Ulinski, Goolkasian, & Hodges, 2004; Pertaub, Slater, & Barker, 2002). While being observed by a crowd of virtual agents, people showed nervousness just as they did with a human audience. Women also show social inhibition effects with virtual agents like they do with humans.

In contrast, more recent research using ITSs has shown that students do not behave the same with computers as they do with humans, as evident in their dialogue acts. When students were conversing with a computer, but believed they were conversing with a human, they used more words and conversed longer than did students who were told they were talking to a computer (Schechtman & Horowitz, 2003). In addition, students provided more explanations and longer turns when they believed they were talking to a human versus a computer, even though they were talking to a computer in both cases (Rosé & Torrey, 2005).

Therefore, results as to how people respond to computers and computer entities, in comparison to humans, are mixed. While previous ITS studies have looked at the content based dialogue (dialogue relevant to the lesson material), we took

a broader perspective and considered other dialogue categories, such as metacognition, because they have also been shown to predict learning gain (Campbell et al., 2009). We examined and compared a human-human and a human-computer tutorial dialogue corpus. We categorized five types of dialogue found in these corpora. Most of the dialogue was related to the content of the lessons. The other four categories of dialogue that were present were management (discussing the flow of the lesson), metacognition (describing one's understanding), social (chit-chat and signs of frustration), and nonsense words (random sequences of letters). For this comparison, we will focus on metacognition, social dialogue, and nonsense words because these are the categories where research hasn't yet explored and, we believe, will also differ in regards to the interactions.

Method

To explore our research questions we conducted a human-human and a human-computer study. The two corpora were then analyzed and compared in terms of their dialogue.

Human-Human Tutoring Study

Data collection environment

A curriculum incorporating lessons on basic electricity and electronics was constructed. The curriculum covered topics including open and closed paths, voltage reading between components and positive and negative terminals, series and parallel configurations, and finding faults in a circuit with a multimeter. These basic concepts were taught in a computer-based learning environment within a single session lasting approximately four hours¹.

Figure 1 shows a screenshot of the learning environment that the participants interacted with during the study. The screen was divided into three sections. The top left-hand section displayed the core lesson material in slide form, including educational text, activities, and discussion questions. The participants were able to move through the lesson slides at their own pace. The top right-hand section provided participants with a circuit simulator, which allowed them to construct and manipulate circuits as a supplement to the material in the slides. The bottom section was the chat window where the participants and tutor conversed by typing.

The tutor and student were located in the same room, but were separated by a divider. The tutor had the ability to observe the student's learning environment and interact with the student through a computer screen and chat window. The tutor gave feedback, technical assistance, and/or encouragement that he or she considered appropriate. Participants directed their answers, comments, and/or questions to the tutor throughout the curriculum.

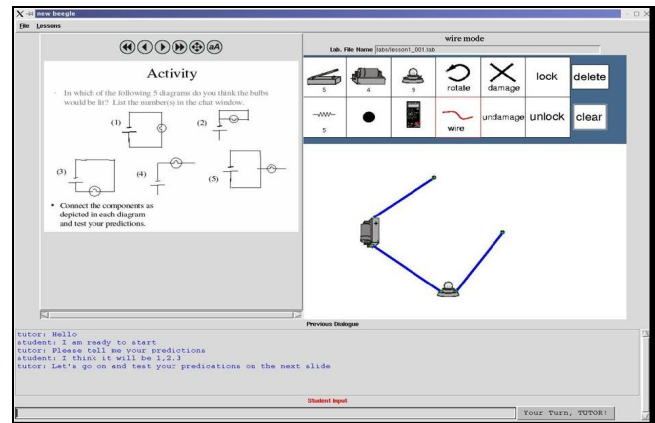

Figure 1. Participant screen for human-human tutoring.

Procedure

After completing informed consent paperwork, participants filled out a demographic questionnaire and took a pre-test consisting of 38 multiple choice questions. The participants were then introduced to their tutor and given a brief demonstration of how to operate the learning environment. The students spent the majority of the experimental session working through the lesson material and building circuits. At the conclusion of the experiment, participants completed a post-test, which included 21 multiple choice questions, and a reaction questionnaire. They were then debriefed and excused.

Corpus

The corpus of the human-human study was comprised of dialogues from each of the thirty participants distributed across three experienced tutors. The average age of the participants was 22.4 years ($SD = 5.0$) and exactly half of them were female. The corpus of this study includes 8,085 dialogue turns taken by the student and tutor and 56,133 tokens (words and punctuation).

Human-Computer Tutoring Study

Data collection environment

As much as possible, the same curriculum as the human-human study was used in the BEETLE II computer tutoring system (Dzikovska et al., 2010). Small changes were made to the curriculum so that the computer would be able to understand student responses (e.g., multi-part questions were simplified into single questions). The computer tutor (ITS) was created to implement the effective tutorial strategies used in our human-human corpus (e.g., hints). The ITS understood and responded to content (by providing feedback) and negative metacognitive statements (by giving a hint) made by a student, but not to the other types of dialogue (management, social, and nonsense). The responses and feedback given by the ITS was modeled after the human tutors from the previous corpus. The ITS used a friendly and encouraging tone similar to the human tutor. In

¹ Note that there was a second session, covering additional topics, but it will not be addressed further in this paper.

fact, in most cases, the ITS used identical phrasing for its comments to the student.

A screenshot of the learning environment is shown in Figure 2. The learning environment was similar to that of the human-human environment. The screen was divided into three sections. The upper left-hand section had the same function as the previous study; however the navigation buttons were slightly different. The right-hand section was the chat window where the participants and tutor interacted through typing. The lower-left section included the circuit simulator, which had the same purpose as the previous study, although the tools used to build circuits had a different display interface.

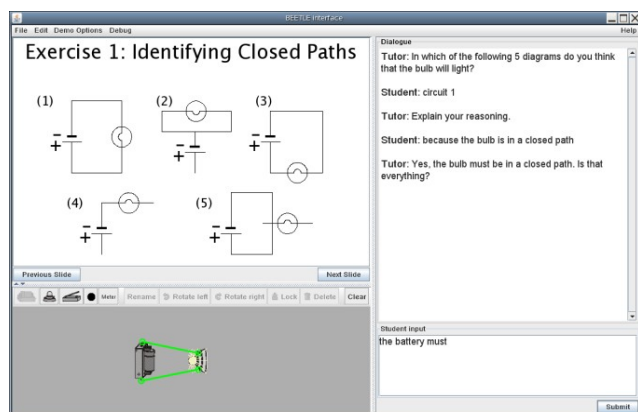

Figure 2. Participant screen for the BEETLE2 ITS.

Procedure

The procedure for the human-computer study was essentially the same as the human-human study with a few exceptions. The pre-test consisted of 22 multiple choice questions and the post-test consisted of 21 multiple choice questions. The human-computer pre-test had fewer questions because we removed questions associated with material from the second session of the human-human study, as mentioned earlier. In addition, instead of a reaction questionnaire at the conclusion of the study, participants were given a usability and satisfaction questionnaire.

Corpus

The human-computer corpus consists of dialogues from each of the forty-one participants in the study. The average age of the participants was 20.8 years ($SD = 3.30$) and there were almost twice as many females as males. The corpus includes an estimated 34,900 total dialogue turns taken by the student and tutor and an estimated 398,410 total tokens. There were many more dialogue turns and total tokens in the human-computer study because the computer asked the questions in this study (versus them being presented on the lesson slides in the previous study). In addition, more questions were presented in this study because, as stated earlier, multi-part questions were simplified into individual questions.

Coding

For the human-human data, two independent raters coded the student-tutor transcripts and were able to identify and distinguish between content, management, metacognitive, and social dialogue statements with perfect reliability ($\kappa = 1.00$). In addition, raters were able to differentiate between positive and negative metacognitive statements made by the student with high inter-rater reliability ($\kappa = 0.99$).

For the human-computer data, four independent raters coded the student-tutor transcripts and were able to identify and distinguish between content, management, metacognitive, social dialogue, and nonsensical statements with high reliability ($\kappa = 0.88$). In addition, raters were able to differentiate between positive and negative metacognitive statements made by the student with high inter-rater reliability ($\kappa = 0.96$).

A summary of the codes used in this study are presented in Table 1.

Content statements were described as comments including domain concepts that pertained to the lesson material. Answering a question fit into the content category (e.g., "The battery and the bulb in diagram 1", "1.5 volts", etc.).

Management consisted of dialogue that dealt with the flow of the lesson but does not contain information relevant to the lesson topics (e.g., "I give up", acknowledging the tutor's instructions to continue by saying, "OK", etc.).

Metacognitive statements were defined as statements that contained the student's feeling about his or her understanding, but did not include domain content. Metacognitive statements were further classified as positive or negative. Positive metacognitive statements were defined as statements that expressed understanding (e.g., "I get it", "I understand", etc.), whereas negative metacognitive statements expressed confusion (e.g., "I don't understand", "Give me a hint", etc.).

Social dialogue includes positive and negative statements. Positive social dialogue was defined as statements that included humor, rapport, chit-chat, and saving face. Examples included "Ha-ha", "Hi, how are you?", etc. Negative social statements included expressions of frustration, explicit refusals to cooperate, and even offensive statements. Examples included "Because I said so", "No", "You're stupid", expletives, etc.

Nonsense was classified as statements that were made up of random letters or numbers that are not content related (e.g., "ufghp", "3i9f", etc.). Nonsense did not occur in the human-human dialogue; therefore it was not coded in those transcripts.

Since we wish to look beyond just the content dialogue, we will focus on metacognition, social dialogue, and nonsense words in our results. Management was left out of the analyses because it was not very prevalent in the computer tutoring data and, when it was, it was ignored by the tutor. Also, it was not a relevant predictor of learning gain with the human tutor.

Table 1. Coding summary

Code	Definition	Example
Content	Statements including domain concepts that pertain to the lesson	"There is a battery and bulb in circuit 1." "1.5 volts."
Management	Dialogue that does not contain information relevant to the lesson material, but deals with the flow of the lesson	"I give up." "O.k." Acknowledging the tutor's instructions to continue
Metacognition	Statements containing the student's feelings about his or her understanding, but does not include domain concepts	Metacognitive statements can be positive or negative.
<i>Positive</i>	Statements that express understanding	"I get it." "I understand." "Oh, o.k."
<i>Negative</i>	Statements that express confusion	"I don't know." "I don't understand."
Social Dialogue	Dialogue that is not related to the content of the lessons and serves as motivation, encouragement, humor, frustration outlets, etc.	Social statements can be positive or negative.
<i>Positive</i>	Statements that include humor, rapport, chit-chat, or saving face	"Ha-ha" "Hi, how are you doing?"
<i>Negative</i>	Statements that include frustration, refusal to cooperate with the system, or offending the system	"Because I said so." "No." "You're stupid." Expletives
Nonsense	Random sequences of letters or numbers that do not pertain to the lesson material	"oidhf" "dsfahdgdfh"

Results

Learning Gain

Pre- and post-test scores were calculated in terms of percentage correct. A learning gain score was then calculated for each participant using the formula: (post-test score – pre-test score)/(1- pre-test score).

Metacognitive Statements

Students made metacognitive statements in both studies, regardless of whether the tutor was a human or a computer; however, the relative frequencies of positive and negative metacognitive statements depended upon the type of tutor. Specifically, students talking to a human tutor made significantly more positive metacognitive statements ($M = 12.9$, $SD = 8.3$) than negative metacognitive statements ($M = 1.8$, $SD = 2.0$), $t(28) = 7.16$, $p < 0.001$. Students talking to a computer tutor, on the other hand, made significantly more negative metacognitive statements ($M = 3.8$, $SD = 5.5$) than positive metacognitive statements ($M = 0.2$, $SD = 0.5$), $t(39) = -4.21$, $p < 0.001$.

The implications of the presence of metacognitive statements also varied depending upon the type of tutor. For students interacting with a human tutor, the amount of positive metacognitive dialogue, but not negative metacognitive dialogue, was significantly negatively correlated with learning gains; $r = -0.543$, $p = .002$ and $r = -0.210$, $p = 0.266$, respectively. However, for students interacting with the computer tutor, the frequency of both types of statements were negatively correlated with learning gains (positive statements: $r = -0.419$, $p = 0.006$; negative statements: $r = -0.537$, $p < .001$).

Social Statements

While students made social statements with both types of tutors, students interacting with a human tutor made exclusively positive social statements and students interacting with the computer tutor made exclusively negative social statements. On average, students interacting with a human tutor typed 37.5 positive social words to their tutor ($SD = 52.3$) and students interacting with the computer tutor typed 8.5 negative social words ($SD = 20$).

Interestingly, the amount of social dialogue with human tutors was unrelated to student learning gains, $r = -0.211$, $p = 0.262$, but the amount of social dialogue that the student produced when interacting with the computer tutor was negatively correlated with learning gains, $r = -0.372$, $p = .017$.

Nonsense

Finally, as mentioned earlier, students spontaneously exhibited a novel type of "utterance" when interacting with the computer tutor – nonsensical sequences of letters and/or numbers. On average, the students submitted nonsense to the computer tutor 1.7 times. There was quite a bit of variability across students in their likelihood of exhibiting this behavior, with a standard deviation of 5.1. This behavior was not statistically related to learning gains, $r =$

-0.073, $p = 0.651$. However, not surprisingly, the frequency of this behavior was significantly negatively correlated to the students' report of satisfaction with the computer tutor, $r = -0.33$, $p = 0.035$.

Discussion

As stated before, ITSs are often modeled after human tutors, but it is uncertain whether these interactions are similar and can be interpreted in the same manner. In fact, we found that students did not respond similarly to the computer tutor as they did with the human tutor. In both corpora, student's dialogue included metacognitive statements, but the nature of those statements was very different. With a human tutor the statements were mostly positive acknowledgements, whereas with the computer they were negative statements expressing confusion.

Social dialogue differed drastically as well. With a human the social dialogue was all positive and served the purpose of creating rapport. With the computer, the social dialogue was all negative and was concerned more with showing frustration with the system. Nonsense did not occur in the human corpus at all. This was a new category that occurred in the computer corpus only.

The human-human and human-computer dialogues also differ in their interpretations, specifically in the metacognition and social categories. In the human-human corpus, metacognition was a negative predictor of learning gain only when it consisted of positive statements. The more frequently students said things like "I get it" the worse they did. In the human-computer corpus, both types of metacognitive statements (positive and negative) were a bad sign, though they rarely gave positive metacognitive statements.

Social interactions also differ in their interpretation. With human-human tutoring, social dialogue was not related to learning gain, whereas in human-computer tutoring it was negatively correlated with learning gain. The social statements made in the ITS environment were all negative, reflecting the participant's frustration. Thus, expressing frustration through social dialogue was a good indicator that the student was struggling with the content.

These results indicate that interactions and interpretations may indeed be different between human-human and human-computer tutoring. They also suggest that perhaps human tutors are able to handle negative metacognitive statements like "I don't get it" more effectively than our computer tutor, since negative metacognition was not negatively correlated with learning gain in the human-human corpus.

Overall, it appears that politeness may be playing a role in human-human interactions, but is put aside in human-computer interactions. When conversing with another human, participants positively acknowledged what their tutor said and participated in rapport building with chit-chat. This seems to be driven by a need to be polite and courteous to the tutor, but wasn't a good indicator of what was really going on as far as learning was concerned. Based on the results, you may not be able to really trust a student who says "I understand" when they are interacting with a human

because it is unclear if they really understand or if they are just being polite.

On the other hand, when interacting with a computer tutor, participants appear to be more honest in terms of their negative statements. If they show signs of confusion or frustration, they really seem to be indicating that they are struggling with the lessons. Such signs can be interpreted as more accurate indicators that additional remediation is needed. The rules of politeness are ignored and the true story seems to emerge.

From this study we found that students will not necessarily act the same with a computer tutor as they do with a human tutor. This suggests that designing an ITS to try to mimic a human tutor may not be the best strategy. The differences in interactions should also be considered. For example, positive social statements were not related to learning gains, so they do not necessarily need to be supported in an ITS; however, negative social and nonsense statements were negatively correlated with learning gains in the ITS and should be addressed. Perhaps additional help should be given or students should be offered a break when these forms of dialogue occur. All forms of metacognition impacted learning gain in the human-computer corpus, thus they should all be addressed in the ITS. Possibly giving additional remediation to students who make metacognitive statements could be helpful.

While modeling a human tutor may be a reasonable first step in the design of an ITS, the design cannot stop there. The ITS needs to be evaluated and tested with users to determine its effectiveness. Tweaks to the system should be made according to the ITS evaluation, like the ones suggested above, for each individual system and curriculum.

In this study we tried to model the human tutor as much as possible, but were limited by the current technological capabilities in computational natural language processing. Further advancements and improvements to the system's capabilities might yield different results. Additionally, these comparisons should be replicated in other domains and other curriculums to see how results compare. It would also be interesting to compare human-human and human-computer tutoring with spoken dialogue to see if the results would hold since tutoring is commonly done in spoken form.

Acknowledgments

We would like to thank our sponsors from the Office of Naval Research, Dr. Susan Chipman and Dr. Ray Perez, three former Research Associates who worked on this project, Leslie Butler, Lisa Durrance, and Cheryl Johnson, and two additional team members, Elaine Farrow and Charles Callaway for their contributions to this effort.

Abstract

We present a computational model for the incremental acquisition of word meanings. Inspired by Complementary Learning Systems theory the model comprises different components which are specifically tailored to satisfy the contradictory needs of (1) rapid memorization of word-scene associations and (2) statistical feature extraction to reveal word meanings. Both components are recurrently coupled to achieve a memory consolidation. This process reflects itself in a gradual transfer of the knowledge about a word's meaning into the extracted features. Thereby, the internal representation of a word becomes more efficient and robust. We present simulation results for a visual scene description task in which words describing the relations between objects have been trained. This includes relations in size, color, and position. The results demonstrate our model's capability to acquire word meanings from few training exemplars. We further show that the model correctly extracts word meaning-relevant features and therefore perceptually grounds the words.

Keywords: Word Learning; Computational Model; Complementary Learning Systems; Categorization

Introduction

When hearing a novel word, a language learner has to associate the word with its meaning. Establishing such word-meaning mappings is an inherently difficult task as the learner initially cannot know to what the word refers to. Quine (1960) illustrated this problem with the example of a stranger who hears a native saying "gavagai" after seeing a rabbit. How can the stranger determine the meaning of "gavagai"? It may refer to the rabbit, a part of the rabbit, its color, any fast moving animal, or even that a rabbit is tasty. This problem, usually referred to as *referential uncertainty*, cannot be solved from a single word-scene pairing. Rather the use of the word in different contexts enables the learner to extract its meaning. Nevertheless, children learn the meaning of words from few exposures to them. They rapidly construct hypotheses about word meanings, which may initially be linked to specific contexts in which the words occurred. Over time, however, children generalize among different observations, even though this may result in an overextension of a word's use (MacWhinney, 1998). This remarkable ability of children has been subject to many studies and resulted in numerous theories on early word learning.

In this paper we present a computational model for the incremental acquisition of word meanings which is inspired by the learning capabilities of children. More precisely, the system has been designed to rapidly build internal representa-

tions of words from few training samples. The thus acquired knowledge can be used to generalize to previously unseen scenes. Moreover, the framework is endowed with a learning mechanism that extracts features which are relevant to the core meaning of a word. This is done by exploiting the statistical evidence which resides from a word's use in different contexts. Our model tightly couples the rapid memorization of word-scene associations with the statistical feature extraction. This results in learning dynamics which resemble a gradual knowledge transfer and consolidation.

We will present experimental results which validate the model. Therefore, the model has been applied in a simulated visual scene description task where words for the relations between pairs of geometric objects have been trained. This includes relations in position, color, and size. The results from this experiment illustrate that our model rapidly acquires word meanings from few training exemplars and further extracts word meaning-relevant features.

The remainder of this paper is organized as follows. Next, we will review existing approaches for word meaning acquisition and relate our model to them. Afterwards, we will state contradictory needs that computational models have to satisfy. We proceed with the presentation of our computational model and subsequently show experimental results for it. Finally, we give a summary and outline our future work.

Related Work

Existing computational models address different levels of referential uncertainty. Firstly, there are approaches which consider the problem of how a learner establishes a mapping between words and a set of pre-defined meanings (e.g. Siskind, 1996; K. Smith, Smith, Blythe, & Vogt, 2006; Fontanari, Tikhonoff, Cangelosi, Ilin, & Perlovsky, 2009). In these models the first occurrence of a word typically induces multiple hypotheses about its meaning. These hypotheses become subsequently pruned either by incorporating learning constraints (Markman, 1990) or via *cross-situational learning* (L. Smith & Yu, 2008) - a technique making use of the statistical evidence across many individually ambiguous word-scene pairings. However, these models disregard the fact that learners can seldom rely on a set of pre-established concepts. Word meanings rather become flexibly constructed and shaped through language use (Boroditsky, 2001).

Therefore, a second group of models further asks how language use yields sensori-motor concepts to which words become associated (e.g. Steels & Kaplan, 2002; Skocaj et al., 2007; KIRSTEIN, WERSING, GROSS, & KÖRNER, 2008; Wellens, Loetzsch, & Steels, 2008). In these models the learner observes the world through multiple (analog or discretized) input channels. The words finally serve as labels for categories, which become incrementally constructed on the multi-dimensional input space and gradually refined by concentrating on the most important input dimensions.

Lastly, there are models which aim at the acquisition of both phonological form and semantic form. Such models either build perceptual clusters in the acoustic space and the semantic space and subsequently associate them with each other (Yu & Ballard, 2003; Goerick et al., 2009) or clustering is directly carried out in the joint acoustic-semantic space (Roy & Pentland, 2002).

The model we present in this paper falls into the second group of methods, i.e. based on the observation of multiple word-scene pairs it acquires perceptual categories by which the words become grounded. To achieve realistic word meaning acquisition we further place several requirements on our model: (1) It should be capable of learning during online operation. Consequently, the model has to apply incremental learning techniques as training exemplars sequentially arise during a learner's interaction with its environment. (2) The model should further rapidly learn from few examples and afterwards apply the acquired knowledge to generalize to novel scenes. (3) However, to be efficient and robust the internally built categories should reflect the core structure underlying the word meanings. Thereby, we use the term *core structure* to refer to the essential aspects which define the meaning of a word. (4) Lastly, for systems with minimum predefined knowledge this core structure is usually hidden and thus cannot be directly accessed by concentrating on input dimensions which carry the meaning. The model rather has to extract word meaning-relevant feature dimensions in terms of a transformation from the input space.

The combination of these requirements is what distinguishes our model from existing approaches. Particularly the combination of rapid incremental learning with word meaning-relevant feature extraction has (to our best knowledge) not been realized previously. In (Skocaj et al., 2007; Wellens et al., 2008) and most notably (KIRSTEIN et al., 2008) feature selection is applied, i.e. the learning focuses on the input dimensions which are considered to be relevant for representing the word meanings. By doing so the approaches inherently rely on the assumption that words can be grounded in a subset of the input dimensions. This in turn means that significant knowledge about the words to learn has to be put into the system by the designer. In contrast, our system generates new word meaning-relevant feature dimensions out of a set of basic input dimensions. We consider this ability to be crucial for life-long incremental learning systems for which the extent of words to be learned is unknown at design time.

Complementary Learning Systems Theory

The way how children acquire the meaning of new words is fascinating in multiple respects. When they hear a word for the first time they already get a glimpse on what it may mean. This ability may be facilitated by learning constraints or biases (Markman, 1990). It is anyway non-disputable that even the exposure to just a few uses of the word enables the child to generalize and apply the word in novel contexts. Even though generalization may occasionally result in errors (MacWhinney, 1998), over time children robustly identify the core meaning of a word.

A Computational Learning Dilemma

Modeling word meaning acquisition computationally, however, is difficult as contradictory needs have to be simultaneously satisfied. McClelland, McNaughton, and O'Reilly (1995) illustrated this fact on the example of artificial neural network models: On the one hand, the learning from few training samples requires a rapid or even one-shot memorization of the items which can be achieved by using high learning rates. This implies that localized representations, which keep the memory items separated from each other, have to be used. Otherwise, a neural network would suffer from *catastrophic forgetting* - the problem that the incorporation of new knowledge overwrites previously memorized items. On the other hand, the extraction of the core structure underlying a word meaning necessitates a statistical learning approach as knowledge has to be accumulated over many training exemplars. Such a learning can be achieved using low learning rates and overlapping representations. Artificial systems, which learn from few examples while they simultaneously extract statistical evidence, are consequently difficult to achieve.

A Solution to the Problem

Obviously, humans (and particularly children) successfully solve this learning task. Endowing artificial systems with mechanisms inspired by human learning may consequently lead a way to overcome the dilemma. *Complementary Learning Systems (CLS) Theory* (McClelland et al., 1995) suggests that the human brain makes use of separate but tightly coupled learning and memory devices which are specifically tailored to satisfy the contradictory needs. More precisely, it is proposed that new memories are first stored in the hippocampal system which is known to perform rapid learning while utilizing localized representations. The hippocampal system further allows the reactivation of recent memories during rest or sleep. This reactivation in turn enables neocortical areas to extract the core structure underlying different memories via *interleaved learning* - a technique where new items become gradually learned while learning is interleaved with the memorization of other items. Consequently, a gradual memory consolidation and transfer from the hippocampal system to neocortical sites can be observed. Furthermore, there is behavioral and neuroscientific evidence which is in accordance with a CLS theory for the lexical and semantic acquisition of novel words (Davis & Gaskell, 2009).

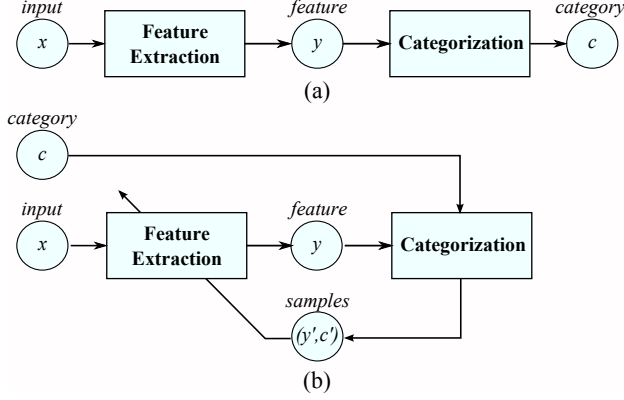

Figure 1: Architecture of the computational model: (a) Input samples x become transformed into feature patterns y which are subsequently categorized. (b) During learning the system components are recurrently coupled (see text for details).

Computational Model

In what follows we treat word learning as category learning. This is reasonable as a word refers to collections of entities which belong to the same category. Word meanings are consequently the conditions underlying category membership (Bloom, 2000). We restrict our description to the learning of one word. Multiple words can be learned straightforwardly by creating multiple instances of the system. As shown in Fig. 1, the framework consist of a feature extraction layer and a categorization layer which are recurrently coupled. The feature extraction transforms an input pattern x into a feature pattern y for which a category membership c is subsequently calculated. Here, c is a binary variable which signals whether the category's word label is appropriate for the description of the input pattern ($c = +1$) or not ($c = -1$).

Our model is largely inspired by CLS theory. Nevertheless, the model is not meant to provide a 1:1 mapping to certain brain areas. It rather resembles CLS theory from a functional perspective. For this reason, we will highlight functional correspondences of our model with different brain areas.

Feature Extraction

In the feature extraction layer word meaning-relevant features, which facilitate the subsequent categorization of a pattern, should become extracted. The learning consequently has to exploit the statistical evidence stemming from the observation of multiple word-scene pairings. Such a statistical feature extraction is obviously part of neocortical learning.

In (Hild, Erdogmus, Torkkola, & Principe, 2006) a learning technique called Maximizing Renyi's Mutual Information (MRMI) has been proposed. MRMI tries to maximize the information that the feature patterns carry about category memberships. Hence it is ideally suited to accomplish the learning task. We restrict learning to a linear feature extraction of form $y = R \cdot x$. We consequently aim at the identification of a transformation matrix R such that the mutual information $I(Y; C) = H(Y) - H(Y|C)$ between the feature patterns and

Figure 2: The architecture of an NGnet.

category labels becomes maximized. By relying on Renyi's quadratic entropy $H_2(Y)$ and its estimation using Parzen windows (Hild et al., 2006) the criterion to be maximized is

$$I(Y; C) = -\log \frac{1}{K} \sum_{k=1}^K G(y(k) - y(k-1), 2\sigma^2) + \sum_{j \in \{-1, +1\}} \left(\frac{K_j}{K} \log \frac{1}{K_j} \sum_{k=1}^{K_j} G(y_j(k) - y_j(k-1), 2\sigma^2) \right). \quad (1)$$

Here, $G(z, \sigma^2 I) = \exp(-\frac{1}{2} \frac{z^T z}{\sigma^2})$ is a Gaussian kernel, $y_{+1}(k)$ and $y_{-1}(k)$ denote the k -th exemplars of feature patterns belonging to a category or not, K_{+1} and K_{-1} are the numbers of such patterns, and $K = K_{+1} + K_{-1}$. Since $y(k) = R \cdot x(k)$, we can estimate R via stochastic gradient ascent on $I(Y; C)$.

To de-correlate the feature dimensions and to perform dimensionality reduction we additionally apply Principal Component Analysis (PCA) on the extracted features. By assuming the inputs x to be white with zero mean and unit variance, the principal feature dimensions can be obtained via eigendecomposition of $R \cdot R^T$. Let Ψ be the matrix of eigenvectors whose cumulative energy content exceeds a threshold. Then we calculate feature patterns y according to

$$y = \Omega \cdot x = \Psi^T \cdot R \cdot x. \quad (2)$$

Categorization

To incrementally learn a category we use an adaptive Normalized Gaussian Network (NGnet) which we recently proposed (Gläser & Joubin, 2010). As shown in Fig. 2, the NGnet is composed of multiple locally operating experts, each of them being responsible for features stemming from its associated input region. The category membership $c \in \{-1, 1\}$ of a feature pattern y is calculated according to

$$c(y) = \text{sign} \left[\frac{1}{\sum_{j=1}^M \phi_j(y)} \cdot \sum_{i=1}^M \alpha_i \cdot \phi_i(y) \right]. \quad (3)$$

Here, M denotes the number of experts and α_i the weight of expert i to the output neuron. Furthermore, $\phi_i(y)$ is the response of the i -th expert to feature y which is described by a multivariate Gaussian of form

$$\phi_i(y) = \exp \left(-\frac{1}{2} \cdot (y - \mu_i)^T \Sigma_i^{-1} (y - \mu_i) \right), \quad (4)$$

where μ_i and Σ_i denote the center and covariance matrix of the Gaussian. The decision whether a feature pattern belongs to a category is finally obtained by application of the sign function to the continuously valued output. The network parameters are determined during online operation via Expectation-Maximization (EM) training as proposed in (Xu, 1998).

Since the NGnet statistically learns an internal category representation which associates inputs from different modalities, our categorization layer functionally resembles multi-modal associative cortices, e.g. the perirhinal cortex. However, our adaptive NGnet is additionally endowed with mechanisms which allow a demand-driven allocation and removal of experts (Gläser & Joubin, 2010). This enables the network to perform a one-shot memorization of word-scene associations. Our categorization layer consequently also models the rapid initial learning as it is carried out by the hippocampus.

More precisely, our model accomplishes network growth and pruning as follows: (1) New word-scene associations become memorized based on the novelty or surprise of an input sample. Similarly, already memorized associations become (2) pruned if they became redundant, (3) split if the internal representation has to be refined, or (4) merged if they are sufficiently similar. For a detailed description of these mechanisms we refer to (Gläser & Joubin, 2010).

Coupling of the Components

Inspired by CLS theory we finally couple the slow statistical feature extraction and the rapid category learning. As shown by the pseudo-code in Alg. 1 the incremental learning mechanism consists of four steps which are carried out every time a new training exemplar is obtained.

Algorithm 1 Incremental Learning

```

Initialize the feature extraction to  $R = I$ ,  $\Psi = I$ 
Initialize an empty NGnet
for all training samples  $(x, c)$  do
    Update the NGnet with  $(y, c)$ 
    Generate a set of samples  $(y', c')$  using the NGnet
    Train the feature extraction on the generated samples
    Adapt the NGnet to the changed feature space
end for

```

After updating the NGnet with a training sample, the internal representation of a category is used to reactivate memorized associations. This step resembles hippocampal dreaming. We consequently produce a set of samples (y', c') composed of feature patterns y' and associated category memberships c' . To do so, we first determine whether a local expert i represents category members ($c' = +1$) or non-members ($c' = -1$) and next randomly draw feature patterns y' from its Gaussian-shaped receptive field. Since the receptive field is described by its mean μ_i and covariance matrix Σ_i , a feature pattern y' can be generated by $y' = \mu_i + B \cdot z$, where $z \sim \mathcal{N}(0, I)$ is a random vector and B is obtained from the Cholesky decomposition $B \cdot B^T = \Sigma_i$.

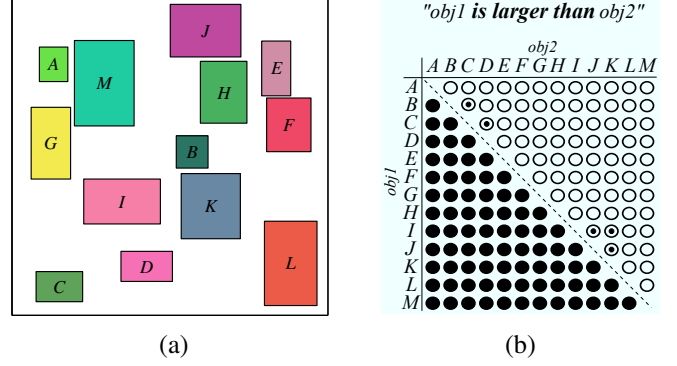

Figure 3: In (a) an example scene used in the visual description task is depicted. In (b) the output of the model after learning the meaning of *is larger than* is shown. Black circles correspond to category members, white circles to non-members, and dotted circles denote errors made by the system.

Afterwards, the generated samples are used to train the feature extraction. In other words, the feature extraction searches for commonalities among the reactivated patterns and tries to extract the condition which discriminates between members and non-members of the category. This learning process changes the feature space the categorization layer is operating on. For this reason, we finally adapt the NGnet to the changed feature space in an analytic way. Since we use a linear feature extraction, the change in the feature space can be expressed in terms of an affine transformation $\tilde{y} = A \cdot y$ with $A = \tilde{\Omega} \cdot \Omega^{-1}$. Here, Ω and $\tilde{\Omega}$ denote the feature extraction matrices before and after the learning. We consequently adjust a local expert's receptive field by calculating its new center $\tilde{\mu}_i$ according to $\tilde{\mu}_i = A \cdot \mu_i$ as well as its associated covariance matrix $\tilde{\Sigma}_i$ according to $\tilde{\Sigma}_i = A \cdot \Sigma_i \cdot A^T$.

Since these learning steps are carried out iteratively, knowledge about a category becomes consolidated as more training samples are processed. The knowledge, which has been first acquired in the categorization layer (via the memorization of word-scene associations), becomes gradually transferred into the extracted features. Due to the fact that the extracted features facilitate the categorization task, this knowledge transfer leads to a more robust categorization as well as a less complex NGnet needed to represent the category.

Experimental Results

We evaluated our computational model in a visual scene description task in which the meaning of words for the relations between objects has to be acquired. Thereby, a learner and a tutor observe a scene composed of geometric objects as the one shown in Fig. 3(a). The tutor selects two out of the objects and describes the relation between them, e.g. by saying

"K is larger than D."

Based on such exemplars of word use the learner has to incrementally build-up internal concepts which correspond to the words' meanings. The training of the model is illustrated in

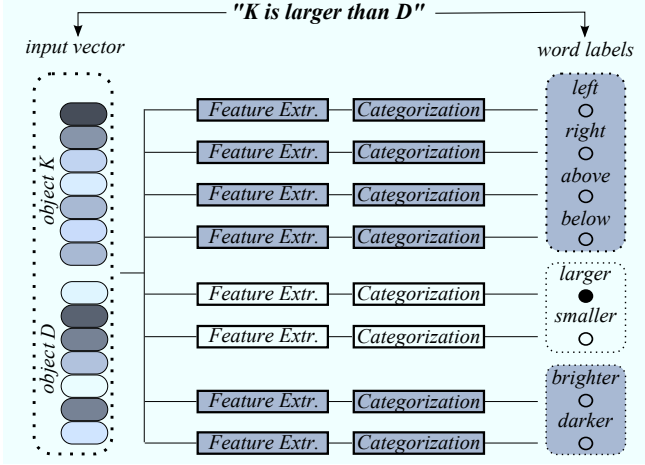

Figure 4: The training of the model in the visual scene description task is illustrated (see text for details).

Fig. 4. For the present experiment we consider the learner to have sufficient syntactical knowledge to identify the objects of interest (e.g. K and D) as well as the word to be learned (e.g. *is larger than*). For computational purposes we further did not carry out the experiment in direct interaction with the system, but rather used simulated scenarios which provide a ground truth for performance evaluation.

Each of the objects in a scene is represented by its absolute position, its width and height, as well as its RGB color value. Consequently, tuples composed of a 14-dimensional perceptual vector (7 dimensions per object) as well as a word label served as training inputs to the system. Words for object relations concerning position (*is to the left of*, *is to the right of*, *is above*, *is below*), size (*is larger than*, *is smaller than*), and color (*is brighter than*, *is darker than*) has been trained. However, it is important to note that the system did not have prior knowledge about the relevance of input dimensions with respect to the meaning of the words. In contrast, important dimensions (e.g. the relative object positions) are even not present and have to be extracted by the system. For each of the words to learn we applied an adaptive NGnet as a binary categorization module and further extracted word meaning relevant features. To cope with missing negative training data we implemented the mutual exclusivity bias between words related to object positions, sizes, and colors, respectively. In other words, a positive training exemplar for *is larger than* has been additionally used as negative training sample for *is smaller than* (Regier, 1996).

The results of this experiment are shown in Fig. 5. In (a) we plot the system performance for the learning of individual words. The performance (correct categorization rate) has been determined on a set of scenes not included in the training data. In (b) we further plot the complexity of the individual classifiers for which the number of local experts comprising the NGnet is an indicator. To keep the plots readable, here we restrict ourselves to curves for the learning of *is to the left of*, *is larger than*, and *is brighter than*. The learning of the other

Figure 5: The evolution of (a) the correct categorization rate and (b) the complexity of the NGnet is shown for the learning of different words.

words resulted in qualitatively similar curves.

From the plots we see that the system performance rapidly increases during the presentation of the first training exemplars and afterwards converges towards a near optimal level. In contrast, the complexities of the classifiers also increase at the beginning, but subsequently decrease and maintain a low level afterwards. The observed behavior of the model is in-line with CLS theory, insofar as it can be explained by two complementary learning processes which run at different timescales: (1) Initially, new knowledge is rapidly memorized. In our model this is accomplished by the on-demand allocation of local experts within the classifier. After a while, the experts adequately represent upcoming training samples such that they do not have to be memorized additionally. Consequently, the classifier complexity as well as the system performance increase at the beginning. (2) Afterwards, knowledge is gradually transferred. In our model the knowledge shifts into the iteratively extracted word meaning-relevant features. These features facilitate the classification task such that a less complex classifier can be applied. At the same time, however, the internal representation of a word meaning becomes more robust and, thus, further increases the system performance.

After training, an analysis of the extracted features revealed that the built categories solely rely on the meaning of the corresponding words. For example, for representing the meaning of *is larger than* the feature

$$(width_{obj_1} + height_{obj_1}) - (width_{obj_2} + height_{obj_2})$$

has been extracted which is an adequate linear approximation of the real decision criteria

$$(width_{obj_1} \cdot height_{obj_1}) - (width_{obj_2} \cdot height_{obj_2}) > 0.$$

Similarly, the relative horizontal and vertical positions have been extracted for the description of spatial relations. This shows that our framework is able to acquire the meaning of words and consequently grounds them.

Finally, the output of the classifiers can be used to describe a visual scene. For the scenario depicted in Fig. 3(a), we show the output of our framework concerning the judgment whether an object *is larger than* another object in Fig. 3(b). As can be seen, objects pairs are correctly categorized except for rare cases in which the object sizes are very similar.

Summary & Future Work

In this paper we presented a computational model for the incremental acquisition of word meanings. The novelty of the framework stems from its combined ability to (1) rapidly build categories which correspond to the learned words while (2) it simultaneously extracts features which underly the meaning of the words. We consider these abilities to be fundamental for life-long incremental learning systems which have to cope with minimal predefined task knowledge. To satisfy the contradictory needs of rapid learning from few examples as well as statistical feature extraction we modeled learning mechanisms which are known to be beneficial for humans. More precisely, our framework resembles CLS theory insofar as it uses separate but tightly coupled components which are specifically tailored to meet these criteria.

We evaluated our model in a visual scene description task, where words for the relations between objects have been taught. Our results demonstrate that the system acquires word meanings based on the observation of just a few word-scene pairings. It subsequently uses its knowledge to generalize to novel scenes. The results further showed that the system implements a memory consolidation process in which knowledge about a word's meaning gradually shifts from the rapidly learned category representation into the slowly extracted features. This consolidation process is beneficial as it abstracts the core meaning of a word and, hence, lets the internal representation of a word become more robust and efficient.

Part of our future work will be the extension of the model to incorporate a non-linear feature extraction. This would allow the system to extract more complex dependencies which may underly a word's meaning. Secondly, we will endow the model with a mechanism which detects the mutual exclusivity between words. This learning bias is currently pre-defined, but has to be autonomously applied by the system to enable a learning of an arbitrary set of words. Lastly, we will extend our teaching scenario to include social learning. Social learning enables an active learning by the system which is useful for testing hypotheses about a word's meaning.

Abstract

Lambert et al. (2003) suggested that stereotyping could be thought of as automatic (implicit) responses that may become magnified in certain social settings through a loss of cognitive control. This type of explanation seems reasonable; however, to date, no attempts have been made to provide a more thorough, mechanistic (computational) explanation of the exact processes underlying the phenomenon. This paper proposes just such a detailed explanation using the CLARION cognitive architecture. Our CLARION-based theory takes into account motivational factors as well as the interaction between explicit and implicit processes and is used to provide a plausible interpretation of data from an identification task in Lambert et al. (2003).

Keywords: CLARION; cognitive architecture; cognitive modeling; motivation; social anxiety; stereotype.

Introduction

In line with existing studies of the effects of social anxiety on stereotype bias (e.g., Lambert et al., 2003; Payne, 2001), an explanation of such a phenomenon can be made within a computational framework, specifically the CLARION cognitive architecture (Sun, 2002, 2003). According to our interpretation, increases in anxiety related motivational drives (Sun, 2007, 2009) have a causal effect on the ability to make controlled (explicit) responses. The reduced capability can lead an individual to revert to a reliance on more “automatic” (implicit) systems.

In the remainder of this paper, we develop a motivationally based, mechanistic theory within the CLARION framework. This CLARION-based theory will then be used to simulate the Lambert et al. (2003) stereotype-inducing identification task and the simulation results will be matched to their human data. The next two sections will examine the task as well as the empirical findings from Lambert et al. (2003). The section following these will present the CLARION-based theory for capturing the phenomenon. The section after that will examine the simulation results and compare them to the human data. The final section will discuss how our theory relates broadly to the phenomenon of cognitive distracters and their impact on cognitive control.

Lambert et al.’s (2003) Experiment

Participants were instructed that they were to identify target objects being presented on a screen as belonging to either the “tool” category or the “gun” category. They were also told that the task required both speed and accuracy. Participants then completed a 48-trial “practice” phase allowing them to become familiar with the requirements of the experiment as well as the target objects (i.e., the tools and guns). After completing the practice trials, participants were told either that all of their responses would be kept confidential (i.e., they were in the private group) or that they would be asked to share and discuss their responses with the other participants in the testing room (i.e., they belonged to the anticipated public group).

For the test phase, an additional element was added to the identification task: the prime, a picture of a person’s face, was presented briefly (for 200 ms.) before being replaced by the target object (which was presented for 100 ms.). Participants were given a total of 550 ms. to make a response (by pressing a button associated with the target’s category).

Participants completed a total of three blocks of trials. In each block, each of the eight primes (4 black, 4 white) was randomly paired with each of the eight targets (4 tools, 4 guns) twice. This yielded 128 trials per block, and a total of 384 trials overall.

After completing the identification task, participants also completed a measure of social anxiety and the Dunton and Fazio (1997) Motivation to Control Prejudicial Reactions Scale. These scales attempted to measure the individual differences in social anxiety and motivations to control prejudicial reactions.

Experimental Results and Discussion

The results from Lambert et al. (2003) showed that participants tended to make stereotypic errors (i.e. misclassifying a tool as a gun when primed with a black face or a gun as a tool when primed with a white face) on tool trials regardless of context ($F = 20.03$, $p < .001$ for the anticipated public group, $F = 3.74$, $p = .058$ for the private group). In other words, when the results were collapsed over context, people who were presented with a tool were significantly more likely to mistake it for a gun when it was coupled with a black prime ($M = .24$) than a white prime ($M = .22$). In

addition, people who were presented with a gun were significantly less likely to mistake it for a tool if it was coupled with a black ($M = .19$) rather than a white ($M = .21$) face. This finding was evidenced by a significant Prime X Object interaction ($F = 22.13$, $p < .001$).

The results further indicated that people in anxiety-inducing situations (e.g. the anticipated public group) made significantly more stereotypic errors than those people who were not distracted by an anxiety-inducing context (e.g., the private group). This was confirmed by a significantly stronger Prime X Object interaction in the anticipated public condition compared to the private condition ($F = 20.03$, $p < .001$ vs. $F = 3.74$, $p = .058$, as mentioned before).

Further, the presence of the black prime had an enhanced effect on participants' responses than the white prime. In other words, on black prime trials, participants were significantly more inclined to make stereotypic errors ($F = 11.52$, $p < .001$ for the main effect of object). This tendency was not evidenced when primed with a white face ($p > .20$).

Based on the process dissociation procedure (Jacoby, 1991), it was found that participants in the private group had higher estimates of cognitive control (.60) than participants in the anticipated public group (.53). These numbers were essentially the same regardless of prime as confirmed by a Prime x Context ANOVA, which revealed a significant main effect for context ($F = 4.54$, $p < .05$), no significant effect of prime ($F = .67$, $p > .05$), and no evidence of a significant Prime x Context interaction ($F = .01$, $p > .05$).

Additionally, Lambert et al. (2003) hypothesized that accessibility bias (i.e., the likelihood of making a stereotyped response when control failed) was a separate (dissociated) process from cognitive control. The results on accessibility bias estimates showed that when participants were primed with a black face, estimates were significantly higher (.56) than when they were primed with a white face ($\approx .50$). To confirm this, a Prime x Context ANOVA was performed revealing a significant interaction ($F = 20.39$, $p < .001$). Beyond this, no other significant effects emerged from these analyses. Of particular importance, accessibility bias was not affected by manipulating context ($F < 1.00$, $p > .05$).

Lambert et al. (2003) also posited that accessibility bias estimates could be used to roughly capture individual variation in stereotypic associations about blacks (i.e., how strongly a person associates guns with this group). Taking into account that control is particularly low for high-anxiety participants in the anticipated public group, Lambert et al. (2003) predicted that, for the aforementioned group, a correlation exists between estimates of accessibility bias and performance. To test this, they constructed an overall index of stereotypic errors: Higher error indices indicated a greater propensity toward making stereotypic errors over counter-stereotypic errors when presented with a black prime.

A few important points resulted from that analysis. First, in the private group context, the relationship between accessibility bias and gun responses was moderate and about the same regardless of anxiety. However, the relationship was especially strong in the anticipated public group, but this

was only among participants who were high in state anxiety. Those participants with higher accessibility bias scores and high anxiety made more stereotyped errors on black primed trials, whereas participants with lower accessibility bias scores made less stereotyped errors on those same trials.

Of additional pertinence to the present work is the effect that context had on reported levels of state anxiety. Recall that at the end of the experiment, participants completed a questionnaire aimed at measuring a person's reported level of anxiety. Analysis of the anxiety measure indicated that, consistent with expectations, participants reported significantly higher levels of (task-specific, i.e., state) anxiety in the anticipated public ($M = 1.89$) compared with the private condition ($M = 1.32$) [$F = 10.03$, $p < .01$].

A CLARION-based Theory

CLARION is a well-established cognitive architecture (Sun, 2002, 2003; Sun et al., 2005). It consists of a number of subsystems. The following three subsystems were used for simulating the task in Lambert et al. (2003): the action-centered subsystem (ACS), the motivational subsystem (MS), and the meta-cognitive subsystem (MCS). Each subsystem is divided into two levels of representation: the explicit (top) and implicit (bottom) levels (see Reber, 1989; Sun, 2002 for justifications).

One of the fundamental theoretical assumptions in CLARION is the distinction between implicit and explicit processing. What we term explicit processing is also known as "controlled" processing (Lambert et al., 2003). Explicit processes are often rule-based, require more time to obtain results, and sometimes require more than one step to reach a conclusion (Sun, 2002). Similarly, implicit processes are often referred to as "automatic" processes. Further, when researchers refer to "a loss in cognitive control", what they are referring to, in CLARION terms, is an inability to adequately rely on explicit processes over (or in addition to) implicit processes. A loss of cognitive control, therefore, is equivalent to using more implicit processes.

Moving now to the representations within the two levels, in the bottom level, CLARION takes note of the fact that the inaccessible nature of implicit knowledge is best captured by subsymbolic, distributed representations (such as in a backpropagation network). It has been extensively argued that the characteristics of distributed representations accord well with the relative inaccessibility of implicit knowledge (Sun, 2002). In contrast, explicit knowledge can be best captured in computational modeling by symbolic or localist representations (Sun, 2002; Sun et al., 2005), in which each unit is more easily interpretable and has a clearer conceptual meaning. This characteristic of symbolic or localist representations captures the characteristic of explicit knowledge being more accessible (Sun, 2002). Accessibility here refers to the direct and immediate availability of mental content for the major operations that are responsible for, or concomitant with, consciousness, such as introspection, forming higher-order thoughts, and verbal reporting, as well as meta-level control and manipulation.

The dichotomous difference in the representations of the two different types of knowledge led to a two-level architecture, whereby each level uses one kind of representation and captures one corresponding type of process (this paper focuses specifically on the interaction between implicit and explicit processing within the action-centered subsystem).

The Action-Centered Subsystem (ACS)

The Action-Centered Subsystem (ACS) consists of implicit processing (in the bottom level of the two-level structure, in the form of a backpropagation network) and explicit processing (in the top level, through explicit action rules; Sun, 2002). When both implicit and explicit knowledge is available in the ACS for determining appropriate actions, the two types of knowledge are “integrated”, for example, through stochastic selection of one type or the other. For further details related to the ACS, see Sun (2002, 2003).

For our simulation, the ACS was responsible for generating responses to a set of featurized inputs (created based on the actual pictures from Payne, 2001, to make the inputs as accurate as possible; see table 1).

The bottom level of the ACS took the featurized descriptions of a prime and target as inputs and output the specification of whether the target item was a tool or gun. The backpropagation network had 25 input nodes (13 describing a person in 6 dimensions, 12 describing an object in 5 dimensions; see table 1), 10 hidden nodes, 2 output nodes (the classification of tool or gun), and the default parameter settings (Sun, 2003). Also, since this task required quick responding, it should be especially prone to noise. We captured this effect by setting the temperature (to .4) involved in stochastic selection of the output.

The bottom level was trained to focus on skin color, because it represents the stereotyping in its simplest form. According to Payne (2001), the primes were designed to filter the characteristics of the faces until race was the only distinguishing feature. We also chose to exclude specific target characteristics during training, because we felt that the link between race and guns was likely a connection between skin color and the concept of a gun (which is the output of the ACS), not any particular gun or tool feature.

Table 1. Featurized inputs as dimension/value pairs.

Primes (people)		Targets (guns/tools)	
Dim.	Val.	Dim.	Val.
Skin Color	Black, White, Gray	Handle Color	Black, White, Gray
Nose Shape	Thin, Wide	Shape	Bent, Straight
Nose Length	Short, Long	Handle Length	Long, Short
Eyebrow Shape	Thick, Thin	Head Length	Long, Short
Eye Size	Big, Small	Head Color	Black, White, Gray
Sex	Male, Female		

Furthermore, we posit that stereotype bias is developed slowly through subtle, cumulative experiences within a society. These biases have evolved from a fundamental need to easily “classify” other members of society for the purpose of ensuring survival. It has been argued that, in general, people have developed “classification” systems to provide help in making reasonable responses quickly to unexpected or unclear circumstances (Sun, 2002). People are not necessarily cognizant of these response mechanisms. In fact, research suggests that tasks requiring quick reactions are often performed implicitly (Reber, 1989; Sun, 2002; Sun et al., 2005). Taking these arguments together, we feel that it is reasonable to think of stereotyping as a form of “classification” that is often best explained as an implicit process.¹

The bottom level was given 500,000 training trials presenting the black and white characteristic in such a fashion that was consistent with the accessibility bias estimates from Lambert et al. (2003). The accessibility bias estimate is the probability that a stereotyped response will be made if control fails, and in our simulation control failing means that only the bottom level of the ACS is used. Hence, it seemed appropriate to use this measure to help guide the training. On about 56% (plus or minus 3.5% for individual differences) of trials where a black face was presented to the network, it was coupled with a gun (on about 44% it was coupled with a tool). Tools and guns were paired at an equal rate (plus or minus 3.5%) when coupled with a white face.

The top level of the ACS learned appropriate response rules mapping inputs concerning specific tool/gun characteristics to the proper tool/gun classification output. The assumption is that these rules represent explicit knowledge learned during the 48 practice trials as well as prior experiences by the human participants.

The Motivational Subsystem (MS)

In addition to the ACS, the motivational subsystem (MS) is another major component in CLARION. The MS is responsible for motivational states (comprised of “drives” and “goals”; Sun, 2007, 2009). In CLARION, drives are fundamental motivational forces behind decision-making (as well as other processes). Anxiety can be thought of as the biological/physiological consequence of heightened (avoidance-oriented) drive strengths (see the discussion of drives in Sun, 2009). Thus, in the simulation, an agent’s drive strengths are set in the MS based on the experimental contexts (e.g., the existence of an anxiety-inducing situation).

Considering the specific aspects of this task, it was determined that a single drive, “honor” (i.e., obeying social norms and codes), best encapsulated the motivating factors involved with the contexts (groups). Based on an agent’s context, its “honor” drive strength level was set in the MS.

The drive strength was obtained using a backpropagation network with 2 input nodes, 4 hidden nodes, 1 output node, and the default parameter settings (Sun, 2003). The first input specified the context (group) to which the agent be-

¹ Note that our interpretation is in line with the arguments made by Lambert et al. (2003).

longed. The second input represented the agent's predisposition toward anxiety in social settings. While more generalized drive-strength equations exist, for the purposes of this simulation, it was determined that a hyperbolic tangent function provided a reasonable approximation for translating "stimulus" (i.e. context) and "deficit" (i.e. the individual predisposition toward anxiety) into a drive strength.

Making the drive sensitive to both the context as well as the predisposition to anxiety is justified by analysis performed by Lambert et al (2003), which found the existence of a significant Context x Anxiety interaction using a hierarchical regression analysis.

Further analysis of the data of Lambert et al. showed that, among participants above the group median in state anxiety, there was a significant effect of context on estimates of control ($\beta = .25$, $p < .05$), reflecting lower control in the anticipated public context compared with the private context ($M_s = .51$ vs. $.60$, respectively). However, context had no significant effect on control for the participants reporting low levels of anxiety ($\beta = .08$, $p = .52$), reflecting the fact that control was relatively high and about equal across the anticipated public and private contexts ($M_s = .57$ vs. $.60$). This effect led to the two different values used for the parameter of the hyperbolic tangent curve for the drive strength in the MS. As a result of the two different parameter values, an agent's drive strength increased more rapidly and reached a higher level in the public group than in the private group. Figure 1 gives a graphical representation of the drive.

The Meta-Cognitive Subsystem (MCS)

Finally, in conjunction with the MS, the meta-cognitive subsystem (MCS) may be used for setting parameters in the ACS. The MCS performs a number of backend actions (including the setting of parameters for action selection, reasoning, and learning, etc.) based on drive states and so on (see Sun, 2007, 2009). In the simulation, (avoidance-oriented) drive strengths (levels of anxiety) from the MS are used as the basis by the MCS to determine the likelihood of making decisions in a more or less explicit (i.e., controlled) way by the ACS.

The MCS contains a module for determining the mode of action decision making (i.e., the proportion of implicit vs. explicit processing in the ACS). A backpropagation network

Figure 1. Graphical representation of the "honor" drive. The x-axis represents the predisposition toward anxiety ($0 \leq x \leq 5$); the y-axis represents drive strength ($0 \leq y \leq 1$). The bottom curve represents the private group [$y = \tanh(.12x)$]; the top curve represents the anticipated public group [$y = \tanh(.36x)$].

with 1 input node, 4 hidden nodes, 1 output node, and the default parameter settings (Sun, 2003) was used. The network was used to produce outputs based on an inverted U curve (see Yerkes & Dobson, 1908) that mapped drive strengths (the input) to the probability of being explicit (i.e., using the top level of the ACS) during action decision making (see figure 2). The working hypothesis in this regard is that when anxiety is at a relatively low level, it has little (or possibly even a positive) effect on the ability to be controlled (explicit) in making action decisions. However, when anxiety reaches a certain higher level, it can begin impairing control, creating a need to revert to faster, more automatic, implicit processes (Sun, 2007, 2009; Wilson et al., 2009; Yerkes & Dobson, 1908)

Simulation Results

In exact correspondence with experiment 2 of Lambert et al. (2003), simulated agents were placed in either a simulated private group or a simulated anticipated public group. Like the human experiment, the test phase was run using 384 trials where each face/tool pairing was observed six times at intervals of 2 times per 128 trials. A total of 128 agents were used (as opposed to 127 human participants in Lambert et al., 2003) and 64 agents were placed into each group.

The results of the simulation were recorded as error rates for the four different possible pairings of prime and target. Consistent with the findings from Lambert et al. (2003), agents in the simulated private group made significantly fewer errors on gun trials than on tool trials when paired with a black prime (.174 vs. .224) [$F = 42.62$, $p < .001$]. Additionally, on trials containing a white prime, in the simulated private group, error rates on gun and tool trials were essentially the same (.202 vs. .199) [$F = .17$, $p > .05$]. In the simulated public group, when a black prime was paired with a gun, error rates were significantly lower than when paired with a tool (.214 vs. .27) [$F = 45.37$, $p < .001$]. Also, when a white prime was paired with either a gun or a tool, error rates were not significantly different (.244 vs. .238) [$F = .491$, $p > .05$] for the simulated public group. These findings were consistent with Lambert et al. (2003).

Further analysis of the simulation data revealed a signifi-

Figure 2. Inverted U-Curve. The x-axis represents the drive strength ($0 \leq x \leq 1$); the y-axis represents the level of cognitive control ($0 \leq y \leq 1$) [$y = -.38x^2 + .2x + .58$].

cant Prime X Object interaction ($F = 48.4$, $p < .001$). Collapsed over situational context, agents were significantly more likely to mistakenly identify a tool as a gun if they were primed with a black face ($M = .247$) than a white face ($M = .219$) [$F = 30.991$, $p < .001$]. Conversely, agents were significantly less likely to mistakenly identify a gun as a tool if they were primed with a black face ($M = .194$) than a white face ($M = .223$) [$F = 26.546$, $p < .001$]. Looking at it another way, agents showed a significantly stronger tendency toward mistaking a tool for a gun when primed with a black face, as opposed to mistaking a gun for a tool, when primed with a black face ($F = 88.42$, $p < .001$ for the main effect of object). When agents were primed with white faces, error rates did not vary significantly across object types ($F = .649$, $p > .05$). These findings were, again, consistent with Lambert et al. (2003).

Moreover, agents in the simulated public group made significantly more errors in general than agents in the simulated private group. This was confirmed statistically by comparing the mean error rates between the simulated public group ($M = .24$) and the simulated private group ($M = .20$) [$F = 56.64$, $p < .001$ for the main effect of context]. In a related statistic, the Object X Prime interaction was stronger in the simulated public group ($F = 28.01$, $p < .001$) compared with the simulated private group ($F = 22.26$, $p < .001$). Figure 3 graphically illustrates the above pattern of data and gives a comparison to Lambert et al. (2003).

Turning to analyses based on process dissociation, inferences into some of the mechanisms within CLARION can be made. First, the cognitive control estimate (Lambert et al., 2003) can be thought of as the probability that a person will be able to use their explicit processes (the top level of the ACS) when making a response (Sun et al., 2005). Second, the accessibility bias estimate (Lambert et al., 2003) can be thought of as the probability of making a gun response when cognitive control fails. According to our interpretation, a failure of control is tantamount to using implicit processing (see Sun, 2002; Sun et al., 2005).

Given this interpretation, there were two methods to report the cognitive control estimate from the simulation: by looking at the probability of using the top level of the ACS (as determined by the MCS), and by the process dissociation procedure (Jacoby, 1991; Lambert et al., 2003). Table 2 shows the MCS determined levels of cognitive control, the cognitive control estimates calculated using process dissociation, as well as the cognitive control estimates reported by Lambert et al. (2003). The cognitive control estimates from the simulation clearly correspond to Lambert et al.'s findings. A Prime X Context ANOVA on cognitive control

Figure 3. The graph on the left shows the human data from Lambert et al. (2003). The graph on the right is the simulation results.

estimates, calculated using the process dissociation equation (Lambert et al., 2003), from the simulation data revealed the expected significant main effect for context ($F = 56.635$, $p < .001$), no significant effect for prime ($F = .861$, $p > .05$), and no significant Prime X Context interaction ($F = .683$, $p > .05$). This analysis provides support to the notion that cognitive control estimates are affected by context but not by prime.

Additionally, as per our interpretation, two methods for reporting accessibility bias estimates from simulation existed as well: process dissociation and actual levels of accessibility bias that were calculated by simply keeping track of the number of times the bottom level chose a gun classification when the bottom level was used. Table 3 shows the actual accessibility bias, the accessibility bias estimates calculated using process dissociation, as well as the accessibility bias estimates from Lambert et al. (2003). As expected, the accessibility bias estimates from the simulation, calculated using the process dissociation equation (Lambert et al., 2003), were significantly higher for a black prime than a white prime and did not vary significantly by context. A Prime X Context ANOVA on accessibility bias estimates confirmed a significant main effect of prime ($F = 37.92$, $p < .001$), no significant effect of context ($F = .039$, $p > .05$), and no significant interaction ($F = .179$, $p > .05$).

Finally, a comparison between a standardized error index, which measured the agent's tendency toward making stereotypic vs. counter-stereotypic errors and the accessibility bias estimates, was calculated. Consistent with the findings from Lambert et al. (2003), the relationship between accessibility bias estimates and gun responses, as specified by the standardized error index, was moderate in the simulated private group, regardless of anxiety. However, this relationship became stronger in the simulated public group, but only when anxiety was high. A graphical representation of this analy-

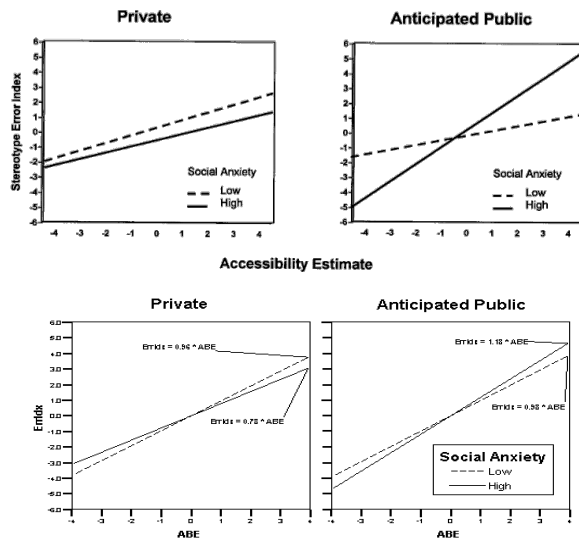

Figure 4. The top graph is the human data from Lambert et al. (2003). The bottom graph is the simulation results.

sis, along with a comparison to the findings from Lambert et al. (2003), can be seen in figure 4. Our finding of the correlation between accessibility bias estimates and error rates, as specified by the standardized error index, lend further support to the implicit nature of stereotyping. In addition, similar to the findings by Lambert et al. (2003), the connection between state anxiety and an agent's ability to make controlled (i.e., explicit) responses is characterized by the lack of a strong correlation between accessibility bias estimates and gun responses in both groups when agents were not highly effected by the anxiety-inducing cues. In other words, agents with lower levels of anxiety made more controlled responses and therefore had less chances of making stereotyped (implicit) responses.

General Discussion and Conclusion

Our CLARION-based theory appears to be capable of modeling the cognitive processes associated with the induction of stereotype biases in a social anxiety context, as illustrated by the successful simulation of Lambert et al. (2003). Moreover, our model captures the essence of the analysis of the empirical data by Lambert et al. (2003) (in a manner consistent with their interpretations).

Of related interest, our simulation supports the argument that stereotyping can be seen as mostly being an automatic (i.e., implicit) response that likely manifests itself as a result of a lessening in the ability to use more controlled (i.e., explicit) processes, as opposed to a strengthening of stereotyping habits (see Lambert et al., 2003 for further details related to this argument).

In conclusion, this article has laid out preliminary foundations that can later be applied to developing a more detailed theory of the mechanistic processes underlying the effects that anxiety and other cognitive distracters, in general, have on the control of cognition. Our theory suggests that the

broader phenomenon (i.e., the effects that cognitive distracters have on performance in a variety of contexts) is explainable in a quantitative, process-based way. In this regard, CLARION provides a useful framework, which has been derived from our prior studies and simulations of human experimental data (e.g., Sun et al., 2005; Sun, 2002; Wilson et al., 2009). Our ability to explore such tasks in a more detailed, more unified fashion should be useful in better understanding the interaction between motivation, meta-cognition, and implicit and explicit performance.

Abstract

People's ability to interact with members of other cultures is determined, in part, by their understanding of the folk psychological theories that explain behavior in those cultures. A comprehensive methodology is offered here for investigating such folk theories. It attempts to characterize the distribution of mental models within a cultural group. A network representation is used to depict the consensus elements (and level of consensus) in a cultural group's knowledge within a domain. The method is general with respect to knowledge domain, though the emphasis here is on folk theories of mind. The methodology is illustrated with two studies directed at Afghan explanations of an Afghan Mullah's decision making in a well-defined context.

Keywords: Cultural epidemiology, cultural modeling, folk psychology, mental models, decision making, mixture modeling.

Background

The epidemiological conception of culture has been gaining fairly wide acceptance among culture and cognition theorists. "Epidemiology" is used in the general sense of describing and explaining the distributions of any property within a population, and "cultural epidemiology" emphasizes explanations of the distribution of ideas within specific populations. According to Sperber (1996), culture is made up of contagious ideas, that is, the ideas that propagate effectively and durably in a population. One line of cultural research within this program seeks to directly explain how some ideas become widely distributed and long-lasting within a population (Berger & Heath, 2005). Other research has focused more on understanding the origins and distributions of complex concepts ("folk theories" or "mental models") that include systematic causal, explanatory beliefs (Atran, Medin, & Ross, 2005; D'Andrade, 1995; Hirschfeld & Gelman, 1994).

With respect to this latter area, cognitive psychology has long characterized the organization of knowledge in terms of networks of interconnected ideas, or mental models (Gentner & Stevens, 1983). Scientific investigations of mental models have spanned physical, biological, and psychological systems. Our research program focuses on understanding decision making within intercultural encounters. In particular, we have been investigating the relationship between how people represent the minds of culturally-different others and the decisions they make as regards those others (cf. D'Andrade, 1987). From this

standpoint, mental models that pertain to psychological and social domains are especially useful.

Research in the psychological domain has sought to establish that people have theories about the workings of other people's minds and behavior, as well as to elucidate the abstract and general properties of theories of mind (Gopnik, & Wellman 1994). There is a general consensus among theory of mind researchers that basic awareness of mental constructs and their relationship with behavior is universal (Wellman, 1998). This, however, does not entail that higher level folk psychology interpretations of these basic theory of mind constructs are culturally universal. In fact, evidence suggests that they are not (Lillard, 1998). For example, in some cultures, "because one wants to" will be considered an important reason for any action. In contrast, within another culture, the most important reason for doing anything might be "because it is prescribed". In such a culture, actions follow a set of rules—often referred to as traditions or rituals. For instance, if upon encountering a Mursi woman from Ethiopia, it would be mistaken to think that she wears a lip plate because 'she wants to.' Now, that does not necessarily mean that she wears it unwillingly—"will" simply has little to do with it.

Recent research in cognitive science on the neural foundations of social learning also provides evidence to support the existence of differences in theory of mind constructs across cultures. For example, Leslie, Friedman, and German (2004) differentiate between the mechanism underlying theory of mind reasoning and the content of the reasoning process. Their research suggests that, along with very basic 'theory of mind' concepts, modular processes that promote attention to mental states and facilitate learning about them appear very early and develop rapidly. On the other hand, the heuristic processes that select appropriate contents for mental states develop over a longer timeframe and undergo several major changes. This timeframe in which the contents of mental states are selected suggests an important window of opportunity for the introduction of cultural variations in mental models of psychology. As children grow up in different cultures with different practices, different languages, and different external circumstances, they would correspondingly also generate different ideas about the mind to fit those experiences.

In summary, there are several reasons to believe that theory of mind functionality is supported by mental models of psychology that vary across cultures, in much the same

way that folk theories of biology differ between cultural groups. The direct investigation of such cultural theories of mind is useful for theoretical development, as it provides a comprehensive base of kinds of explanations, as well as correlations among explanatory elements. It also has considerable practical potential, primarily for the purposes of enhancing understanding of a crucial component of thought between culturally distinct groups. In order to support such investigations, we provide a method for directly eliciting, analyzing, and representing cultural models in any domain, and illustrate its use for mapping cultural theories of mind.

Cultural Network Analysis

We describe a comprehensive method for modeling culture as networks of ideas that are distributed among members of a population (Sieck, Rasmussen, & Smart, 2010). The method, Cultural Network Analysis (CNA), represents an interdisciplinary synthesis of techniques drawn from the fields of cognitive anthropology, cultural and cognitive psychology, and decision analysis. CNA is used to develop *cultural models* for groups and populations. The development of cultural models reflects a well-established practice in cognitive anthropology (D'Andrade, 2005; Quinn, 2005). Furthermore, CNA follows a similar overall pattern of research to other approaches for building cultural models, beginning with qualitative studies, followed by quantitative study and analysis. One refinement to the customary anthropological practice includes a common format for representing cultural models. Specifically, CNA cultural models are typically depicted as a network representation of the culturally-shared concepts, causal beliefs, and values that influence key decisions (Sieck, Rasmussen, & Smart, 2010). This and other refinements of the process are discussed more extensively by Sieck (2010). Here, we focus on providing a general overview of the process.

As mentioned, Cultural Network Analysis encompasses both qualitative, exploratory analysis, and quantitative, confirmatory analysis. The specific techniques used to achieve each step in the analysis depend on whether the cultural researcher is employing exploratory CNA or confirmatory CNA.

A primary goal of exploratory CNA is to develop an initial understanding of the concepts and characteristics that are culturally relevant within the domain. In exploratory CNA, concepts, causal beliefs, and values are extracted from interviews and other qualitative sources. Semi-structured interviews employ questions intended to elicit antecedents and consequences of concept states, as in the "explanatory models framework" sometimes used in cognitive anthropology (Garro, 2000). Questioning along these lines draws out a more comprehensive set of ideas than would typically be verbalized in standard think aloud procedures, and places particular emphasis on drawing out perceived causal relations. We have also combined this interview approach with "value focused thinking" from

decision analysis to elicit values and objectives directly, along with the causal beliefs that link more fundamental values with the means intended to achieve them (Keeney, 1994; Rasmussen, Sieck, & Smart, 2009). Qualitative analysis and representation at this stage yield insights that can be captured in initial cultural models.

Influence diagrams have proven to be quite useful for representing mental models relevant to key judgments and decisions (Bostrom, Fischhoff, & Morgan, 1992). We further believe they are an important representation format for depicting cultural models, especially for showing both qualitative structure and numeric prevalence information. In an influence diagram, nodes are linked by arrows that represent local causal influences. That is, the value of the concept at the beginning of an arrow affects the value of the concept at the arrow's point. Fully-specified influence diagrams can also represent numerical quantities, but the basic structure is useful as well. Specifically, an influence diagram provides a relatively simple and useful representation of a cultural model of another's mind that includes key judgments and decisions of interest to the researcher, as well as the culture-specific concepts, values, and causal beliefs typically used to explain those decisions within a population.

Confirmatory CNA serves to test the structure of previously developed qualitative cultural models, as well as to elaborate the models with quantitative data on the prevalence of ideas in the population(s) of interest. In confirmatory CNA, specially-designed structured questionnaires are used to obtain systematic data that can be subjected to statistical analysis. Most questionnaires treat ideas as independent entities, and so do not provide any means for revealing their interrelated, network form. A few studies have attempted to capture first-order causal beliefs. We have begun developing questionnaires that permit the analysis of longer causal belief chains by starting with influence diagram representations of qualitative cultural models from exploratory CNA to provide a suitable reference.

Statistical models, such as cultural consensus theory and mixture models are employed in confirmatory CNA to assess the patterns of agreement from the "causal-belief" surveys, and derive statistics describing the distribution of concepts, causal beliefs, and values. Cultural consensus theory is a collection of formal statistical models that has been long used within cognitive anthropology to assess agreement in knowledge and beliefs among a set of respondents (Romney, Weller, & Batchelder, 1986). When a cultural consensus is found, it provides the consensual responses that indicate culturally shared knowledge and estimates of the strength of consensus for those responses.

Our group has increasingly been relying on mixture modeling as an alternative approach to cultural consensus theory, primarily as it permits direct segmentation of cultural groups based on clusters of consensus (Mueller & Veinott, 2008; Sieck & Mueller, 2009). Mixture models have been applied in many scientific fields, including

marketing, biology, medicine, and astronomy. A mixture model, or “finite mixture model,” is given as a combination of different groups, each described by a distinct probability distribution. Mixture models sort through the data and group them into sets of relatively homogeneous cases or observations. In cultural modeling applications, the distinct segments resulting from the analysis represent *cultural groups*, i.e., groups defined by the similarity of their ideas.

Finally, influence diagram representations of the cultural models are constructed in confirmatory CNA that illustrate the statistical properties, as well as the qualitative structure elucidated in exploratory CNA. In the confirmatory CNA application, the influence diagram represents the “culturally correct” concepts, values, and causal linkages as determined by mixture modeling for each cultural group that was found. Furthermore, the numerical probability values in the diagram are populated with the prevalence of each idea, as measured by selection percentage, within a group. The result in this case is a summary of the full distribution of ideas, with probabilities indicating the consensus on any particular causal link (or node).

As discussed above, CNA provides an integrated collection of techniques and procedures that can be usefully employed to build cultural models in virtually any knowledge domain. Here, we illustrate their use for building cultural models that pertain to folk psychology. Specifically, the substance of our research primarily considers the general concept of corruption and its relationship to explanations of individual decisions in the context of Afghanistan.

Exploratory CNA: Afghan Expatriates

Method

Participants 14 Afghans living in the U.S. participated in the study. Most (80%) were men, aged between 20 and 34 (mean 26.7) years, and had resided in the U.S. for a time between 3 months and 9 years (mean 2.7 years). All spoke English in addition to Dari or Pashto.

Materials The interviews were structured around short scenarios based on real events. All involved Afghan actors who engaged in some behavior that puzzled Americans. Here, we focus on a scenario involving a Mullah who was helping a group of Afghans and Americans to distribute humanitarian assistance supplies in several villages. The scenario included that the Mullah was extremely helpful, especially in facilitating positive interactions with village elders. Everything was going very well. After finishing with the distribution, as everyone was packing up to leave, the American leader learns that the Mullah has kept a truckload of the supplies. The American who originally relayed this incident indicated a belief that the Mullah was operating out of a desire to increase his own wealth. As will be seen, the Afghan interpretations are somewhat different.

Procedure Each participant was interviewed individually using the same CNA interview guide. A primary and

secondary interviewer were present for all interviews. The primary interviewer was responsible for covering the questions in the interview guide. The secondary interviewer took notes and asked additional questions of clarification. The interview guide consisted of open-ended questions to elicit participants’ overall explanations of the situation, as well as their beliefs regarding the Mullah’s intentions, objectives, fundamental values, and causal links between them. Questions also covered participants’ beliefs about the Mullah’s decision process, value conflicts, and anticipated reactions to possible mitigating actions.

Results and Discussion

Coding Two independent coders read through all of the transcripts and identified segments that contained concept - causal belief - value chains. Next, the two analysts coded each segment by identifying the antecedent, the consequence, and the direction of the relationship between the antecedent and consequence (increasing or decreasing) for each causal belief. Percent agreement for the coding was 95.2%.

Representation The concept - causal belief - value chain fragments were then integrated into a network diagram that synthesized participants’ models of the Afghan Mullah’s mind, as bounded by the scenario (See Figure 1). In the diagram, circles depict concepts, arrows represent causal beliefs, and values are indicated by color of the circles. One analyst constructed an initial draft of the overall diagram by first focusing on fragments related to key decision points and fundamental values within the scenario, and subsequently adding further detail. Three other analysts independently reviewed the resulting diagram against the original set of codes, and a final version determined by consensus.

Findings A rich structure emerged from the process, as illustrated in Figure 1. As can be seen in Figure 1, three main sections of peoples’ beliefs about the Mullah’s mental states are represented: 1) Mullah successfully acquiring supplies, 2) Mullah being caught taking supplies, and 3) Mullah’s concept of theft. As shown, respondents believed that the Mullah’s intentions for the supplies included using them within his own household, selling them, or distributing them among people within his village (this latter category can be further decomposed into distinct groups of people, as described in Study 2). Interestingly, the fundamental values projected onto the Mullah rarely reflected considerations of material gain for the sake of wealth alone. Instead, the Mullah’s fundamental values guiding his decisions in this situation were believed to comprise considerations of status, respect, power, and honor. These considerations are examined further in Study 2. Being caught with the supplies was generally felt to negatively impact these four values, and so come at a significant personal cost to the Mullah. However, respondents believed the degree of impact would be minimized or exacerbated depending on how discreetly

Confirmatory CNA: Afghans in Afghanistan

Participants Participants were 405 men from 4 provinces (Balkh, Kandahar, Kabul, Herat) representing north, south, east, and west regions of Afghanistan. Approximately half were from rural villages (54%), and the remainder lived in urban areas. Ages ranged from 18 to 78 years old (mean = 32.6). The vast majority (96.8%) spoke either Pashto or Dari as their primary language.

Again, the survey options presented were not created by the researchers, but instead derived from interviews with Afghans in the exploratory CNA study. The sequences ultimately led to six fundamental values that were also derived in the exploratory phase of the study: *status*, *honor/respect*, *wealth*, *power*, *safety*, and *family approval*. The CNA survey was translated into Dari and Pashto languages, and back-translated to ensure preservation of meaning (Brislin, 1970).

Procedure The survey was administered to participants through structured face-to-face interviews. The interviews were conducted by trained Afghan interviewers who live in the same province where they collected data. Before the data collection began, supervisors from each provincial data collection center met with the principal investigator at the opinion research center headquarters in Kabul to discuss the study purpose, survey content, and data collection procedures. The supervisors then returned to their provincial centers and held similar sessions for the local Afghan interviewers. Local interviewers then collected data

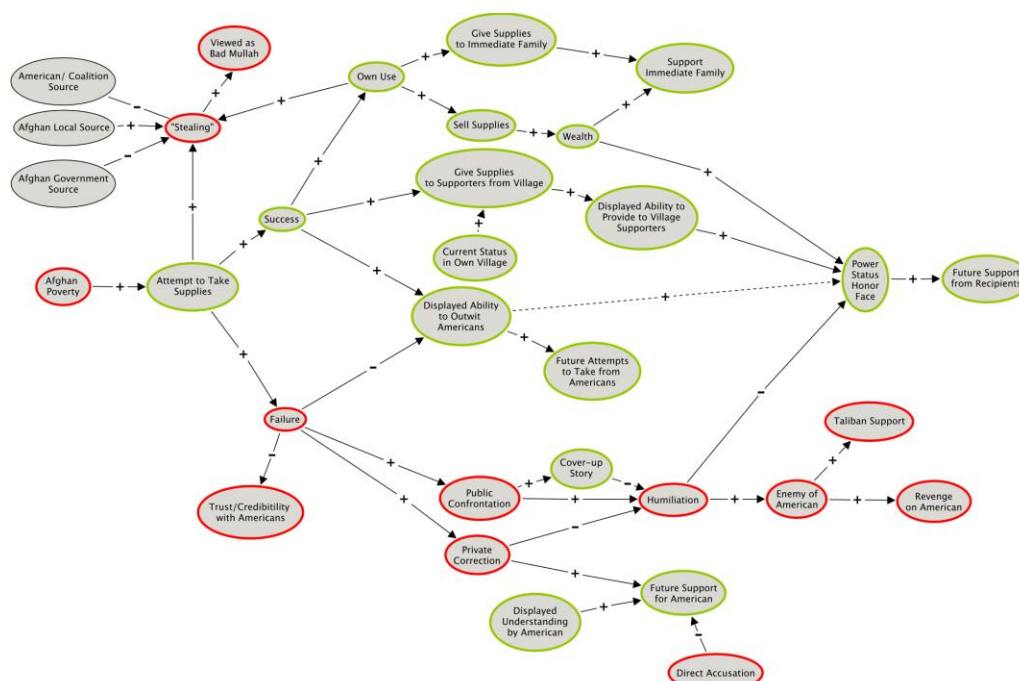

Figure 1. Qualitative cultural model of a Mullah's mind.

1. Use in his immediate household;
2. Sell or trade them;
3. Give them to his close friends or supporters;
4. Give them to his extended family; and
5. Give them to needy people in his own village.

at randomly assigned sampling points in their province. Participants were interviewed individually by one interviewer. The interviewer documented participant responses to the survey using paper-and-pencil. The survey took approximately 1 hour to administer.

Model fitting was conducted using a statistical package called “FlexMix” (Leisch, 2004). FlexMix uses an iterative maximum likelihood procedure called the, “EM algorithm,”

for model estimation. A mixture of binomial distributions was fitted to the data set, after categorical variables were recoded in binary terms. The possible (“finite”) number of resulting groups was allowed to vary between 1 and 7. The best fitting model was selected using the Bayes Information Criterion (BIC) statistic. The BIC statistic indicated that the best fit was achieved with 3 cultural groups (BIC = 73096.7) of roughly equivalent size ($n_1=121$, $n_2=152$, $n_3=132$).

Differences between the groups appeared to be fairly subtle. For brevity, a trimmed version of the cultural model is presented for Group 2, only (see Figure 2). As illustrated in Figure 2, participants in this group tended to believe the Mullah would use the supplies within his own household, though reasonable proportions felt he would either sell them, or distribute them among the needy in his village. Interestingly, the majority of possible motivations for Mullah actions center around fundamental values of status and respect. The possibility that the Mullah is simply seeking to increase his wealth appears to constitute a minority view among Afghans. This finding corroborates the initial results from the exploratory CNA study, and again differs from the original American interpretation that the Mullah was operating out of greed.

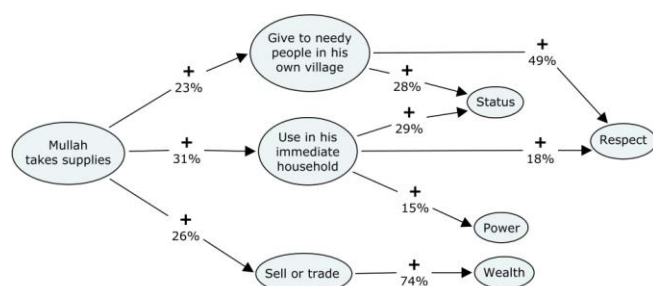

Figure 2. Quantitative cultural model of a Mullah's mind.

Discussion

We all have the ability to think and speculate about the behavior of objects, events, and other people. We do this naturally in a variety of domains. In the social domain, we are able to make guesses about other people's thoughts and therefore speculate about their intentions and their motives and use those guesses to generate plausible explanations for their behavior. Human interaction and communication relies heavily on our ability to anticipate each other's actions and questions. In fact, one could argue that the ability to predict and explain the behaviors of people around us in common terms is central to our ability to thrive in the local social environment. Methods to support the investigation of such explanations and predictions among localized populations are clearly warranted.

In this article, we described a method that can be used to study folk theories of psychology. The method, Cultural Network Analysis seeks to explicitly map the distribution of mental models within a cultural group. Specifically, the

distribution of a cultural group's knowledge within a domain and situation is analyzed and displayed using a network representation of consensus elements. We also illustrated the use of the method to explicitly represent folk theories of mind in a cultural context. In particular, we used exploratory and confirmatory CNA, respectively, in two studies to tease out Afghan explanations of an Afghan Mullah's decision making in an ethically-charged scenario.

A core assumption of our program is that peoples' intuitive understandings of human psychology are fundamental to many more complex domains of interest in cultural research and applications (e.g., reading intentions, negotiating, and collaborating across cultures). Hence, cultural investigations of mental models of psychology using cultural network analysis, among other methods, will provide a useful starting point for addressing these more complex cultural domains.

Some Attention Learning “Biases” in Adaptive Network Models of Categorization

Toshihiko Matsuka
Chiba University

James E. Corter
Teachers College, Columbia University

Arthur B. Markman
The University of Texas

Abstract

In two simulation studies, we compare the attention learning predictions of three well-known adaptive network models of category learning: ALCOVE, RASHNL, and SUSTAIN. The simulation studies use novel stimulus structures designed to explore the effects of predictor diagnosticity and independence, and differentiate the models regarding their tendencies to learn simple rules versus exemplar-based representations for categories. An interesting phenomenon is described in which the models (especially SUSTAIN and RASHNL) learn to attend to a completely nondiagnostic constant dimension.

Keywords: category learning; selective attention; simulation.

Introduction

A key assumption of many computational models of categorization is that category learners do not merely form associations between instances and categories, but also learn how to allocate attention to each individual stimulus “dimension” (e.g., color). The present paper focuses on three such adaptive network models of classification learning: the ALCOVE model of Kruschke (1992); RASHNL (Johansen & Kruschke, 1999); and SUSTAIN (Love & Medin, 1998). These models are multilayer adaptive network models that accept as input a stimulus description (in the form of a set of input feature values), and produce as output category membership predictions that are based on the activation levels of a set of output nodes that correspond to the possible category responses. Over the course of training, these models learn both what dimensions to attend to, and how to correctly classify all the stimuli in the training set.

These three adaptive network models differ in several key aspects. ALCOVE and RASHNL are exemplar models, in the sense that each stimulus in the training set is allocated a node in the “hidden” or middle layer of the network. In contrast, SUSTAIN can form either exemplar-level or prototype-based representations. Prototypes are handled by using a reduced number of nodes in the hidden layer, corresponding to potential generalizations. SUSTAIN dynamically allocates new prototypes, allowing it to possibly use *multiple* prototype nodes for each category defined by the training feedback.

Exploring how these models adapt their attention weights is crucial to understanding their usefulness and validity by relating their learning accuracy predictions more directly to learning strategies. In previous studies (e.g., Matsuka & Corter, & Markman, 2002; Corter, Matsuka, & Markman, 2007), we found that all three models can account for human classification accuracy learning curves, but show distinct patterns in their “learning curves” for dimensional

attention weights. In particular, ALCOVE and RASHNL seem to pay more attention to relatively independent predictors, while SUSTAIN shows the reverse pattern. The present Simulation 1 seeks to confirm this finding with a novel stimulus structure designed for this purpose, while Simulation 2 investigates an interesting phenomenon whereby the models sometimes learn to pay attention to a completely nondiagnostic feature. First, we briefly describe the models.

ALCOVE (Kruschke, 1992) is a multi-layer adaptive network model of categorization based on the Generalized Context Model (Nosofsky, 1986). The first layer of ALCOVE is a stimulus input layer. Each node in this layer represents the value of the presented stimulus on a single dimension. Importantly, each dimension has an attention strength (α_i) associated with it. Typically, attention strengths are initially equal across dimensions. However, the model learns to reallocate attention as learning proceeds, by adjusting these weights. The second layer in the network is the exemplar layer. Each node in this layer corresponds to an exemplar, described by its position in the multidimensional stimulus space. The activity of the exemplar nodes is fed forward to the third layer, the category layer, whose nodes correspond to the categories being learned. Separate learning rates are assumed for the association weights and attention strengths.

RASHNL (Kruschke and Johansen, 1999) is a modified and extended version of ALCOVE. The modifications introduced in RASHNL include: limited attention capacity; a capability for large and rapid shifts of attention; a gradually decreasing learning rate; and a parameter for salience of cues or features. RASHNL’s architecture is similar to that of ALCOVE. However, each dimension has a dimensional salience parameter, the values of which are prespecified by the experimenter (i.e., not adjusted by learning). The dimensional attention strengths, α_i , are derived functions of separate underlying parameters, termed the “gains”, which are adjusted by learning. An additional parameter P is incorporated, that can be set to vary between fixed attention capacity ($P = 1$) or unlimited attention capacity ($P = \infty$).

SUSTAIN (Love & Medin, 1998; Love, Medin & Gureckis, 2004), is comprised of two separate adaptive network components, a “supervised” network and an “unsupervised” one. The unsupervised network is a competitive network that clusters stimuli into prototypes. The term ‘prototype’ is used broadly, however, because an experimenter-defined category might be represented by one or many prototypes, and a prototype might represent only a single stimulus. This

flexibility also gives SUSTAIN the capability to form prototype-plus-exception representations or even exemplar-level representations. This clustering network is dynamic and incremental in its behavior, in the sense that new prototypes and/or exceptions are created when current prototypes are not predictive.

The “supervised” network is a feedforward network that classifies a stimulus based on similarity between the input pattern and the prototypes created by the unsupervised network. The activation of node j in the internal layer depends on several parameters: λ_i , which represents the “tuning” of the receptive field for a given dimension i , the distance between the centroid of prototype unit j and the input node on dimension i , and r , an overall attentional parameter that can be adjusted to create tighter or looser focus on highly tuned dimensions. The “tuning” (λ_i) parameters in SUSTAIN are the primary determinants of differences in attention among dimensions. When λ_i is large, difference between the input and the prototype node on dimension i are “stretched” or emphasized. At the output layer, SUSTAIN allows only the internal-layer unit with the highest post-transformed activation to determine output node activations, leading to “winner-take-all” learning.

Comparing the Models’ Accounts of Attention Learning

We are interested in the attention learning behavior of these models. One clear difference between models is that RASHNL was designed with multiple attention learning iterations on each trial, in order to account for rapid shifts in attention that ALCOVE cannot predict. However, other differences among the models’ assumed attention mechanisms have unknown implications. For example, it is not clear what follows from SUSTAIN’s use of feedback from only the most-activated prototype to update the dimensional tuning parameters. Because of the complexity of these multilayer network models and their dynamic nonlinear performance, simulation studies are useful to establish the models’ actual attention-learning behavior in complex learning tasks.

SIMULATION STUDIES

Simulation 1

Our previous findings (e.g., Corter et al., 2008; Matsuka et al. 2002) suggest that ALCOVE and RASHNL tend to incorporate dimensions that are relatively independent, even orthogonal, to the other predictors, compared to SUSTAIN. As an alternative (but related) hypothesis, it may be that relatively independent predictors are preferred by ALCOVE and RASHNL because such dimensions often are more useful for distinguishing exemplars, especially between categories. Simulation 1 explores this hypothesis by decoupling predictor diagnosticity (correlation with the criterion), predictor independence (inversely related to correlation with the other predictors), and “exemplar separation” (i.e., whether a predictor can be used in conjunction with other strong predictors in order to distinguish exemplars from different categories).

Method: Table 1 shows the category structure used in Simulation 1. In a typical classification learning task the classes (A and B) might be diseases, the exemplars patients, and the five “dimensions” might represent five types of test results or symptoms (each with two possible values). Correlations with the criterion are equal to .6 for Dimensions D1 and D2, to .2 for D3 and D4, and zero for D5. D3 and D4 differ in their configural validities, however: The variable subset (D1, D2, D3) gives a perfect R-square (RSQ) of 1.0 when these three dimensions are used in a linear model predicting the criterion, while the variable subset (D1, D2, D4) yields an RSQ of only .77. Addition of the orthogonal variable D5 alone does not increase the RSQ of the predictor set (D1, D2), which is equal to .60.

The dimensions also differ in their degree of independence from the other predictors. Dimension D3 is correlated .6 with D1 and with D2, while D4 is correlated -.2 with each of these two predictors. D5 has a zero correlation with all the other predictors and the criterion. However, the predictors D3-D5 are all comparable in one regard: each one can be used in conjunction with D1 and D2 to distinguish all category A exemplars from all category B exemplars. Thus, the simulation results for this structure should shed light on our hypothesis that this “exemplar separation” measure is key to predicting ALCOVE’s and RASHNL’s attention allocation behavior, by holding this factor constant across the “extra” dimensions D3-D5.

Table 1. Stimulus structure used in Simulation 1.

Class	D1	D2	D3	D4	D5
A	1	1	1	1	1
A	1	1	1	0	0
A	1	1	1	0	1
A	1	0	0	1	0
A	0	1	0	1	1
B	1	0	1	0	1
B	0	1	1	0	0
B	0	0	0	1	1
B	0	0	0	1	0
B	0	0	0	0	1

Using the three models, we simulated subjects (N=10,000) who were trained for 20 blocks on the stimulus structure shown in Table 1. For each individual subject parameter values were randomly selected from a uniform distribution within reasonable limits for each parameter. The main results recorded were the final-block attention weights for the five dimensions.

Results: Although we cannot identify any of the simulated subjects as being descriptively more plausible than others due to the lack of empirical data for this structure, we can assess the normative success of each simulated subject, by calculating their predicted final-block classification accuracy. Table 2 shows the mean final-block attention parameters for each model, by dimension. The table shows the final weights only for “successful” simulated learners, those achieving at least 80% correct classification accuracy

by the final block. The results do not differ if all simulated learners are included, however. All three models give highest attention weight to the two high-diagnostic dimensions D1 and D2. However, they differ widely in how they distribute attention to the three remaining dimensions. In particular, the results for ALCOVE show a surprising pattern, with nearly as much attention paid to D4 and D5 as to the two most diagnostic dimensions and with D3 weighted least, even though D3 has the highest configural validity ($RSQ = 1.0$) in conjunction with D1 and D2. Thus, this pattern of weights can be said to be non-optimal; it is a surprising result in that D5 is completely uncorrelated with the criterion. This ordering is consistent with the hypothesis that ALCOVE prefers relatively independent predictors, and cannot be ascribed to differences in “exemplar separability”, because this latter factor is held constant for D3, D4 and D5.

Table 2. Simulation 1: Final block relative attention weights for dimensions for each model, for “successful” simulated learners, with number (N) of successful learners out of 10,000 total.

	N	D1	D2	D3	D4	D5
ALCOVE	8480	.248	.247	.098	.199	.209
RASHNL	7463	.274	.286	.183	.123	.135
SUSTAIN	6855	.240	.248	.230	.136	.148

RASHNL and SUSTAIN both predict normatively satisfactory patterns of attention weights in the sense that they give highest attention to D1 and D2, with D3 third highest. This set of predictors is the minimal sufficient set for perfect prediction, therefore these weights may be considered to be the monotonically “optimal” weights. However, both RASHNL and SUSTAIN weight D5 higher than D4. Again this is surprising, since D5 has zero correlations with the criterion (but also with the other predictors).

Discussion: In this simulation RASHNL and SUSTAIN yielded weights that are normatively justifiable by the customary criterion of “configural validity”, by giving highest weighting to the three dimensions yielding a perfect multiple-R in predicting the criterion. However, they still gave nontrivial weights to the two remaining dimensions, D4 and D5. In this sense their attention allocation patterns cannot be described as optimal. Furthermore, most simulated learners gave attention to more than one of these “supplementary” dimensions, showing that the network models do not always learn minimal sufficient rules.

ALCOVE also gave highest weights to D1 and D2, but gave third highest weight to D5, a dimension that has a correlation of zero with the criterion and with all the other predictors. This pattern seems “irrational” by the usual criterion of configural validity. However, we note that it is reasonable from the standpoint of “exemplar separability”: by this measure, the set (D1, D2, D5) is adequate for the classification task. ALCOVE also gives non-trivial weights to the remaining two dimensions, D3 and D4, again demonstrating that the network models do not tend to learn minimal representations across a broad range of parameter

values. Finally, ALCOVE weights D5 higher than D4 and D4 higher than D3, an ordering that is consistent with the degree of independence of the three dimensions, while RASHNL weights D5 over D4 (but weights D3 highest, in line with its configural validity). This result supports the hypothesis that ALCOVE tends to give higher weight to more independent dimensions, even at the cost of finding a non-optimal solution. RASHNL and SUSTAIN both find the “optimal” configuration of dimensions (D1, D2, D3), and in fact exhibit the same ordering of weights ($D1 \approx D2 > D3 > D5 > D4$). However, given that only SUSTAIN weights D3 nearly as high as the two diagnostic dimensions, the results are consistent with the hypothesis that this model “prefers” dimensions that are correlated with other important predictors, compared to the other models.

Simulation 2

Simulation 2 explores two issues. The first is the idea that SUSTAIN favors dimensions that are correlated with other predictors, at least relative to the other models. The second issue is the tendencies of the models to utilize exemplar versus simple rule based strategies when both strategies are sufficient for perfect performance.

Our previous simulations suggest that ALCOVE and RASHNL favor relatively independent predictors of the criterion. A form of independence that can arise with a very poor predictor of a criterion is the case of a constant predictor. A constant has a correlation of zero with the other predictors, and also with the criterion (very bad diagnosticity indeed). We explore whether ALCOVE and RASHNL have any attraction to this type or predictor.

There is reason to suspect that SUSTAIN may try to incorporate such a predictor. Although a constant dimension has zero correlation with other predictors, it will have maximal within-category consistency for any cluster. Thus, the inclusion of a constant dimension allows us to unconfound diagnosticity and between-predictor correlation from within-cluster consistency, possible aspects of the type of dimensions found to be attractive to SUSTAIN in previous simulations.

Inclusion of a constant dimension simulates important aspects of experimental stimuli that are usually ignored. The stimuli used in studies of category learning typically have many perceptually or conceptually salient aspects that are not coded or discussed by the experimenters, being treated as irrelevant because they are constant for all stimuli. For example, stimuli that are line drawings of bug-like creatures may differ in head shape, number of legs, and type of tail, aspects that are coded and manipulated by the experimenter to define the diagnostic input features to categorization models. But the line drawings all share certain basic characteristics that are constant across stimuli. Many models of similarity (e.g., Tversky, 1977; Markman & Gentner, 1993) assume that common features increase the similarity (and confusability) of stimuli. Thus, it seems interesting to use a simulation study to investigate what

predictions the three network models make for use of such constant or common-feature information.

Method: The category structure used for Simulation 2 is shown in Table 3. There are four exemplars of each category, A and B. Dimension D1 is a binary-valued variable, with values that are logically necessary-and-sufficient to identify each category. Dimension D2 is a constant dimension that has values of 1 for all exemplars in the population, regardless of category membership. Dimensions D3, D4, and D5 are binary-valued dimensions that together uniquely identify all eight exemplars. Note that this structure ensures that each network model not only has a relatively easy categorization strategy available (a unidimensional rule on D1), but can adopt a minimal attentional strategy that enables unique identification of all exemplars (attending to D3-D5).

Using the three models, we simulated subjects ($N=100,000$) who were trained for 20 blocks on the stimulus structure shown in Table 3. As in Simulation 1, for each individual subject parameter values were randomly selected from a uniform distribution within reasonable limits for each parameter. The main results recorded were the final-block attention weights for the five dimensions.

Table 3. Simulation 2: A simple two-category structure with one necessary-and-sufficient “category” dimension (D1), a constant dimension (D2), and three dimensions (D3-D5) that uniquely identify exemplars.

Class	D1	D2	D3	D4	D5
A	1	1	1	1	0
A	1	1	0	1	1
A	1	1	1	0	1
A	1	1	0	0	0
B	0	1	1	1	1
B	0	1	0	1	0
B	0	1	1	0	0
B	0	1	0	0	1

Results: Table 4 reports the mean pattern of relative attention in the final block for the successful classification learners, defined as those who had at least 80% classification accuracy in the final block.

Table 4. Mean final relative dimensional attention weights, by model, for the best-fitting simulated subjects of Simulation 2. Maximal mean attention weight for each model shown in bold type.

Model	D1	D2	D3	D4	D5
ALCOVE	.338	.097	.188	.188	.188
RASHNL	.375	.231	.132	.132	.132
SUSTAIN	.389	.389	.074	.075	.075

As can be seen in the table, learners simulated by ALCOVE gave the highest weight to D1, the dimension defining the simple rule. However, the total attention weight allocated by ALCOVE to the three dimensions uniquely identifying the exemplars (D3-D5) was greater than that given to the rule dimension D1, a pattern that could be interpreted as showing predominantly exemplar-

based learning.¹ ALCOVE was relatively successful at ignoring the constant dimension D2, giving it about 1/4 the weight of the “rule” dimension D1. RASHNL showed a different pattern of final weights, giving the highest weight to the dimension (D1) defining the unidimensional category rule, an intermediate level to the constant dimension D2, and the least attention to the exemplar-identifying dimensions D3-D5. RASHNL’s capability to emphasize D1, the rule dimension, is consistent with its capability to model simple rule-based strategies in other simulations we have conducted. It is somewhat surprising that this model cannot learn to ignore the constant dimension D2. SUSTAIN gave the least weight of any model to the “exemplar” dimensions D3-D5, and roughly as much weight as RASHNL to the perfectly diagnostic D1, but was the worst at ignoring D2, the constant dimension, giving it equal weight with D1.

Examination of the pattern of attention results across different regions of the parameter space for each model revealed that one key parameter affecting the results is the learning rate for association weights in the network. In order to display these results, we have created plots of the final pattern of attention weights for each model, separately for different ranges of the learning rate parameter.

Figure 1 presents the results for ALCOVE. The left panel plots the final attention weight for D2 (the constant dimension) versus that for D1 (the rule dimension). It can be seen that ALCOVE does not completely ignore D2 at any value of the learning rate, although D2 is consistently given lower weight than D1. The right panel plots the summed final attention weights for D3-D5, the “exemplar” dimensions, versus the weight for D1. These plots show a strong and consistent effect of the learning rate for associations. For higher values of this parameter (the upper row of the panel), the total attention weight given to the exemplar dimensions tends to exceed that for D1, meaning that exemplar learning predominates. For lower values of the learning rate (the bottom row) the dimension defining the unidimensional rule (D1) is weighted highly, sometimes even exclusively, meaning that a rule-based strategy is being used.

Figure 2 presents the corresponding plots for RASHNL. The left panel shows that RASHNL has trouble ignoring D2, the constant dimension, at any value of λ_w . However, D1 (the rule dimension) tends to receive more attention than D2 in the majority of solutions. The right panel shows that most simulated subjects pay more attention to D1, the rule dimension, than to the exemplar dimensions. This is especially true when the learning rate is very low (bottom row). However, the bottom row of the left panel

¹ Support for this interpretation is given by supplementary simulations we have conducted, in which various numbers of dimensions (1, 2 or 3) are used to uniquely code the exemplars. Across all of these simulations, the total final weight given to these “exemplar” dimensions is roughly constant, regardless of the number of dimensions involved.

underscores that for the low learning rates, considerable attention is also paid to D2, the constant dimension.

Figure 3 shows that SUSTAIN yields a very different pattern of results for this structure. For all values of λ_w SUSTAIN predicts that equal attention will be paid to D1 (the rule dimension) and D2 (the constant dimension). Also, the total amount of attention directed at D3-D5, the “exemplar” dimensions, is fairly stable across values of the learning rate, but there is more variability at the higher learning rates. Interestingly, the apparent constraint that the weights given to D1 and D2 be equal is so strong that any increase or decrease in the total weight given to D3-D5 trades off against the summed relative weight given to D1 and D2, creating a line of possible solutions with a slope of -2 in each plot of the right-hand panel.

Figure 1. Simulation 2: Final relative attention weights for ALCOVE, separately for different values of λ_w , the learning rate for network association weights. Left panel: D2 (y-axis) versus D1 (x-axis) attention weights. Right panel: summed attention weights for D3, D4 & D5 (y-axis) versus D1 (x-axis) attention weights. In each panel, the nine plots summarize results for various ranges of the λ_w parameter. Top row: (>.8; .8-.4; .4-.2). Middle row: (.2-.15; .15-.10; .10-.05). Bottom row: (.05-.025; .025-.125; <.125).

Figure 2. Simulation 2: Final relative attention weights for RASHNL

Figure 3. Simulation 2: Final relative attention weights for SUSTAIN

Discussion: The results of Simulation 2 are striking. First, both RASHNL and SUSTAIN pay considerable attention to a constant dimension (that has zero diagnosticity) under a wide range of parameter settings. In fact, RASHNL shows many solutions with relative weight exceeding 50% for D2 (with 5 dimensions). SUSTAIN invariably gives equal attention weight to D2 and D1, the unidimensional rule dimension. In this sense it is the least successful of the three models at ignoring D2. An explanation for this behavior of SUSTAIN is given below.

Second, the network models also differ in their tendencies to adopt the rule-based solution (using dimension D1) versus the exemplar-level representation (using D3-D5). For ALCOVE, successful learners tend to give high total attention weight to the “exemplar” dimensions D3-D5. These exemplar-based attention patterns occur often when the association learning rate is high, but rule-based attention patterns predominate when it is very low (Figure 1). For RASHNL, successful learners tend to weight the simple rule dimension (D1) more than the exemplar dimensions (D3-D5), and this tendency increases for low learning rates. Of the three models, SUSTAIN’s successful learners give the least attention to the exemplar-identifying dimensions D3-D5. SUSTAIN pays somewhat more attention to these exemplar-identifying dimensions when the association learning rate is very low, the opposite pattern to that shown by ALCOVE and RASHNL.

Surprisingly, SUSTAIN gave the same amount of attention to D2 as to D1. Clearly, this tendency of SUSTAIN must arise from the structure and processing assumptions of the model. In fact, the reason that SUSTAIN finds D1 and D2 equally compelling is easy to identify, and stems from how SUSTAIN utilizes its reference points (i.e., clusters or prototypes) in learning. SUSTAIN utilizes only the single most activated cluster to determine an exemplar’s classification and to guide learning. In this model, the update in attention strength for each dimension is inversely proportional to the distance from the most activated cluster’s mean value and the value of the current input stimulus on that dimension (i.e., the smaller the dimensional distance, the more attention is increased for that dimension). For a constant dimension, any cluster and any input stimulus will have zero distance on that dimension, thus attention will be increased to the maximal degree possible on the constant dimension. In the present simulation, D1 is a perfect predictor with constant values *within* categories, thus any cluster that does not combine exemplars from across categories will also have zero distance on that dimension between the cluster centroid and the input stimulus, leading to an equivalent increase in attention strength to D2.

The critical aspect of the processing assumptions here is the winner-take-all nature of the utilization of the clusters, which means that the diagnosticity of a dimension relative to contrasting clusters has less effect. The net result in statistical terms is that the potential increase in attention to a dimension is a function of the similarity of the input

stimulus and the cluster centroid on that dimension. This places greater emphasis on within-category similarity and less on between-category differentiation, relative to the processing assumptions of ALCOVE and RASHNL. This line of analysis suggests that SUSTAIN will tend to select dimensions whose values have high category validity, $P(f|c)$, over those with high cue validity, $P(c|f)$, or with the best information gain (cf. Corter & Gluck, 1992).

Failing to ignore a dimension with zero diagnosticity seems like a major flaw of the three models, at least from a normative standpoint, because incorporating a constant dimension in a category's representation has cost without any obvious adaptive value. However, human data is needed to see if constant dimensions are indeed attended to and incorporated into a category's representation. It seems unlikely that in a category learning experiment human learners would waste time and effort memorizing or checking properties of a stimulus if those properties were seen to be useless for the task at hand.

On the other hand, it might be that such constant properties are learned implicitly, whether or not they are useful in a specific experimental task. An example might indicate why this is a reasonable possibility. A child learning the category *animal* might notice that all animals have mass. Is this fact incorporated into the child's representation? This certainly seems reasonable, though some normatively motivated theories of mental organization (e.g., Collins and Quillian, 1969) hold that the property of having mass should be stored at a superordinate level (say, under the category *object*) and merely inferred as needed in order to reason about animals and their properties.

Conclusions

The present analyses and simulation results show that the models examined here, ALCOVE, RASHNL, and SUSTAIN, incorporate differing attention learning mechanisms and processing assumptions that lead to distinct predictions regarding attention learning in the simulation studies reported here. The results from Simulation 1 supported the hypothesis that SUSTAIN tends to attend to dimensions that are correlated with other predictors, while the other models give relatively greater attention to more independent predictors, perhaps because they better support exemplar-level processing. Simulation 2 showed that the three models differ in their tendencies to use rule-based versus exemplar-based learning strategies. Another surprising result from Simulation 2 was that all three models incorporated a constant (i.e., completely nondiagnostic) dimension into their representations to some degree.

We believe that simulation studies on attention allocation in category learning are valuable for two reasons. First, they help us to better understand the behavior of complex computational models of category learning. Second, they can help to guide empirical work on attention by suggesting new hypotheses about human attention learning, hypotheses that can be verified using methods for assessing attention such as eye-tracking (e.g. Rehder & Hoffman, 2005) or

information-board methods (Matsuka & Corter, 2008). These hypotheses may then be used to design empirical studies by suggesting stimulus structures and tasks that best differentiate predictions of the models.

Investigating Insight Using Compound Remote Associate Problems

Edward A. Cranford (eac53@msstate.edu)

Jarrold Moss (jarrod.moss@msstate.edu)

Department of Psychology, Mississippi State University
Mississippi State, MS 39762 USA

Abstract

Many new problems and paradigms have been developed to answer questions pertaining to insight problem solving. One problem type that may be useful to the study of insight is the Compound Remote Associate (CRA) problem, developed by Bowden & Jung-Beeman (2003). However, it is uncertain to what extent CRA problems are insight problems. We performed a protocol analysis of people solving CRA problems and found that CRA do exhibit some characteristics of insight. However, certain considerations should be taken into account. Particularly, problems solved when the solution is the first thing considered are often judged to be insight by participants, but these problems do not exhibit any characteristics of insight aside from the 'Aha' experience.

Keywords: Insight; Problem Solving; Restructuring; Impasse

Introduction

Problem solving enables us to discover solutions to problems. Sometimes, however, we reach an impasse, or road block, in the problem solving process. We may realize there is some flaw in our efforts, and the solution may seem unattainable, but the source of our error remains hidden. We may contemplate for a long period of time until, all of the sudden, the answer seems obvious. This phenomenon has been termed insight, and is loosely defined as achieving a solution without knowing where the solution came from.

Some phenomenological features are unique to insight. Insight solutions often appear from nowhere and solvers experience an affective response of suddenness and surprise (Aha! experience), sometimes resulting after an impasse; insight solutions are obtained through processes known as restructuring, whereby an incorrect representation of the problem is changed, leading to the access of an insightful, correct representation of the problem (e.g., Bowden, Jung-Beeman, Fleck, & Kounios, 2005; Ohlsson, 1992; Schooler, Fallshore, & Fiore, 1995). The key components of insight are often described as impasse, restructuring, and 'Aha!'.

Problems Used for Insight Research

Many types of problems have been used to study insight. Classic insight problems have been used extensively, and sometimes the reason is solely based on the fact that they have previously been used to study insight (Weisberg, 1995). With the emergence of advanced neuroimaging techniques (e.g., functional Magnetic Resonance Imaging [fMRI], Electroencephalography [EEG], etc.), and the great amount of time it takes to solve (if at all) complex, classic insight problems, new problems and paradigms have been used to investigate insight (Bowden et al., 2005). One

specific problem type that has been used is the compound remote associate (CRA) problem (Bowden & Jung-Beeman, 2007). CRA problems involve finding the one word that can form a compound word or phrase with each of three different words. For example, if three words—tree, sauce, and big—are presented, the solution is apple. CRA problems are solved much quicker than classic insight problems. They can be solved by insight or by noninsight, search processes (i.e., generate-and-test or trial-and-error), and individual problems can be solved with insight regardless of learning effects over multiple trials (Bowden & Jung-Beeman, 2007). Given these differences between classic insight problems and CRA problems, the question is to what extent CRA problems are insight problems.

Are CRA problems Insight Problems?

Though differences have been found between insight-CRA problems and noninsight-CRA problems (Bowden & Jung-Beeman, 2007; Bowden et al., 2005; Jung-Beeman et al., 2004; Kounios et al. 2006), we need more empirical evidence that CRA problems can be used to study insight. Specifically, evidence is needed to show that CRA problems exhibit properties characteristic of insight, and that there are differences between solving a CRA problem with insight and solving one without insight beyond the Aha experience.

Bowden and Jung-Beeman (2003; 2007) and Bowden et al. (2005) claim CRA problems exhibit phenomenological features and components of insight found in classic insight problems and, therefore, should be used to study insight. The processing is often unreportable, the problems misdirect (or fail to direct) retrieval processes, and people experience the Aha!. These are reasons to assume that CRA problems can be used to study insight. However, because CRA problems are hybrid problems, rated insight or noninsight by the solver on a forced choice scale, and are such short and simple problems, there is concern about their use to study insight. A critical component not listed above for CRA problems is the process of restructuring, and it is unclear to what extent CRA problems exhibit restructuring prior to insight solutions.

We designed a study using concurrent verbal protocols of CRA problem solving to determine if CRA problems solved with insight exhibit more characteristics of insight, than CRA problems solved without insight. The characteristics of insight examined are impasse, restructuring, and verbal overshadowing. We expect higher rates of impasse and more restructuring processes in insight solutions than noninsight solutions. Concurrent verbalization of cognitive processing has been shown to inhibit solving a problem with

insight (Schooler, Ohlsson, & Brooks, 1993) resulting in a lower solution rate such that fewer problems are solved with insight than when problems are not verbalized. However, other research (i.e., Fleck & Weisberg, 2004) suggests verbalization does not necessarily inhibit solutions by insight and differences in verbalization instructions may differentially influence problem solving processes. In fact, the present research used an adaptation of the coding scheme used by Fleck and Weisberg as well as similar verbalization instructions, therefore, it is plausible that insight solutions may not show this verbal overshadowing effect. The results of this study should further inform the use of CRA problems in the study of insight.

Method

Participants

Participants were 31 undergraduates enrolled in a psychology course at Mississippi State University who received course credit for their participation. All participants were native English speakers.

Design

The design was a 2 (Verbal-Task: verbalization, nonverbalization) \times 3 (Solution-Type: insight, noninsight, other) within-subject design. Solution-Type was measured by the subjective ratings given by the participant, rather than manipulated.

Materials

The task, described as word association problems to participants, consisted of a set of 60 CRA problems taken from a larger set of 144 normed CRA items (Bowden & Jung-Beeman, 2003). Problems were chosen based on information from a baseline study at Mississippi State University using all 144 problems. Problems with the highest solution rates that had been solved with insight, on average, half of the time were included in the set. An additional six problems from the set of 144 problems were used for practice trials. The 60 problems were presented in random order and randomly assigned to Verbal-Task condition for each participant. The problems were displayed on a 17-in. computer monitor and answers were given by typing on a keyboard. The task procedure was implemented using E-Prime software (Schneider, Eschman, & Zuccolotto, 2002). Concurrent verbal protocols were obtained via headset and recorded using E-Prime.

Procedure

Participants were run individually. After receiving informed consent, participants were instructed on the task and given descriptions of the differences for rating a problem with insight, noninsight, or other. These instructions were very similar adaptations taken from Jung-Beeman et al. (2004) and Kounios et al. (2006). The experimenter answered any questions the participants had about the tasks and the rating

scale. Then the experimenter started the experiment on the computer, and the participants were instructed to read the directions presented for a second time via computer. After reading the general instructions, specific task instructions were given depending on the Verbal-Task condition for each participant. Participants were counterbalanced between Verbal-Task conditions so that half experienced the verbalization task first and the other half experienced the nonverbalization task first. For the verbalization condition, participants were instructed on how to verbalize their thoughts during problem-solving efforts based on the think-aloud instructions found in the appendix of Ericsson and Simon (1993). Participants who were asked to think aloud first were given instructions and training in how to verbalize their thoughts before the first task and told that they did not have to think aloud anymore right before the second task. If the first task was to solve problems without thinking aloud then participants were asked if they had any questions and allowed to continue. For these participants, think-aloud instructions were given after completing the nonverbalization task.

Participants were given three practice CRA problems before each Verbal-Task condition to make sure that they understood the difference in responses for rating a problem (insight, noninsight, and other), were verbalizing correctly, and understood the task requirements. The practice problems may have also helped to reduce some carryover effects from prior verbalization. Participants began the CRA task by pressing a button. The problem words were presented for a maximum of 30 seconds. Participants could give a solution at any time during the 30 second interval by typing their answer. If the given solution was incorrect they could continue work on the problem until time ran out. Upon correct solution within the time limit, participants were prompted to give a rating of whether they solved the problem via insight, noninsight, or other. The order of ratings was counterbalanced so that for half of the participants a rating of 1 was insight and a rating of 3 was noninsight and, for the other half, a rating of 1 was noninsight and a rating of 3 was insight. After a rating was given or solution time ran out, the next problem was presented. Thirty problems were presented and then the participant was asked to stop and notify the experimenter. The experimenter then gave the participant the appropriate instructions for the second Verbal-Task condition; after which, the participant continued to solve the next 30 problems while thinking aloud or keeping silent. Upon completion of the CRA task, participants were debriefed.

Results

Six subjects were dropped from all analyses ($n = 25$) due to outlier and zero data. One subject reported solutions by "other" much more often than any other subjects and five subjects reported solving problems only with insight, or only with noninsight, within at least one level of Verbal-Task.

Solution Rates and Times

Solution rates were calculated in each Verbal-Task condition for each Solution-Type as a percentage of problems solved (e.g. Insight percentage = number of insight solutions/number of total problems attempted). Response times were obtained for each solved problem to calculate the average time to solution for each Solution-Type and each Verbal-Task. Time started when the problem first appeared and ended when the final solution was entered. A verbal overshadowing effect is present if thinking aloud has a negative affect on response time and the number of problems solved (particularly with insight).

Overall, participants solved an average of 52.4% ($SD = 11.10\%$) of problems. For solved problems, participants reported solution by insight 52.04% ($SD = 15.27\%$) of the time, noninsight 37.14% ($SD = 17.58\%$) of the time, and other 10.81% ($SD = 11.16\%$) of the time. Average time to solution was 10.67 seconds ($SD = 1.57$). There were no effects of counterbalancing the orders of ratings or verbalization task conditions within subjects, so the data were collapsed across these levels of counterbalancing.

A 2 (Verbal-Task) X 3 (Solution-Type) within-subjects repeated measures analysis was performed to analyze the effects of Verbal-Task and Solution-Type (Insight, Noninsight, Other) on the percentage of problems solved (solution rates). More problems were solved in the Nonverbalization condition ($M = 56.40\%$, $SD = 11.37\%$) than in the Verbalization condition ($M = 48.40\%$, $SD = 14.52\%$), $F(1,24) = 8.64$, $p = .007$. Solution rates also differed for different Solution-Types, $F(2,48) = 30.69$, $p < .001$. Pairwise comparisons revealed that more problems were solved with Insight ($M = .279$, $SD = .117$) than Noninsight ($M = .192$, $SD = .093$), $t(24) = 2.58$, $p = .016$, and Noninsight than Other ($M = .053$, $SD = .054$), $t(24) = 5.353$, $p < .001$. Verbalization did not differentially affect the proportion of solutions across problem types as the Verbal-Task by Solution-Type interaction was not significant, $F(2,48) = .464$, $p = .631$ (Figure 1 shows a breakdown of the solution rates). Subsequent paired t-tests comparing the distributed proportions of correct insight, noninsight, and other solutions between levels of Verbal-Task also revealed no significant effects, all $t(24) < .70$, all $p > .50$, indicating that verbalization may affect the total number of problems solved but not the distribution of solution types.

For all following analyses only two levels of Solution-Type were used (Insight and Noninsight but not Other) because many subjects did not report "other" for any solved problems. A 2 (Verbal-Task) X 2 (Solution-Type) within-subjects repeated measure analysis was performed for solution response times. Response times were longer for Noninsight solutions ($M = 12.9$ seconds, $SD = 3.29$) than Insight solutions ($M = 9.8$ seconds, $SD = 4.18$), $F(1,24) = 5.74$, $p = .025$, and longer for Verbalization ($M = 12.3$ seconds, $SD = 2.46$) than Nonverbalization ($M = 10.4$ seconds, $SD = 2.41$), $F(1,24) = 10.21$, $p = .004$. As seen in the prior analysis, the interaction between Verbal-Task and Solution-Type was not significant, $F(1,24) = .553$, $p = .464$.

Figure 1: Solution rates of attempted problems. Mean percentage of attempted problems solved with insight, noninsight, or other while verbalizing and while not verbalizing. Error bars indicate one standard error.

Though it takes people longer to solve problems while thinking aloud, people will not likely solve any more problems if given more time. The results show that thinking aloud while attempting to solve CRA problems inhibits solution regardless of the solution method (insight, noninsight, or other) indicating an overarching verbal overshadowing effect. However, verbalization does not differentially affect insight and noninsight CRA solutions, which indicates that verbalization is not influencing the way in which the solution occurs but only if it occurs at all. Therefore, the verbal protocols may be used as data.

Verbal Protocol Analysis

The verbal protocols were coded for occurrences of impasses and restructuring elements. Impasse was calculated as the average number of impasses reached per correct solution and was coded into five different types. Restructuring was calculated as the average number of times restructuring occurred per correct solution and were coded into three different types. Because the amount of time a person spends on a problem affects the amount of impasses and restructuring that can possibly be obtained, each score for each problem was first divided by the amount of time it took to solve the problem before obtaining an average score for each participant. Details of each coding scheme are discussed below with each respective analysis.

When examining the verbal protocols we identified two distinct types of insight solutions. The first type of insight solution, termed "immediate-insight," occurs when the first candidate solution verbalized by the participant was the solution and this solution occurred within 15 s of the problem being presented. The second type of insight solution, termed "delayed-insight," are all other insight solutions not classified as "immediate-insight". A person may report the quickly solved problems as insight simply because they came to a solution so fast that it seemed sudden and surprising. However, it is unclear whether this should be called insight. Immediate insight solutions do not

Table 1: Within-subjects Repeated Measures Analysis for Each Level of Impasse (n=22).

Analysis	Means			
	Combined Insight	Immediate-insight	Delayed-insight	Noninsight
Rereading	0.0028 (0.0086)	0 (0)	0.0049 (0.0115)	0.0024 (0.0065)
Regenerating	0.0007 (0.0035)	0 (0)	0.0029 (0.0138)	0 (0)
Discontinuing	0.0006 (0.0020)	0 (0)	0.0028 (0.0099)	0.0038 (0.0131)
No New	0.0038 (0.0089)	0 (0) **	0.0089 (0.0173)	0.0058 (0.0083)
Frustration	0.0024 (0.0047)	0 (0) **	0.0135 (0.0297)	0.0071 (0.0157)
Total Impasse	0.0105 (0.0171)	0 (0) **	0.0332 (0.0375)*	0.0191 (0.0281)

Notes. Values represent mean number of occurrences per second. Standard deviations are in parentheses. Noninsight means remained the same for all analyses and are compared to each type of insight. Significant effects are represented by stars (*) in the "Insight" columns.

* $p < .10$. ** $p < .05$.

exhibit any observable signs of impasse or restructuring in the verbal protocols and are the first solution candidate reported (clearly not insight as it is traditionally defined). Of solutions reported as insight, 77.73% ($SD = 17.16\%$) were immediate-insight and 22.3% ($SD = 17.16\%$) were delayed-insight. There were almost no immediate noninsight solutions. Therefore, in all subsequent analyses, noninsight solutions were not separated in order to simplify comparisons.

Three analyses for each coded variable were performed with only two levels of Solution-Type (Insight and Noninsight) and one level of Verbal-Task (verbalization). Three additional subjects were dropped from the analyses ($n=22$) because they did not report any delayed insight solutions. In an initial analysis we compared the combined delayed- and immediate- insight solutions ("combined insight") to noninsight solutions. A second analysis compared immediate-insight to noninsight solutions. A third analysis compared delayed-insight to noninsight solutions. The results of splitting insight into two categories reveal large differences between the effects seen in the combined insight versus noninsight analyses and the effects seen in the delayed-insight versus noninsight analyses.

Impasse Five types of Impasse were coded (Regenerating, Rereading, Discontinuing, No-New, and Frustration). Regenerating meant that a person generated the same solution candidate two or more times within a problem. Rereading meant that a person reread the problem words three or more times in succession without generating a solution candidate. Discontinuing meant that the person completely stopped solving the problem and in which no progress toward solution was being made. No-New meant that a person stopped generating new solution words for at least 15 seconds after onset of a problem or at least 10 seconds between candidates. Finally, Frustration meant that a person exhibited clear signs of emotional frustration and experienced real difficulty with the task or specific problem. The individual scores were summed to get a total impasse score. Two independent raters coded the data, and

agreement between raters on the number of total impasses per solution was good (Pearson $r = .84$, Kendall's tau = .77).

Three within-subjects repeated measure analyses were performed on total impasse scores per Solution Type. In the first analysis, the amount of total impasse was no different for Noninsight ($M = .191/\text{second}$, $SD = .028$) than Combined Insight ($M = .0105/\text{second}$, $SD = .017$) problems, $F(1,21) = 1.687$, $p = .208$ (see Figure 2). In the second analysis, there was significantly less impasse for Immediate-insight solutions ($M = 0$, $SD = 0$) than Noninsight solutions, $F(1,21) = 10.11$, $p = .005$. When comparing Delayed-insight and Noninsight solutions, the amount of total impasse for Delayed-insight solutions ($M = .033/\text{second}$, $SD = .038$) is marginally greater than that of Noninsight solutions, $F(1,21) = 3.649$, $p = .070$ (see Figure 2). When immediate- and delayed- insight solutions are combined in the analysis there is a higher rate of impasse for noninsight solutions due to the effect of immediate-insight solutions, but when only delayed-insight solutions are included there is a lower rate of impasse for noninsight solutions (see Table 1).

Figure 2: Mean rate of impasse for combined insight, immediate-insight, delayed-insight, and noninsight solutions. Immediate-insight does not show because it is zero. Error bars indicate one standard error.

Table 2: Within-subjects Repeated Measures Analysis for Each Level of Restructuring (n=22).

Analysis	Means			
	Combined Insight	Immediate-insight	Delayed-insight	Noninsight
Re-encoding	0.0174 (0.0199)	0 (0) **	0.0510 (0.0460)**	0.0296 (0.0332)
Elaboration	0.0039 (0.0096)	0 (0) *	0.0123 (0.0330)	0.0036 (0.0083)
Constraint Relaxation	0.0008 (0.0029)	0 (0)	0.0028 (0.0093)	0.0016 (0.0056)
Total Restructuring	0.0221 (0.0209)	0 (0) **	0.0660 (0.0497)**	0.0348 (0.0312)

Notes. Values represent mean number of occurrences per second. Standard deviations are in parentheses. Noninsight means remained the same for all analyses and are compared to each type of insight. Significant effects are represented by stars (*) in the "Insight" columns.

* $p < .10$. ** $p < .05$.

Restructuring Restructuring was coded into three different types (Elaboration, Re-encoding, and Constraint Relaxation). Elaboration meant that a person switched to a different meaning of a problem word after trying and failing to find a solution with the first meaning of a word (i.e. star has multiple meanings: starlight or superstar). Re-encoding meant that a person switched to a different problem word to try and find a solution after failing with a previous word. Finally, Constraint Relaxation meant that a person revised the idea of the goal. The person switched the method for solving the problem or clearly stated that they needed to try something different to get a solution. Individual scores were summed to obtain a total restructuring score. Two independent raters coded the data, and agreement between raters on the number of total restructurings per problem was good (Pearson $r = .77$, Kendall's tau = .71).

Three within-subjects repeated measure analyses were performed on total restructuring scores per Solution Type. In the first analysis, the amount of total restructuring was no different for Noninsight solutions ($M = .0348/\text{second}$, $SD = .0312$) than Combined Insight solutions ($M = .0221/\text{second}$, $SD = .0209$), $F(1,21) = 2.251$, $p = .148$ (see Figure 3). In the second analysis, there is significantly less restructuring for Immediate-insight solutions ($M = 0$, $SD = 0$) than Noninsight solutions, $F(1,21) = 27.47$, $p < .0001$. Again, when comparing Delayed-insight and Noninsight solutions the amount of total restructuring is significantly greater for Delayed-insight solutions ($M = .066/\text{sec}$, $SD = .050$) than Noninsight solutions, $F(1,21) = 8.847$, $p = .007$ (see Figure 3). When immediate and delayed-insight solutions are combined in the analysis there is a higher rate of restructuring for noninsight solutions due to the effect of immediate-insight solutions, but when only delayed-insight solutions are included there is a lower rate of restructuring for noninsight solutions (see Table 2).

Discussion

The purpose of the experiment was to determine if CRA problems can reliably used as insight-like problems. If CRA problems are insight problems, then there should be higher restructuring scores and impasse scores for insight solutions compared to noninsight solutions. Also, according to Schooler et al. (2003), there should be a verbal overshadowing effect.

Figure 3: Mean rate of restructuring for combined insight, immediate-insight, delayed-insight, and noninsight solutions. Immediate-insight does not show because it is zero. Error bars indicate one standard error.

The results indicate at least some verbal overshadowing effect when solving CRA problems while thinking aloud. Verbalization hindered solution rates and response times for both insight and noninsight solutions. Short-term memory, working memory, and long-term memory retrieval are impacted by concurrent verbalization of processes that are not normally verbalized (Ericsson & Simon, 1993; Schooler et al., 1993). Verbalizing may hinder people from keeping track of where they are and where they are going (in working memory) as well as accessing seemingly distant concepts (in long-term memory). Therefore, both insight and noninsight CRA problem solving methods can be affected by concurrent verbalizations.

The analysis of verbal protocols provided a few unique findings. The results of the impasse and restructuring analyses comparing combined insight and noninsight solutions indicated that noninsight solutions had a slightly higher rate of impasse and restructuring. However, closer inspection of insight solutions revealed that many problems solved with insight were simply the first word that came to mind. The processes used here might not actually be that of insight. People may report insight simply because the answer was sudden. Or, there may have been insight, but that it occurred so quickly that participants were not able to verbalize much before solution. Using people's subjective 'Aha!' experience as a marker of insight might not be a

reliable indicator of insight by itself (or at least it indicates that different problem solving processes can lead to insight).

Further analyses revealed a significant difference in the methods used to solve the problems. The problems solved immediately with insight had no observable characteristics of insight (impasse and restructuring), while the delayed insight solutions had more of the characteristics of insight. When analyzed together insight solutions are derived faster and have significantly less rates of impasse and restructuring than noninsight solutions, but when immediate insight solutions are removed from the analysis the results differ. Delayed-insight solutions are derived in about the same time as noninsight solutions and have significantly more rates of impasse and restructuring than noninsight solutions. There may be two different methods for obtaining insight for CRA problems. Paraphrasing Newell (1973), people may perform a task using different methods and psychologists should take this into account when analyzing data. The effect of averaging over methods “conceals, rather than reveals” (p. 295) any true effect.

From the results, there is some concern that some prior results may have been clouded by averaging the data of the two distinct types of insight (immediate and delayed). For example, neuroimaging results using CRA problems have found more activity in the right anterior superior temporal gyrus, possibly indicating the sudden emergence of the correct solution, that may be facilitated by cognitive control activity prior to problem onset in the dorsal anterior cingulate cortex (Jung-Beeman et al., 2004; Kounios et al., 2006; Subramaniam et al., 2009). However, the results likely include many immediate-insight solutions in the data. There might be different, or additional, areas that are necessary for insight, which are not revealed in prior studies. The areas noted in these prior studies might actually be specific only to immediate-insight and not delayed-insight which often involve restructuring (a staple of the traditional insight definition).

The conclusion drawn is that separating the two types of insight solutions during analysis may reveal different results than prior studies. By pulling apart the two types of insight solutions the processes of insight can be further explored. For example, delayed-insight solutions reveal restructuring elements in the verbal protocols. Immediate-insight solutions do not show observable elements of restructuring. Therefore, the pattern of activation for immediate-insight solutions (and associated processes) may greatly differ from the pattern of activation for delayed-insight solutions. Comparing the solution types may reveal cortical areas necessary for restructuring while eliminating the activation of other common “insight areas.” After all, the delayed type insight solutions seem to resemble real world insight more than the immediate type and fit better to the traditional definition of insight. In conclusion, CRA problems can, and should, be used to study insight. However, future work should differentiate immediate- and delayed- insight solutions.

Acknowledgments

We would like to thank Andrew Watkins, Willie Sullivan, Ariel Sibley, and Alesha Lindsey for their help in data collection. Special thanks go to Joshua Liddell for many hours helping to transcribe and code verbal protocols.

Abstract

This paper describes the results of a study investigating the process by which writers develop their understanding through writing. It argues that, contrary to problem-solving models of writing, the crucial ingredient is implicitly guided text production. Two groups of writers, varying in the extent to which their writing is assumed to be directed towards rhetorical goals, were asked to write either planned or non-planned texts. Key-stroke logs were collected, and changes in subjective understanding about the topic were measured. The results show that developments of understanding are strongly related to the extent to which writers modify their texts during writing, and this is highest in the conditions expected to promote implicitly guided text production. We conclude that these findings support a dual-process model of writing.

Keywords: Planning; knowledge change; writing processes; keystroke logging; text production.

Introduction

Writing is an ideal area in which to study the ebb and flow of thought. Although the end product is a fixed knowledge object which has to be comprehensible in the absence of the writer, the process by which it is produced is an extremely dynamic one, in which writers both have to work out what they think about a topic and how best to communicate this to their readers. For this reason, writing is typically characterized as a process of discovery. Bereiter and Scardamalia (1987), for example, characterize expert writing as a knowledge-transforming process, during which writers actively transform their thought in response to their evolving goals, and contrast this with the knowledge-telling process employed by novice writers, in which a fixed store of ideas in long term memory is translated directly into text. They claim that the knowledge-transforming model accounts for the "the peculiar value that many have claimed for writing as a way of developing one's understanding" (Bereiter & Scardamalia, 1987, p. 302). In this paper, we describe the results of an experiment investigating the conditions under which writers develop their understanding and how this is related to a simple indicator of one of the processes involved in writing.

According to Bereiter and Scardamalia's (1987) knowledge-transforming model, discovery through writing is a consequence of rhetorical problem solving. This claim has three important features. The first is an emphasis on the explicit thinking processes involved in the generation and evaluation of content rather than on the processes involved in translating thought into language. Second, and following from this emphasis, the crucial contrast between the knowledge telling and knowledge transforming processes is the goals toward which writing is directed. Thus, in the knowledge-telling model, the goal is to retrieve ideas stored in memory and translate these into text. By contrast, in the knowledge-transforming model, content retrieval and evaluation is mediated by the writer's communicative goals: expert writers develop an elaborate representation of their audience and the rhetorical situation and use this to guide the generation of content. This leads to the re-evaluation of existing content in long term memory and to the formulation of new content. Third, the extent to which writers are able to engage in this reflective evaluation of content depends on how they manage the interaction between high-level thinking processes and the formulation of content in text. Translating processes and higher level thinking processes are assumed to compete for limited cognitive resources, and hence it is assumed that writers will be less able to engage in rhetorical problem-solving the more they try to carry out text production at the same time as generating content. It is this conflict which is assumed to be responsible for the beneficial effects of outlining prior to writing. Kellogg (1988) has provided convincing evidence that outlining is associated with the production of better quality text, and that this is because it enables writers to clearly separate the reflective processes involved in generating, organizing and evaluating ideas from the processes involved in formulating these ideas in well-formed text.

Overall, the knowledge-transforming model and associated research on the benefits of outlining suggests that discovery through writing is a consequence of the strategic modification of content in order to satisfy rhetorical goals, and that this will be enhanced when the writer is able to focus on higher level thinking processes free from the demands of simultaneously formulating full text.

Recently, Galbraith (2009) has questioned this account on empirical grounds. In a series of experiments examining the conditions under which writers develop their understanding, Galbraith and his colleagues have found different patterns of development of understanding through writing than would be expected on the basis of the rhetorical problem-solving model. In brief summary, the essential pattern of their findings is as follows. First, although writers whose writing is assumed to be directed towards rhetorical goals (high self-monitors) do develop more new content after making notes than when they are required to write full text, as would be expected if discovery depended on the extent to which writing was directed towards rhetorical goals, this new content was not associated with increases in writers' subjective understanding of the topic. Second, there was also evidence that writers whose writing was assumed, not to be directed towards rhetorical goals, but rather to be implicitly organized (low self-monitors), developed new content after writing full text, without pre-planning, and that this was associated with developments of subjective understanding. (See Snyder and Gangestad, 1986, for a review of differences between low and high self-monitors.)

On the basis of these experiments, Galbraith has suggested an alternative dual-process account of discovery through writing. This proposes that the development of understanding in writing depends on an interaction between two different kinds of process. The first of these is an explicit planning process. This involves the retrieval of content from an explicit store of ideas and the goal-directed manipulation of these ideas in working memory designed to create a coherent knowledge object that satisfies rhetorical goals. This is essentially equivalent to the knowledge transforming model of Bereiter and Scardamalia, with the crucial difference that, by itself, this process only involves the reorganization of existing knowledge and is not associated with developments of understanding. The second is an implicit text production process. This operates on an implicit store of conceptual knowledge in semantic memory, which Galbraith defines as the writer's disposition towards the topic, and involves synthesizing content during text production. The key features of this process, for present purposes, are that it is engaged when writers have to formulate their thought in explicit propositions, and that, because the process is guided by the implicit organization of material in semantic memory, the sequence in which content is produced is unpredictable. Content is synthesized in the course of formulation rather than being directly retrieved from memory and translated into text. This process is assumed to lead to developments of understanding when the content it produces is different from the explicit content stored in episodic memory.

The model suggests that the implicit text production process will be at a maximum when writing is (i) dispositionally guided, i.e. for low self-monitors, and (ii) not outline planned, i.e. the order in which content is produced is governed by the implicit organization of content in semantic memory rather than by an explicit, pre-determined

plan in working memory. The implicit text production process will be minimized when writing is (i) directed towards rhetorical goals, i.e. for high self-monitors, and (ii) controlled by an outline, i.e. when the sequence of text production is pre-determined. Furthermore, it suggests that, because changes in content can be induced by both explicit planning and implicit text production, but only implicit text production leads to the development of understanding, there will be no direct relationship between the overall amount of change in content and the development of understanding. Instead, the development of understanding will be directly linked to the extent that new content is produced by the implicit text production process.

This experiment set out to test these claims by using key-stroke logging to provide a direct measure of the extent to which content was modified during the course of text production, and examined how this varied depending on the conditions under which writing took place, and how it was related to developments in the writer's personal understanding of the topic. The present paper will report the results for a simple indicator of content modification during text production, which we will label as the *text modification index*. This corresponds to the total number of words recorded by key-stroke logging divided by the total number of words appearing in the final text. When writers transcribe their thoughts directly into text the index should be 1: all the words that are written down during text production will be retained in the final text. To the extent that the writer changes the way that they express their ideas during text production the index should increase: writers will produce more words during the process of text production than appear in the final text.

The design of the experiment was based on a previous experiment by Galbraith, Torrance and Hallam (2006) and manipulated two variables: self-monitoring and planning. Each group was asked either to make an outline before writing or to sum up their overall opinion of the topic prior to writing (a procedure we call synthetic planning, and which differs from outline planning in that it does not specify the order in which content should be produced during text production.). Our aim was to replicate the conditions of this earlier experiment with a view to assessing how the text modification index varied under these conditions. We expected that, if the dual-process model is correct, the text modification index should be at a maximum when low self-monitors produce synthetically planned texts, and that increases in subjective understanding should be associated with high levels of text modification, rather than with the overall amount of change in content produced in the different conditions.

Method

Participants

84 students from the faculty of Arts of the University of Groningen were recruited to participate in the experiment. They were all native Dutch speakers, average age 22.2 years

($SD = 3.8$), and were pre-selected using Snyder's revised 18 item self-monitoring scale (Snyder & Gangestad, 1986). Participants could only take part if they were classified either as a high or a low self-monitor. They were classified as *high self-monitors* (HSM, $n = 42$) if they scored 11-18 on the scale and as *low self-monitors* (LSM, $n = 42$) if they scored 0 - 8 on the scale.

Design and procedure

High and low self-monitors were randomly allocated to the two planning conditions resulting in the following four experimental groups: (i) HSM outline planning, (ii) HSM synthetic planning, (iii) LSM outline planning and (iv) LSM synthetic planning.

Writing task In all four conditions, participants were asked to plan and write an article for the university newspaper discussing whether "our growing dependence on computers and the Internet is a good development or not". The writing task was divided into three phases.

In phase 1, participants were first given 10 minutes to list all the ideas they could think of relevant to the topic. It was stressed that each idea should be no longer than a sentence in length. They were then asked to rate how much they felt they knew about the topic on a 7-point scale.

In phase 2, participants were given 5 minutes to either write down a single sentence summing up their overall opinion (synthetic planning) or to construct a structured outline (outline planning). They were then given 30 minutes to write a well-structured article for the university newspaper. It was stressed that they had to produce a reasoned argument reflecting their own opinion about the matter. Participants were allowed to consult their written outlines. During writing, keystrokes were logged using Inputlog (Leijten & Van Waes, 2006).

In phase 3, immediately after writing, participants were asked again to rate how much they felt they knew about the topic. They were then given 10 minutes to again list all the ideas they could think of relevant to the topic. Finally, they were asked to compare the lists produced before and after writing, and to rate the extent that ideas on list 2 corresponded with ideas on list 1, using a 6-point scale ranging from 1=identical point to 6=no correspondence.

Measures

Subjective development of understanding The ratings of knowledge were used to assess subjective changes in understanding as a consequence of writing.

Development of ideas This was assessed using the procedure used in previous research. New ideas were defined as ideas in the second list that received ratings from 4 to 6 for their correspondence with ideas in the first list. Preserved ideas were defined as ideas in the second list that received ratings from 1 to 3 for their correspondence with ideas in list 1. The average length of these ideas was also calculated. These were assessed against baseline measures

of the number and average length of ideas in the list produced before writing.

Text modification index In order to assess the process by which writing is carried out a text modification index was calculated. For the text modification index the total number of words recorded by Inputlog are divided by the number of words appearing in the final text.

Data screening Preliminary analysis of the data revealed 6 outliers (i.e. scores more than 3 SD's above or below the mean). Three participants had extremely low scores on the initial or post knowledge rating. One had an extremely high score on the mean length of ideas. Two had extremely high scores on the text modification index. These participants were removed from all analyses.

Results

Development of subjective understanding

A two-way (2×2) between subjects ANCOVA with self-monitoring and planning as factors and with prior knowledge as a covariate revealed a significant main effect of type of planning on subjective understanding after writing ($F(1,73) = 4.61, p = .035, \eta^2 = .033$). Figure 1 shows the mean ratings of knowledge before and after writing in each condition (with error bars showing standard errors).

Figure 1: Development of subjective understanding as a function of type of planning.

Planned comparisons comparing mean knowledge ratings before and after writing in the synthetic and outline planned conditions showed that there was a significant increase in knowledge in the synthetic planned condition ($t(39) = 3.34, p = .002$) but no significant difference in the outline planned condition ($t(37) = 0.47, p = .64$).

Effects on idea change and relationships with developments of subjective understanding

To assess the relationship between changes in the content of the lists produced before and after writing and changes in subjective understanding, we converted the knowledge

ratings to a category variable representing the extent to which knowledge increased, decreased or remained the same. We then carried out a 3-way between subjects MANCOVA, with self-monitoring, type of planning and change in knowledge as independent variables; the number of new and preserved ideas, and the average length of these ideas, as dependent variables; and the number of ideas produced before writing and their average length as covariates. Using Pillai's trace, this showed a significant main effect of type of planning ($V = .14$, $F(4, 60) = 2.51$, $p = .05$) and a significant interaction between type of planning and knowledge change ($V = .32$, $F(8, 122) = 2.85$, $p = .006$). To describe these effects, we will consider them in two stages, starting with the main effect of type of planning and then considering the interaction between type of planning and change in knowledge.

Main effect of type of planning There were two important findings here. First, as can be seen in figure 2, the preserved ideas were significantly reduced in length in the outline planning condition but not in the synthetic planning condition ($F(1, 66) = 5.80$, $p = .019$, $\eta^2 = .05$). There was no equivalent effect for the new ideas.

Figure 2: Words per idea for ideas in list 1, preserved ideas in list 2 and new ideas in list 2.

A possible explanation for the effect is that when an outline is constructed it is held in working memory to guide text production. In consequence, when writers refer to ideas in the outline, they label the idea held in memory in an abbreviated form. Although this effect may prove useful as a marker of the extent to which individuals within different conditions construct a mental outline during writing, it does not suggest a substantive effect of type of planning on the content of the lists produced after writing.

The second important finding here is a negative one. The follow-up analysis of the multivariate analysis revealed no apparent effect of either self-monitoring or type of planning on the number of new or preserved ideas produced after writing. Possible reasons for this will be considered in the discussion.

Interaction between type of planning and knowledge change To determine the source of this effect, we carried

out simple effects analysis within the synthetic planning and outline planning conditions, using 1-way MANCOVAs, with change in knowledge as the independent variable, the four measures of the lists produced after writing as dependent variables, and the number of ideas in the initial list and their average length as covariates. This confirmed that there was no significant relationship between idea change and changes in subjective knowledge within the outline planning condition ($V = .191$, $F(8, 54) = .71$, $p = .68$). However, there was a highly significant effect of within the synthetic planning condition ($V = .645$, $F(8, 60) = 3.57$, $p = .002$). Univariate ANOVAs, followed by planned comparisons, on each of the dependent variables showed that there were significant effects for 3 of the variables.

First, there was a significant effect on new ideas ($F(2, 34) = 6.25$, $p = .005$, $\eta^2 = .25$), with planned comparisons showing that participants whose knowledge remained the same produced more new ideas ($M = 7.8$, $se = 0.68$) than both participants whose knowledge decreased ($M = 1.69$, $se = 2.34$, $p = .05$) and participants whose knowledge increased ($M = 4.85$, $se = 0.91$, $p = .045$). Although increased knowledge was associated with more new ideas than decreased knowledge, this difference was not significant ($p = .65$).

There was also a significant effect on the average length of new ideas ($F(2, 33) = 5.94$, $p = .006$, $\eta^2 = .14$) with participants whose knowledge decreased producing longer new ideas than those whose knowledge remained the same ($p = .008$) and those whose knowledge increased ($p = .04$). Finally, there was a marginally significant effect on the average length of preserved ideas ($F(2, 34) = 2.46$, $p = .10$, $\eta^2 = .04$), with a tendency for participants whose knowledge remained the same to produce preserved ideas shorter in length than those produced by participants whose knowledge either increased or decreased.

Taken together, these findings suggest, first, that decreases in knowledge occurred in this condition when writers were relatively unable to think of new ideas, and to express what ideas they could think of concisely. This implies that thinking of new content is generally necessary in order to produce satisfactory text. Second, increases in knowledge were associated with the production of fewer new ideas than when knowledge stayed the same. This contradicts previous research. A possible explanation for this is that new ideas were produced by different processes when knowledge remained the same than when it increased. On the assumption that the length of preserved ideas reflects the extent to which writing has been controlled by an outline (see above), then the marginally significant effect on the length of preserved ideas could indicate that texts where knowledge remained the same were relatively more outline planned than the texts where knowledge increased.

Relationship with processes

The preceding analysis revealed that, despite the significant difference between synthetic and outline planning in the extent to which writers reported increases in understanding,

there were no differences in idea change within the two planning conditions, and generally that there were no relationships between the amount of change in ideas and increased knowledge. According to the dual-process model, this is because new content is produced by two different processes -explicit rhetorical planning and implicitly guided text production- and only implicit text production leads to the development of understanding. To test these claims, we carried out a 3-way between subjects ANOVA on the text modification index, with self-monitoring, type of planning and knowledge change as dependent variables. This produced clear evidence to support these claims.

First, both self-monitoring and type of planning had a clear effect on the extent to which ideas were modified during text production. There was a significant main effect of type of planning ($F(1, 66) = 5.55, p = .02, \eta^2 = .06$), a close to significant main effect of self-monitoring ($F(1, 66) = 4.53, p = .06, \eta^2 = .03$) and a significant interaction between self-monitoring and type of planning ($F(1, 66) = 4.45, p = .04, \eta^2 = .04$). Figure 3 shows that low self-monitors produced higher levels on the text modification index than high self-monitors and this was reduced when text production was preceded by outline planning.

Figure 3: The text modification index as a function of type of planning and self-monitoring.

Second, there was a significant interaction between knowledge change and type of planning ($F(2, 66) = 3.67, p = .03, \eta^2 = .07$). Analysis of simple effects, followed by planned comparisons of the differences between different types of knowledge change, revealed that there was a highly significant main effect of knowledge change within the synthetic planning condition ($F(2, 34) = 5.59, p = .008, \eta^2 = .22$). As can be seen in figure 4, this was a consequence of the fact that increases in knowledge were associated with significantly higher levels of text modification than when knowledge remained the same ($t(34) = 3.29, p = .007$). Although decreased knowledge was also associated with lightly elevated levels of text modification, this was not significantly different from the other conditions.

Figure 4: The text modification index as a function of type of planning and knowledge change.

Discussion

The dual-process model claims that new content is produced during writing by two different kinds of process: explicitly controlled planning to satisfy rhetorical goals and implicitly guided text production articulating the writer's developing understanding. This contrasts with the knowledge-transforming model in two key respects. First, it claims that, although explicitly controlled planning does lead to changes in content after writing, this is essentially a matter of retrieving already existing knowledge which is more appropriate to the rhetorical context than the ideas initially considered relevant to the topic, and hence that changes in content produced by explicit planning will not lead to developments in understanding. Second, it claims that implicitly guided text production is not simply a matter of translating the output of planning into words, but is an active knowledge-constituting process in its own right. Our results provide strong support for both claims.

First, there was clear evidence that content was produced by different processes in the outline planned and synthetically planned conditions. The outline planned condition involved significantly lower levels of text modification during writing than the synthetically planned condition. This is compatible with the claim that changes in content in this condition are a consequence of higher level thinking processes rather than of the modification of content in the formulation of the text itself. By contrast, text modification was at its highest in the condition – the low-self-monitors' synthetically planned texts – where the dual process-model assumes that text production is most implicitly guided, and where new content is assumed to be formulated in the text itself rather than through planning prior to text production.

Second, although both conditions led to a similar amount of change in ideas, as would be expected if both processes play an active role in developing content during writing, only the synthetic planning condition was associated with significant increases in subjective ratings of understanding.

This clearly supports the claim that explicit planning is less strongly associated with the development of understanding than implicitly guided text production is.

Third, there was no relationship between the amount of change in content in the different conditions and increases in subjective understanding. The dual-process model provides a straightforward explanation for this: increases in understanding depend on the extent to which new content is produced by implicitly guided text production. This explanation is strongly supported by the fact that synthetically planned writing involved significantly higher levels of text modification, and that it was precisely those writers within this condition whose understanding increased who produced the highest levels of text modification. The only exception to this extremely clear pattern was that the few writers who experienced decreases in knowledge in any of the conditions also appeared to engage in relatively high levels of text modification. The important feature of these writers, however, is that they also produced few new ideas. This leads to the general conclusion that increases in understanding occur when writers develop new ideas in the course of formulating the text itself. Understanding will remain the same when text production is either controlled to conform to a higher level plan (as in outline planning) or when the writer's knowledge prior to writing is sufficiently clear for text to be fluently produced. Understanding will decrease when text production does not lead to the formulation of coherent new content.

There is one aspect of these results which does not match previous research. Previous studies (see Galbraith, 2009) have found that low self-monitors typically produce more new ideas than high self-monitors under synthetic planning conditions, and that, under these conditions, the number of new ideas is positively correlated with increases in subjective understanding. The dual process model assumes that this is because high self-monitors typically impose more control on text production than low self-monitors, so reducing the extent to which ideas are formulated during text production. This was partially supported in the present experiment in that high self-monitors did engage in significantly less text modification than low self-monitors in the synthetic planning condition. However, there was no difference in the extent to which low and high self-monitors produced new ideas in this condition, and there was a negative rather than a positive relationship between the number of new ideas and increases in understanding.

We believe that this is a consequence of a difference in the constraints under which synthetic planning was carried out in this experiment. In previous research, the external constraints for the text under synthetic planning conditions have either been left unspecified or writers have been actively instructed to write down their thought free from rhetorical constraints. By contrast in this experiment, writers were instructed to produce a finished article for the university newspaper in the time available. According to the dual-process model, this should lead to an increase in the

extent of explicit planning processes, and since these are prioritized by high self-monitors, a greater increase in the number of new ideas produced by high self-monitors compared to low self-monitors. Furthermore, since these new ideas are produced by explicit planning, which according to the dual-process model is not associated with changes in understanding, there will no longer be a straightforward relationship between the amount of new ideas and increases in subjective understanding, just as we found in this experiment. This explanation could be tested by comparing low and high self-monitors writing synthetically planned text, either with clear rhetorical constraints, as in the present experiment, or free from rhetorical constraints as in previous research.

Our general conclusion is that in order to explain how writers develop their understanding it is necessary to examine the processes by which their ideas are created rather than just assess the extent to which they have modified their beliefs. The simple index of text modification that we have used in this paper has shown clear distinctions between different kinds of knowledge change, which strongly supports the broad claim that the development of thought during writing depends on two different kinds of process. Further research is needed, using on-line measures such as key-stroke logging, to examine in detail how ideas are formulated during text production and how this results in developments of the writer's understanding.

Abstract

Building on prior work, the current study evaluated whether connectionist models can account for the distance and size effects in adults and the development of the distance effect in children. A family of models was constructed by orthogonally varying training environment (naturalistic versus non-naturalistic) and number representation (one-to-one versus magnitude). The ability of the models to account for the adult distance and size effects depended critically on a naturalistic training environment but was relatively independent of number representation. With respect to the developmental data, the naturalistic/one-to-one model provided a good account of response times and errors. The relation between the current models and prior models and avenues for future exploration are discussed.

Keywords: number comparison; distance effect; size effect; connectionism; models; development

Introduction

The nature of number representations is an enduring question in cognitive science. One clue to this representation is the *distance effect*: the time it takes to judge the greater (or lesser) of two numbers decreases with the distance between the numbers (Moyer & Landauer, 1967). For example, 1 vs. 9 is judged faster than 1 vs. 3. Another clue is the *size effect*: the time to judge the greater (or lesser) of two numbers that are a fixed distance apart increases with the absolute magnitude of the numbers (Parkman, 1971). For example, 7 vs. 9 is judged more slowly than 1 vs. 3. The distance and size effects conform to psychophysical laws (i.e., $RT = K \log\left(\frac{\text{larger}}{\text{larger}-\text{smaller}}\right)$) and are therefore commonly interpreted as evidence that numbers are represented as analog representations, perhaps localized to the intra-parietal sulcus (Dehaene, Piazza, Pinel, & Cohen, 2003). Researchers have proposed various implementations of these analog representations. The classic ones are as points on a compressed mental number line (Dehaene & Mehler, 1992; Rule, 1969) and as points on a linear mental number line associated with increasing variability (e.g., Gallistel & Gelman, 2000). More recently, two connectionist models of number representation have appeared. Zorzi and Butterworth (1999) assumed magnitude representations whereby numbers are represented by banks of overlapping units. This model was able to account for the adult distance effect. By contrast, Verguts, Fias, and Steven

(2005) assumed a coarse-coded representation, with each number corresponding primarily to one unit, but with graded activation of adjacent units. This model was able to account for the adult distance and size effects.

The purpose of the current study was to evaluate the ability of connectionist models to (1) account for the adult distance and size effects as a function of training environment and number representation and to (2) account for the development of the distance effect. In these regards, the reported simulations are the first of their kind.

With respect to training environment, some connectionist models (Zorzi & Butterworth, 1999) have employed a *non-naturalistic* training environment (i.e., every one-digit number appears with equal likelihood). However, corpus studies indicate that the frequency of a number falls off as a power function of its magnitude (Dehaene & Mehler, 1992), implying that one-digit numbers are non-uniformly distributed in a *naturalistic* environment. Some connectionist models have employed a naturalistic training environment (Verguts et al., 2005). We sampled comparisons (i.e., pairs of one-digit numbers) from these contrasting training environments to evaluate whether the distance and size effects were contingent upon naturalistic input.

With respect to number representation, we considered the magnitude representation implemented by the Zorzi and Butterworth (1999) model and a one-to-one variant of the coarse-coded representation implemented by the Verguts et al. (2005) model¹.

Finally, in the first study to model the development of the distance effect, we evaluated whether improvements in model performance throughout training parallel improvements in children's response times and error rates throughout development.

Method

We developed four connectionist models by orthogonally varying training environment (naturalistic versus non-naturalistic) and number representation (magnitude versus one-to-one). The models were implemented within a common connectionist architecture patterned after Verguts et al. (2005).

¹ Both of these codings represent exact numbers. We use the label "magnitude" to reflect the fact that the number of representation nodes activated in this coding corresponds to the number being compared.

Figure 1: Schematic of models using one-to-one coding (left) and magnitude coding (right).

This architecture consisted of three layers of units (*input*, *representation*, and *decision* layers) (Figure 1). Each layer contained left and right fields. On each trial, the input units corresponding to the numbers being compared were clamped to an activation level of 1, and activation spread forward throughout the network. When a decision unit (*left larger* or *right larger*) reached an activation of 0.5 or greater, the model was considered to have made a decision

Architecture and Number Representation

Each model consisted of three layers of units. The input layer consisted of two fields of nine units each that corresponded to the numbers 1-9. The left field corresponded to the number presented on the left and the right field to the number on the right. Each number corresponded to one (and only one) unit in the input layer.

The representation layer consisted of two sets of nine units. The left field, M , represented the number presented on the left, and the right field, N , represented the number presented on the right. The left input field was connected to the left representation field and the right input field to the right representation field by connections with weights 0 or 1. The number representation scheme of the model determined the pattern of connection weights between the input and representation layers. For magnitude representations, the number of units activated in a representation field corresponded to the magnitude of the number presented (e.g., if the number 5 was presented on the left, the 5 leftmost units of the left representation field would be activated). For one-to-one representations², one (and only one) unit in a representation corresponded to the number presented. The weights of the connections between the input and representation layers were held constant

throughout learning to maintain the type of representation that the model *a priori* employed.

The decision layer consisted of two units representing *left larger* and *right larger* decisions. Units in the representation layer were fully connected with units in the decision layer. The initial weights of these connections were randomly sampled from a uniform distribution (0 to 1) and were adjusted during training by a supervised learning rule.

Model Dynamics

On each trial, the model compared two numbers, judging which was greater. (Following prior work, we did not model both greater and lesser judgments.) The left number was presented to the left input field by clamping the activation of the corresponding unit to 1, and the right number was presented similarly to the right input field. Activation spread from the input layer to the representation layer according to the equation³:

$$(1) \Delta r_{Mk}(t) = r_{Mi}(t-1) + \sum_{i=1}^{i=9} w_{Mkin_i} [in_i(t) - \theta]^+$$

Where $\Delta r_{Mk}(t)$ is the change in the activation of the k^{th} representation unit in the left field (M), $in_i(t)$ is the activation of the i^{th} input unit, w_{Mkin_i} is the weight of the connection between these two units, and θ is a firing threshold (set to .08 for these simulations). This equation results in the activation of representation units asymptotically approaching their maximum values.

Activation spread from the representation layer to the left-larger unit of the output layer according to the equation:

$$(2) \Delta o_{Left}(t) = o_{Left}(t-1) + \sum_{i=1}^{i=9} w_{Mi,Left} [r_{Mi}(t) - \theta]^+ + \sum_{i=1}^{i=9} w_{Ni,Left} [r_{Ni}(t) - \theta]^+$$

Where $\Delta o_{Left}(t)$ is the change in the activation of the left-larger unit, $r_{Mi}(t)$ is the activation of i^{th} representation unit

² We employed one-to-one representations instead of coarse-coded representations (Verguts et al., 2005) to equate the architecture across models. Coarse-coding would have required adding additional units to the representation layer of models that employed magnitude representations, muddying the comparison of the models.

³ All equations are for left fields. Equivalent equations governed model dynamics in the right fields.

in the left field, $w_{Mi,Left}$ is the weight of the connection between these two units, $r_{Ni}(t)$ is the activation of the i^{th} representation unit in the right field, and θ is the firing threshold. This equation results in the activation of decision units asymptotically approaching their maximum values once the representation units have reached the firing threshold. A decision was considered made once activation in one of the decision units exceeds a threshold of 0.5.

Supervised Learning

During learning, weights between representation and decision units were adjusted according to the delta rule:

$$(3) \Delta w_{ik} = \epsilon(t_k - o_k)r_i$$

Where Δw_{ik} is the change in the weight between the i^{th} representation unit and the k^{th} decision unit, ϵ is a learning rate parameter, $(t_k - o_k)$ is the difference between the target decision unit activation t_k (1 for larger, 0 for smaller) and the actual decision unit activation o_k , and r_i is the activation of the i^{th} representation unit. The delta rule apportions blame for incorrect decisions and adjusts weights accordingly. For this study, the learning rate parameter ϵ was set to 0.02. During learning, activation was allowed to settle prior to weight adjustment. Each model was trained for 30,000 trials, and weights were adjusted at the end of every trial.

Training Environment

Models were trained on one of two training environments. Naturalistic training environments were constructed by assuming, following Dehaene and Mehler (1992), that the frequency of a number in the environment is a decreasing function of its magnitude. Although Dehaene and Mehler favored a power function, Verguts et al. (2005) adopted a closely related exponential function. To facilitate the comparison of our results, we formed training comparisons by sampling pairs of numbers from an exponentially decreasing distribution (where the frequency of number i is $e^{-0.2i}$). The distribution of individual numbers and of comparisons (as a function of distance) is shown in Figure 2.

Non-naturalistic training environments were constructed by assuming that numbers are distributed uniformly in the environment. Training comparisons were formed by sampling from this distribution. The results are also shown in Figure 2.

It is interesting that naturalistic and non-naturalistic training environments result in strikingly similar distributions of comparisons as a function of distance. However, as we shall see, these environments have important differences as indicated by the ability of the resulting models to account for the adult distance and size effects.

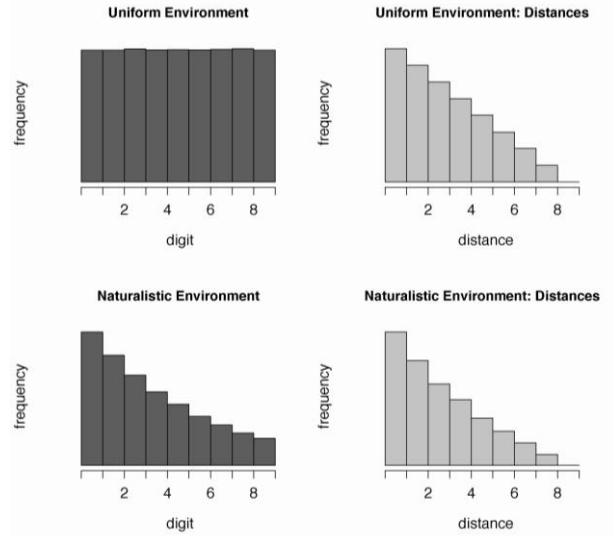

Figure 2: Training environments. Dark gray histograms give the distribution of numbers in the environment, light gray histograms the distribution of distances between the resulting comparisons (i.e., number pairs).

Training and Testing

Ten copies of each model (naturalistic versus non-naturalistic crossed with magnitude versus one-to-one) were created. Each copy was trained for 30,000 trials (following Verguts et al.) and tested with all possible pairs of numbers between 1 and 9 (excluding ties).

Results

Distance Effects

All four models produced distance effects (Figure 3).

Figure 3: Distance effects for the four models.

Table 1: Model fits for the distance effect.

Representation	Training	R^2	p
Magnitude	Naturalistic	.73	< .001
Magnitude	Uniform	.43	< .001
One-to-One	Naturalistic	.78	< .001
One-to-One	Uniform	.46	< .001

To evaluate the fit of each model to human performance, we followed Zorzi and Butterworth (1999) in regressing human performance as captured by the equation:

$$\widehat{RT} = K \log \left(\frac{\text{larger}}{\text{larger} - \text{smaller}} \right) + C$$

against the number of cycles to make a decision. The results are shown in Table 1.

First, consider the question of training environment. The results indicate that models trained in naturalistic training environments provide better accounts of the distance effect than models trained in non-naturalistic environments. Although Figure 2 suggests that the difference between the training environments is negligible with respect to the amount of experience with different distances, the fit statistics indicate that differences between uniform and naturalistic environments are critical to the distance effect.

Next, consider the question of number representation. The results indicate that a model's ability to account for the distance effect is independent of whether it uses magnitude or one-to-one number representations. Additional work is necessary to determine how fundamentally different types of numerical coding can produce such similar results with respect to the distance effect.

Size Effect

The size effects produced by the four models are shown in Figure 4. There is a striking qualitative difference in the performance of models trained with naturalistic versus non-naturalistic training environments.⁴ The former produce a generally positive linear relation between number size and judgment time, with the exception of distances 1-2. By contrast, the latter shows a size effect only for distances 5-8, and diverge considerably from a linear relation for distances 1-4. Additional modeling is necessary to determine what factors contribute to the failure of the uniformly-trained models to produce size effects for distances 1 and 2.

Figure 4: Size effects for the four models. Each line represents comparisons of the same distance.

By contrast, the ability of a model to account for the size effect appears to be relatively independent of whether it uses a magnitude or one-to-one number representation. As with the distance effect, additional work is necessary to determine how fundamentally different types of number representation can produce such similar results with respect to the size effect.

Development of the Distance Effect

We next turn to the development of the distance effect. The results thus far indicate that naturalistic training environments are critical for accounting for adult distance and size effects. Additionally, pilot simulations indicated that models that utilize magnitude number representations do not produce enough errors to account for that dimension of development. For these reasons, we focused our developmental efforts on the naturalistic/one-to-one model.

Sekuler and Mierkiewicz (1977) investigated the distance effect in kindergarten, first grade, fourth grade, seventh grade and adult subjects. Their results are shown in Figure 5. They reported that kindergarteners were significantly slower than other ages, first graders were significantly slower than all age groups except kindergarteners, and that the decision times of fourth graders, seventh graders and adults did not differ significantly. They also reported that the slope of the distance response curves was steeper for kindergarteners than other age groups.

Figure 6 presents the distance effect (averaged across 10 simulations) produced by the naturalistic/one-to-one model after 1200, 1600, 2000, 2400, and 2800 trials⁵. The model provides a nice qualitative account of the developmental data, showing distance effects at all time points as well as a steady decrease in response time.

⁴ At the time of submission, we did not have access to empirical data on the size effect to quantify these models fits. We are working on gaining such access.

⁵ These time points were chosen to align model-produced error rates with the error rates reported by Sekuler and Mierkiewicz.

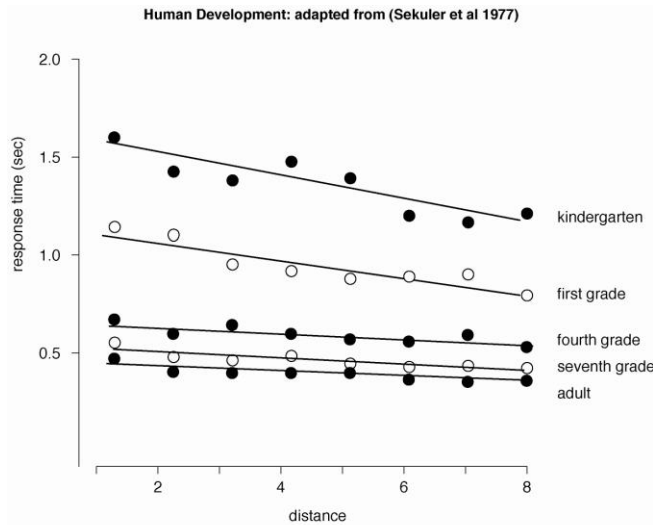

Figure 5: Development of distance effect from kindergarten to adulthood (adapted from Sekuler & Mierkiewicz, 1977).

Figure 6: Development of distance effect for the naturalistic/one-to-one model from 1200 to 2800 trials)

However, the model fails to capture the interaction reported by Sekuler and Mierkiewicz : the slope of the 1200 trial line (corresponding to the kindergarten distance effect) is not qualitatively steeper than the slope of the 2800 trial line (corresponding to the adult distance effect).

We were unable to evaluate the quantitative fit of the model to the Sekuler and Mierkiewicz (1977) response time data because it is no longer available. However, Holloway and Ansari (2008) recently performed a similar experiment.⁶ They had six, seven, and eight year old children make comparisons at distances 1-6. Their results are shown in Figure 7.

Figure 7: Distance effects at age 6, 7, and 8 years old (data from Holloway & Ansari, 2008).

We linearly regressed the performance of the model at 1200, 1600, and 2000 trials against their six, seven, and eight year old data, respectively. The model accounted for 44% of the variance in the data ($R^2 = .441$, $p = .003$).

Although we were unable to evaluate the quantitative fit of the model to Sekuler and Mierkiewicz's response time data because it was not available, we were able to evaluate the fit of the model to their error rate data because it was reported numerically in the original article. Table 2 presents their developmental error rate data and the error rates of our model. The model provides a good quantitative account of error rate as a function of age. The correlation between the model and the human data is 0.97 ($p = .004$).

Table 2: Error rates for the developmental simulations of the naturalistic/one-to-one model.

Human (Age)	Errors (%)	Model (Trials)	Errors (%)
Kindergarten	18.4	1200	18.3
First Grade	16.7	1600	15.1
Fourth Grade	11.8	2000	12.8
Seventh Grade	12.5	2400	12.1
Adult	7.9	2800	8.3

⁶ We thank Daniel Ansari and Ian Holloway for sharing their data with us.

Discussion

The current study extends prior connectionist efforts to understand the distance and size effects. We systematically varied training environment and number representation and examined the effects on the adult distance and size effects. Models trained in naturalistic training environments, where the frequency of numbers falls off as a function of their absolute magnitude, provide better quantitative accounts of the distance effect and better qualitative accounts of the size effect. By contrast, the choice of number representation had little effect on these models' ability to account for the adult distance and size effects.

The current study is the first to address the development of the distance effect. The naturalistic/one-to-one model provided a good qualitative account of distance effects at different ages. It also provided a good account of decreasing error rates with development.

One limitation of the development simulation was that it did not account for the interaction observed by Sekuler and Mierkiewicz (1977), whereby the distance effect is most pronounced for kindergarteners and decreases throughout development. Further research is necessary to understand this limitation of the model.

Another limitation, one shared with the pioneering Zorzi and Butterworth (1999) model, is that the models considered here only perform the comparison task. By contrast, the Verguts et al. (2005) model also performs naming and parity judgment tasks and can thus be evaluated against a broader range of data. Future research is required to extend the range of the models considered here to new tasks.

Although the developmental model produced changes in error rates and comparison speed that parallel human data, further work is necessary to more completely model the development of number comparison. In particular, the model needs to account for the more pronounced distance effect of younger participants reported by Sekuler and Mierkiewicz. One reason our model may have failed to capture this trend is that we trained the model using distributions based on the occurrence of numbers in adult language. One approach to improving the developmental simulations may be to use training data that parallel the distributions of numbers in children's and child-directed speech.

Causal stream location effects in preschoolers

David W. Buchanan (david_buchanan@brown.edu) and David M. Sobel (dave_sobel@brown.edu)

Abstract

Based on the predictions of a computational model, we test preschoolers' ability to reason about *stream location effects*: reasoning that interventions that occur on a common part of a causal process should be more likely to affect multiple relations, than interventions which occur on independent parts of a causal process. In two experiments, we show that 3- and 4-year-olds both show a stream location effect. Children show this effect for both familiar and unfamiliar interventions.

Keywords: causal reasoning, cognitive development, models of causal reasoning.

Introduction

Even when we do not explicitly understand the details of how a causal system works, we often have strong intuitions about the effects of different interventions on that system. Consider a phenomenon that is a mystery to most adults – the way that a remote turns on a television. Even though most of us could not verbally describe the mechanism, we know that removing the batteries from the remote would make it fail. We also know that the television must be plugged in. We even know about correlations between relations: Say you have two remotes that both turn on your television – for instance, the one that came with your television, and a universal remote you bought to control all your devices. One day, both fail to turn on the television. You replace the batteries in remote A, and it now succeeds in turning on the television. You would not expect this intervention to change the efficacy of remote B – it would be odd if replacing the batteries in one remote made both effective. On the other hand, if you had noticed that the television was unplugged, and plugging it in had restored the efficacy of remote A, you would not be surprised if remote B started working as well. These inferences seem obvious, even to a person who knows nothing about how these devices operate. Interventions in one place in a causal system are expected to have wide-ranging effects, while interventions in other locations are not. Why is this?

To explain this intuition, we will use the metaphor of a *causal stream*. For instance, imagine we introduce pollution into a river that has several branches. The further upstream the pollution occurs, the more branches of the stream will be polluted. When we think of causation as flowing down a branching path, we can start to formalize these intuitions. Elsewhere (Buchanan, Tenenbaum, & Sobel, 2010) we have proposed a computational model that generates causal structures that have a branching, stream-like character. We call it the *causal edge replacement process*, or CERP. While the details are beyond the scope of this paper, we will outline its main implications.

CERP makes use of causal graphical models, a way of representing causal relations using graphs (Gopnik et al., 2004;

Figure 1: Examples of causal graphical models. Nodes represent events, and edges represent causal relations. Dashed edges indicate inhibitory relations. On the left, the simplest graph that captures a common effect relation: A and B both cause C. On the right, a graph generated by CERP, which allows us to make predictions about stream location effects. Intervening on X disables both relations, but intervening on Y or Z disables only one.

Pearl, 2000; Spirtes, Glymour, & Scheines, 2001). Nodes represent events, and directed edges represent causal relations. Figure 1a shows an example, the simplest way of representing the common effect relation of the television (C) and the two remotes, A and B. There are other ways of representing this relation; CERP tends to generate graphs that are more complex, like Figure 1b. In this graph, we have enough detail to represent interventions on the mechanism that relates cause and effect. For instance, X is such an intervention, which disables both relations, preventing causation from flowing down the edge on which it falls. (The dashed edge indicates an inhibitory relation.) CERP implies that when causal relations share a node, they always share part of the path from cause to effect. In a common cause relation such as the television example, interventions (like X) that occur late in the causal stream (close to the common effect) are more likely to fall on this shared path, changing both relations. Interventions (like Y and Z) that occur early in the causal stream, are more likely to fall on the independent path, changing only one relation. We call this difference a *stream location effect*. Note that these implications are general and structural, and do not depend on the specific causal system involved.

The stream location hypothesis is that human beings should expect stream location effects even about systems for which we have little or no knowledge of the causal mechanism involved (like the television remote, for most of us). While this hypothesis was inspired by CERP, it is not the only model which is consistent with these predictions. For instance, evidence that supports the stream location hypothesis

is not inconsistent with a general approach to causal graphical models. But only models (like CERP) that have a branching character directly and specifically predict stream location effects.

There is already some empirical evidence that suggests that stream location effects may exist in adults. Mayrhofer, Hagmayer, and Waldmann (2008) told participants a cover story involving mind-reading aliens: When the “cause” alien thought of food, he often caused the three “effect” aliens to think of food as well. The experimenters manipulated the number of other aliens that thought of food, and asked subjects to judge the probability that a given alien would also think of food, given that the cause alien was thinking of food. For instance, when the cause alien and two other effect aliens were thinking of food, participants judged it highly likely that the third alien was thinking of food. When the cause alien was thinking of food, but the two other effect aliens were not, subjects judged it less likely that the third effect alien was thinking of food.

This difference is known as a *nonindependence* effect, which CERP fits well in general¹: Adults predict that collateral effects of a common cause should be correlated, even given their common cause. Crucially for the stream location hypothesis, the strength of nonindependence could be manipulated by changing the cover story. In the “sending” condition, participants were told that the cause alien sometimes had trouble concentrating; there was a strong nonindependence effect in this condition. In the “receive” condition, the effect aliens sometimes had trouble concentrating; there was a significantly weaker nonindependence effect in this condition. Mayrhofer et al. succeeded in showing that by changing the description of the mechanism, they could change the degree of nonindependence observed. We hypothesize that a stream location effect was responsible for this difference: the location of the described inhibitor (trouble concentrating) in the causal stream was different between conditions. Of course, we are only explaining their data in hindsight. The experiments in this paper present a more direct predictive test of the stream location hypothesis.

Because CERP makes such strong predictions about situations in which we have little or no knowledge, the best tests of the stream location hypothesis will be in children’s causal reasoning. This is because children often have little specific causal knowledge about individual causal systems; we can see their reasoning as revealing the expected form of causation more than the expected content of causation. For instance, infants seem to initially expect that novel abstract objects need to make physical contact in order to interact causally (Leslie & Keeble, 1987). Among preschoolers, Bullock, Gelman, and Baillargeon (1982) found that even 3-year-olds expect that causes must precede their effects. They also found that 3-year-olds could reason appropriately about interventions on causal systems: They could recognize that some interventions would change a relation, whereas some

would not. Buchanan and Sobel (submitted) showed that this ability depended on the specific causal system involved. For instance, 3-year-olds could not reason correctly about interventions on electrical connection, but they could reason correctly about interventions on batteries. On the other hand, 4-year-olds could reason appropriately about both connection and batteries. Because of these developmental differences, and numerous other studies on preschoolers’ causal reasoning, we chose to test 3- and 4-year-olds in these experiments.

Our overarching hypothesis, which we test in two experiments, is that preschool-aged children will show stream location effects, expecting different changes to arise from interventions at different locations in the causal stream. Further, we predict that these differences will continue to hold regardless of the familiarity of the intervention involved, as long as that unfamiliar intervention appears to change the causal relation in the same way.

Experiment 1

In this experiment, we tested the hypothesis that children would reason differently about interventions to a causal system, depending on the location of the intervention in a causal stream. We presented children with a novel common effect relation in which both relations failed. Then we made a change, either early or late in the causal stream, which apparently enabled one of the relations. We asked children whether this change would enable the other relation as well. Our hypothesis was that in accordance with CERP, children would judge the late intervention as more likely to affect both relations than the early intervention.

Methods

Participants We tested 16 three-year-olds, (8 girls, mean age = 40.3 months, range = 36-45 months) and 16 four-year-olds (2 girls, mean age = 52.25 months, range = 48-59 months). Three additional children were tested, but were excluded due to experimenter error or equipment failure. About half the children were recruited from birth records, and the other half were recruited and tested either at a children’s museum or at a local preschool. Children were randomly assigned to either the “early inhibitor” ($n = 16$) or “late inhibitor” ($n = 16$) condition. There were an equal number of 3- and 4-year-olds in each condition.

Materials Materials consisted of two sets of commercially available closet lights, modified for the experiment. In one set (the “cause lights”) there were 8 lights, each 10 cm in diameter, with a large white button that illuminated only when actively depressed. These lights had a battery compartment on the underside that could hold two batteries; they required the presence of both batteries, inserted properly, in order to illuminate when pressed. It was possible to insert one battery backwards, in order to be able to show the presence of two batteries, without the light illuminating when pressed. The compartment also had a cover, which could be left on or off. The casing of each light was painted a different color, so that

¹For details of this fit, see Buchanan et al. (2010)

Figure 2: The push lights environment used in the present experiments, shown from the point of view of the child.

children could easily differentiate the lights.

Another set (the “effect” lights) consisted of four similar but larger lights, each about 14 cm in diameter. The effect lights were rendered distinguishable from one another by placing pipe cleaners of different colors around their casing. These lights each held four batteries. One of these lights was modified using radio-controlled car components, such that it illuminated only when a hidden remote was activated – depressing the light was not the actual cause of its illumination. It was possible to give adults and children the impression that they were causing the light to activate by depressing it, by activating the remote only when they pressed the light. The experimenter (a trained magician) practiced this effect until a convincing causal impression was achieved. The remote allowed the experimenter freedom to control which actions, if any, appeared to cause the effect light to illuminate. In post-tests, the experimenter was often able to use the remote to convince children that pressing their nose activated the effect light. All such children were subsequently debriefed, and allowed to play with the remote.

The lights were mounted on a piece of cardboard, together with wires that appeared to connect the lights. The cardboard was used so that the experimenter could easily retract the whole setup, controlling when and if children could intervene on the lights. The setup is shown in Figure 2. We refer to this setup as the “push lights environment.”

Procedure The experimenter began by showing children all the lights to be used in the procedure, in order to establish that there were a large number of them. Then he showed them the push lights environment, arranged as shown in Figure 2: There were two small “cause” lights, connected to one large “effect” light using the wires. This began the training phase. The experimenter said: “I have some of these lights. When you push on them, they light up. See: [pushes on effect light, and it illuminates.] Here, you try.” Children pushed the effect light, which illuminated. “Sometimes, when I push on these little lights, they’ll make the big light go. Watch.” He then pushed each cause light, both of which appeared to cause the large light to illuminate simultaneously. He then pointed to each of the cause lights and asked: “Does this one

make the big light go?” Most children (26 out of 32) correctly answered “yes” to this question. The remaining children answered “yes” after one instance of corrective feedback. Excluding children who required feedback on this or any other training question did not change the statistical significance of the results we report.

The experimenter then removed the three initial lights, and arranged three visibly different lights in the same configuration. This began the first of three test phases. In the “late inhibitor” condition, the effect light in each test phase light was missing one battery. In the “early inhibitor” condition, the cause lights in each test phase were each missing one battery, and thus did not illuminate when pressed. The battery covers were left off so that the absence of batteries was visible, but only when the lights were flipped over. These new lights failed to activate the effect light. Children were asked about the efficacy of the relations. Most children (26 out of 32) correctly answered “no” to these questions on all three trials. Five responded correctly after one round of feedback, and one child required two rounds. Excluding these children did not change the significance of reported results. Note that at this point in the procedure, children had correctly answered “no” to two questions with feedback, and “yes” to two questions with feedback. Thus children were not coached on a strategy that would allow them to answer the test questions correctly.

At this point in the test phase, the experimenter made a modification to the causal system, which depended on the condition. In the “late inhibitor” condition, the experimenter flipped over the large light, exposing the fact that there was a battery missing. He said: “Look, this light has room for a battery, but there’s no battery in there. Let’s put a battery in.” He then inserted a battery into the space, and replaced the light in its original position. In the “early inhibitor” condition, he instead flipped over and added a battery to one of the cause lights. Then he said “Let’s try this light now.” He pressed one cause light (side counterbalanced, and in the early inhibitor condition, always the effect light that had been intervened on), which made the effect light illuminate.² The experimenter then asked, pointing to this light: “Does this one make the big light go now?” All children answered “yes.” He then pointed to the other light: “What about this one? Will this one make the big light go now?” Children’s responses to this test question were recorded and analyzed. The experimenter repeated the test phase three times with three visibly different sets of lights, for a total of three answers from each participant. This meant that we collected three yes/no answers from each child, making 24 for each age group/ condition combination.

²In the “early inhibitor” condition, the cause light did not illuminate even when it was effective. Otherwise the illumination of the cause light would be diagnostic of its efficacy in causing the effect light to illuminate. That is, in the “early inhibitor” condition, when the experimenter pressed on an effective cause light, only the effect light illuminated.

Results

No effects were found for the age or gender of the children, or whether the question was initially asked about a light that was on the left or on the right. Results are shown in Table 1. In the “early inhibitor” condition, only 2 out of 24 responses from 3-year-olds, and 1 out of 24 responses from 4-year-olds were “yes.” Both of these patterns were significantly below the proportion of “yes” responses predicted by chance, Binomial test, $p < 0.01$ in both cases. In the “late inhibitor” condition, all 3- and 4-year olds answered “yes” to every question, meaning that both age groups answered “yes” to 24 out of 24 questions. This was significantly above chance, Binomial test, $p < 0.01$ for both conditions.

Table 1: Mean number of “yes” answers in Experiment 1.

Age Group	Condition	“yes”/trials	Mean	SD
3-year-olds	Early($n = 8$)	2/24	0.25	0.46
	Late ($n = 8$)	24/24	3.00	0.00
4-year-olds	Early ($n = 8$)	1/24	0.12	0.35
	Late ($n = 8$)	24/24	3.00	0.00

Children of both ages were significantly more likely to answer “yes” in the late inhibitor than in the early inhibitor condition. For 3-year-olds, the average number of “yes” responses out of three was 0.25 in the early inhibitor condition and 3.00 in the late inhibitor condition. Among 4-year-olds, the means were 0.12 and 3.00, respectively. We ran a 2(age group) \times 2(condition) ANOVA, which revealed a main effect of condition, $F = 746.05$, $p < 0.01$, partial $\eta^2 = 0.96$, but no main effect of age, $F = 0.37$, $p = 0.55$, partial $\eta^2 = 0.01$ or interaction, $F = 0.37$, $p = 0.55$, partial $\eta^2 = 0.01$. Because of the apparent difference in the variances, we supplemented this analysis using a Mann-Whitney U test: We found a significant difference between conditions, $U = 0.00$, $Z = 5.37$, $p < 0.01$, but not in the number of correct answers (“yes” in the late condition, and “no” in the early condition) between age groups, $U = 20.00$, $Z = 0.60$, $p = 0.78$.

Discussion

Children were significantly more likely to predict a change in both relations in the “early inhibitor” than in the “late inhibitor” condition. These results indicate that both 3- and 4-year-olds are sensitive to the location of an intervention in a causal stream. An open question is whether this is due primarily to structural inferences that apply to causal streams in general, or acquired knowledge about this specific intervention. Previous research (i.e. Buchanan & Sobel, submitted; Gottfried & Gelman, 2005) indicates that even 3-year-olds understand enough about batteries to make appropriate inferences about relevant and irrelevant modifications to a causal system when batteries are involved. To support stream location as a general structural principle, we needed to show a stream location effect for an unfamiliar intervention.

Experiment 2

The goal of this experiment was to show a stream location effect in a similar environment, but using an intervention that was not usually associated with a change in causal relations. In this experiment, instead of adding batteries, we added a battery cover. Since the presence of battery covers is not actually causally related to the efficacy of toys, children could not base their inferences on previous causal learning. We hypothesized that we would find the same effect in this experiment as in Experiment 1. We were agnostic as to whether children would be more uncertain in this experiment, generating a significantly more variable pattern of responses.

Participants As in Experiment 1, we tested 16 three-year-olds, (3 girls, mean age = 40.67 months, range = 36-46 months) and 16 four-year-olds (5 girls, mean age = 52.18 months, range = 48-57 months). One additional child was tested, but was excluded due to experimenter error. About half the children were recruited from birth records, and the other half were recruited at a children’s museum or local preschool. Again, children were randomly assigned to either the “early inhibitor” ($n = 16$) or “late inhibitor” ($n = 16$) condition, with an equal number of 3- and 4-year-olds in each condition.

Methods Experiment 2 was identical to Experiment 1, using the same materials and procedure, except for two changes: First, all battery slots were filled, but as in Experiment 1 the battery covers were left off initially. Second, during the procedure, the experimenter did not add batteries; instead, he pointed out that each light was missing a cover, and added one. Thus, he said: “Look, this one does not have a cover. Let’s put a cover on there.” Just as in Experiment 1, in the early inhibitor condition, the cause lights did not illuminate. This was done in order to maintain similarity between experiments. Also as in Experiment 1, intervening on the light (the cause light in the late inhibitor condition, and the effect light in the early inhibitor condition) apparently changed the efficacy of one of the cause lights. Children were asked to verify this. Most children (22 out of 32) required no corrective feedback during this procedure. Six children required one round of feedback, two children required two rounds of feedback, one child required three rounds, and another four. Excluding all children who required any feedback does not change the statistical significance of the results reported below. In the test question (for which no feedback was provided), children were asked to predict the efficacy of the other cause light. To avoid negative effects on children’s causal learning, all children were debriefed on the deception at the end of the procedure: They were allowed to play with the remote, and observed that replacing the covers did not in reality make the lights effective.

Results

Results are shown in Table 2. Again, no effects were found for gender, or the location of the intervened-on light. As in

Experiment 1, chance analyses showed that in all four condition/age group combinations, the proportion of “yes” responses was significantly different from what would be expected by chance, Binomial test, $p < 0.01$ in each case. In the “early inhibitor” condition, children were below chance, and in the “late inhibitor” condition, they were above chance.

Table 2: Number of “yes” answers in Experiment 2.

Age Group	Condition	“yes”/trials	Mean	SD
3-year-olds	Early ($n = 8$)	4/24	0.5/3	0.27
	Late ($n = 8$)	23/24	2.87/3	0.12
4-year-olds	Early ($n = 8$)	3/24	0.37/3	0.74
	Late ($n = 8$)	21/24	2.62/3	1.06

For 3-year-olds, the average number of “yes” responses out of three was 0.25 in the early inhibitor condition and 3.00 in the late inhibitor condition. Among 4-year-olds, the means were 0.12 and 3.00, respectively. As in Experiment 1, we ran a 2(age group) \times 2(condition) ANOVA, which revealed a main effect of condition, $F = 72.05$, $p < 0.01$, partial $\eta^2 = 0.72$, but no main effect of age, $F = 0.47$, $p = 0.497$, partial $\eta^2 = 0.017$ or interaction, $F = 0.05$, $p = 0.82$, partial $\eta^2 = 0.002$. Because of the apparent difference in the variances, we supplemented this analysis using a Mann-Whitney U test: We found a significant difference between conditions, $U = 11.50$, $Z = 4.27$, $p < 0.01$, but not in the number of correct answers (“yes” in the late condition, and “no” in the early condition) between age groups, $U = 123.00$, $Z = 0.26$, $p = 0.87$.

Anecdotally, several 4-year-olds seemed surprised that merely changing the cover had changed the efficacy of the relation. Some initially responded “maybe” to the test question – they were asked to choose either a “yes” or “no” response. All children eventually responded appropriately to the test question.

Because of this phenomenon, we also tested for differences between the experiments: We gave each child a score based on the number of correct (“yes” in late inhibitor, and “no” in early inhibitor) responses they made. We then performed a t-test on the difference between scores in the two experiments. In Experiment 1, the mean score was 2.90, ($SD = 0.29$), and in Experiment 2, the mean score was 2.65, ($SD = 0.74$). This difference was only marginally statistically significant, $t = 1.76$, $df = 62$, $p = 0.08$. Because of the difference in the variances, we supplemented this analysis using a Mann-Whitney U test, which also failed to show a significant difference, $U = 443.50$, $Z = 1.48$, $p = 0.14$.

Discussion

Even in the case of an intervention that is not normally causally related to efficacy, 3- and 4-year-olds were able to reason appropriately about stream location. That is, when the unfamiliar intervention that resulted in a change in efficacy was early in the causal stream, children predicted that

the other causal relation would be unaffected, but when the unfamiliar intervention was late in the causal stream, they predicted that both relations would be affected. The data are inconclusive about whether there is an effect of familiarity, possibly making children’s responses more variable. Even if this effect exists, it is probably small, and manifestly not large enough to eliminate the stream location effect we observed.

General Discussion

Both experiments supported the stream location hypothesis: Children were significantly more likely to predict a change in both relations in the late intervention than in the early intervention condition. The results in both age groups indicate that children have a strong understanding of stream location, even as early as three years old. Furthermore, Experiment 2 showed that children would make these inferences even for an unfamiliar intervention. This suggests that stream location may reflect knowledge of the structure of causation in general, rather than just experience with a specific causal system. Further work is necessary to provide more support for this possibility. For instance, we may be able to find stream location effects when the intervention is not just unfamiliar but opposite to past associations – if batteries disable rather than enable the relation, for example.

CERP predicts and supports these findings. The model prescribes that early interventions on a common effect structure are likely to fall on the independent portion of the path from cause to effect, changing only one relation, whereas late interventions on a common effect structure are likely to fall on the shared portion of the path from both causes to the effect, changing both relations. While the data we present are consistent with the general causal graphical model framework – we have shown that children prefer Figure 1b over Figure 1a – only CERP explains *how* this preference is generated.

In Experiment 2, adding a cover appeared to change the efficacy of a the causal relation, a situation that would be counter to children’s experiences (if any) with such causal systems in the real world. Why, then, did they not show a significantly different pattern of responding in Experiment 2? For instance, we might expect children to guess. The answer comes from noticing that the intervention was perfectly correlated with a change in efficacy: the light never worked until we added a cover. It seems that children required an explanation for this change, and the addition of the cover was the only explanation available. This is in line with previous research (i.e. Schulz & Sommerville, 2006) that shows that children are determinists: they attribute such changes in efficacy to human interventions, rather than attributing them to randomness. In work currently underway, we are exploring the interaction between this type of determinism, and inferences about hidden interventions on a causal stream. CERP makes clear predictions here: for instance, if failures sometimes occur without an intervention, a given failure is less indicative of a changed causal relation. Thus, more variable relations should show weaker stream location effects.

The existence of stream location effects in preschoolers provides support for CERP as a model of causal reasoning. Although CERP arose from attempts to make quantitative fits to data on a different phenomenon with adults (namely, the nonindependence phenomenon mentioned above), it nonetheless predicted a novel, qualitative effect that could be detected in children. We see this as one of many examples (i.e. Sobel, Tenenbaum, & Gopnik, 2004; Thelen, Schoner, Scheier, & Smith, 2001) of a productive dialog between experiments and models in cognitive development and cognitive science.

Acknowledgments

This work was supported by NSF (DLS-0518161 to DMS). We would like to thank all of the parents and children who participated, and the Providence Children's Museum and Brown/Fox Point preschool for allowing us to recruit and test on-site. We also thank Karis Casagrande, Caroline Kleeman, Brianna Doherty, Katie Green, Rachel Shelley-Abrahamson, Kristen Swan, for help with data collection and analysis.

Abstract

The elicitation of uncertainty is a topic of interest in a range of disciplines. The conversion of expert beliefs into probability distributions can play a role in assisting key decisions in industry. However, elicitation methods can be prone to bias. In this paper we investigate the effect of changing the presentation of stimulus information and question format on elicited judgments of marginal, conditional and joint probabilities. Participants taught a probability distribution in one structure were expected to have difficulty assessing the distribution in another structure. While this pattern was not found, it turned out that training participants on the more difficult task (learning from a conditional structure) improved overall performance.

Keywords: decision making; cognitive biases; elicitation; probability learning

The “elicitation of uncertainty” is a general term that is often used to refer to methods for translating a set of implicit beliefs into an explicit probability distribution (Wolfson, 2001). The reason for using these methods is to allow researchers to incorporate subjective expert knowledge into a quantitative model that makes predictions about future events (Morgan & Keith, 1995). In view of this, good elicitation methods can play an important role in guiding decision making in a range of industries in which uncertain outcomes are central.

One of the main impediments to widespread use of elicitation techniques in applied settings is the inherent difficulty of the task. This difficulty is caused by the many well-known decision-making heuristics and biases, which can distort the estimates of the underlying beliefs. For instance, anchoring and adjustment, representativeness, availability, base rate neglect and overconfidence (see Tversky & Kahneman, 1974; Bar-Hillel, 1980; Lichtenstein, Fischhoff, & Phillips, 1982) have all been found to influence the judgments people make in an elicitation context, in both lay and expert populations (see, e.g., Eddy, 1982; Welsh, Bratvold & Begg, 2005). Moreover, people often mistake conditional probabilities for joint probabilities (Pollasek et al., 1987) since these are easier to compute (Lewis & Keren, 1999), and often experience difficulties with characterizing the conditioning event (Bar-Hillel & Falk, 1982). People may confuse one conditional probability $P(A / B)$ with another $P(B / A)$, or have difficulties interpreting instructions related to probability (Bar-Hillel, 1980; Fiedler et al., 2000).

Problem Representation

A consistent finding in the decision-making literature is that people are sensitive to the surface representation of a problem. For instance: options described in terms of gains are evaluated differently to the same options when described in terms of losses (Kahneman & Tversky, 1979); changing the surface form of the Tower of Hanoi problem can alter the difficulty of the task (Gunzelmann & Blessing, 2000); and statistical problems expressed in terms of frequencies seem to be easier than the same problems described in terms of probabilities (Gigerenzer & Hoffrage, 1995).

One interesting variation on the question of problem representation arises when people need to learn about and report on the joint distribution of two variables, A and B . Mathematically, we can describe the distribution to be learned and subsequently elicited in three formally equivalent ways, by noting that:

$$P(A, B) = P(A | B) P(B) = P(B | A) P(A) \quad (1)$$

For the current purposes we refer to each of these three variations as a “problem format”, and note that while all three formats describe the same distribution over A and B , there is no guarantee that people will treat them as such. Indeed, in view of the known differences in how people estimate marginal probabilities, conditional probabilities and joint probabilities, we would expect to observe fairly substantial differences between formats.

In this paper we describe an experiment that examines (1) whether one format for the problem leads to superior learning and subsequent probability estimation in general, and (2) whether learning in one format makes it easier to report on questions framed in the same format. Should either of these two effects be observed, a natural method for improving elicitation in an applied context would be to alter the presentation format to be more suited to the expectations of the expert whose beliefs are to be elicited.

Method

Participants

Participants were 60 students (18 male) studying at the University of Adelaide, aged 18 to 37 years, and were paid \$15 for their time.

Procedure

The experiment involved three learning tasks, and two testing conditions, and the measurement of several key covariates. All participants completed all three learning tasks, but were tested in only one of the two testing conditions (based on a random assignment to one of two groups). The basic procedure was as follows. Participants were individually tested in a quiet, well-lit room in front of a computer. Firstly, basic demographic data were collected. Participants then did a simple practice task to demonstrate how the interface works and to illustrate what they would be tested on. Participants then undertook all three learning-plus-elicitation tasks in a random order, with the covariate measurement tasks (APM & MHV; see later) used as filler tasks to help prevent order effects and learned probabilities from previous urn distributions affecting recall of later distributions. Participants were not allowed to use external resources (e.g., pen and paper, calculator) to aid calculations.

The learning tasks

The experiment involved showing participants 20 “candies” which could vary in color (red or blue) and shape (circle or triangle). The participants’ task was to learn the distribution over colors and shapes. The experiment was conducted on computer, and the interface was designed so that the stimuli could be presented to participants in all three formats (i.e., $P(A, B)$, $P(A / B)$ $P(B)$ and $P(B / A) P(A)$). The cover story told participants that they had encountered a “vending machine” (which we refer to as the urn) filled with candies, which was varied slightly between conditions. Participants were shown the 20 candies one at a time: each candy appeared after the participant clicked on a “vend” button (see Figure 1). After viewing all candies, they were asked various elicitation questions (described later).

In the *wrapped* candy condition, participants were told that the candy was covered in a yellow wrapper. As a result, when they clicked on the “vend” button (see Figure 1) they would be able to see the shape of the candy but not its color. If they then clicked the “unwrap” button, the color would be revealed. Because of the sequential way in which the stimulus characteristics were revealed, the format in which “the world” presents the items is naturally described in terms $P(\text{color} / \text{shape}) P(\text{shape})$.

In the *masked* candy condition, the distribution was also shown to people in a sequential fashion. However, the color of the candy was shown before the shape, so that participants would see items in a $P(\text{shape} / \text{color}) P(\text{color})$ format. The cover story in this case implied that the participants were initially viewing the candies through a small window, so they could see the color but not the shape. In this condition, the “unwrap” button was replaced by a “retrieve” button, which then revealed the shape.

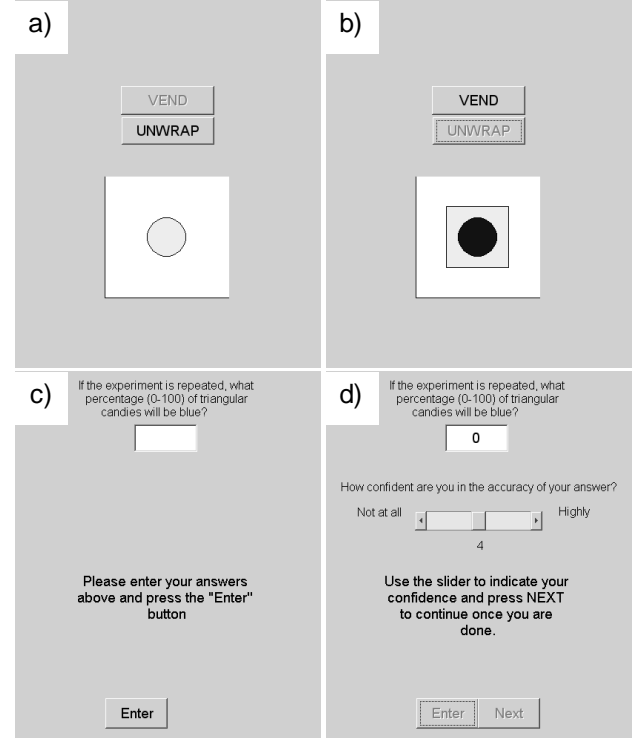

Figure 1: GUI of wrapped candy condition. Vended circular candy (a) unwrapped to reveal blue color (b). Percentage estimate requested (c) before confidence rating (d). All GUIs presented the same basic layout.

The *unveiled* candy condition was the simplest of the three, and presented the two features together as soon as the participants clicked on the “vend” button. As a consequence, participants observed the joint distribution $P(\text{color}, \text{shape})$ in a more direct fashion.

To allow for between-participant comparisons, the base rate for each type of candy was preset in all three conditions (see Table 1). The shape and color of each candy was randomly determined at each trial. After completing 20 trials, the elicitation questions were asked.

The elicitation questions

Participants answered 10 possible questions about the percentage of particular candies in a *future* urn distribution (two regarding marginal probabilities, four conditional probabilities, and four joint probabilities). The questions were asked in a random order. Participants in group 1 were asked to give estimates in terms of a “shape preceding color” structure. These estimates were therefore elicited in the same format in which the distribution of candies was learnt in the wrapped candy condition (e.g., $P(\text{circle})$, $P(\text{red} / \text{circle})$, $P(\text{red}, \text{circle})$ etc). Participants in group 2 were requested to give estimates in terms of a “color preceding shape” structure, hence estimates were elicited in the same format in which the distribution of candies was learnt in the masked candy condition (e.g., $P(\text{red})$, $P(\text{circle} / \text{red})$, $P(\text{circle}, \text{red})$ etc).

Thus, in order to produce estimates, participants in group 1, for example, needed to “flip” the probability distribution (using Bayes’ theorem) that they learnt for candies in the masked candy condition (see Table 1). As shown in Figure 1, the elicited percentage was typed in an editable text box. Additionally, for every probability judgment that participants were asked to make, they were subsequently asked rate their confidence in their accuracy, using a horizontal scroll bar to enter a value that ranged from 1 (*not at all*) to 7 (*highly*). This process was repeated for each elicitation question. All GUI controls were sequentially locked and unlocked to prevent backtracking and to ensure that the participant answered questions in the prescribed order.

Covariate controls

Given that participants with higher cognitive functioning have been found to perform better on tasks involving conditional reasoning (Stanovich & West 1998) and to be less susceptible to overconfidence (Pallier et al., 2002), intelligence measures were included as controls. Bors and Stokes’ (1998) short form of Raven, Court and Raven’s (1988a) Advanced Progressive Matrices (APM) was used to measure fluid intelligence. Crystallized intelligence was measured using Senior Form 1 of the Mill Hill Vocabulary Scale (MHV) (Raven, Court, & Raven, 1988b). Finally, information regarding participants’ TER (percentile Tertiary Entrance Rank derived from students’ performance in the final year of secondary education in several Australian states) was collected.

Results

The accuracy of any given judgment was assessed in terms of the absolute error – the magnitude of the difference between the empirical probability experienced by the participant, and the participant’s subjective estimate of that probability. Since the distribution of absolute errors was skewed to the right, a log transformation was performed on absolute error data points prior to model fitting (with the addition of 1 to each data point to prevent negative values).

Order, format and question type effects

It was hypothesized that participants taught a probability distribution in one conditional structure would have difficulty estimating probabilities in another conditional structure. Since group 1 participants were asked to answer questions consistent with the format learnt in the wrapped candy condition (i.e., a shape preceding color structure), they were expected to give estimates closer to the empirical rate than would group 2 participants. The same was expected for group 2 participants in the masked candy condition (i.e., a color preceding shape structure). Because a joint distribution was presented in the unveiled candy condition, question format was expected to have no effect on performance in either group.

Table 1: Base rates of candy color (red or blue) and shape (circle or triangle) and consistency of question format with presentation of candy features in each of the three conditions for group 1 and group 2. Since the unveiled candy condition contained a joint distribution, question format was neither consistent nor inconsistent.

	Condition		
	Wrapped	Masked	Unveiled
Average base rate (%)			
Color			
Red	10	30	30
Blue	90	70	70
Shape			
Circle	30	90	30
Triangle	70	10	70
Format consistent			
Group 1			
Shape, color	Yes	No	–
Group 2			
Color, shape	No	Yes	–

Examination of the relationship between questions of conditional probability and log absolute error in Figure 2a) showed what may be weak evidence for the predicted effect. That is, group 1 produced better conditional probability estimates in the wrapped candy condition, and group 2 produced better conditional probability estimates in the masked candy condition. There was also an effect of question type with the log absolute error score highest on questions of conditional probability (see Figure 2b).

Note that in the experimental phase there were four sets of questions that should sum to 100%: questions 1 and 2, which concerned marginal probabilities; 3 and 4; 5 and 6, which concerned conditional probabilities; and 7 to 10, which asked for joint probabilities. Errors within each set should therefore be positively correlated (e.g., if a participant estimated 50% of candies would be circular when the true value was 25%, the absolute error would be 25% and a similar absolute error score would thus be expected in their estimate of triangular candies). Moreover, there were participant-level correlations – some participants consistently had poorer or better performance than others. Linear mixed effects models were therefore fitted to further investigate the effect of condition (wrapped candy, masked candy and unveiled candy), group (1 or 2) and question type (marginal, conditional or joint) on absolute error while adjusting for interdependence of the data.

To adjust for the dependence in estimates within the same question set and within estimates from the same participant for a condition, random effects for participant and question set × condition × participant were added to the linear mixed effects models. Condition, group and question type were treated as fixed effects (predictor variables) in the model. The three-way interaction

Figure 2: Mean log absolute error scores, with 95% confidence intervals, for (a) group 1 and 2 estimates of conditional probability in the wrapped and masked candy conditions; (b) combined estimates of marginal, conditional and joint probability; and (c) combined estimates in wrapped, masked and unveiled candy conditions. Group 1 $N = 30$, Group 2 $N = 30$. Sample size of estimates is $N = 240$ in each candy condition in (a); $N = 120$ for marginals, $N = 240$ for conditionals, $N = 240$ for joint in (b); and $N = 600$ for each candy condition in (c).

between these variables and all two-way interactions were examined. APM, MHV and TER scores were also included as fixed effects in the models to assess their influence on absolute error. Degrees of freedom were calculated using the containment method (see Littell et al., 1996).

There were no significant interactions so interaction effects were removed from the model. Significant main effects were found for question type $F(2, 1061) = 31.38$, $p < .001$; and condition (i.e., urn type), $F(2, 1061) = 4.75$, $p < .01$, as can be seen in Figures 2b) and 2c).

Bonferroni post-hoc tests indicated questions of conditional probability (adjusted $M = 2.18$, $SE = .10$) were associated with higher log absolute error relative to questions of marginal probability, (adjusted $M = 1.71$, $SE = .11$), $F(1, 1061) = 25.40$, $p < .001$; and questions of joint probability, (adjusted $M = 1.61$, $SE = .11$), $F(1, 1061) = 55.20$, $p < .001$.

The unveiled candy condition (adjusted $M = 2.03$, $SE = .12$) had a significantly higher log absolute error than the wrapped candy condition, (adjusted $M = 1.68$, $SE = .12$), $F(1, 1061) = 9.12$, $p < .01$ and masked candy condition, (adjusted $M = 1.79$, $SE = .12$), $F(1, 1061) = 4.12$, $p = .04$.

Intelligence and accuracy

Participants with higher APM, MHV and TER scores were expected to provide more accurate probability estimates and a significant main effect was found for APM, ($F(1, 1061) = 3.20$, $p = .04$). Looking at Table 2, it seems that MHV scores were also weakly related to accuracy on the estimation task, with 8 of 9 correlations in the predicted direction ($p = .002$ by a sign test), four of which were significant in their own right. TER scores, however, had no predictive power. Independent samples t-tests confirmed that there was no significant difference between groups on the covariates, specifically: the APM

(group 1 $M = 10.47$, $SD = 2.16$; group 2 $M = 10.77$, $SD = 2.93$; $t(58) = -.45$, $p = .65$); and MHV (group 1 $M = 58.37$, $SD = 10.48$; group 2 $M = 56.40$, $SD = 10.53$; $t(58) = .73$, $p = .47$).

Table 2: Spearman correlations between MHV score, APM score, TER score and log absolute error broken down by question type.

Question type	Score	Condition		
		Wrapped	Masked	Unveiled
Marginal	MHV	-.08	-.11	.01
	APM	-.29**	-.23**	-.20*
	TER ^a	-.13	.02	.20
Conditional	MHV	-.09	-.11*	-.08
	APM	-.06	-.11	-.26**
	TER ^a	.12	.05	.02
Joint	MHV	-.16**	-.15**	-.12*
	APM	-.10	-.12*	-.19**
	TER ^a	-.06	.03	-.02

Note. * $p < .05$, ** $p < .01$, one-tailed. $N = 60$, unless otherwise indicated. ^a $n = 41$. Sample size of estimates is $N = 120$ for marginals, $N = 240$ for conditionals, $N = 240$ for joint.

Confidence and accuracy

It was predicted that confidence ratings would decrease as absolute error scores increase. All correlations were significant and in the expected, negative direction (see Table 3).

Linear mixed effects models were also fitted to assess the relationship between confidence rating and absolute error. The relationship between confidence rating and log

absolute error was highly significant – with every one unit increase in confidence rating, log absolute error was expected to decrease by $-.19$ units. That is, an approximately 20% reduction in absolute error, $t(1559) = -7.31$, $p < .001$. No significant interaction effects were found but a significant main effect was found for condition, $F(2, 1061) = 14.69$, $p < .001$.

Table 3: Spearman correlations between confidence rating and log absolute error broken down by question type and condition.

Question type	Condition		
	Wrapped	Masked	Unveiled
Marginal	-.32**	-.22**	-.31**
Conditional	-.25**	-.20**	-.13*
Joint	-.27**	-.16**	-.19**

Note. * $p < .05$, ** $p < .01$, one-tailed. $N = 60$. Sample size of estimates is $N = 120$ for marginals, $N = 240$ for conditionals, $N = 240$ for joint.

Bonferroni post-hoc tests indicated confidence ratings were significantly lower for the unveiled candy condition ($M = 3.92$, $SE = .20$) compared to the wrapped candy condition ($M = 4.57$, $SE = .20$), $F(1, 1061) = 28.41$, $p < .001$; and the masked candy condition ($M = 4.35$, $SE = .20$), $F(1, 1061) = 12.53$, $p < .001$.

Discussion

In this study we found no significant evidence to suggest that performance on probability estimation tasks changes as a function of the order in which information is acquired. When items were presented in the $P(A / B) P(B)$ format, there was no advantage to eliciting participants' knowledge in this same format, as compared to eliciting the knowledge in the $P(B / A) P(A)$ format. However, we did find that participants who were shown the stimuli in the $P(A, B)$ format actually had significantly higher error than participants taught in either of the other two formats, regardless of what type of question was asked. Given that joint probabilities are presumably easier to process than conditionals, one possibility is that this is a depth of processing effect (Craik & Lockhart, 1972). Recall that, when studying urns with a conditional structure, participants were presented with one characteristic of the candy at a time. This two stage learning process presumably required more attention, involvement and time spent to process each stimulus than the one stage learning process of the joint distribution. This may have contributed to the improvement in overall performance, precisely because the task is harder.

The expected effect of question type was also observed. Absolute error was smallest on questions related to marginal probabilities, and largest on questions related to conditional probability. This was observed regardless of question format or distribution format.

These findings are consistent with previous research (see, e.g., Lewis & Keren, 1999), as is the relationship between accuracy and intelligence (see Stanovich & West, 1998). Finally, participants did seem to be aware of how accurate their performance was, since confidence and accuracy were related in a sensible fashion.

Future directions

Our finding that training on the more difficult task improves elicitation warrants further investigation. Future research could determine whether performance is improved by only the two stage learning process used here or by any training format that fosters increased depth of processing.

Limitations

Before concluding, it is worthwhile considering the limitations of this study. It should be noted, for example, that participants provided estimates for each urn distribution based on only 20 trials, which may not have been sufficient for them to form strong beliefs about the distribution. Increasing the number of trials to 100 might allow participants to get a better sense of the underlying distributions, while a larger sample size would enable a clearer understanding of the results; for example, clarifying whether the suggestive results seen in Figure 2a) actually reflect the hypothesized interaction between learnt distributional formats and probability estimates.

A secondary concern is the level of control over the empirically observed rates; although the "true" base rate for each urn was the same, random draws from the true distribution contain sampling error that results in participants observing slightly different empirical rates from each other, diluting control over the experiment. One solution to this would be to use a pseudo-random distribution with a fixed empirical rate, rather than the truly probabilistic approach taken here.

A third possibility is that the sequential presentation method did not have a strong effect because only one stimulus (the candy) was perceived. That is, the nature of the task may have undermined the experimental manipulation to some extent. A task in which A and B refer to distinct but causally related stimuli (instead of two features of a single object) might provide a better test of the hypothesis.

Conclusions

Although one of the main predicted effects did not appear, the overall results paint an intriguing picture of the potential impacts that training format can have on elicited probability estimates. For example, the fact that training people on the harder task improves estimates is interesting, and of potential applied value. The longer-term goal is thus to see how well these findings can be adapted to improve the elicitation of uncertainty in real world contexts.

Of Parrots and Parsimony: Reconsidering Morgan's Canon

Matthew Brian Welsh (matthew.welsh@adelaide.edu.au)

University of Adelaide, North Terrace
Adelaide, SA 5005 Australia

Abstract

Morgan's Canon is a specific restating of Occam's Razor that dictates that any description of animal behavior should never call upon higher order psychological processes if the behavior could, fairly, be explained in terms of lower processes. Herein, the Canon is discussed both historically and in light of current research into animal behavior. A reconsideration of the principle of parsimony, taking into account current states of knowledge, is also considered. In short, it is argued that Morgan's Canon, while a useful guideline, may have been over-enthusiastically applied in situations where the state of knowledge about a species would dictate that descriptions of its behavior in terms of higher order processes would be equally or more parsimonious. The potential benefits of reconsidering the Canon are then discussed.

Keywords: parsimony; animal behavior; comparative psychology; theory of mind; individual differences.

Morgan's Canon

In no case is an animal activity to be interpreted in terms of higher psychological processes, if it can be fairly interpreted in terms of processes which stand lower in the scale of psychological evolution and development. (Morgan, 1903).

Comparisons between animal and human behaviors have a long history, with scholars as far back as Aristotle (340BC/1952) arguing that 'reason' divides humans from the rest of the animal kingdom. This division, embedded in the Christian distinction between the creation and place of men and animals, was carried through the writings of such philosophers as Descartes (1640/1988) who placed the seat of reason in the soul; and little seems to have challenged this view until the publication of Darwin's *Origin of Species* (1876/1988).

The arguments presented by Darwin, regarding the common descent of all animals through natural selection acting on ancestor populations, broke down the clear-cut division between human and animal that had previously held sway in Western thought and promoted the idea that, across species, one should expect to see variation in traits – including such mental attributes as intelligence (Darwin, 1899/1965). Thus, while humans might be the species blessed with the greatest reasoning ability, one would expect that other species would have this to a greater or less extent – with the further understanding that closely related species would, likely, have similar levels of intelligence.

Romanes (1882), following this parsimonious line of reasoning, produced his book *Animal Intelligence* in which he described a great variety of animal behaviors (both collected by himself and sent to him by correspondents) in

terms of the mental states and understanding required to produce them. The anecdotal nature of this work, however, provoked the responses of Morgan (1903) and Thorndike (1911), whose use of observational study of animals convinced them that many of the cases of 'intelligent' behavior reported by Romanes were, in fact, easily explained as the result of trial-and-error learning.

The reaction to Romanes' book and the subsequent research on conditioning by Pavlov (1927) led to a drastic change in approach to animal behavior research. Rather than considering the pre-existing knowledge of common lineage, researchers were, instead, motivated to explain behavior in the simplest, possible psychological terms. This was partly the result of a genuine belief in the equipotentiality principle (Pavlov, 1927) – which regarded all animals as largely equivalent in terms of their ability to learn through conditioning – but seems also to have resulted from a revision of people's interpretation of the principle of parsimony with a greater focus on the simplicity of the explanatory rules and less on the need for accord with prior knowledge.

Thus, for the greater part of the 20th century, Morgan's Canon has held sway – and been interpreted to mean that animal behaviors should be explained, wherever possible using simple, conditioning-based explanations as these were judged to be most parsimonious and, thus, best.

Occam's Razor and Parsimony

Parsimony in scientific research is often regarded in terms of Occam's Razor, which literally translates as "entities must not be multiplied beyond necessity" but is commonly understood to mean that the simplest hypothesis explaining an observation is the best (Kneale & Kneale, 1962). However, this simple restatement ignores the key phrase in the original: "beyond necessity". Thus, a more complete restatement would require that the best explanation be the simplest one that accords with our state of knowledge about the object or event in question.

The relevance of this to animal behavior research is that, when considering the most parsimonious explanation for an animal's behavior, we must take into account what we already know about that species, related species and even animals in general. Imagine, for example, if one were to see a small animal (of an unfamiliar species) moving along the ground and were interested in starting to explain its behavioral repertoire. Starting with the very broadest of behaviors, for example, we might ask whether the creature's appearance in this location is indicative of its environmental predilections and behaviors.

That is, is the simplest (most parsimonious) explanation for its presence that it is a terrestrial creature native to the area? The answer, in the absence of additional information should, clearly, be yes – this is the simplest explanation that explains the limited data we have. It does not require us to hypothesize about any alternative modes of movement beyond the observed, terrestrial movement nor does it require an additional explanation about why a non-native creature might be here.

If, however, while still unfamiliar with the species in question, you recognize that it is a type of bird this would, almost certainly, change the description judged most parsimonious. Given a general knowledge of birds, it would seem reasonable to decide, instead, that the most parsimonious explanation is that the creature is capable of flight and only currently on the ground – as the vast majority of birds are capable of flight. To take the example a step further, imagine that, in addition to recognizing the creature as a bird, you also recognize that it is, in fact, a type of penguin. This would cause another revision in the best explanation for its behavior (current and potential); in this case, concluding that it is, most probably, flightless and aquatic - as are all other penguin species.

Thus, knowledge about related species changes both the description of current behavior and *expected* behavioral repertoire of an animal; and, any attempt to find the *simplest* (most parsimonious) explanation for an animal's behavior must incorporate this knowledge.

Animal Cognition

Few people, of course, would disagree with the above examples and ethologists such as Tinbergen (1951) and Lorenz (2002/1949), despite their largely behaviorist viewpoints would, doubtless, start any observations of a new species with assumptions regarding its behavior based on the behavior of known, related species. The behaviors described by ethologists and those considered of greatest import by those comparative psychologists holding to Morgan's Canon, however, differ in significant ways. For the most part, ethologists deal with general types of instinctive behavior in the natural environment whereas comparative psychology concerns itself with animal cognition to gain insight into human cognition. That is, to what extent are animals capable of reason, learning and self-awareness and how can this knowledge be used to better understand human behavior?

As noted above, the behaviorist school of psychology (see, e.g., Skinner, 1938) applied Morgan's Canon uniformly and attempted to explain both human and animal behavior in terms of conditioned responses as the equipotentiality principle argued for all organisms learning in, essentially, the same fashion with differences only in the speed at which learning occurred.

The cognitive revolution, starting in the 1950s, however, convinced most psychologists that attempts to explain complex, human behaviors such as language use within a simple, reinforcement-learning paradigm was infeasible

(see, e.g., Neisser, 1967). Perhaps the single greatest effect of this revolution was to move psychology away from regarding the mind as a black box about which nothing could be known beyond inputs (stimuli) and outputs (observed behaviors). Instead, it was recognized that: firstly, the mind cannot be a blank slate prior to learning because a blank slate will not react to inputs in any way (for a recent summary of the cognitive revolution, see Pinker, 2003); and, secondly, that observing the manner in which behaviors change as stimuli change allows us to meaningfully hypothesize about cognitive structures/processes.

This recognition of the need to understand an organism's cognitive processes or mind was not restricted to humans, however. Breland and Breland (1961) identified instinctive drift (the tendency for animals' trained behaviors to revert to the nearest equivalent instinctive behavior) and Garcia and Koelling (1966) exposed the difficulties of training animals when the conditioned and unconditioned stimuli did not 'match' (e.g., illness could be induced in rats by a flavor but not by a light or sound). That is, it was demonstrated that, in order to predict and understand experimental results, one needs to know not just the stimulus and resultant behavior but also the cognitive processes of the organism in question.

Despite such work, however, the shift from behaviorism to cognitive psychology stalled in animal research – no doubt partly because access to human cognitions is often as easy as asking someone what they are thinking while animal minds are much harder to read; but also, it seems, due to a continued belief that the most parsimonious explanation are those that posit the simplest possible processes without reference to 'human' cognitive processes (see, e.g., Wynne, 2007).

The question, though, how *should* our understanding of parsimony affect our beliefs regarding the best explanations for animal behaviors in terms of psychological processes? This is discussed in greater detail as regards two central areas of animal cognition that have provoked significant discussion: animal intelligence and theories of mind.

Animal Intelligence

Between Species Differences

Most people have very little difficulty in believing that certain types of animal are more intelligent than others. This seems to be one case where our understanding of the concept of common lineage has led us to conclude that animals more like us are likely to be more intelligent; and experimental work has offered some support for this. Work by Warren (1977), for example, comparing fish, chickens, mice and cats on a learning task returned the expected order of results – with the cats performing best, then the mice, the chickens and, finally, the fish – although only the cats performed significantly better than the other species.

The problem with such assessments, however, is clear. The very differences described by the Brelands (1961) and Garcia and Koelling (1966) make cross-species comparisons difficult as differences in instinctive behaviors mean that certain species learn particular tasks more easily, thus

making it difficult to determine whether any differences result from differences in “intelligence” or just differential degrees of match between a species and the task/apparatus being used.

Individual and Strain Differences

To avoid these problems, most researchers concentrate, instead, on within-species analyses as these should eliminate most differences in instinctive behavior and allow meaningful conclusions to be drawn. However, between research into human and animal intelligence lies a vast gulf - in the form of differential treatment of individual and group differences within a species.

In human research, individual differences is a major field of research, while group differences are very much a sideline – a result, Fraser (1995) argues, of the feeling that research into group differences in intelligence (in particular) is motivated by prejudice. By comparison, animal research is dominated by comparisons between strains of the same species – with tests of such attributes as spatial ability, memory and even reasoning using pigeons (Wilkie & Wilson, 1995), mice (Tang, et al., 1999) and rats (Anderson, 1992), respectively. These often include neuroanatomical studies to associate the cognitive differences with particular brain structures (the hippocampus, for example, is strongly linked to spatial learning by the above studies).

Individual differences in animals, by comparison, have been largely ignored or even dismissed – as by Warren (1977), who claimed that there was no evidence of individual animals performing above the level of their peers. This dismissal, however, seems to be driven, in part at least, by adherence to the narrow interpretation of Morgan’s Canon described above. That is, individual differences in animal intelligence are not discussed because intelligence (which is largely understood in terms of studies of individual differences in humans) is regarded as a ‘higher’ order cognitive process and, therefore, inappropriate to apply to animal behavior.

This position, however, is at odds with both our everyday experience – those people who interact with animals on a regular basis such as animal trainers and researchers are adamant that certain, individual animals are smarter than others (see, e.g., Goodall, 1968; Kohler, 1925; Pepperberg, 1990) – and knowledge available to us from a variety of fields, including evolutionary theory and the strain differences studies mentioned above.

The first point, of course, relies on the same anecdotal evidence that led to the formulation of Morgan’s Canon and runs the risk of the Clever Hans effect (Pfungst, 1911) where the trainer’s own unconscious behavior is responsible for apparent differences in learning. As such, it must be treated with caution.

The second point, however, argues strongly for there being individual differences in animal “intelligence” – broadly defined here as any cognitive faculty affecting performance on a task. Specifically, according to the theory of evolution by natural selection, it is individual, genetic

differences in traits that cause differential survival and (eventually) speciation (Darwin, 1876/1988). As such, if the argument is to be made that there are differences between the cognitive abilities of different species (for example, that humans have better reasoning abilities than other species) then these differences must have their origins in individual differences within the ancestral populations from which the compared species are descended (Griffin, 1976). Thus, in the ancestral species from which humans and chimpanzees are both descended, there must have been individuals with better reasoning abilities than their peers – otherwise these reasoning abilities could not be selected for and, thus, contribute to the evolution of differences between humans and chimpanzees.

Logically, this argument holds at every point of speciation where one believes there is a difference in cognitive abilities between current species. While this argument does not, in and of itself, make any statement regarding individual differences within *current* species, any attempt to argue that individual differences might, no longer, exist in species other than our own would seem so unlikely as to strain credibility. That is, the claim would have to be that: while, at every point in the past, individual differences in cognitive ability existed within a wide variety of species, now, for unexplained reasons, only one species has such individual differences.

In addition to the argument from parsimony proposed above, we also have evidence for individual differences in cognitive abilities in the form of our ability to selectively breed strains of a species for particular cognitive tasks such as maze-solving (Stewart, 1961); and the observation that strain differences are known to exist on a variety of tasks including those described above. Given the derivation of these strains from common, ancestor populations, it seems unavoidable to conclude that individual differences in the various cognitive abilities discussed do exist and that strain differences are just these writ large.

In addition to these logical arguments, there are also a number of studies (see, e.g., Anderson, 1992; Locurto & Scanlon, 1998; Welsh, 2002) that have shown individual differences in the performance of not just specific tasks but also the emergence of factor structures amongst various tasks reminiscent of the structure of human intelligence as described by Carroll (1993). Specifically, there is some evidence for attributes akin to human spatial intelligence and memory and learning (G_v and G_y in Carroll’s model).

Given this, it seems reasonable to argue that, when attempting to explain animal behavior, appeals to differential levels of cognitive ability between individuals is not an ‘unnecessary multiplication of entities’ nor does it violate Morgans’s Canon as, given the evidence for individual differences in various cognitive abilities, animal behavior cannot be *fairly* described without reference to such higher order cognitive constructs. In fact, any explanation for an animal’s behavior that excludes this knowledge is likely to be overly simplistic rather than parsimonious.

Animal Theories of Mind

Another area of argument in which Morgan's Canon is frequently applied regards whether animals have a 'theory of mind'. That is, to what extent should animals be regarded as possessing minds in the way that humans do; are they self aware and aware of the minds of others (Premack & Woodruff, 1978)? A number of tests of this are commonly used and interpretations of experimental results are often hotly debated in terms of whether the behavior of the animals in questions indicates a theory of mind or can be explained via simple, stimulus-response relationships.

The goal, herein, is not to attempt to fully restate the debate; rather, key aspects of the debate will be considered along with findings relating to these and the interpretations will be discussed in terms of their parsimony in explaining not just the specific behavior at hand but also prior knowledge including phylogenetic relationships.

Attention

One of the preliminary tests for a theory of mind relates to whether an organism reacts to another organism's attention. That is, if one animal is looking in a particular direction, will the other animal look there as well. This is regarded as a test of an organism's theory of mind as it, theoretically at least, requires that the second organism be able to determine where the first creature is looking and what it could see from there.

For example, chimpanzees have been shown to understand point-of-view – that is, their behavior changes according to what an observing creature could see from its perspective (Hare, Call, Agnetta, & Tomasello, 2000). Further tests of this ability to understand attention have included observations of canine communication, where dogs' behaviors are affected by whether they can currently be seen by other dogs (Horowitz, 2009) or people (Call, Brauer, Kaminski, & Tomasello, 2003).

These tests of attention, however, are often criticized (in terms of their relevance to animal theories of mind) as their results can be explained in terms of selective rewards. That is, in environments when a human is directly facing them, a dog is more likely to have been punished for disobeying a command than when a human is facing away. Thus, differential learning could occur such that greater obedience is observed when the dog-human dyad is in certain spatial relations but not in others. This explanation requires only simple psychological processes to be hypothesized and, as a result, is often claimed to be a more parsimonious interpretation of animals' apparent ability to understand the attentional states of others.

Whether it is, in fact, a simpler explanation, though, is questionable. For example, the ability of the dog to distinguish between the situations when a second creature is and is not looking at it – as required by the stimulus-response explanation – requires the dog to have been in sufficient situations like this one to have learnt the difference between the various orientations of other creatures and their responses to various communication

methods. That is, it pre-supposes a history of learning for which no evidence is presented.

Further, given that we know that one social mammal (humans) definitely has the ability to determine where another creature is attending (which assists with social communication and cooperative behaviors), should our starting assumption be that a species bred from another highly sociable mammal (wolves) and further selected for its ability to cooperate with humans does or does not have the same ability?

Imitation

Another central theme in theory of mind research is imitative behavior. That is, if an organism can observe another organism and then *imitate* the behavior, then this is argued to indicate its ability to understand the intentions of the first creature. Of course, there are provisos added to this simple description. The observer must be able to distinguish between accidental and deliberate behaviors and must also be able act in an intentional way – that is, the assumption must be that the organism's goal in imitating the behavior is to achieve the *outcome* that they observed the other creature achieving – rather than to simply mimic the action (Tomasello, Kruger, & Ratner, 1993).

The ever-present difficulties in designing animal experiments such that the animal is motivated to do as the experimenter intends make such analyses difficult with other species – to the extent that Zentall (2006) suggested that, given the number of social and non-social learning factors that need to be distinguished from imitation, inclusion of the recognition of intent might preclude any finding of imitation in non-verbal animals (including young humans).

Instead, Zentall (2006) proposes controlling for a list of pre-identified non-imitative learning behaviors and then, by a process of elimination, calling any learning that still occurs "imitative". Using this looser definition, there are a number of studies that compare how often organisms utilize a particular method to achieve a specific task – having seen conspecifics perform the task in one of the possible ways. Such studies, using budgerigars (Dawson & Foss, 1965), monkeys (Custance, Whiten, & Bard, 1999) and rats as subjects, show that an animal's preferred method of achieving specific aims varies according to how it has seen other animals perform the same task.

This has been demonstrated most clearly in chimpanzees (Buttelmann, Carpenter, Call, & Tomasello, 2007) who operated a device with their foot when an unencumbered human demonstrated its operation in this way but used their hands after seeing a human with his hands full operate the device with his foot. That is, they seem capable of differentiating between cases when the person could and could not use their hands and concluding that, when he could but didn't, there must have been a reason for this.

Once again, we are left with a question to answer: is it more likely, given the evidence we have seen from other species, that so useful a learning mechanism (bridging the

gap between instinctive and self-learned behaviors, as Zentall, 2006, notes) is restricted to a single species or that imitative learning is likely to be a common ability of many social species?

False Belief

Perhaps the best known of the tests for theory of mind are those for false beliefs. That is, whether an organism can predict the actions of another organism based on the differences between their knowledge about a situation. The ability to understand false beliefs has proved very difficult to demonstrate in animals – in part, no doubt because of the required complexity of the task.

The classic design of such tests is to have an animal observe a conspecific observe a reward being hidden and then have the first animal observe the reward being moved while the second is not watching (see, e.g., Call & Tomasello, 1999; Hare, et al., 2000). The behavior of the first animal is then used to attempt to determine whether it realizes that the second animal's belief about the location of the reward is false.

The majority of attempts to test animals understanding of false beliefs, however, have failed. Chimpanzees and other great apes, generally regarded as the most likely of animals to share any particular trait with humans, have not shown an ability to distinguish between ignorance and false belief (Call & Tomasello, 2008). In fact, other than humans aged 5 and over, only dolphins have shown significant evidence of understanding false beliefs (Tschudin, 2006). Thus, false beliefs may mark a qualitative difference between human and (at least the majority of) animal minds. That said, chimpanzees are able to distinguish between another animal's true beliefs and ignorance, indicating some understanding of the complexities of other minds (Call & Tomasello, 2008).

Discussion

There has been a tendency, when considering the results of animal experiments to interpret parsimony as applying to each, new experiment as if it is independent of all other observations. That is, within each experiment, Morgan's Canon is applied and the researchers attempt to explain the results in the simplest psychological terms, without reference to our pre-existing stores of knowledge from previous experiments, related fields, similar organisms and so forth. It is like a physicist who, rather than attempting to create universal laws, attempts to explain the results of each, individual experiment in the simplest terms without reference to the known laws of physics.

Given the research and argument presented above, it seems difficult to conclude that restricting discussion of animal behaviors to 'lower' level psychological process (typically stimulus-reward learning) is an appropriate approach. While an explanation of any behavior can be attempted in stimulus-reward terms, the adequacy of said explanation must be considered. Where such an explanation has to posit the existence of a large number of unobserved

learning trials in a variety of different contexts, and alternative explanations exist that accord with our knowledge about the behavior of other species and the relationships between them, a principled application of parsimony would seem to require a reconsideration of Morgan's Canon.

That is, while recognizing the potential dangers of anthropomorphism, it would seem that to adequately explain the findings from a variety of animal studies requires the use of higher-level psychological concepts such as intelligence and an understanding that animals are likely to have at least a limited theory of mind. In short, we need to consider animal behavior from a more cognitive view-point.

Future Research

An acceptance that animal behavior can meaningfully be discussed in similar, cognitive terms to that of humans opens up a range of research opportunities. For example, advancements in genetics and the mapping of the complete genomes of various species allows for the use of synteny homology (the fact that portions of one species genome have corresponding regions on other species genomes where large numbers of genes are found in the same order) would allow the use of analyses to investigate the genetic basis of cognition.

That is, those higher-level psychological processes that have clear equivalents between humans and animals could be isolated using animal genetic models, which have the advantage of large litter sizes and short inter-generational intervals, and then mapped to the human genome. This approach is, in fact, already underway in the medical sciences (see, e.g., Tang, et al., 1999) but its acceptance within psychology has been limited (for exceptions, see Anderson, 1992; Locurto & Scanlon, 1998; Welsh, 2002) with the result that those best suited to isolating and measuring the cognitive traits of animals have yet to start playing a major role.

Conclusions

Morgan's Canon has, over the past century been applied in a manner which, while seeming rigorous, has actually reduced the parsimony of explanations of animal behavior. Moving away from this too-broad application of the Canon, in addition to being necessary in order to develop the best and most parsimonious explanations of animal behavior, will allow animal research to join the cognitive revolution and allow comparative, cognitive research which will shed further light on human cognition.

Abstract

Language understanding is a socially coordinated activity, but the mechanisms of social coordination in language are poorly understood. Evidence from embodied cognition has shown that movement-induced fatigue of actions slows comprehension of language that refers to those actions. Research on the mirror neuron system suggests that action systems of the brain are also involved in social understanding of actions performed by another, empathy, and possibly language. Here, we show that simultaneous performance and observation of kinematically similar actions produced a fatigue-like effect in sentence judgment times relative to dissimilar control actions. The results suggest that the same action systems used in language processing are influenced by social actions.

Keywords: language comprehension, embodied cognition, social cognition, joint action, motor plasticity, mirror neuron system.

Introduction

Language is fundamentally a social activity in which individuals coordinate their actions (Clark, 1996; Grice, 1975). Conversation involves intricately timed verbal and non-verbal signals for clarifying, initiating, guiding, and ending dialog (Clark, & Wilkes-Gibbs, 1986; Garrod & Anderson, 1987). The mechanisms of language coordination are of current interest.

According to theories of dialog, conversation is successful to the extent that there is similarity of mental states between participants (Garrod & Anderson, 1987). For example, dialog requires that participants share a common ground, or similarity in mental states about referents (Clark, 1996; Clark & Wilkes-Gibbs, 1986). Interlocutors tend to show similarity across linguistic and non-linguistic levels, including word use (Garrod & Anderson, 1987), syntax (Branigan et al., 2000), semantics (Clark, & Wilkes-Gibbs, 1986) and movements (Chartrand & Bargh, 1999). It has been proposed that the same neural systems used for action imitation are also used in dialog (Garrod & Pickering, 2004; Pickering & Garrod, 2006b).

Recent evidence from embodied cognition has shown a close link between action and language. Glenberg and

Kaschak (2002), for example, implicated the action system's influence on language comprehension. Participants in this study responded to a series of sentences depicting transfer, either away from ("Close the drawer") or toward the body ("Open the drawer"). After reading each sentence, participants deemed it sensible or nonsense by pushing "yes" or "no" buttons and in so doing, were required to move their hands either toward their bodies or away. The results demonstrated an action-sentence compatibility effect (ACE). Sentence judgment times were shorter when the sentence depicted movement compatible with the movement required to make a sensible response. The ACE effect has been demonstrated for sentences describing both concrete and abstract (or metaphorical) transfer (Glenberg, Sato, Cattaneo, Riggio, Palumbo, & Buccino, 2008).

More recent evidence has shown that language comprehension is influenced by prior fatigue of the motor system. Glenberg, Sato, & Cattaneo (2008) demonstrated that fatigue of specific actions influences comprehension of written language depicting those actions. To fatigue the neural motor systems involved in toward and away movement, participants were asked to engage in a repetitive action in a toward or away direction. Participants moved 600 beans individually from a container to a target. They were then asked to read a series of sentences describing transfer either toward ("Mark deals you the cards") or away from the body ("You deal Mark the cards"), and judge them as sensible or nonsense by pressing a button. Response times (the time to read the sentence and push the button) were longer when the sentence depicted motion congruous to the movement the participant had previously fatigued. When the sentence depicted an incongruous movement, response times were shorter. This finding was taken as evidence that repeated movement induced plasticity in motor areas recruited in language processing. In particular, the repetition of movement induced muscular fatigue, forcing action-controlling neurons in Broca's region to increase their output, but no longer target the specific action (Glenberg et al., 2008). Thus, participants' comprehension of written depictions of the compatible action (toward or away) was slowed, compromised by shared involvement in both action and language in Broca's region (Gallese, 2008).

Although these studies demonstrate a close link between action and language, they do not address language as a joint action. Research on the mirror neuron hypothesis (Rizzolatti, Craighero, & Fadiga, 2002) suggests that action systems of the brain, including Broca's region, are involved in social understanding of actions, emotions, and possibly language (Rizzolatti & Arbib, 1998).

Mirror neurons, first discovered in the premotor cortex of the macaque monkey, fire both during execution and observation of the same action (di Pellegrino, Fadiga, Fogassi, Gallese, & Rizzolatti, 1992). A comparable mirror neuron system (MNS) in humans may contribute to a wide range of behaviors, including action understanding (Iacoboni, 2005; Rizzolatti, Fogassi, & Gallese, 2001), empathy (Blakemore & Decety, 2001; Carr et al, 2003; Gallese, 2003; Gallese, Keysers, & Rizzolatti, 2004), and language understanding (Aziz-Zadeh, Wilson, Rizzolatti, & Iacoboni, 2006; Rizzolatti & Arbib, 1998).

Evidence supports the existence of a mirror-neuron-like mechanism in humans in which the observed actions of another are processed using the motor system of the observer. In one study, Fadiga, Fogassi, Pavesi, & Rizzolatti, (1995) used transcranial magnetic stimulation (TMS) to increase activation of the motor cortex responsible for grasping an object, while participants observed the same action, or just the object. The dependent variable was the motor evoked potentials (MEPs) in the muscle affected by the stimulated motor cortex. Muscle activation increased during action observation relative to the control conditions, showing that observed actions potentiate the execution of similar actions in the observer.

Other evidence shows that this mirror-like mechanism is specific to kinematically similar actions. Using fMRI, Calvo-Merino, Glaser, Grezes, Passingham, & Haggard (2005) showed that action observation produces the greatest increase in premotor and other cortical area activation for actions that the observers had been trained to perform themselves. And Stefan et al. (2005) used TMS to demonstrate the formation of a kinematically specific motor memory through action observations.

The role of the putative MNS in language has begun to be examined. Using fMRI, Aziz-Zadeh, Wilson, Rizzolatti, & Iacoboni (2006) asked participants to read sentences and observe actions involving either the foot, hand or mouth. They first located brain regions in each subject that were most active during observation of foot, hand, and mouth actions. Next, they compared activations in each region during the reading of sentences involving foot, hand, and mouth actions. They found congruence between areas active during observed actions and the activation levels during reading of sentences describing those actions. Brain regions responded most to sentences that involved the body part for which it was most active during action observation.

If the putative MNS in humans shares neural mechanisms with the action-based language system, then observing another agent repeatedly performing an action should elicit

a generalizing response from action controllers similar to that observed by Glenberg, Sato, and Cattaneo (2008).

To test the influence of social actions in language comprehension, the present study adds to the beans task of Glenberg et al. (2008) and manipulates activation of action controllers through two kinds of simultaneous observed movements. In the Mirrored condition, the movement of both participants is kinematically identical; that is, both participants move beans in the same direction relative to their own bodies. In the Control condition, participants' movements differ in the direction of movement; one participant moves the beans away from their body, while the other participant moves beans toward their body.

By definition of the MNS, both observation and execution of an action activate the same neural systems, and therefore simultaneous observation and execution of action in the Mirrored condition should elicit greater net activation of action controllers than in the Control condition. Based on the results of the Glenberg, Sato, & Cattaneo (2008) study, it is expected that greater activation of action controllers in the Mirrored condition will enhance the fatigue effect in sentence comprehension, relative to the control condition. That is, fatiguing movements toward or away from the body will slow the comprehension of sentences describing transfer toward or away from the body (respectively), and this effect will be enhanced in the Mirrored condition.

Participants

Participants were 80 Introductory Psychology undergraduate students at the University of Wisconsin—Madison (53 females, 27 males). Participants were native English speakers recruited using the UW psychology department's appointment scheduler and were offered course credit for their participation. They were paired randomly, irrespective of gender or handedness. All participants were treated in a manner consistent with the APA's "Ethical Principles of Psychologists and Code of Conduct" (American Psychological Association, 2002).

Design

The experiment consisted of a 2 (practice movement Mirrored or Control) x 2 (practice movement toward or away) x 2 (sentence movement toward or away) mixed design with repeated measures on the third independent variable. The first independent variable consisted of two levels—Mirrored or Control movement. In the Mirrored condition, both participants in a pair transferred beans from one container to another in the same direction, either toward or away from their bodies, while seated across from one another at a small table. In the Control condition, participants transferred the beans in opposite directions (see Figure 1 for a schematic illustration of these conditions). The second independent variable consisted of two levels - practice movement toward or away from the body. The third independent variable consisted of sentences describing transfer either toward the body ("Tony gives you the cup"), or away from the body ("Sarah passes the tray to you").

Figure 1: Schematic diagram of the Mirrored toward and away conditions (top row) and Control toward and away condition (bottom row).

In the reading task, the dependent variable was sentence judgment time; that is, the time between a sentence appearing on the screen and the participant pressing the “yes” button or “no” button to evaluate the sentence as nonsensical or sensible.

Materials

Experimenters used a protocol to guide the setup of materials, to assign participants to a condition, and to instruct participants in each phase of the experiment. For the first phase, the setup included four tupperware bowls on a card table, two for each participant. For each participant, one bowl contained three hundred beans, and the other bowl was empty but lidded with a hole in the top to serve as a target. All four containers were attached to the table by Velcro tabs.

For the second, reading comprehension phase of the experiment, short sentences were displayed one at a time on a computer monitor. Participants indicated that the sentence made sense or did not make sense using “yes” or “no” buttons located on the “3” and “8” keys on a keyboard.

For each participant, 280 sentences were shown in total. Half (140) of all sentences were sensible and half were nonsense (“You iron Linda the theory”). Of the 140 sensible sentences, 100 described transfer (“You give Angela a photo”), and the remaining 40 filler sentences did not (“Angela and you discuss the photo”). Following Glenberg, et al. (2008), half (50) the sensible sentences described transfer of a concrete object (“Tony gives you the cup”), and half described abstract transfer (“Liz tells you a story”). Also, half (50) the sensible sentences described transfer toward the body (“Meg hands you a paper” or “Liz tells you a story”), and half described transfer away from the body (“You hand Meg a paper” or “You give Chris advice”). Sentences were divided equally into two experiment halves. Example stimuli are provided in Table 1.

Table 1: Sample stimuli.

Sentence type	Example
Concrete transfer towards the body	Paul throws you the ball. Meg hands you a paper. Tony gives you a cup.
Abstract transfer towards the body	Chris gives you advice. Eric tells you a fact. Liz tells you a story.
Concrete transfer away from the body	You give Tony the cup. You throw Paul the ball. You hand Meg a paper.
Abstract transfer away from the body	You tell Liz a story. You give Chris advice. You tell Eric a fact.

Procedure

Participants were run in pairs. After participants signed consent forms, the experimenter read from a script, giving an overview of the experiment. First, the experimenter instructed each participant to go to one of two computer booths for practice in the language comprehension task. Practice consisted of instruction in the reading task, and six test trials. After finishing with practice, participants came out of the computer booths and were instructed to move 300 beans one at a time from the full container to the empty one using their right hands. Participants began the beans task at the same time. After both participants finished the bean transfer task, they returned to the reading booths to complete the first half of the sentence comprehension task. Participants typically finished the beans task within 1 minute of each other.

The experimenter then reversed the direction of movement for each participant by reversing the positions of the two containers. After both participants finished the first half of the reading task, they were instructed to return to the table and transfer the beans again, still using the right hand, to the empty container. When finished, the participants returned to the computer booths for the second half of the language task. When finished, participants were debriefed, thanked, and given course credit.

Results

Due to computer difficulties, experimenter error, or participant error, 7 participants were excluded from the analysis. We analyzed the data of the remaining 73 participants (48 females, 25 males; 70 right handed, 3 left handed). Because participants’ accuracy in responding “yes” or “no” to the sensibility of each sentence reflects their reading comprehension, two participants with error rates higher than 10% were excluded from the analysis. Also excluded were trials containing erroneous responses or filler sentences. Only trials with raw sentence judgment times within two standard deviations of each participant’s mean judgment time were used in the analysis.

We decided that the within subjects measure, away and toward movement, could produce carryover effects in the second half of the experiment. The analysis therefore includes only the first half of the experiment. A regression analysis adjusted judgment times to control for sentence length; these residual judgment times provide clearer data and the focus of our interpretation, but both raw and residual data were analyzed.

We predicted that participants in the congruent-toward practice direction condition would have higher (slower) judgment times on toward sentences than away and participants in the congruent-away practice direction condition would have higher judgment times on away sentences than toward sentences. Although we did not have specific predictions for participants in the incongruent condition, it was expected that less MNS stimulation and, by extension, less fatigue, would occur than in the congruent condition.

A three-way ANOVA was conducted separately for raw and residual judgment times. In the raw judgment times, there was a main effect of sentence direction on judgment times, $F(1, 69) = 10.33, p = .002$, showing longer judgment times for toward sentence ($M=1718, SD=336$) than for away sentences ($M=1669, SD=305$).

Contrary to the hypothesis, the difference between the Mirrored and Control conditions in raw judgment times only approached significance, $F(1, 69) = 3.48, p = .066$. An interaction between movement condition (Mirrored vs. Control) and practice direction (toward vs. away) also approached significance, $F(1, 69) = 3.89, p = .053$. None of these interactions were significant in residual judgment times.

Critically, the expected three-way interaction of sentence direction, practice direction, and movement condition was found in both raw [$F(1, 69) = 4.60, p = .035$] and residual judgment times [$F(1, 69) = 6.01, p = .017$]. That is, the interaction of action and language depended on the movement condition. Mean residual judgment times for the three-way ANOVA are listed in Table 2.

Table 2: Mean residual judgment times.

	Practice toward	Practice away
Mirrored condition		
Toward sentences	41.0	10.3
Away sentences	-43.5	-8.0
Control condition		
Toward sentences	-19.8	31.6
Away sentences	18.7	-24.9

To decompose the three-way interaction, we ran a 2-way ANOVA for Mirrored and Control conditions separately. The 2-way interaction was not significant for the Mirrored condition in either raw or residual judgment times, but it was significant for the Control condition in both raw [$F(1, 36)=7.86, p=.008$] and residual judgment times [$F(1,36)=6.88, p=.013$].

To identify the source of the 2-way interaction in the Control condition, we conducted dependent-samples t-tests. There was a significant difference between raw judgment times for toward and away sentences after away practice [$t(18)=3.420, p=.003$], but not after toward practice [$t(18)=.654, p=.522$]. Similarly in residual judgment times, there was a significant difference between toward and away sentences after away practice [$t(18)=2.575, p=.019$], but not after toward practice [$t(18)=1.235, p=.233$].

We are aware that there are other ways to analyze the data that can take the nested design into consideration, and these alternatives are currently being explored.

Discussion

The aim of this study was to test one potential mechanism of social language coordination. Our results indicate an interaction between socially observed actions and language processing and support the hypothesis of Glenberg, Sato, and Cattaneo (2008) that action controllers in Broca's region are involved in comprehension of language describing concrete or abstract transfer. This study also adds to this hypothesis, suggesting that action controller output may increase during observation of others' similar actions. This finding implicates a mirror-neuron-like mechanism in mediating language comprehension and conversation.

As predicted, the pattern of results in the Mirrored condition indicates the fatigue of action controllers through simultaneous self-produced action and observation of action in the MNS. Participants in the Mirrored-toward practice direction, as expected, read toward sentences more slowly than away sentences. Participants in the Mirrored-away practice condition similarly demonstrated the expected pattern, judging away sentences more slowly than toward sentences.

In contrast, participants' judgment times in the control condition seem to reflect the opposite, or a facilitation effect. Participants in the Control-toward condition read toward sentences faster than away sentences and participants in the Control-away condition read away sentences faster than toward sentences. This finding is somewhat consistent with our prediction of a reduced fatigue effect in the control condition. We may attribute the discrepancy to an adjustment in procedure. Whereas participants in the Glenberg, et al. (2008) study transferred 600 beans in each condition, those in our study transferred only 300. Thus, the Control condition activates action controllers, although not to the point of fatigue. In this case, we would expect a pattern similar to an action-sentence compatibility effect (ACE) in which reading times are shorter when there is a match between the direction of motor response and the direction implied by the sentence. The fatigue effect found in the Mirrored condition would have resulted from the dual action and observation of movement, more closely approximating the experience of moving twice as many, or 600, beans.

The findings are generally consistent with several areas of research. The results support embodied theories of language

comprehension in which action systems of the brain play a role in processing of language about actions (Glenberg & Kaschak, 2002). In particular, we replicate the findings of Glenberg et al. (2008) in which action induced motor plasticity affected language processing. Here however, we extend the source of neural plasticity from action-induced fatigue of action controllers to socially induced fatigue of action controllers, in which the MNS is the hypothesized mechanism.

Our findings differ from those of Glenberg et al. (2008) by revealing a U-shaped effect of motor practice on the output of action controllers, with smaller amounts of practice leading to facilitation, and larger amounts of practice leading to fatigue.

Second, the findings support the existence of a MNS in humans in which the observed actions of another are processed using the motor system of the observer (Rizzolatti, & Craighero, 2004). Studies of the human MNS have shown that action observation potentiates the execution of kinematically similar actions in an observer (Calvo et al., 2005; Stefan et al., 2005). Similarly, it was recently found that concurrent observation of a similar action not only produces a kinematically specific motor memory in the observer, but also enhances the effect of training, relative to physical training alone (Stefan, Classen, Celnik, & Cohen, 2008). We found that observation of a kinematically similar action contributes to a fatigue-like effect associated with neural plasticity. To our knowledge, this is the first demonstration that action observation elicits practice-like effects in language comprehension.

Third, the results are consistent with the view of language as fundamentally a joint action (Clark, 1996) in which successful communication of meaning is achieved through alignment of mental states (Garrod & Pickering, 2004; Pickering & Garrod, 2006).

The results can also be compared with the literature on S-R compatibility (e.g., the “Simon Effect”). Whereas that literature has shown that motor responses can reflect the “fatigue” of a spatial features of an irrelevant stimulus (e.g. Proctor & Lu, 1999), we show that such a fatigue effect can be modified by observation of another person doing a related movement.

This study suggests a mechanism by which alignment takes place, namely by the matching of motor states via the mirror neuron system. Interlocutors converge in terms of linguistic features, including grammatical structure (Bock; Branigan, 2000), word use, semantics (Clark & Wilkes-Gibbs, 1986), speech characteristics (Giles, H., Coupland, N., & Coupland, J., 1992), and phonetics (Pardo, J. S., 2006). But motor behavior also converges in social interaction (Chartrand & Bargh, 1999), particularly when there is a desire to create rapport (Lakin & Chartrand, 2003). Our results may shed light on the recent finding that physiological concordance correlates with client-therapist bond (Marci, Ham, Moran, & Orr, 2007). An interesting question is whether dyads in our study would report a

greater sense of rapport in the Mirrored versus Control condition.

Recent theory suggests that the function of the MNS is for interpersonal coordination, rather than imitation of actions (Newman-Norlund, van Schie, van Zuijlen, & Bekkering, 2007), although the evidence for this view is equivocal (Kokal, Gazzola, & Keysers, 2009). Because our movement conditions differed only in terms of the similarity of movement rather than the coordination required by the task, our results support the view that the MNS is involved in imitation.

Nevertheless, understanding how the MNS interacts with brain mechanisms for interpersonal motor coordination is likely to shed light on how conversational alignment supports joint actions in communication.

Acknowledgments

We would like to acknowledge the invaluable research assistance of Katie Krol, and Arbor Otolara-Fadner, and Arthur Glenberg for his helpful comments and support.

Considering the Source: Preschoolers (and Adults) Use Talker Acoustics Predictively and Flexibly in On-Line Sentence Processing

Sarah C. Creel (creel@cogsci.ucsd.edu)

Department of Cognitive Science, University of California-San Diego
9500 Gilman Drive, La Jolla, CA 92093-0515 USA

Abstract

The identity of the person talking is likely to constrain the things that they talk about. Adults can use talker acoustics to make on-line predictions about upcoming spoken material (Van Berkum et al., 2008). However, this cue to meaning may take time to learn. Do preschoolers consider who is talking when they are comprehending spoken sentences? I explored this question in two eye-tracked picture selection experiments. Experiment 1 showed that children and adults use vocal cues to talker identity in predicting the color of upcoming referents in spoken sentences. Experiment 2 showed that children and adults flexibly use acoustic cues to talker for first-person requests (“I want the square”) but reference to individuals for third-person requests (“Billy wants the square”). This suggests that children aged 3-5 years use who is talking to constrain the scope of reference in sentence processing, and know when this cue is likely to be useful.

Keywords: language development, talker identification, perspective-taking, spoken language processing

Introduction

No two people sound alike. Some research indicates that this poses a challenge for language processing (Mullennix, Pisoni, & Martin, 1989; Nusbaum & Morin, 1992). However, it may also provide additional, helpful information to the comprehender. That is, knowing who is talking can provide useful information in processing spoken language. For instance, adult listeners make different predictions about upcoming information in a sentence depending on who is speaking it (Van Berkum, Van Den Brink, Tesink, Kos, & Hagoort, 2008), suggesting they have particular semantic associations with certain voice characteristics (e.g., a child’s voice vs. an adult’s voice). Thus, acoustic differences among talkers potentially have rich semantic associations (Geiselman & Crawley, 1983). But how long does it take the developing language learner to form and use these associations in comprehending language?

Children are sensitive to familiar perceptual information about talkers from a very early age. For instance, they are better at generalizing words between talkers with a familiar accent than between talkers with an unfamiliar accent (Schmale & Seidl, 2009). This suggests that they are sensitive to the acoustic details in the speech signal. Less is known about how much semantic information children glean from talker acoustics. We do know that children have less positive affective responses to (Kinzler, Dupoux, & Spelke, 2007) and associate unfamiliar clothing, and

dwelling with (Hirschfeld & Gelman, 1997) speakers who sound unfamiliar (they speak foreign languages). These studies suggest that children associate familiar-sounding speech with familiar objects and positive affect.

Beyond this, it is not clear whether children store more nuanced semantic information in relation to speech acoustics. This information might be somewhat difficult to learn for two reasons. First, children may be working to *ignore* talker-related acoustics to extract the attributes related to meaning (*dog* spoken by Mom still means the same thing as *dog* spoken by Dad, so why pay attention to irrelevant acoustic variation?). Second, knowing who is talking may only be useful what the person is referring to himself (“I really need a vacation”) and not when talking about things irrelevant to himself (“It’s raining outside”). That is, talker information may only be a reliable cue to meaning in a limited set of circumstances.

Use of other non-phonemic acoustic attributes in comprehension

Though talker information has not been explored as an influence on children’s on-line sentence processing, recent studies on other non-phonemic acoustic cues—prosody and vocal affect—provide some hints about the potential of talker as a semantic information source during development. Children seem adept at processing prosodic information. Snedeker and Yuan (2008) showed that children were sensitive to a speaker’s intonational phrase boundaries in their interpretations of prepositional-phrase attachment. Ito, Jincho, Minai, Yamane, and Mazuka (2009) and Bibyk, Ito, Wagner, and Speer (2009) found that children as young as 6 years use pitch accent to constrain upcoming referents to a set of items contrasting on the pitch-accented dimension. These studies suggest that children attend to non-phonemic sound patterns that cue differences in meaning.

Children seem to have more difficulty processing cues to vocal affect. Morton and Trehub (2001) found that when vocal affect conflicts with verbal content (e.g. hearing “I get to eat ice cream” in a sad voice, or “My dog got hit by a car” in a happy voice), children cannot ignore the verbal content when reporting the talker’s affect (reporting the first sentence as sounding happy, and the second as sounding sad). Nonetheless, recent work by Berman, Graham, and Chambers (2009) using eye tracking, a more sensitive, implicit measure, suggests that children associate positive and negative vocal affect cues with positively- and negatively-valenced pictures (e.g. intact vs. broken dolls).

Children may be using these cues by making associations between sound properties and semantic attributes. For instance, pitch accent seems to semantically activate contrast sets. In the vocal emotion case, children might have associations between sad vocal cues and non-intact objects (Berman et al., 2009). This leaves open whether children are able to use non-phonemic acoustic information in the speech signal to make high-level inferences about the perspective of the talker.

In sum, children show some ability to glean semantic information from two non-phonemic acoustic information sources, prosody and vocal affect. Thus, one might expect that children would gain semantic information from non-phonemic acoustic cues to talker as well. However, it is not clear that children can go so far as to use it to invoke a particular talker's perspective.

The current study

To explore children's ability to exploit talker information in comprehending spoken language, I presented child and adult participants with an eye-tracked picture selection task (Cooper, 1974; Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995) directed by two fictional child talkers, Anna and Billy. Each child professed a preferred color (pink vs. blue), and then asked for pictures on screen (e.g. "the square"), which were always their preferred colors. The question of interest was whether children would visually fixate the pictures in the talker's preferred color over the non-preferred color pictures based on which talker they hear.

I deliberately chose gender-stereotyped color preferences, reasoning that capitalizing on children's preexisting knowledge would minimize working memory demands that might mask sensitivity. I also queried the children's own color preferences, to determine whether they were able to predict color preferences (i.e., make looks to the talker's preferred-color pictures) when those preferences did not match their own.

In Experiment 1, I considered whether children (as well as adults) were able to use talker information early in the sentence as a cue to upcoming referent color. That is, are they able to infer what shape the talker might request, given that the talker is Anna, who prefers pink? In Experiment 2, I assessed children's flexibility in using talker information by making talker identity on its own a useless cue to referent color. Specifically, each child talker asked for a shape for herself half of the time, and for the other child the other half of the time.

Experiment 1

Method

Participants. Children ($n = 24$, ages 3-5 years) were recruited from local day-care and preschool facilities, and participated in the study at their day-care/preschool location. They were given a small toy as a thank-you gift. An additional two children were excluded due to high error

rates (50% and 63%). Adults ($n = 29$) were recruited from the University of California San Diego human participant pool, and received course credit for participation.

Visual stimuli. Pink and blue squares, triangles, circles, and five-pointed stars were constructed in Microsoft PowerPoint and saved as 200 x 200 pixel .jpg files. Scenes of Anna with pink objects (a tutu, a bed, bunny slippers) and Billy with blue objects (a truck, a baseball cap, a watergun) were 1024 x 768 pixel .jpg files.

Auditory stimuli. Two native southern-Californian university students recorded requests for shapes, and descriptions of Anna's and Billy's favorite colors, in child-directed English. Recordings were made in a sound-attenuated chamber and saved to .wav files on a computer. Each utterance was edited for clarity, saved to its own sound file, and normalized to 70 dB. Target word (e.g. "square") onset was at 1003 ms after the sentence began, on average.

Procedure. Each experiment had four brief phases. During each phase, sound was presented over high-quality headphones as visual stimuli were presented on an LCD monitor. First, each talker appeared, surrounded by three pink (or blue) objects, and stated his/her preferred color. The talker named each colored object in turn. Children were then tested in their ability to distinguish the colors: on eight trials, they saw two of the same shape and heard Anna (Billy) ask "Where's the pink (blue) one?" Children did not proceed until they answered at least 7 of 8 trials in a row correctly. This verified that they could distinguish the two colors, and further reinforced each talker's preference. The two favorite-color trials were then presented again. Finally, there was a 32-trial test phase where Anna and Billy each requested objects (stars, squares, triangles, or circles). On each trial, children heard (for instance) Anna saying

(1) Can you help me find the square?

On every trial, two pictures were pink, and two were blue. Each talker requested squares, triangles, circles, and stars equally often. In this phase, neither talker used a color term, referring merely to the shapes themselves. Each shape+color combination occurred equally often in each screen position across trials. Each talker spoke on 50% of trials.

Adults clicked the desired picture with a computer mouse. Children pointed to their desired responses, which were then mouse-clicked by an experimenter. The measure of interest was whether participants, before knowing what shape was to be requested, would visually fixate pink things upon hearing Anna's voice and blue things upon hearing Billy's voice.

Equipment. The experiment was run in Matlab using PsychToolbox3 (Brainard, 1997; Pelli, 1997) and interfaced with the eye tracker using the Eyelink Toolbox (Cornelissen, Peters, & Palmer, 2002). Participants' eye movements were recorded by an Eyelink Remote eye

tracker (SR Research, Mississauga, ON) at 4-millisecond (ms) resolution. Offline, this was down-sampled to 50-ms resolution to enable easier processing.

Results

Figure 1 suggests that both children and adults were visually fixating pictures of the talker's preferred color well before the onset of the target word. To quantify this, I analyzed the data as follows. First, trials with erroneous responses (7% overall) were discarded. Then, a measure of color preference was calculated, which I will call the "color-look score." This was the proportion of looks to the non-target picture of the talker's preferred color, minus averaged looks to the two nonpreferred-color pictures. When this quantity was zero, listeners were not looking at pictures of either color more than the other. When it exceeded zero, listeners were looking more toward the talker's preferred color. (Negative values would imply looks to the talker's nonpreferred color, but this result did not occur in the current experiment.) Bear in mind that eye movements based on spoken material were most likely planned about 200 ms before they occurred, meaning that eye movements planned based on a signal at 1000 ms will show up around 1200 ms (Hallett, 1986).

An analysis of variance (ANOVA) was calculated on participants' color-look scores in three 400-millisecond (ms) time windows, with Time Window (200-600, 600-1000, 1000-1400) and Age (child, adult) as factors. The only significant factor was Time Window ($F(2,102) = 23.49, p < .0001$). Individual t -tests indicated that both children and adults had color-look scores greater than zero—that is, they were looking more to the talker's preferred color—by 200-600 ms (children: $t(23) = 2.27, p = 0.03$; adults: $t(28) = 3.21, p = 0.003$), which was also significant at 600-1000 ms ($t(23) = 4.49, p = 0.0002$; $t(28) = 5.64, p < .0001$) and 1000-1400 ms ($t(23) = 7.35, p < .0001$; $t(28) = 5.99, p < .0001$). Thus, both groups seem to be adept at utilizing talker information to decide whose preferences to invoke.

Figure 1: Adults' (solid) and children's (filled) looks to pictures in Experiment 1. Upper right inset: an example display where black=pink, gray=blue.

Note that children cannot be egocentrically fixating their own preferred color. If they were, then they should show no overall effect of the talker's preferred color: pink looks on pink trials and pink looks on blue trials should cancel each other out. A more subtle version of this egocentricity hypothesis is that children only fixate the talker's preferred color when it matches their own preferred color. This does not explain the results either: children whose preferred color matched neither talker ($n = 12$) still showed above-chance looks to the talker's preferred color at 600-1000 ms ($t(11) = 3.75, p = 0.003$) and 1000-1400 ms ($t(11) = 5.65, p = 0.0001$). This implies that children can use their knowledge of other individuals' color preferences, even when different from their own, to constrain the domain of reference.

Discussion

Both children and adults were able to use talker information early in the sentence to "predict" the color of the upcoming referent: they looked more at blue things when Billy began talking, and at pink things when Anna began talking. This verifies that, in a relatively simple situation, children use talker identity to constrain the referential domain of upcoming sentential material. Children showed looking effects equivalent to adults, suggesting that they are as able as adults to integrate talker information with verb information (Anna + want = pink, Billy + want = blue). This may depend on event knowledge that children have obtained through lifetime experience, or based on experimental conditions, but in either case, children are able to exercise this knowledge.

This experiment nicely demonstrates that children as well as adults are able to use talker characteristics to shape predictions of upcoming referents. One account of these data is that children and adults are using talker information to decide whose preferences to invoke to determine upcoming reference—they are constraining the domain of expected reference by talker. However, another explanation is that participants made a simple low-level audio-visual association between talker-related acoustic properties and color. That is, they associated the sound of a talker's voice with pinkness or blueness, rather than using talker acoustics to access a representation of the talker as an individual with a color preference. On this latter account, they might look at pink things even if Anna were to say "Let me out of this cage" because her voice is associated with pink things.

Related to this issue is whether children are aware of contexts where talker information is even useful in real-world language processing. In particular, talker identity in the real world may only be useful for prediction when the talker is talking about himself. When the talker is talking about someone else—for instance, if Billy said that Anna wanted to see a particular shape—it would be disadvantageous to activate colors associated with Billy's voice. This means that a smart listener would be able to use talker information in some (first person) situations, and ignore it in other (e.g. third person) situations. Presumably

adults do this readily, but it is unclear whether children do so.

Experiment 2

Experiment 2 explored whether children and adults were able to use talker information to activate characteristics (i.e., color preferences) of each individual. The experiment was introduced as before, but now in the test phase each talker asked for a shape either for herself or for the other talker, followed by “Can you show me/him/her where it is?”:

- (2) Anna: I want to see the square. Can you ...
- (3) Billy: Anna wants to see the square. Can you ...
- (4) Billy: I want to see the square. Can you ...
- (5) Anna: Billy wants to see the square. Can you...

If children are learning low-level auditory-visual associations between talkers and colors, they should fixate pink things for (2) and (5) and blue things for (3) and (4). However, if they are learning information about *individuals*, then they may use talker information only in first-person cases, and use reference to Anna or Billy in third-person cases, to determine whose preferences to invoke. If so, they should look to the *agent's* preferred color-pictures, looking at pink things in (2) and (3) and blue things in (4) and (5).

Figure 2: Adult fixations to targets and other pictures on 1st-person (circles) and 3rd-person (squares) trials.

Methods

Participants. Children ($n = 33$) and adults ($n = 39$) were recruited as in Experiment 1. Two more children with extremely high error rates (34% and 44%) were excluded.

Auditory stimuli. A new set of spoken instructions were recorded by the same individuals as in Experiment 1.

Procedure and Equipment. These matched Experiment 1 in all respects.

Results

Both adults (Figure 2) and children (Figure 3) seem to use talker information flexibly: when Anna is the agent of the sentence, they fixate pink things, regardless of whether Anna is the person talking. There were also somewhat later target fixations in the 3rd-person condition than in the 1st-person condition. While visually striking, this simply results from the 3rd-person sentences being slightly longer in duration than the 1st-person sentences (averaging 970 ms to word onset vs. 798 ms to word onset, respectively).

Error trials (5%) were discarded. Then, I conducted an ANOVA on color-look scores with Age (child, adult), Time Window (200-600, 600-1000, 1000-1400) and Person (1st person, 3rd person) as factors. This bore out the above observations. There was an interaction of Age x Time Window x Person ($F(2,140) = 5.18, p = 0.007$), so individual ANOVAs were conducted for each Age. For adults, only Time Window was significant ($F(2,76) = 10.3, p = 0.0001$), with color-look scores increasing over time. *T*-tests indicated that both 1st- and 3rd-person trials showed significant color looks at 600-1000 ms ($t(38) = 2.13, p = 0.04$; $t(38) = 2.73, p < 0.01$), and 1000-1400 ms ($t(38) = 2.25, p = 0.03$; $t(38) = 4.08, p = 0.0002$). For children, there was an effect of Time Window ($F(2,64) = 23.48, p < .0001$), with color-look scores increasing over time, and a Time Window x Person interaction ($F(2,64) = 3.36, p = 0.04$). *T*-tests comparing 1st-person and 3rd-person looks suggested nonsignificant differences in each time window (only 600-1000 ms approached significance, $t(32) = 1.82, p = 0.08$). Regardless, both 1st- and 3rd-person color-look scores were significant at 600-1000 ms ($t(32) = 2.22, p = 0.03$; $t(32) = 4.84, p < .0001$) and 1000-1400 ms ($t(32) = 8.11, p < .0001$; $t(32) = 4.78, p < .0001$). This suggests that children, as well as adults, used the talker's voice on 1st-person trials, but reference (the child's name) on 3rd-person trials, to determine whose color preferences to use in constraining the referential domain. As before, results held for children ($n = 18$) whose favorite colors were neither pink nor blue.

Figure 3: Child fixations to targets and other pictures on 1st-person (circles) and 3rd-person (squares) trials.

Discussion

Children and adults in Experiment 2 succeeded at predicting the agent's color preference. That is, they made more visual fixations to shapes of the *agent's* preferred color on both first-person ("I want") and third-person ("Anna/Billy wants") trials. This implies that they use talker acoustics not just as a low-level auditory-visual association, but as a source of information about a participant in an action. Thus, children as well as adults can use non-phonemic acoustic information to activate information about an individual, and then infer the likely referential domain for that individual.

General Discussion

Two experiments suggest that children are able to use their knowledge about particular talkers to constrain the domain of upcoming referents. In Experiment 1, listeners were instructed that Anna liked pink things, and Billy liked blue things. They then heard Anna and Billy request shapes of their preferred color. Both children and adults made more visual fixations to the shapes of the talker's preferred color than of the talker's nonpreferred color. This suggested that children were able to identify the talkers and use their individual preferences to constrain on-line interpretation of the request.

However, an equally good explanation was that children had associated female voice characteristics with pinkness, and male voice characteristics with blueness, a low-level auditory-visual cue correspondence rather than knowledge of an individual's preferences. Experiment 2 ruled out this explanation: listeners again heard Anna and Billy requesting shapes, but half the time, each talker requested a shape for the other talker. This meant that only on first-person trials ("I want") was talker a useful predictor, while on third-person ("Anna wants") trials, it was a misleading predictor. Impressively, children and adults were both able to use talker information on first-person trials, and proper nouns on third-person trials, to infer the identity of the sentential agent. That is, they always showed a visual fixation preference toward the *agent's* preferred-color shape, even when the agent was not the talker. This implies that, in a relatively simple task, children are able to use talker information selectively (only on first-person trials) to infer the identity—and thus the color preferences—of the agent.

Implications for development of language processing

This research adds to the existing literature on cue integration in spoken language processing. Specifically, this work demonstrates that, in addition to prosody and vocal-emotional cues, non-phonemic acoustic cues related to talker can also be used to constrain processing on-line fairly early in life. This suggests excellent facility on the part of children to use non-phonemic acoustic cues to talker identity to understand the situation described by a sentence. This work is similar to adult research by Van Berkum et al. (2008), in which listeners showed a larger semantic

mismatch potential (N400) when the talker's identity and the action described were incongruous (e.g. a young child saying "I like to drink a glass of wine") than when they were congruous (an adult saying the same sentence). The current work suggests that preschool-aged children are similarly able to use talker acoustics to calculate likely (and unlikely) referents.

The current work, as well as Van Berkum's, fits nicely with a perspective on language processing (Kamide, Altmann, & Haywood, 2003; Bicknell, Elman, Hare, McRae, & Kutas, 2008) in which comprehenders use any available linguistic and nonlinguistic cues to construct event representations on-line. Acoustic information linked to talker identity is apparently useful in constructing event representations. Moreover, it is a robust enough cue that preschool-aged children can use it rapidly on-line (see Bates & MacWhinney, 1987; Snedeker & Trueswell, 2004 for further discussion of cue robustness and development).

Perhaps the most unique contribution of this study is the implication that children are using talker acoustics to infer *properties of individuals*, or at least of groups of individuals. That is, children are able to encode that Anna and Billy have particular color preferences, even when Anna and Billy have different preferences than the children themselves. As demonstrated in Experiment 2, this does not seem to be a simple auditory-visual association between Anna's voice (or female voices) and pink, and Billy's voice (or male voices) and blue, but an association with Anna and Billy as entities who have different preferences for color.

Remaining questions

One obvious question is how much of children's ability to use talker information in this task is subserved by children's long-term knowledge of gendered color preferences. A quick visual search of major toy retailers' products confirms strong tendencies for female toys to be pink (or purple), and for male toys to be blue (or a number of other colors, but not pink). Thus, children's use of talker information here could be due to a lengthy learning process through exposure to gender-stereotyped objects in their environments. On the other hand, children might readily associate idiosyncratic preferences with particular individuals. If so, then children should also be able to use learned, non-gender-stereotyped color preferences to constrain on-line language processing.

An experiment in progress addresses this question, using black and white as the preferred colors. Only one child (1.5%) in Experiments 1 and 2 reported black as his favorite color, and none reported white, suggesting that children have little experience or gender-preference information for black and white. Further, color preference is counterbalanced across talker gender. With 15 child participants so far, there are robust looks to talkers' preferred colors. This suggests that neither conformance to a gender-stereotypical color mapping nor long-term learning is necessary for children to be able to use talker information predictively. However, talker gender itself may still be an

important social anchor point for encoding talker preference.

Another question is how subtle children are in their appreciation of talker information. Are they as keen in their perceptions as adults? If not, how do they differ from adults? Direct comparisons may be limited somewhat by children's level of social knowledge relative to adults—adults may only seem more adept at using talker cues because they have more subtle knowledge of social variation.

Finally, it is unknown how semantic knowledge based on talker characteristics relates to talker-specific perceptual facilitation of word-forms (e.g. Goldinger, 1996; see also Creel, Aslin, & Tanenhaus, 2008). Does talker-specific perceptual information covary with semantic usefulness? Despite these remaining questions, though, the current research forms a solid basis for further explorations of children's sensitivity to talker as a cue to meaning.

Abstract

Reward-maximizing performance and neurally plausible mechanisms for achieving it have been completely characterized for a general class of two-alternative decision making tasks, and data suggest that humans can implement the optimal procedure. A greater number of alternatives complicates the analysis, but here too, analytical approximations to optimality that are physically and psychologically plausible have been analyzed. All of these analyses, however, leave critical open questions, two of which are the following: 1) How are near-optimal model parameterizations learned from experience? 2) How can sensory neurons' broad tuning curves be incorporated into the aforementioned optimal performance theory, which assumes decisions are based only on the most informative neurons? We present a possible answer to all of these questions in the form of an extremely simple, reward-modulated Hebbian learning rule for weight updates in a neural network that learns to approximate the multi-hypothesis sequential probability ratio test.

Keywords: Hebbian learning; diffusion model; neural network; multi-hypothesis sequential test; sequential probability ratio test; speed-accuracy tradeoff; response time

Introduction

We examine the problem of maximizing earnings from a sequence of N -alternative decisions about the identity of noisy stimuli, with $N > 2$. Our goal is to parameterize a simple neural circuit model whose behavior approximates optimal performance in such tasks, while simultaneously accounting for the fundamental role of tuning curves in the neural representation of sensory stimuli. Throughout, we take 'optimal' to mean *reward maximizing*, and we assume that correct decisions earn rewards for the decider.

As we show, simple principles of neural computation are sufficient to approximate this form of optimality quite closely in a class of N -choice tasks involving response-terminated stimuli: that is, stimuli that provide information continuously until the time (the response time) at which participants decide for themselves when to stop observing and make a response. This is somewhat surprising, given that a general decision policy that guarantees truly optimal performance cannot even be explicitly formulated for such tasks, as we discuss below.

N -choice, response-terminated decision tasks

We assume that participants earn rewards for correct responses, and earn less for errors (for simplicity, we assume errors earn nothing). In the simple tasks we consider, each stimulus type has a fixed prior probability within a block of

trials, and the average signal-to-noise ratio of each stimulus is fixed. The duration, rather than the number of trials, is also held fixed, and the distribution of response-to-stimulus intervals (RSIs) that delay the onset of the next stimulus after a response is stationary. In this case, maximizing the rate of reward also maximizes the total reward.

Maximizing gains in this and a variety of similar tasks requires probabilistic inference. While the importance of a principled inference process is widely understood in psychology and neuroscience, the complexity of optimal decision policies in tasks with response-terminated stimuli (also known as 'free response' or 'response time' tasks) and $N > 2$ choices appears to be less well appreciated.

For 2-choice tasks of the type just described, reward-maximizing performance has been completely characterized (Bogacz et al., 2006): a sequential probability ratio test (SPRT) should be carried out in which the current likelihood ratio of the two hypotheses is multiplied by the probability of a given data sample under one hypothesis and divided by the probability of that data sample under the other hypothesis (equivalently, the logs of these probabilities can be added and subtracted, respectively — from now on, we will cast our discussion in terms of log-likelihoods). A response should be made when the resulting log-likelihood exceeds a fixed threshold (Wald & Wolfowitz, 1948). There exists an optimal starting point of the log-likelihood ratio (e.g., 0, for equally likely stimuli) and an optimal separation between the two response thresholds (one greater and one less than zero) that depends on the signal-to-noise ratio (SNR) and the RSI (Bogacz et al., 2006). Gold and Shadlen (2001) have demonstrated that for systems consisting of a neuron/anti-neuron pair, each of which is tuned for one of the two stimulus types in a 2-choice task, the log-likelihood ratio is approximately proportional simply to the difference between the activations of the two neurons, suggesting an extremely simple neural implementation of the SPRT.

In contrast, if the number of choices is greater than 2, the optimal policy for deciding based on accumulated information is nontrivial. In particular, a natural (but definitely sub-optimal) approach to N -choice decision making is to compute the posterior probability of each of the N hypotheses, and then select whichever one first exceeds a fixed threshold. In fact, the best decision is made when the entire set of posterior probabilities meets conditions that are nontrivial func-

tions of the posterior values. A thought experiment may help make clear why this is true. Consider the case of a 3-choice task in which one choice has attained an 80% posterior probability of being correct, while the other posteriors are 10% and 10%. A fixed 80% threshold will therefore not distinguish this case from a case in which the posteriors are 80%, 19% and 1%. These two cases are quite different, however, and dealing optimally with them requires taking account of all posterior probabilities in a more sophisticated way. Because of this, and because of the inherent difficulty in defining truly optimal decision policies to apply to the posteriors, multi-hypothesis sequential probability ratio tests (MSPRTs) were designed to approximate optimality with a decision policy consisting of fixed thresholds applied to posteriors or likelihood ratios (Dragalin, Tartakovsky, & Veeravalli, 1999).

Tuning curves

Tuning curves are ubiquitous in neural responses to stimuli (Butts & Goldman, 2006). The relationship between tuning curve shape and decision making performance has intrigued researchers for several years (e.g., Pouget, Deneve, Ducom, & Latham, 1999). Naively, one may suppose that task participants improve their performance by sharpening the tuning curves of the neurons involved. However, wider tuning curves are in some cases more efficient in conveying information, and the most informative tuning curve shape depends strongly on the noise and correlations (Zhang & Sejnowski, 1999; Seriés, Latham, & Pouget, 2004). Moreover, in several tasks, participants may improve performance without significantly altering the shapes of the tuning curves in the neurons involved. For instance, in an angle discrimination task, monkeys are able to learn to discriminate between finer angles over time, while the tuning curves of primary sensory neurons are altered very little (Ghose, Yang, & Maunsell, 2002; Law & Gold, 2008). This suggests that improvements in performance take place in a learning process downstream from the receptor neurons.

In this paper we explore the ways in which a subject may improve performance in decision tasks, given tuning curve shapes in receptor neurons. We do not consider the alteration of receptor units' tuning curves, but rather how the information in tuning curves can be utilized more efficiently over the course of many trials.

The leaky competing accumulator model for decision making

We propose a three layer neural model for decision making (defined in Table 1, and depicted in Fig. 1). The first layer acts simply as a sensory amplifier; the next layer integrates the information from the first layer, but also exhibits competitive dynamics that gradually build a commitment to one course of action over the alternatives; the last layer triggers a discrete motor response when commitment to one response is sufficiently strong. For convenience, we refer to these three layers, respectively, as the MT, LIP and SC layers. These

labels reflect the fact that our model exhibits known properties of neurons in the monkey middle temporal area (MT), the lateral intraparietal area (LIP) and the superior colliculus (SC) in decision making tasks requiring eye movements in response to visual motion stimuli (i.e., random dot kinematograms; Shadlen & Newsome, 2001). The architecture of this circuitry is expected to apply without major modification to other stimulus and response types, however.

Table 1: Three layer model with weight learning rule.

$S_i, i = 1, \dots, n$	input signals (MT)
$dx_i = \left(-kx_i - m \sum_{j \neq i} x_j + S_i \right) dt + \dots$ cdB_i	accumulators (LIP)
$z_i = H(y_i - \Theta), \quad y_i = \sum_{j=1}^n w_{ij}x_j$	decision units (SC)
$w_{ij}^{\text{new}} = (1 - \alpha)w_{ij}^{\text{old}} + \alpha \Delta w_{ij}$ $\Delta w_{ij} = rz_i x_j$	LIP to SC weight-learning rule

Figure 1: Neural network model with 4 accumulators and 3 alternatives. The weight matrix W denotes the weights of the connections between the x_i 's and z_j 's. Arrows represent excitatory connections; circles represent inhibitory connections.

We suppose that MT neurons have tuning curves that are preferentially sensitive to a single, given direction of visual motion, and that another layer is stimulated by the activity in this input layer. By virtue of their excitatory connections to LIP, model MT units' tuning curves and their feed-forward connections to LIP in turn define tuning curves for LIP units. Questions of major importance in computational neuroscience are: Through what sort of learning process do these tuning curves arise? Can we define an optimal connection scheme that maximizes some function, such as the rate of reward earned by the model? We attempt to make progress on these questions while making the simplifying assumption that the brain circuits in question are approximately

linear systems (at least over a limited range of inputs), and that they employ simple learning schemes (such as Hebbian learning, or error-updating rules such as the Widrow-Hoff, Rescorla-Wagner or delta rule). Recent work (e.g. McMillen & Holmes, 2006; Bogacz & Gurney, 2007) that avoids discussion of tuning curves and learning shows that these assumptions allow simple neural network models to map precisely onto one or another form of MSPRT. We now demonstrate that a similar model that learns connections strengths and accounts for tuning curves does remarkably well at approaching optimal (reward maximizing) performance in decision making tasks with multiple alternatives. The model's layers are represented mathematically by S , x , and z .

Upon presentation of a stimulus, the model's MT layer presents a vector of signals to accumulators in the LIP layer. The signal presented to the i th unit in the LIP layer is referred to as S_i , representing the total weighted sum of MT signals to the i th accumulator. Each stimulus corresponds to a unique signal, so that the set of signals to the LIP layer may be represented as a vector indexed by μ :

$$S^\mu = (S_1^\mu, S_2^\mu, \dots, S_n^\mu).$$

The task is to determine which of N possible signal vectors this represents. Notice that the number of vectors can be different from the number of signals, i.e. in general $n > N$.

Although it is not required, we will generally take the S^μ signals to be Gaussian:

$$S_i^\mu = a \exp \left[-\frac{(i - \text{dir}_\mu)^2}{2\phi^2} \right], \quad i = 1, \dots, n. \quad (1)$$

Here dir_μ is the peak of the signal, a is the height of the peak and ϕ is the width of the curve. As in McMillen and Behseta (2010), we interpret the S^μ in terms of approximately Gaussian MT tuning curves and weights from MT to LIP that preserve this Gaussian tuning in the LIP units. Notice that if $\phi = 0$, then

$$S_i^\mu = a \delta_{i, \text{dir}_\mu},$$

where $\delta_{i,j}$ is the Kronecker delta, so that the signal is concentrated in the channel dir_μ . But, if $\phi > 0$, the signal will have a spread around the peak. For MT units associated with the dot-motion task, tuning curves have been measured to have a width of about 40° (Law & Gold, 2008). The situation is illustrated in Fig. 2. Angles far apart have very little overlap in the signals, but when the angles are close the overlap is substantial. For a two-alternative task in which dots travel on average either up or down, the signals have very little overlap. Signals for alternatives corresponding to more similar motion directions have more overlap.

We model the LIP layer as a set of n leaky competing accumulators. The linearized model for their evolution is a stochastic differential equation (Usher & McClelland, 2001; Bogacz et al., 2006; McMillen & Holmes, 2006):

$$dx_i = \left(-kx_i - m \sum_{j \neq i} x_j + S_i \right) dt + c dB_i, \quad i = 1, \dots, n, \quad (2)$$

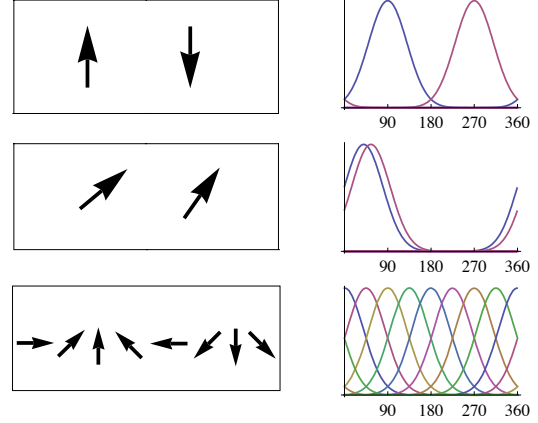

Figure 2: Possible directions of coordinated movement (left panels) and corresponding signal vectors (right panel).

where k is the decay rate, m is the mutual inhibition, and B_i is a Wiener process (integrated white noise) representing the noise in the signal and from other sources. The signal-to-noise ratio is the ratio of the magnitude of the largest signal to the variance of the noise, i.e. a/c . We can thus model changes in the direction coherence by changing this ratio. The effect of decay and inhibition is to concentrate the values of the accumulators onto the signal vectors. Thus, moderate values of w and k tend to increase the accuracy. Best results are achieved when decay and inhibition are balanced, i.e. $w = k$ (McMillen & Holmes, 2006). For simplicity, and to be concrete, throughout the rest of this paper we will present results for $k = w = 0.5$, $a = 2$ and $c = 1$. Results are qualitatively insensitive to these choices.

The output from accumulator j feeds into the i th unit of SC with weight w_{ij} . SC units apply step functions H with thresholds Θ to their inputs. A response is made when SC unit j transitions from 0 to 1 (i.e., when $y_j = \sum_{i=1}^n w_{ij} x_i > \Theta$).

The results in this paper are generally applicable, but to be precise we consider a motion direction task with 36 accumulators and interpret these as representing increments of 10° . If the direction $j \cdot 10^\circ$ is presented, the signal vector takes the shape S_i^μ as in (1), with $\text{dir}_\mu = j$. For concreteness we consider four possible directions of motion: $30^\circ, 60^\circ, 140^\circ, 220^\circ$. Thus, if say, the direction of coordinated movement is 60° , the signal vector has a peak at the sixth accumulator. The four possibilities are represented by the four possible signal vectors with peaks at accumulators 3, 6, 14 and 22. In this paper we only consider the case when all the possibilities are equally likely, in which case the appropriate initial condition for the accumulators is $x_i(0) = 0$.

McMillen and Behseta (2010) showed that the optimal weights w_{ij} in the above are achieved when the weights mimic the shape of the possible incoming signal vectors. That is to say, a threshold crossing test best approximates an MSPRT when $w_{ij} = S_j^{\mu_i}$. The magnitude of the weights

are not important in terms of optimality, as the magnitude may be incorporated into the thresholds. The performance of the threshold crossing tests is illustrated in Fig. 3. Here we consider a test with 36 accumulators and the four alternatives as described above. In Fig. 3 we plot the mean response time (MRT) for a fixed value of the error proportion (ER). For each value of the spread we compute the threshold such that $ER = 0.1$, and find the corresponding MRT. Each panel demonstrates an important fact, as we elucidate below.

In the left panel of Fig. 3 we take the signal vectors to be as (1), and allow ϕ to vary. Thus, $\phi = 0$ corresponds to the case when the signal is concentrated in a single channel. Positive values of ϕ correspond to signals that are spread about a peak. In these computations, the weights are as desired for MSPRT approximation, i.e. $w_{ij} \propto S_j^{u_i}$. This panel thus shows the minimal MRT that can be achieved by a threshold crossing test for an ER of 0.1. We see that there is an advantage to a moderate spread in the signals if this information can be utilized by the decision mechanism. In fact, the optimal spread is near $\phi = 3$. It is interesting to note that this corresponds to a width in the shape of the signal vectors of about 30° , while the width of tuning curves in MT associated with the direction task as measured in Law and Gold (2008) are approximately 40° .

In the right panel we fix the spread in the signal vectors at $\phi = 4$, and compute MRT for various spreads in the weights. In order to get an idea of how the spread in the shape of the weights affects performance when the signal shape is fixed, in these simulations we suppose that the weights also have a Gaussian shape:

$$w_{ij} = w_0 \exp \left[-\frac{(i-j)^2}{2\phi_W^2} \right], \quad j = 1, \dots, n,$$

where w_0 is a normalizing factor chosen so that $\sum_{j=1}^n w_{ij}^2 = 1$ (this normalization step is not in fact required). The spread ϕ_W controls how the values of the accumulators are weighted before making a decision. In the case $\phi_W = 0$, we have $y_i = x_i$, so that the accumulator values are not weighted. When $\phi_W = \infty$, each y_i is the same, i.e. the sum of all accumulators. The right panel of Fig. 3 shows that MRT is minimized when $\phi_W = \phi$. That is, the optimal weights occur when the width of the weight shape is the same as that in the signal vector.

To reiterate, a moderate spread in the signals is a significant advantage, but only if the LIP-to-SC weights can be tuned to take on the same shape as the possible signal vectors defined by MT activity. In the following section we consider how the weights may be modified over the course of trials.

An algorithm for learning the LIP to SC weights

We propose a simple Hebbian weight learning algorithm for the weights w_{ij} . The learning algorithm is a modification of a classical Widrow-Hoff rule (see, e.g., Hertz, Krogh, & Palmer, 1991). In rules of this type, the connection strength being modified acts as a filter that tracks an input signal. At

Figure 3: Effects of signal spread and weight shape. Left panel: Simulated MRT vs. spread in the signal vectors, where the weights have the same shape. Right panel: MRT vs. spread in shape of weights with signal vector fixed with $\phi = 4$. In all cases the threshold is such that $ER = 0.1$.

any point, its value is an approximately exponentially decaying, weighted average of past input values. High frequency changes in this signal (representing noise) are filtered out by the algorithm, producing little change in the updated weight. In contrast, low frequency signal changes (representing, hopefully, the uncorrupted input signal) produce significant changes in the weight. If the signal is constant and noise is absent, the weight will converge approximately exponentially on the value of the signal. If what is being tracked is a signal that depends on the product of activations in a sending unit and a receiving unit, then this rule is simply a Hebbian update rule with a decay term for forgetting old co-activation levels — a useful feature in a noisy neural system.

After each trial the subject responds with a choice among alternatives, say i . At this time the weights to the output unit z_i corresponding to the choice made are updated, according to whether a reward is received or not. Then, if the choice corresponding to z_i is chosen, the weights are updated by the rule

$$w_{ij}^{\text{new}} = (1 - \alpha)w_{ij}^{\text{old}} + \alpha \Delta w_{ij}, \quad (3)$$

$$\Delta w_{ij} = r z_i x_j, \quad (4)$$

where r is the magnitude of the reward, and α is the learning rate. Notice that only the weights to the unit corresponding to the choice made are updated, and this is the sense in which the rule is Hebbian. For simplicity, we assume here that a reward is either earned or not, so that r is either 1 or 0 depending on whether a correct decision is made.

Thus, after each trial, if a correct decision is made the weights to the correct output unit are increased in proportion to the values of the accumulators \mathbf{x} . There is no need to estimate the probability of making a correct decision or an expected value of the reward, as for example in reinforcement learning methods, since only the values of the units are used in the update rule. With this rule the weights track the shape of the vectors being passed from the LIP layer. The weights thus tend to oscillate around the means of the accumulator

values, $\langle x_j(t) \rangle$.

The accumulator values on average take on the shape of the signal vector from the MT layer. This can be proved analytically, but here we show only simulation results. The update rule (3-4) thus causes the weights to track values whose means take on the shape of the MT-to-LIP signal vectors. Therefore the weights tend, on average, to mimic the shape of the signal vector, with oscillations about this shape that depend on the learning rate.

Results of simulations

Figs. 4 and 5 show results of simulations using the update rule (3 - 4). The weights are initially chosen randomly, with a peak added at w_{ii} . Fig. 4 shows how the weights evolve over time, and how this affects the performance of the subject. The reward rate continually increases on average, and the ER continually decreases. The bottom panels show the weights to SC corresponding to $i = 14$, or to angle 140° . The weights for the other alternatives behave similarly. Simulations in which the weights are chosen differently show similar improvements in performance and similar matching of the weight profiles to the signal vector shapes. Cases in which the weights are all chosen randomly show a more dramatic improvement in reward rate (RR) since then the accuracy will initially be very low. Fig. 4 shows that even when the weight has a peak at the right position, a dramatic improvement occurs: for example, the RR more than doubles and the RT and ER both decrease over time.

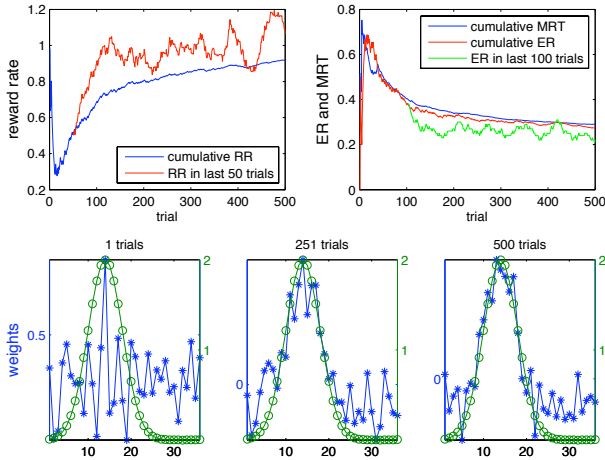

Figure 4: Effects of weight learning rule. The threshold is fixed at $z = 1$. There are four alternatives (3, 6, 14, 22), and the learning rate is $\alpha = .05$. In the bottom panel the signal strength is plotted on the right axis (circles), and the weights are shown on the left axis (stars). The inter-trial delay used in the calculation of reward rate (RR) here is 500 msec.

Figure 4 shows one block of 500 trials. In order to see how the weight update rule behaves on average, we carried out the same simulation for a number of blocks and averaged

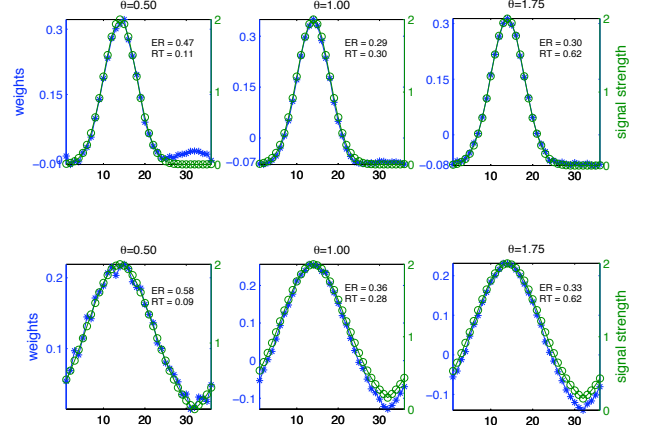

Figure 5: Averaged weights over 150 blocks of 500 trials. In the top row $\phi = 4$; in the bottom row $\phi = 8$.

the weights over each block, and then took the average over 150 blocks of trials. Fig. 5 shows the averaged weights for different values of the threshold, as well as different values of the spread in the signals. We see that on average, the weight profile shape is very close to the signal shape. Also indicated in these figures are the ERs and MRTs for these blocks of trials. Notice that in the lower left panel, the $ER = .58$ is not much smaller than would be achieved by random guessing (.75). In this case the threshold is very small, as is the corresponding MRT of .09. In this situation it will take the weights much longer to learn the shape of the signal vectors, since most of the time the decision will be incorrect. This is why the weights appear more erratic in this frame than in the others. However, even in this case, the average values of the weights take the same shape as the signal vector. Similar comments apply, *mutatis mutandis*, to the upper left panel.

Generally, the model is insensitive to changes in the parameters a, c, k, m , in the sense that the weights tend on average toward the optimal weight shape mimicking the shape of the signal vectors. If the learning rate α is made smaller, the weights take longer to track to the shape of the signals, but there is less variation around these mean values.

Fig. 6 shows the dynamics of evidence accumulation within trials, demonstrating that Gaussian bumps of activation arise on the LIP layer (preserving the Gaussian input signal profiles, and therefore producing Gaussian LIP-to-SC weights through Hebbian learning).

Discussion

The simple rule (3-4) works remarkably well at learning the shapes of the signal vectors from MT to LIP. This leads to a dramatic improvement in performance, and occurs without any direct connection to the MT layer. The three layer model incorporates integration of information, a rule for making the decision, as well as a simple algorithm for learning to optimize reward rates by learning the shapes of the vectors of

Figure 6: Panel A, top, shows LIP unit activations at several time points within a decision. Activations are averaged over many instances of stimulus type 2, which produces maximal activation in LIP unit 6 (visual angle 120°; here we arbitrarily quantized visual angle into 18 levels). Panel A, bottom, shows the weighted values of these activations feeding into each of 3 SC units. Panel B shows the average state of evidence accumulation for choice 2 (input to SC unit 2; blue) and average LIP unit 6 activity (red) within fixed-viewing time trials, without thresholds applied to the evidence (the interrogation protocol). Panel C shows the average state of weighted evidence accumulation for choice 2 (blue) and average unit 6 activity (red) within free response trials (black line indicates threshold). The weighted sum produces a higher signal-to-noise ratio, and therefore better performance than evidence from unit 6 alone. Red and blue traces fall off over time because the average is based on fewer and fewer trials as time progresses (more and more decisions have already taken place by the end of the plot).

neural signals coming from an input layer. These features are essential elements of a complete decision-theoretic model.

Abstract

How do characteristics of caregiver speech contribute to a child's early word learning? We explore the relationship between a single child's vocabulary growth and the distributional and prosodic characteristics of the speech he hears using data collected for the Human Speechome Project, an ecologically valid corpus collected from the home of a family with a young child. We measured F0, intensity, phoneme duration, usage frequency, recurrence, and MLU for caregivers' production of each word that the child learned during the period of recording. When all variables are considered, we obtain a model of word acquisition as a function of caregiver input speech. Coefficient estimates in the model help to illuminate which factors are relevant to learning classes of words. In addition, words that deviate from the model's prediction are of interest as they may suggest important social, contextual and other cues relevant to word learning.

Keywords: language acquisition; word learning; corpus data; prosody

Introduction

How does the linguistic environment contribute to children's early word learning? We address this question by making an in-depth study of a single child's vocabulary growth and the relationship of this growth to prosodic and distributional features of the naturally occurring caregiver speech that the child is exposed to. Studying this relationship has the potential to illuminate not only the role of environmental factors in word learning, but also the child's underlying learning mechanisms.

Children's linguistic environments plays a crucial role in determining what they learn, but the precise relationship between what children hear (their input) and what they learn is still unknown. Much of the debate about the role of the linguistic environment has centered around whether the particular properties of child-directed speech (CDS) are useful for the acquisition of syntax. On the one hand, Snow (1986) emphasized the importance of CDS for conveying communicative intent and its consequent importance to development. However, the work of Newport, Gleitman, and Gleitman (1977) challenged the assumption that CDS is a simplified teaching language that facilitates the acquisition of specific syntactic constructions. More recent work has focused on broader patterns of development, documenting a correlation between grammatical and lexical developmental trajectories (Bates & Goodman, 1999).

Stronger evidence for the contributions of CDS to language development have been found in the realm of lexical acquisition. For example, Huttenlocher, Haight, Bryk, Seltzer, and

Lyons (1991) found a positive correlation between the quantity of CDS and a child's vocabulary size and rate of growth. Increased frequency of use of particular words in CDS has also been tied to earlier acquisition of those words by the child (Huttenlocher et al., 1991; Goodman, Dale, & Li, 2008; Roy, Frank, & Roy, 2009). Frequency is not the only factor that affects acquisition, however. The production of a word in isolation is also a consistent predictor of lexical development (Brent & Siskind, 2001). Finally, prosodic factors in caregiver speech also likely play a role in acquisition: Echols and Newport (1992) found that children were much more likely to produce and recognize syllables that were stressed in caregivers' speech.

While previous studies of the relationship between CDS and children's vocabulary acquisition have largely focused on examining a small section of the input to a range of children, here we take a different approach. We make a very detailed study of this relationship in a very large, dense, longitudinal dataset collected in an ecologically valid setting. This dataset was collected as part of the Human Speechome Project (Roy et al., 2006). At present, the Speechome Corpus consists of time aligned orthographic transcripts as well as a complete audio and video record of all data collected. Therefore, our analysis is not limited to factors like frequency (which can be computed from transcripts alone): instead we are able to include additional prosodic variables that can only be computed from aligned audio and transcripts.

Our goal in this current analysis is to predict the child's age of acquisition (AoA) for individual words on the basis of information from CDS. AoA is usually categorized as the age of *receptive* and *productive* acquisition. Receptive acquisition is typically determined by the caregiver via diary studies or checklists, and is consequently relatively difficult to assess with high accuracy for a large sample of words. Age of productive acquisition is more easily measured from transcripts, although there are complications here as well, since early productive word forms often differ from the corresponding adult word form. However, we are able to overcome this limitation to a greater extent than previous studies, because of the density of our data and the accessibility of caregivers for help in the transcription process.

The plan of our paper is as follows. We begin with an overview of the Human Speechome Project. We then review the regression framework we used for the prediction of vocabulary acquisition and describe in detail the predictors we included in this framework. We report both simple correlations

between individual predictors and age of word acquisition as well as the results of a series of regression models. We end by considering the implications of our work for future research in language acquisition.

The Human Speechome Project

The Human Speechome Project (HSP) (Roy et al., 2006) was launched in 2005 to study early language development through analysis of audio and video recordings of the first two to three years of one child's life. The house of one author's (DR) family was outfitted with fourteen microphones and eleven omnidirectional cameras at the time of birth of their first child. Audio was recorded from ceiling mounted boundary layer microphones at 16 bit resolution with a sampling rate of 48 KHz. Due to the unique acoustic properties of boundary layer microphones, most speech throughout the house including very quiet speech was captured with sufficient clarity to enable reliable transcription. Video was also recorded to capture non-linguistic context using high resolution fisheye lens video cameras that provide a bird's-eye view of people, objects, and activity throughout the home.

The Speechome project captures one child's development in tremendous depth. While this aspect of the project limits conclusions about general aspects of language development, the dense sampling strategy affords many advantages over other corpora (eg. (Lieven, Salomo, & Tomasello, 2009)). First, the Speechome corpus is higher in density than other reported corpus, capturing an estimated 70% of the child's wakeful experiences during the recording period. Second, since data were collected without specific theoretical assumptions or hypotheses, they can be reanalyzed in multiple ways from different theoretical perspectives. Finally, since high resolution video was also collected the role of non-linguistic context can also be studied (though in the current study we restrict our analysis to aspects of speech input).

The current study builds on our first analysis of the Speechome data (Roy et al., 2009). In that study, we focused on the child's 9-24 month age range and explored several aspects of word learning, examining variables such as the child's vocabulary growth, increase in mean length of utterance (MLU) as well as properties of caregiver speech such as caregiver MLU over time. Due to the high density of data, with several days per week fully transcribed over the course of this 9-24 month period, a surprising picture emerged of the tuned relationship between the child's development and caregiver speech. Congruent with other reports, we found that words used more frequently in caregiver speech tend to be learned earlier by the child, with a much stronger effect when words are grouped by class (Huttenlocher et al., 1991; Goodman et al., 2008).

Methods

The Speechome Audio Corpus

The dataset collected for the Human Speechome Project comprises more than 120,000 hours of audio and 90,000 hours of

video. Most analysis depends on annotated data, however, so an effective annotation methodology is critical to the project's success. We have developed a semi-automated speech transcription system called BlitzScribe that facilitates fast and accurate speech transcription (Roy & Roy, 2009). Automatic speech detection and segmentation algorithms identify speech segments, presenting them to a human transcriber in a simple user interface. This focuses human effort on the speech and leads to a smoother transcription process. We have obtained an approximately five-fold performance gain at comparable accuracy to other tools.

Speaker identification algorithms are then applied to the transcribed audio segments, selecting from one of the four primary speakers (mother, father, nanny, and child) and producing a classification confidence score. Speaker annotation tools allow a human to review low confidence segments and make corrections as necessary. Since identifying CDS currently requires significant human effort, we operationalized the definition to refer to caregiver speech when the child is awake and close enough to hear. We refer to this as "child available speech" (CAS).

Our current study focuses on the child's 9-24 month age range, and the corresponding subset of the corpus contains 4260 hours of 14-track audio, of which an estimated 1150 hours contain speech. Of the 488 days in this time range, recordings were made 444 of the days with a mean of 9.6 hours recorded per day. The current results are based on 72 fully transcribed days containing an average of 23,055 words per day of combined CAS and child speech, totaling 1.66 million words. We estimate that the fully transcribed 9-24 month corpus will contain 12 million words. Our long term goal is to fully annotate all speech in the corpus with transcriptions, speaker identity, and prosodic features.

Three limitations of the speech annotation process required us to filter the 1.66 million words of transcripts and only use a subset of the transcripts for the current analyses. First, roughly 700,000 words belong to utterances marked by human transcribers as containing more than one speaker. In other words, about 40% of pause separated spoken utterances contain abutting or overlapping speech of two or more people, reflecting the realities of "speech in the wild." Since our objective here is to examine interaction of CAS and child speech, and since we cannot currently distinguish the sources of this type of speech, we removed these utterances. Second, to reduce errors due to automatic speaker identification, we sorted utterances based on a confidence metric produced by the speaker identification algorithm and removed approximately the bottom 50% of utterances. Third, about 15% of the remaining utterances were deemed by human transcribers to be of insufficient clarity to transcribe reliably. After removing those utterances, we obtained the 399,141 word corpus used for all analyses in this paper.

Outcome and Predictor Variables

The goal of our study was to use measurements of the prosodic and distributional characteristics of CAS to predict

Figure 1: Schematic of the processing pipeline for outcome and predictor variables.

AoA for the child’s early vocabulary. We use linear regression to provide a computational framework for this goal. We therefore used age of acquisition as our outcome variable and extracted six predictor variables to quantify aspects of CAS. Figure 1 shows the pipeline used to extract these predictor variables from our speech and transcription files. Below we give our operational definition for age of acquisition and for each of the six predictor variables we used in our analysis. All variables are computed using the sample up to the AoA for a particular word.

Age of Acquisition We defined the AoA for a particular word as the first time in our transcripts that the child produced a word. Using this definition, the first word was acquired at nine months of age with an observed productive vocabulary of 517 words by 24 months (though the actual productive vocabulary might be considerably larger when transcription is completed). In order to ensure reliable estimates for all predictors, we excluded those words from the child’s vocabulary for which there were fewer than six caregiver utterances. This resulted in the exclusion of 56 of the child’s 517 words, leaving 461 total words included in the current analysis.

Frequency Frequency measures the count of word tokens in CAS up to the time of acquisition of the word divided by the period of time over which the count is made. Thus, this measure captures the average frequency over time of a word being used in CAS.

Recurrence Distinct from frequency, recurrence measures the repetition of a particular word in caregiver speech within a short window of time. The window size parameter was set by searching all possible window sizes from 1 to 600 seconds. For each window size, we performed a univariate correlation analysis to calculate the correlation between recurrence at that window size and AoA. We then selected the window size which produced the largest correlation (51 seconds).

MLU The MLU predictor measures the mean utterance length of caregiver speech containing a particular word. In order to be consistent with the direction of correlation for

other variables (a negative correlation with the AoA) we use $1/\text{MLU}$ as the predictor.

Duration The duration predictor is a standardized measure of word duration for each word. We first extracted duration for all vowel tokens in the corpus. We next converted these to normalized units for each vowel separately (via z-score), and then measured the mean standardized vowel duration for the tokens of a particular word type. For example, a high score on this measure for the word “dog” would reflect that the vowel that occurred in tokens of “dog” was often long relative to comparable vowel sounds that appeared in other words. We grouped similar vowels by converting transcripts to phonemes via the CMU pronunciation dictionary.

Fundamental frequency The fundamental frequency predictor is the measure of a word’s change in fundamental frequency (F0) relative to the utterance in which it occurred. We first extracted the F0 contour for each utterance in the corpus using the PRAAT system (Boersma & Weenink, 2009). We then calculated the change in F0 as a sum of two terms shown in the equation below. The first term captures the change in F0 for the word relative to the utterance in which it’s embedded. $\overline{F0}_w$ is the mean F0 value of the word, and $\overline{F0}_{utt}$ is the mean F0 of the whole utterance. The second term captures the maximum change in F0 within the word. t_{max} and t_{min} are the times at which the max and min F0 values occur within the word. α_0 and α_1 are constants set using the same optimization technique described in the recurrence section.

$$\alpha_0 * |\overline{F0}_w - \overline{F0}_{utt}| + \alpha_1 * \left| \frac{\max(F0_w) - \min(F0_w)}{t_{max} - t_{min}} \right|$$

Intensity Relative word intensity was calculated in the same manner as F0 using the intensity contour in place of the F0 contour. The intensity contour was extracted using the PRAAT system.

Results

Correlation analysis

Correlations between AoA and the six variables we coded in caregiver speech are shown in Figure 2. All correlations were negative and highly significant (all p -values less than .001) though their magnitude varied. Correlations with recurrence and intensity were largest, while correlation with F0 was smallest.

Replicating results in Roy et al. (2009), the correlation with frequency was -.23. This figure is slightly lower than the -.29 reported in the earlier paper. There are two differences in analysis that account for the different result. First, a small subset of words were excluded from this analysis due to data sparsity. Second, frequency data are estimated only up to the time the child first produces the word. This second difference leads to a potentially interesting conclusion. If the distribution of word frequencies is stationary with respect to time, then correlations should go up as more data are included for

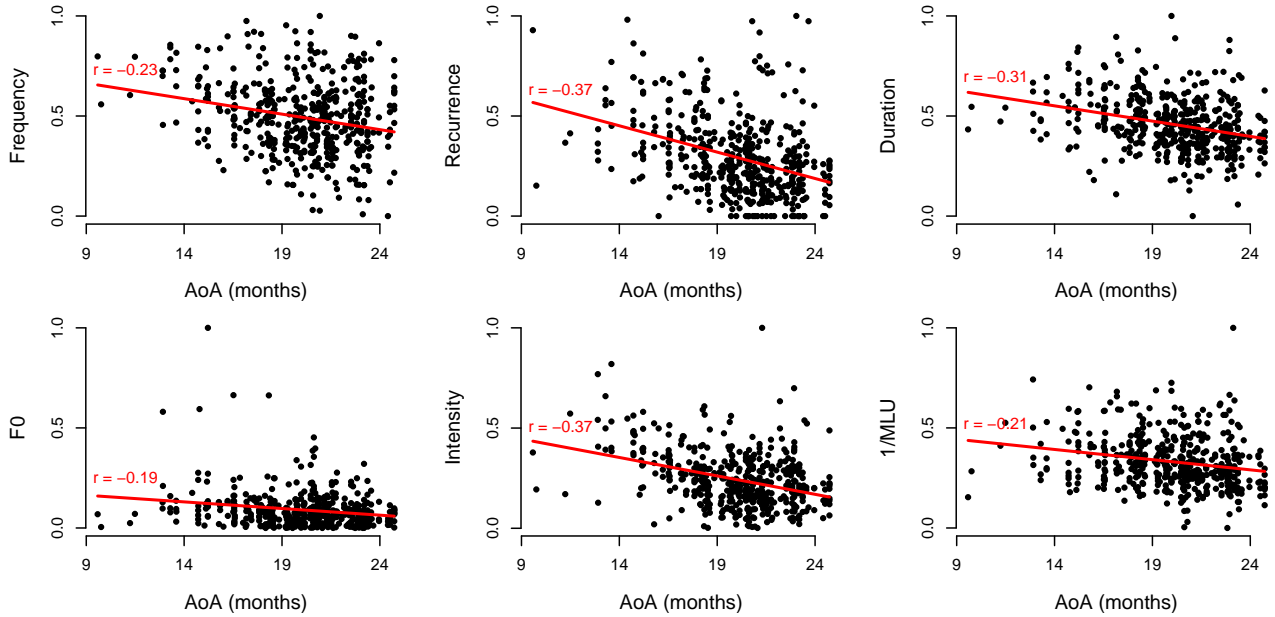

Figure 2: Each subplot shows the univariate correlation between AoA and a particular predictor. Each point is a single word, while lines show best linear fit.

Table 1: Correlation coefficients (Pearson’s r) between all predictor variables. Note: $' = p < .1$, $* = p < .05$, and $** = p < .001$.

	Recur	Dur.	F0	Int.	1/MLU
Frequency	.36**	-.05	.19**	.35**	-.22**
Recurrence		.25**	.20**	.22**	.10*
Duration			.12*	.22**	.33**
F0				.10*	-.15*
Intensity					.02

each word. In contrast, if caregivers tune the frequency distribution of words to an estimate of the child’s knowledge, correlations should go down as more data are included. Because we observed (slightly) larger correlations with frequency for the earlier dataset, this provides some evidence against caregiver tuning of word frequencies.

Correlations between predictor values are shown in Table 1. The largest correlations were between frequency and recurrence, frequency and intensity, and inverse MLU and duration. The correlation between frequency and recurrence is easily interpreted: the more times a word appears, the more likely it is to recur within a small window. On the other hand, correlations between prosodic variables like frequency and intensity or duration and inverse MLU are less clear. For example, perhaps words are more likely to have longer duration vowels when they are being accented in a shorter sentence.

Regression analysis

We next constructed a regression model which attempted to predict AoA as a function of a linear combination of predic-

tor values. The part of speech (POS) was included as an additional predictor. We created POS tags by first identifying the MacArthur-Bates Communicative Development Inventory category (Fenson, Marchman, Thal, Dale, & Reznick, 2007) for each word that appeared in the CDI and generalizing these labels to words that did not appear in the CDI lists. To avoid sparsity, we next consolidated these categories into five broad POS categories: adjectives, nouns, verbs, closed-class words, and other. The inclusion of POS as a predictor significantly increased model fit ($F(4) = 107.37$, $p < .001$).

Coefficient estimates for each predictor are shown in Figure 3. All predictors were significant at the level of $p < .05$. The full model had $r^2 = .32$, suggesting that it captured a substantial amount of variance in age of acquisition.

The largest coefficients in the model were for intensity and inverse MLU. For example, there was a four-month predicted difference between the words with the lowest inverse MLU (“actual,” “rake,” “pot,” and “office”) and the words with the highest inverse MLU (“hi,” “silver,” “hmm,” and “sarah”). Effects of POS were significant and easily interpretable. We used nouns as the base contrast level; thus, coefficients can be interpreted as extra months of predicted time prior to acquiring a word of a non-noun POS. Closed-class words and verbs were predicted to take almost two months longer to acquire on average, while adjectives and other words were predicted to take on average less than a month longer.

Assessing model fit

Residuals from the basic linear model were normally distributed. Figure 4 shows the relation between predicted age of acquisition (via the full predictive model including part of

Figure 3: Coefficient estimates for the full linear model including all six predictors (and part of speech as a separate categorical predictor). Nouns are taken as the base level for part of speech and thus no coefficient is fit for them. Error bars show coefficient standard errors. For reasons of scale, intercept is not shown.

speech) and the age of acquisition of words by the child. One useful aspect of plotting the data in this way is that it makes clear which words were outliers in our model (words whose predicted age of acquisition is very different than their actual age of acquisition). Identifying outliers can help us understand other factors involved in age of acquisition.

For example, words like “dad” and “nannynname” (proper names have been replaced for privacy reasons) are learned far earlier than predicted by the model (above the line of best fit), due to their social salience. Simple and concrete nouns like “apple” and “bus” are also learned earlier than predicted, perhaps due to the ease of individuating them from the environment. In contrast, the child’s own name is spoken later than predicted (20 months as opposed to 18), presumably not because it is not known but because children say their own name far less than their parents do. Future work will use these errors of prediction as a starting point for understanding contextual factors influencing word learning.

Interactions and more complex models

Our first linear model had two limitations. First, we found that there was significant variation in the effects of the six predictors depending on what POS a word belonged to. Second, we did not include any interaction terms. We followed up in two ways. First, in order to investigate differences in predictor values between word classes we built separate linear models for each POS. Second, we used stepwise regression to investigate interactions in our larger model.

Table 2 shows coefficient estimates for five linear mod-

Figure 4: Predicted AoA vs. true AoA. To to avoid overplotting, only half of the 461 words are shown. The red line shows the line of best fit.

Table 2: Coefficient estimates for linear models including data from adjectives, nouns, closed-class words, verbs, and all data. Note: ‘ = $p < .1$, * = $p < .05$, and ** = $p < .001$.

	Adj.	Closed	Nouns	Verbs	All
Icept	27.66**	25.03**	25.00**	25.93**	25.57**
Freq	0.38	6.73	-5.84**	-0.89	-1.53*
Recur	-2.36	-12.02*	-1.53'	-7.47**	-2.85**
Dur	-5.22*	1.81	0.09	-2.74	-2.66*
F0	-7.43	-6.42	-2.28'	0.54	-3.42*
Int.	-8.60*	-12.16	-4.66**	-1.56	-4.78**
1/MLU	-5.70*	-9.37	-3.71*	-5.26	-3.89**

els, each one for a different group of words. None (including the “all” model) include a predictor for POS. Coefficient estimates varied considerably across models, suggesting that different factors are most important for the acquisition of different kinds of words. For example, frequency, intensity, and inverse MLU were most important for nouns, suggesting that hearing a noun often in short sentences where it is prosodically stressed leads to earlier acquisition. In contrast, adjective AoA was best predicted by intensity, duration, and inverse MLU, congruent with reports that children make use of prosodic cues in identifying and learning adjectives (Thorpe & Fernald, 2006). Finally, both verbs and closed-class words were best predicted by recurrence, supporting the idea that the meanings of these words may be difficult to decode from context; hence frequent repetition within a particular context would be likely to help (Gleitman, 1990).

We next constructed a model that included every pairwise interaction between each of the six predictors and between the predictors and POS. We then used stepwise regression to remove predictors that did not increase model fit. Stepwise regression prunes predictors using AIC, a measure which balances increases in likelihood with complexity. This model increased r^2 to .44, and added a large number of interaction

terms. We report only the general outlines of results in this model as they confirm intuitions from other analyses.

While frequency had an overall *positive* coefficient value in this model, all four interactions were negative, indicating that there was considerable shared information between frequency and other predictors. Recurrence and intensity also interacted significantly, suggesting that when words were spoken repeatedly with high intensity (possibly because they were a topic of discourse over a period of time) they were acquired at earlier ages. Finally, both duration and intensity interacted with POS, with significant coefficients for closed-class words. As seen in Table 2, longer closed-class words are acquired slightly later (probably because longer closed-class words are less frequent). In addition, higher intensity closed-class words are acquired considerably earlier, probably because one major challenge in function word acquisition is understanding their prosodic structure (Demuth & McCullough, 2008).

Discussion and Future Work

Our study quantified six variables describing the prosodic and distributional characteristics of words in child-available caregiver speech: frequency, recurrence, mean length of utterance, duration, fundamental frequency, and intensity. We found that each of these variables helped to predict the age at which the child acquired words. There were considerable differences in the predictive power of each variable across different parts of speech, however. For example, frequency and intensity mattered most for nouns, while recurrence in a small window of time seemed to matter more for verbs and closed-class words. These results complement previous smaller-scale, cross-sectional investigations and provide a variety of new directions for potential experimental manipulations.

Our current model only takes into account variables in caregiver speech, omitting the visual and social context of word learning. One of the benefits of the Speechome Corpus is that this information is available through rich video recordings. Computer vision algorithms and new video annotation interfaces are being developed to incorporate this aspect of the corpus into future investigations. In addition, our current investigation has been limited to the child's lexical development; our plan is that future work will extend the current analysis to grammatical development.

Finally, the analysis and findings presented in this paper assume a linear input-output model between child and caregivers: the caregivers produce input to the child, who then learns. In other words, our current model treats the child as the only agent whose behavior can change. Beyond a first approximation, however, this assumption is inconsistent with our own previous findings (Roy et al., 2009). Our ongoing work continues to investigate the mutual influences between caregivers and child and to measure the degree of adaptation in this dynamic social system.

Abstract

This study investigated the effect of concreteness on preschool children's ability to recognize simple relations. Participants, age 3.0 to 5.0 years, were asked to make one-shot relational matches from a base to a target display. Two types of questions were posed: Generic in which the base display contained simple geometric shapes and Concrete in which the base display contained colorful familiar objects. Two between-subjects conditions varied the order in which the Concrete and Generic questions were asked. The results reveal relational matching on Concrete questions was significantly higher when preceded by Generic questions than when answered first, suggesting children transferred relational knowledge acquired through the Generic questions to answer the Concrete questions. However, there was no improvement on Generic questions when preceded by Concrete questions. These are novel findings suggesting that young children can better acquire and subsequently transfer relational knowledge from a generic format than from a concrete, perceptually rich format.

Introduction

The ability to recognize common relations across different situations is not always easy, but tends to improve through the course of development. Most researchers agree that some form of a relational shift occurs in development (e.g. Gentner, 1988; Gentner & Ratterman, 1991, see also Goswami, 1991); young children are more likely to attend to object-level similarities between systems or displays and overlook relations. Later in development, people become more likely to attend to relational similarities. For example, when given a simple metaphor such as a plant stem is like a straw, children's interpretation is often based on superficial attributes, such as both are thin and straight. Adults tend to interpret such metaphors through deeper relations; in this case, both can carry water (Gentner, 1988).

One category of theoretical accounts of relational development is that the relational shift is knowledge-driven (Brown, 1989, Brown & Kane, 1988; Gentner, 1988, Gentner & Ratterman, 1991, Vosniadou, 1989). By such accounts, domain-specific knowledge is the primary predictor of ability to attend to relations. In support of this position, there is considerable evidence that while young

children may fail to reason analogically (i.e. based on relational structure) in many instances, they can reason analogically in contexts that are familiar to them (see Gentner, Ratterman, Markman, & Kotovsky, 1995 for discussion). For example, Gentner (1977a, 1977b) found that when 4-year-old children were shown a picture of a tree and asked, "If a tree had a knee, where would it be?", they interpreted the relational correspondence and responded as accurately as adults. Similarly, preschool children, aged 3 to 5 years, successfully transferred problem-solving strategies from contexts involving simple, familiar relations such as mimicry and camouflage (Brown & Kane, 1988). Additionally, 4-year-olds applied relational reasoning on tasks involving known relations, such as cutting and melting (Goswami & Brown, 1989). Taken together, there is ample evidence of successful relational reasoning by young children when the relations are known to them.

Yet, even in the context of simple relations and familiar objects, attention to relations can be diverted by interference of surface similarities across the base and target domains. For example, preschool children, age 3 and 4 years, were tested on their ability to make relational matches involving the relation of monotonic increase or decrease of three items (Gentner & Rattermann, 1991; see Gentner, et al., 1995 for summary). In the task, the experimenter and the participant each had sets of three items arranged in monotonically increasing or decreasing order. The child was asked to close his/ her eyes while the experimenter hid stickers under one object in each set. The stickers were always placed under items in the same relational roles across sets. When the child opened his/her eyes, the experimenter showed the child an object with sticker in the experimenter's set and asked the child to find the sticker was in the child's set. This study had a 2 x 2 design: literal similarity or cross-mapping by stimuli type. In the literal similarity condition, the correct item matched the target on both object appearance and relational location. In the cross-mapping condition, the correct item differed in appearance and matched the target only on relational location. Also, in the cross-mapped condition, an incorrect relational choice matched the target object in appearance. Hence, children could make either relational matches or appearance matches. The stimuli type varied the perceptual richness of the objects: either sparse,

such as clay pots or blue boxes, or rich, such as colorful toys or silk flowers.

It was found that children were more likely to choose relational responses in the literal condition than in the cross-mapped condition. Four-year-olds were very accurate on matching literal similarity for both rich and sparse material. However, 3-year-olds had difficulty with the sparse stimuli. In the cross-mapped condition, 3- and 4-year-olds generally matched on object appearance rather than on relational role. Furthermore, performance was much worse for perceptually rich objects than for perceptually sparse objects, suggesting that the richer objects were more likely to divert attention from relations than the more sparse objects.

Adults are also susceptible to interference from cross-mapped elements involved in complex relational tasks (Ross, 1987, 1989). When attempting to transfer mathematical solution strategies from one example problem to another, college students tend to align structure based on similarity of elements, placing similar elements in the same relational roles. This leads to incorrect solutions if the similar elements do not actually hold analogous roles.

The ability to perceive common relational structure underlies not only simple analogies, but also higher-order cognitive processes such as the acquisition and transfer of mathematical knowledge. This is because mathematical concepts are defined, not by surface features, but by their relational structure. Therefore, relational knowledge can potentially be transferred between situations that appear very different on the surface but have the same underlying structure. For example, the same probability principles can be applied to problems involving the number of ways computers can be assigned to offices or the number of ways toppings can be applied to pizza (e.g. Ross, 1987). Therefore, the study of factors that promote the recognition of common relations has importance to both the study of general cognition as well as practical importance for the potential improvement of acquisition of abstract concepts such as mathematical concepts.

One way of facilitating recognition of common relations is through explicit comparison (e.g. Catrambone & Holyoak, 1989; Loewenstein, Thompson, & Gentner, 1999; Gentner, Loewenstein, Thompson, 2003). Learners are more likely to recognize common relational structure between two instances when they explicitly compare them than when they encounter them sequentially. The process of comparison requires alignment that highlights common structure. Comparison appears to promote the formation of a schema which can in turn allow for successful transfer of relational knowledge to novel analogous situations (Gentner, et al., 2003; Gick & Holyoak, 1983).

Another factor that has been shown to affect the detection of common relations is the concreteness of the learning material. Concreteness of a given instantiation of an abstract concept can be construed as the amount of information communicated to an individual by that particular instantiation. By this interpretation concreteness can be in the form of perceptual richness or contextual richness

including prior knowledge. In contrast to concrete instantiations, generic instantiations communicate little extraneous information. Concrete, perceptually rich objects and contexts can hinder performance on relational tasks in comparison to more abstract generic instantiations of the same concepts. This pattern is suggested by the performance of preschoolers on the relational matching task involving monotonic increase and decrease mentioned above (Gentner & Rattermann, 1991; see Gentner, et al., 1995). Children were more likely to make relational responses in the face of conflicting object matches when the task was conducted with perceptually sparse material than with perceptually rich material.

Other evidence for the hindering effects of concreteness is found from studies investigating the development of children's symbol use (DeLoache, 1995a, 1995b, 1997, 2000). Successful symbol use requires the detection of common relations. For example, to effectively use a map as a symbol for a real location, one must recognize the common relations between entities on the map and their real-world analogs. Young children have difficulty using concrete, perceptually rich objects as symbols. In a series of studies, 2½ to 3-year-old children were shown a 3-dimensional scaled model of a real room and told that a stuffed animal was hidden in the actual room. The experimenter then placed a miniature toy in the model telling the children that the location of the miniature toy in the model corresponded to the location of the actual toy in the real room. The children were then asked to retrieve the real toy. Only 16% of the children were able to make errorless retrieval of the actual toy. The children were then asked to retrieve the miniature toy. The accuracy of the miniature toy retrieval was 88% implying that the poor performance on the retrieval of the actual toy was not due to inability to remember the location, but an inability to realize that the model symbolically represented the actual room. In subsequent studies, the salience of the model was decreased by putting it behind a glass window. Under this condition, more than half of the participants accurately retrieved the toy. Similarly, when children were shown the location in a picture and not a 3-dimensional model, 80% of participants ably retrieved the real toy.

By 3 years of age, most children are successful in such a task. However, when the 3-year-old study participants were encouraged to play with the model first only 44% of them successfully retrieved the toy, compared to 78% of 3-year-olds who retrieved the object with no opportunity to play. The physical interaction with the model made it more difficult for the children to treat it as a symbol. In sum, decreasing the concreteness of the objects increased the ease of their symbolic use.

The hindering effects of concreteness demonstrated in the mentioned studies were found in the context of similarities between the base and target situations. In the Gentner and Ratterman study, object similarity was directly pitted against relational similarity. In the DeLoache et al. studies, there was some alignable similarity across base and target as

the model was intended to represent the real room. Little is known about the effects of concreteness on children's relational reasoning in absence of either relationally alignable or cross-mapped similarities between base and target.

There is some recent evidence for an advantage of generic material over more concrete material for children's relational reasoning in the absence of overt interdomain similarities. Kindergarteners were more likely to acquire the concept of proportion and correctly match displays of different objects based on proportion when training instantiated proportions using generic shapes than when proportions were instantiated with colorful, concrete objects (Kaminski & Sloutsky, 2009).

There is also evidence that concreteness can hinder the ability of adults to detect common relations (Kaminski, Sloutsky, & Heckler, 2006). Undergraduate students were less able, or often unable, to transfer complex relational knowledge to novel analogous when knowledge was acquired in a concrete format than when knowledge was acquired in a more generic format (Goldstone & Sakamoto, 2003; Goldstone & Son, 2005; Kaminski, Sloutsky, & Heckler, 2008; Sloutsky, Kaminski, & Heckler, 2005).

Taken together, prior research shows that adults are better able to recognize learned relations in novel contexts when they have initially acquired those relations through a more abstract, generic instantiation than through a more concrete, contextualized one. Generic instantiations also have advantages over concrete instantiations for children's ability to acquire novel relations such as proportion. It is unclear whether this advantage will hold for young children's ability to recognize simpler relations such as monotonic increase in the absence of surface similarities. It is possible that without competition of element similarity, children's attention can be focused on the underlying relation. At the same time, relations are less observable than elements and perhaps added perceptual richness of the elements will itself detract from relations.

The goal of the present study was to examine the effect of concreteness of elements on young children's ability to detect common relations. We considered the relations of monotonic increase, monotonic decrease, and symmetry involving three elements. These relations should be easier for children to recognize than proportion (Kaminski & Sloutsky, 2009) because they are built on the simple and familiar relation of "bigger than". Like previous research, we asked 3- and 4-year-old children to make one-shot relational matches across displays. This task prompts participants to compare two displays instantiating the same relation, therefore it allowed us to see whether or not generic instantiations can provide an advantage for recognition of relations beyond the comparison process alone.

Experiment

Method

Participants Participants were 100 preschool children from middle-class, suburban preschools and child care centers in the Columbus, Ohio area (51 girls and 49 boys). Participants' ages ranged from 3.0 to 5.0 years ($M = 3.72$ years, $SD = .47$ years).

Materials and Design Participants were shown two displays presented side by side involving a common relation. The task was to choose an item in the right display that was in the same relational role as an indicated item in the left display. Each display involved three objects. The relations considered in this experiment were monotonic increase, monotonic decrease, and symmetry. There were a total of 18 test questions (six increase, six decrease, six symmetry); half were Generic questions and half were Concrete. Generic questions presented simple colored, geometric shapes (circles, triangles, rectangle, or non-rectangular parallelograms) in the base display. Concrete questions presented colorful perceptually rich objects (dogs, bugs, little girls, shoes, piggy banks, frogs, cats, jack-o-lanterns, and slices of cake) in the base display. The target display for all questions involved colorful perceptually rich objects (ducks, cats, fish, crayons, birds, flowers, ice cream, rocking horses, and ginger bread houses). Each of the target objects were used twice, once for a generic question and once for an analogous concrete question (see Figure 1). The color of the shapes for a generic question was the same as the predominant color of the perceptually rich objects in the analogous concrete question.

Participants were randomly assigned to one of two conditions (Generic-then-Concrete or Concrete-then-Generic). In the Generic-then-Concrete condition, participants were presented with the Generic questions first and then presented with the Concrete questions. The Concrete-then-Generic condition presented the Concrete questions first followed by the Generic questions. Prior to the test questions, participants were shown one example which illustrated the relation of bigger than. The base display of this example showed a bigger boy and a smaller boy in the Concrete-then-Generic condition and a bigger triangle and a smaller triangle in the Generic-then-Concrete condition. For both conditions, the target display showed a bigger teddy bear and a smaller teddy bear.

For the example and all test questions, the elements were identical except in size within each display. For example, in the questions shown in Figure 1, the triangles, dogs, and fish are identical except in size. There were no variations between elements in any other surface features.

Figure 1: Example of a Generic question (upper) and its analogous Concrete question (lower).

Procedure Participants were asked to play a matching game with the experimenter. All questions were presented on the computer.

The experimenter told the child that he/she would see two pictures and showed the child the example of “bigger than”. The experimenter explained that one picture had a certain pattern in it and the same pattern was in the other picture, but it looked different. The following is the script:

“See, in the top picture, there are a bigger boy and a smaller boy. This is the bigger boy, and this is the smaller boy (*the experimenter pointed to each as described*). Now in the bottom picture, there is a bigger bear and a smaller bear (*the experimenter pointed to each as described*). See, the same pattern happens in both, but it looks different. Now, in this game, first you have to figure out what the pattern is that happens in both pictures. Okay? Then I am going to point to one thing in one picture, and your job is to tell me what is in the same part of the pattern in the other picture.”

“So here, we have a bigger boy and a smaller boy, and a bigger bear and a smaller bear. Now I am going to point to the smaller boy (*the experimenter pointed*). Which one is like the smaller boy in the bottom picture according to the pattern? Which one is in the *same part* of the pattern in the bottom picture?”

The Generic condition presented an analogous script which replaced the word “boy” with the word “triangle”. The experimenter gave corrective feedback to this example.

Test questions first presented the base display alone on the left side of the computer screen and participants were told to “look for the pattern between things in this picture”.

The next slide showed the original base display and a new target display on the right side of the screen. In addition an arrow appeared over one of the objects in the base (left) display. The experimenter asked the child, “According to the pattern, what in this picture (*the experimenter gestured to the right picture*) is like this?” (*the experimenter pointed to the object with the arrow*). The experimenter recorded the child’s response on a paper. Then feedback which explicitly stated the relation was given after both correct and incorrect responses. For example, the feedback to the Concrete question that appears in Figure 1 was: “Right or No, actually... because in this picture (*the experimenter pointed to the left picture*), these dogs are getting bigger and bigger (*the experimenter gestured*) and I pointed to the biggest one. And in this picture (*the experimenter pointed to the right picture*), these fish are also getting bigger and bigger and this is the biggest one. So, you should point to this one (*the experimenter pointed*).”

Results and Discussion

In both the Generic-then-Concrete and Concrete-then-Generic conditions, children were successful at relational matching on both the Generic and Concrete questions. Mean test scores are presented in Figure 2. Scores were above a chance score of 33% (3 out of 9 correct), one-sample t-tests, $t_s > 8.1$, $p_s < 0.001$. However, there was a significant difference in performance as a function of the order in which participants received the Generic and Concrete questions. Test scores were submitted to a two-way analysis of variance with order of the test question type as a between-subjects factor, age as a covariate, and test question type as a repeated measure. The analysis indicated a significant order \times question type interaction, $F(1,91) = 11.09$, $p < .001$, $\eta_p^2 = .11$. There were no differences in scores on the Generic questions between the Generic-then-Concrete condition and the Concrete-then-Generic condition, independent samples t-test, $t(92) = .079$, $p > .93$. At the same time, there were differences in scores on the Concrete questions, participants in the Generic-then-Concrete condition scored significantly higher than participants in the Concrete-then-Generic condition, independent samples t-test, $t(92) = 3.16$, $p < .003$. These findings suggest that children who first answered the Generic questions acquired knowledge of the relevant relations that they were able to transfer to the Concrete questions. The reverse was not the case, answering the Concrete questions first did not improve scores on the Generic test. Therefore, experience answering the Generic questions offered an advantage for subsequent transfer that answering the Concrete questions did not.

Additionally, there were improvements with age in test scores on both question types, ANCOVA $F(1,91) = 21.66$, $p < .001$, $\eta_p^2 = .19$. Figures 3 and 4 present accuracy for the Concrete and Generic questions respectively split across the participant age range. Figure 3 illustrates that the differences in accuracy on Concrete questions is present across the age range. Therefore, while development leads to better

Figure 2: Mean test scores (% correct) by order of test. Error bars represent standard error of mean. Chance score is 33%.

Figure 3: Mean test scores (% correct) on Concrete questions by age of participant in years. Error bars represent standard error of mean.

Figure 4: Mean test scores (% correct) on Generic questions by age of participant in year. Error bars represent standard error of mean.

recognition of relations, there is a consistent transfer advantage when first answering the Generic questions.

General Discussion

Previous research has demonstrated the difficulty young children have attending to common relations across displays particularly in the face of competing surface similarities (e.g. Gentner & Ratterman, 1991; Gentner et al, 1995,

Richland, Morrison, & Holyoak, 2006). Explicit comparisons, as well as the use of relational language, have been shown to increase relational reasoning (e.g. Gelman, Raman, & Gentner, 2009). There is also evidence that learning a generic instantiation of an abstract concept can facilitate subsequent relational transfer for adults (Goldstone & Sakamoto, 2003; Goldstone & Son, 2005; Kaminski, Sloutsky, & Heckler, 2008; Sloutsky, Kaminski, & Heckler, 2005). However, little research has considered what types of learning instantiations might help promote young children's relational reasoning in the absence of competing surface similarity.

The present study considered preschool children's ability to recognize the relations of symmetry and monotonic increase and decrease. Preschool children were asked to make one-shot mappings across displays of three items. This task encourages participants to make comparisons between instantiations of the same relations. Participants were given generic questions in which relations were mapped from displays of generic shapes to displays of colorful, concrete items. They also answered concrete question in which the mapping was between two displays of different colorful, concrete objects. The results found that when participants first answered the generic questions they scored markedly higher on the subsequent concrete questions than when the concrete questions were answered first. This suggests that by answering the generic questions, participants acquired solid knowledge of the relations which they ably transferred to the concrete questions. At the same time, there were no differences in scores on the generic questions as a function of when they were answered. Therefore, answering the concrete questions provided no benefit for subsequent transfer of relations.

In order to successfully recognize common relations in two different instantiations, the learner must focus attention on the relations between the objects and not directly on the objects themselves. Perceptually rich, concrete objects communicate much more information than perceptually sparse objects. Consider how much more information is communicated by the dogs versus the triangles in the base displays of Figure 1. This abundance of extraneous information may divert the learner's attention from relevant relations making it difficult to recognize these relations. In addition, the present findings suggest that when acquiring relations in the presence of extraneous concrete information, learners may form a weaker representation of the relational knowledge that can hinder future transfer.

Simple generic objects likely have less potential to capture attention, allowing more attentional resources to be focused on relevant relations. Therefore, instantiating relations with generic elements may provide an advantage for later transfer even for very young children.

While it is well accepted that the process of comparison can facilitate abstraction of relations and transfer, these findings suggest that comparisons between some types of instantiations may be more beneficial than comparison between other types of instantiations. Furthermore, this

advantage may not be detectable in immediate performance, but in later tasks involving the same relations.

How does the presence of a label affect attention to other features?

Abstract

Are labels cues to category membership or simply highly salient features? This question is difficult to answer definitively because of the challenge in identifying empirical predictions that would be distinct in each case: either way, one would expect labels to be highly interesting, easy to process, and preferentially used as the basis of generalization. Here we suggest that one difference should be in how the label directs (or fails to direct) attention to the other, less-salient features of the object. We perform a categorization experiment with complex objects containing many low-salience features, and find that labels affect attention to the other features in the same way that highly salient features such as color or sounds do (and unlike an explicit cue to category membership). This results in a diminished ability to use the less-salient features of the categories to generalize appropriately.

Keywords: labels; features; categorization; generalization

Introduction

Shakespeare once famously asked “What’s in a name?” Over the past few decades, psychologists have studied the scientific version of this question: what is the role of labels in category learning? How do labels affect categorization: the categories people form, the inductions they license, and the generalizations they make? What assumptions about labels do people bring to the tasks of word and category learning? These questions have been of special interest in the study of language acquisition, because understanding the assumptions children bring to the problem of word learning is key to understanding their linguistic development.

Much evidence demonstrates that children assume that labels are special in some way. Infants familiarized to items from a novel category will treat it like a category if they hear a label attached to the items, but not if they hear a non-linguistic sound (Balaban & Waxman, 1997; Fulkerson & Waxman, 2007) or hear nothing at all (Waxman & Markow, 1995; Waxman & Braun, 2005). Moreover, infants use labels but not sounds for individuation (Xu, 2002) and as a basis for inductive inference (Gelman & Markman, 1987; Davidson & Gelman, 1990; Graham, Kilbreath, & Welder, 2004).

Why do labels have this special status? Although infants appear uniquely interested in speech (Vouloumanos & Werker, 2004), they are equally capable of learning mappings involving non-linguistic sounds as words (Roberts & Jacob, 1991; Woodward & Hoyne, 1999). This suggests that the “specialness” of labels is not solely due to increased attention or interest in speech in general (although it may be related to the fact that the input is auditory; see Robinson & Sloutsky, 2004, 2006). Furthermore, when labels are inconsistent with apparent category structure or similarity, infants and

children are much more reluctant to form categories based on them (Davidson & Gelman, 1990; Waxman & Braun, 2005; Plunkett, Hu, & Cohen, 2008); this may suggest that words are important because they tend to pick out useful categories. Perhaps children make the assumption that labels map cleanly onto category structure because labels are referential: younger infants will categorize using symbolic forms other than words (e.g., gestures or pictograms) if they are used in a referential context (Namy, 2001; Campbell & Namy, 2003), and older infants will use labels to pick out global categories only if they are presented in person by an experimenter rather than a recording (Fulkerson & Haaf, 2003). Another possibility is that infants assume that words identify useful categories because they statistically tend to do so (Samuelson & Smith, 1999), and infants’ statistical learning mechanisms are well-attuned for picking this sort of pattern up (Smith, Jones, & Landau, 1996).

As this discussion illustrates, there is some disagreement about how and why labels are special. It may be that labels are special because they are linguistic – referential and used for communication – and infants realize this (Balaban & Waxman, 1997; Namy, 2001; Xu, 2002; Fulkerson & Waxman, 2007). Alternatively, it may be that infants have learned to pay special attention to words because they are statistically likely to be useful indicators of category structure (Smith et al., 1996). The special status of labels may also be perceptual in origin: perhaps labels play a unique role in category formation because of their auditory properties (Robinson & Sloutsky, 2004, 2006, 2007).

This debate parallels a similar, but not identical, discussion in the adult literature – one focused on whether labels act as category indicators or just a highly salient feature. On one hand, labels certainly do appear to hold a privileged psychological status in some ways. When objects share a label, this is sufficient to increase their similarity (e.g., Goldstone, Lippa, & Shiffrin, 2001), and people often make inductive inferences based on an object’s label rather than its features or overall similarity (e.g., Yamauchi & Markman, 2000; Johansen & Kruschke, 2005). On the other hand, formal models of categorization have often been remarkably successful at matching human performance simply by treating labels as another – possibly highly salient – feature of the stimulus (e.g., Anderson, 1991; Gliozi, Mayor, Hu, & Plunkett, 2009).

One of the difficulties inherent in resolving this debate is that it is hard to identify characteristics that an indicator of category membership would have but a very salient feature would not. For instance, one might suggest that the differ-

ence might be that if something is an indicator of category membership, it should be used to pick out categories even when it seems to be inconsistent with the observed similarity or category structure. There is evidence that this is the case for labels when they are mildly inconsistent (Yamauchi & Markman, 2000), but not when they grow too inconsistent (Davidson & Gelman, 1990; Waxman & Braun, 2005). But does this mean that words are strong markers of category membership or salient object features? The problem is that the results make sense under either theory. On one hand, if labels are especially salient features then one would expect them to be followed even if other (less salient) features seemed to pick out a different category structure; on the other hand, if labels are treated as markers to category membership without being features themselves, they could still be such strong markers that they are nearly impossible to override.

More generally, both highly salient features and cues to category membership should share many other characteristics: easy to represent, quick to process, and preferentially used as a basis for generalization. What, then, is the difference between them? To address this question, it helps to consider the two possibilities individually.

- *What are the cognitive effects of a salient feature?* Much work suggests that salient features share two important characteristics. One is that they tend to be the features that people examine first when making choices (e.g., Tversky, 1972; Gigerenzer & Goldstein, 1996). The other is that if the feature is predictive and useful, it will become even more salient over the course of learning (Kruschke, 1992, 2003). As a consequence, if a feature is initially quite salient and later turns out to be predictive of category membership, even more attention will be devoted to it, and the attention devoted to the *other* features will decrease commensurately, particularly if they themselves are not salient or are difficult to process.
- *What are the cognitive effects of a cue to category membership?* Less research bears directly on this question, but we can begin by considering the case of something that is unequivocally a cue to category membership and also unequivocally *not* a feature: explicit instruction. Imagine telling someone that objects from category *A* were sorted into one box and objects from category *B* were sorted into another. Those boxes (along with the instructions) would be cues to category membership, but not features of the objects. How would this affect processing of the objects? Not surprisingly, providing this kind of structure in the visual presentation of stimuli tends to improve learning by calling attention to the relevant features and minimizing the processing load imposed on the learner (e.g., Bruner, Goodnow, & Austin, 1956, ch. 4). As a result the effect on attention is expected to be in the opposite direction: those object features that are less salient, will be processed much more than they otherwise might.

Do the cognitive effects of labelling look more like those

of features, or of cues to category membership? We address this question by presenting participants with a simple categorization task involving objects with numerous non-salient and difficult-to-process features paired with a *category indicator* of some sort. In one condition, the category indicator is intended to be a strong cue to category membership: the objects are explicitly categorized by being sorted into boxes. In two other conditions, the category indicator is a highly salient non-linguistic feature (a color or a non-linguistic sound). In two final conditions, the category indicator is a label (either written or oral). After sorting the objects, participants are asked how they would classify new objects for which the category indicator is unknown. Importantly, because the category indicator is unknown and the other features so complex and low-salience, performance on the generalization task reflects how much people have attended to those features. If the category indicator acts like a cue to category membership by calling attention *to* the less-salient features, generalization on the basis of them should be improved when given the indicator; however, if the category indicator acts more like a salient feature by directing attention *away from* the less-salient features, generalization should be poor. Our results suggest that labels behave much like other extremely salient features in the way that they focus attention away from other features of an object.

Method

92 adult participants were recruited from the University of Adelaide and surrounding community and were paid \$5 for their participation in the half-hour experiment. Two participants were excluded due to failure to understand the task, leaving 18 people in each of five possible conditions. Each participant saw a series of trials in which they were asked to sort novel objects into categories. They were then asked two generalization questions about how they would categorize additional objects without category indicators. Each of the objects has eight features, four of which vary coherently according to the category structure, and four of which are random. In half of the trials (the NO INDICATOR trials), participants were asked to sort these objects into clusters. In the other half (the INDICATOR trials) the task was the same except that the objects were also each associated with a category indicator, the nature of which varied by condition.

Items. Each item consists of a square with four symbolic characters (one in each quadrant) surrounded by circles (also containing symbolic characters) at each corner; we refer to each location as one of the eight low-salience *features* of the objects, and the particular character in that location as its *feature value*. Each feature can take on a value corresponding to one of ten specific characters, and there is no overlap of possible character sets (feature values) from feature to feature. For each participant and trial, features were generated independently, according to the following pattern: four features are randomly selected to be *dispersed*, meaning that they do not respect category structure because they are uniformly se-

Figure 1: Example INDICATOR trial in the BOXES condition (for visual clarity, we show 6 objects rather than 8 or 16). In this condition, objects are presented already sorted into boxes corresponding to two categories. Here the four coherent features are the two upper circles, the upper right square, and the lower right circle. These features have a 75% coherence level: each of the four coherent features has 25% probability of being “flipped” from the value appropriate to its category.

lected from the possible set of values for that feature. The other four are *coherent*, meaning that they correspond to the underlying category structure: feature A corresponds to category structure if all members of category X share a the same feature value for A (say, all of them have a δ in the upper left corner of the square). We systematically varied the coherence¹ level of the four *coherent* features so that half of the trials involved items with a coherence level of 75%, and half involved a coherence of 100%. This mimics real-world categories, which have a probabilistic, graded structure.² It is possible to identify the correct categories on the basis of the coherent features, as people have succeeded in doing in other studies (Perfors & Tenenbaum, 2009). However, because these features are numerous, of low salience, and representationally complex, it can be difficult.

Sample objects as they appeared in the experiment are shown in Figures 1 and 2.

Trial structure. Each participant saw eight NO INDICATOR and eight INDICATOR trials. In order to ensure that participants were not relying on external knowledge about how many categories the correct sorting contained, trials varied in the number of items (8 or 16) and the number of categories (2 or 4). Since items varied also in coherence, this resulted in the following factorial design: 2 (INDICATOR or NO INDICATOR) x 2 (coherence level of 75% or 100%) x 2 (containing 8 or 16 items total) x 2 (categories made of 2 or 4 items). This resulted in 16 trials per participant. Due to a coding error, trials with 8 items and 2 categories were not properly counterbalanced according to category indicator, so all analyses excluded these trials and therefore consisted of 12 trials per participant. Figure 1 shows the sort of situation a partic-

Figure 2: Example NO INDICATOR trial, which participants in all conditions were exposed to. In this sort of trial, people are told to sort the objects in whatever way appears sensible, and are not told in advance how many categories there are or what features are important or useful. In this trial the coherence level is 100%: each of the four coherent features (which are the same as in Figure 1) follow the category structure precisely.

ipant might see on an INDICATOR trial in the BOXES condition, while Figure 2 shows a typical NO INDICATOR trial.

Conditions. The five conditions are defined by the nature of the category indicator involved in the INDICATOR trials. In the BOXES condition, participants saw the objects already pre-sorted into boxes; this is intended as an explicit cue to category membership, and was described to participants as such. In two of the other conditions, the objects in the INDICATOR trials were associated with a label. In the WRITTEN LABEL condition, participants were told that the label would be written above the object. To evaluate whether it mattered if the label was presented visually or orally, in the ORAL LABEL condition, the label was presented out loud (over headphones) whenever the participant clicked on the object. Since participants had to click on all objects in order to sort them, they ended up hearing the labels for every object at some point. The label conditions were compared to two conditions in which the category indicator was simply a highly salient feature. In the COLOR condition, objects were colored (unlike the objects in the NO INDICATOR trials and other conditions, which were always white). And in the SOUND condition, objects were associated with non-linguistic sounds (distinct buzzes, beeps, and tone sequences without semantic associations). As in the ORAL LABEL condition, these sounds were heard through headphones whenever the participant clicked on the object.

Procedure. Each trial consisted of two phases. The first was the “sorting” phase, in which participants were presented with all of the objects in the trial randomly scattered on the computer screen and asked to sort them in categories. (The exception is the INDICATOR trials in the BOXES condition, in which the objects appeared already sorted with square “boxes” drawn around each of the categories, as depicted in Figure 1). During the sorting phase, participants were allowed unlimited time in which to move the objects around on the screen by clicking and dragging them into clusters. They then drew boxes around the objects to indicate cate-

¹A coherence of c means that a feature value has a $(100 - c)\%$ chance of being randomly generated rather than following category structure.

²There were no interaction effects between coherence and any of the results of interest here, so all analyses combine coherence levels.

Figure 3: Performance in the sorting task. Subjects in the ORAL LABEL, WRITTEN LABEL, and SOUND conditions used the category indicators to sort at close to optimal levels. When there was no category indicator, people were able to use the less-salient features to sort, but were significantly worse than when there was one.

gories. People were told ahead of time that not all trials would have the same number of items or categories, and they should just sort in whatever way seemed sensible.

After the sorting task was completed, the items remained on the screen and participants were presented with two generalization questions in random order. In *first-order* generalization, participants were shown one of the items they had sorted (without category indicator) and asked which of two novel items would go in the same category as that one. The correct answer had the four coherent features in common with the first, and the incorrect answer had the four other features in common. The *second-order* generalization trials were identical, except that the item shown to the participants had specific feature values that had not been seen before: a person could only answer correctly if they realized that the coherent features (rather than specific values) were what mattered for category organization. As in Perfors and Tenenbaum (2009), our participants performed identically in the first- and second-order generalization, so all analyses collapse them together into one variable, *gen*.

Results

There are two natural questions to ask. First, does the nature of the category indicator affect people’s sorting behavior? Second, does it affect how people pay attention to the other, less-salient features of the objects? We can address the second question by examining generalization performance in each condition, since our generalization tasks do not include the category indicator and therefore necessarily rely on the other features. The answer to the first is important for knowing how to interpret the answer to the second: for instance, if generalization performance is poorer because people cannot figure out the correct categories, that does not tell us anything about how people are attending to the less-salient features *given* those categories. We therefore begin with addressing how sorting performance depends on the nature of the category indicator.

Sorting performance

Sorting performance is evaluated using a standard measure for evaluating the similarity between two clusterings of items known as the adjusted Rand Index (*adjR*) of Hubert and Arabie (1985). In this case, we use *adjR* to measure the similarity between the correct category clustering and the category assignments made by the participants. An *adjR* of 1 indicates that the clusters are identical, while 0 is the score one would expect from two random clusterings; scores below 0 indicate that the clusters match less than one would expect by chance.

Figure 3 indicates that category indicator has a strong effect on sorting performance.³ Participants in the ORAL LABEL, WRITTEN LABEL, and SOUND conditions sorted nearly optimally, which suggests that they used the category indicators to create their categories (since sorting according to category indicator is optimal sorting). Participants on the NO INDICATOR trials were able to use the less-salient features to sort at an above-chance level, but performed worse than when given a category indicator. Finally, people in the COLOR condition sorted halfway in-between, suggesting that color was a more salient feature than the symbolic characters, but not as salient as labels or sounds.

Generalization

Based on sorting performance it appears that participants generally created sensible categories. Were they able to form generalizations about category membership based on the less-salient features? We test this, as explained earlier, by presenting participants with additional items and asking how they would categorize a novel item they had not seen before. Figure 4 demonstrates that generalization in the BOXES condition was generally superior to generalization in the other conditions, all of which were similar to each other.⁴ Since generalization depends on what the participant notices about the less-salient features *other* than the category indicator, this suggests that in the BOXES condition people were paying more attention to those features than in any of the other conditions.

These two results, taken together, drive the main conclusion of this paper: labels appear to act more like highly salient features than overt category indicators (boxes). Labels, like highly salient features, support accurate sorting, but are associated with poorer levels of generalization to new items. We have suggested that the reason for this may be because the labels and salient features are directing attention away from the non-salient features during the sorting task; this impairs generalization because attention to the non-salient features is

³A one-way Anova on *adjR* by condition was significant: $F(4, 158) = 9.77, p = 4.34e^{-7}$. Post-hoc comparisons using the Tukey-Kramer test indicated that the mean *adjR* in the NO INDICATOR condition was significantly different than mean *adjR* in the ORAL LABEL, WRITTEN LABEL, and SOUND conditions.

⁴A one-way Anova on generalization by condition was significant: $F(5, 176) = 2.91, p = 0.0149$. Post-hoc comparisons using the Tukey-Kramer test indicated that the generalization in the BOXES condition was significantly different from the NO INDICATOR and ORAL LABEL conditions, and nearly significantly different from the other three.

Figure 4: Generalization on the basis of the non-salient features in the BOXES condition was superior to generalization in the other conditions, suggesting that participants in the other conditions did not attend as much to the less-salient features when generalizing.

necessary for accurate generalization of novel items (which are not associated with a label or highly salient feature). This would explain why generalization in those conditions is lower than generalization in the BOXES condition.

However, one minor yet confusing aspect of these results remains: if the salient features are truly directing attention away from the non-salient features, why is generalization performance not poorer on the INDICATOR trials than the NO INDICATOR trials, at least in all conditions other than BOXES? After all, it might be assumed that people are *less* able to use the non-salient features when they have the distracting, highly-salient features around, especially since those features do a very good job at picking out the category members.

Relating sorting and generalization

We address this question by realizing that two factors drive generalization performance, which depends ultimately on knowing which of the less-salient features pick out which categories. It therefore requires not only being able to attend to and identify the less-salient features, but also knowing what the correct categories are. On the INDICATOR trials in the WRITTEN LABEL, ORAL LABEL, SOUND, and COLOR conditions, participants may be less able to attend to the non-salient features, but be better at identifying the categories in the first place. These factors may therefore be cancelling each other out, resulting in generalization that is very similar to the NO INDICATOR conditions.

This possibility yields a testable prediction, namely that in the NO INDICATOR trials sorting performance should be positively correlated with generalization, but in the INDICATOR trials it should be more irrelevant.⁵ We would not expect it to be *entirely* irrelevant since, after all, one must be able to identify the categories in order to generalize correctly. However, the converse is not necessarily true: identifying the categories in the INDICATOR conditions would not imply that

⁵Note that when we refer to sorting in the INDICATOR trials, we are excluding the BOXES condition, since participants do not actually have to sort anything – the items are already placed into boxes. All of these analysis, therefore, excluded the BOXES condition from the INDICATOR trials.

one should be able to generalize correctly, since generalization requires attention to the less-salient features but categorization does not. We test this by calculating the correlation between sorting accuracy (*adjR*) and generalization (*gen*) for both the INDICATOR and NO INDICATOR trials. Although both are significant, the size of the effect on the INDICATOR trials is markedly weaker.⁶ While not conclusive, this is consistent with our interpretation of the results: sorting is less predictive of generalization in the INDICATOR trials because sorting does not depend on the less-salient features in those trials, unlike in the NO INDICATOR situation.

Discussion

This research is motivated by the question of whether labels are cues to category membership or simply highly salient features. The question is difficult to answer in part because it is hard to predict what would be empirically different in each case: no matter what, one would expect labels to be highly interesting, easy to process, and preferentially used as the basis of generalization (but also to be ignorable if they were inconsistent with category structure). We suggest that one difference between cues to category membership and highly salient features is their effect on the processing of the other, less salient features of the objects: highly salient features should direct attention away from the less salient ones, while cues to category membership should direct attention toward them. We tested this by presenting participants with a sorting task involving objects with many complex, low-salience features, and then posing generalization questions that required attention to the less-salient features to answer correctly. Our main results, shown in Figures 3 and 4, suggest that labels act more like highly salient features than they act like boxes (an explicit external cue to category membership).

One might object that this result is not very surprising. After all, stimuli in the BOXES condition may be easier to process since they have one fewer feature – the cue to category membership is the box and the visual organization of the objects, not any features inherent to them. However, in a very real sense this is precisely our point: if something is acting as a cue to category membership, it *should* improve performance by reducing the load required to process the actual features of the objects. Labels, whether oral or written, did not do that in our study.

An important subtlety lies in how we define salience. In what way are the labels in our study really “highly salient”? All of them except for the written label are perceptually noticeable; is this what we mean? The written label was actually fairly small relative to the size of the entire object, so why do people treat it as highly salient? In answer, we note the importance of distinguishing *perceptual* salience from what we might call *conceptual* salience. A feature is perceptually salient because our basic perceptual mechanisms automatically notice and process it preferentially or more easily; this

⁶Spearman’s: INDICATOR: $\rho = 0.192, p = 0.007$; NO INDICATOR: $\rho = 0.499, p < 0.0001$.

might be true of speech input (Vouloumanos & Werker, 2004) or auditory input in early childhood (Robinson & Sloutsky, 2004). By contrast, a feature may be *conceptually* salient if we have learned to attend to it preferentially for more abstract conceptual reasons – perhaps because it has proven useful in the past, or if it is easier to process because we have practiced processing it for many years. If the written labels are highly salient, this is probably the sense in which they are. The distinction between the two types of salience gets somewhat blurry at the edges, since many features may be both perceptually and cognitively salient, or change in salience over time. The important point, however, is that for our purposes something is salient if it invites preferential attention or is easier to process; that may be because of perceptual factors, learned conceptual factors, or some mixture of both, and we do not address that question in this work.

One limitation of our study is the fact that it was presented entirely on a computer using bizarre objects with many representationally complex features. The complexity of the features was intentional since we wanted to maximize our chances of creating a situation in which low attention to the features had a measurable effect on generalization; however, it is possible that, due to the unnaturalness of the situation, people adopted a strategy unlike that which they use in the real world. It is also possible that labels, since they are normally referential and communicative, might have a different effect when presented in a communicative, social context rather than on a computer. There is evidence that for children, labelling by a person results in different behavior to labelling by a recorder (Fulkerson & Haaf, 2003), and that non-labels can behave more like labels when presented in a referential context (Campbell & Namy, 2003). However, it is unclear how (or if) these findings will generalize to children, to more naturalistic stimuli, or to different contexts; future work is necessary.

Abstract

The ‘wisdom of the crowds’ effect describes the finding that combining responses across a number of individuals in a group leads to aggregate performance that is as good as or better than the performance of the best individuals in the group. Here, we look at the wisdom of the crowds effect in the Minimum Spanning Tree Problem (MSTP). The MSTP is an optimization problem where observers must connect a set of nodes into a network with the shortest path length possible. A method is developed that creates aggregate solutions based only on the nodes connected in individuals’ solutions, without access to spatial information about the nodes. Across the three problems analyzed, the solutions produced by the aggregation method perform better than even the best individual, leading to a strong wisdom of the crowds effect. We show this effect can be observed even with sample sizes as small as 6 individuals.

Keywords: Wisdom of the Crowds; Minimum Spanning Tree Problem; Decision Making; Problem Solving

Introduction

When a problem is posed to a group of individuals, a variety of answers or solutions may be returned. If the accuracy of the individual solutions is unknown, it would be useful to have the ability to extract the collective wisdom contained in the collection of individual responses by aggregating their solutions. The idea that an aggregate solution will perform better than the majority of individuals in the group is referred to as the ‘wisdom of the crowds’ effect (Surowiecki, 2004). Unlike most research in the topic of distributed cognition and collective intelligence (see Goldstone & Gureckis, 2009 for an overview), where individuals are able to interact in some fashion, individuals in a wisdom of the crowds environment tend to operate independently of one another. Despite this independence and the fact that group members may have widely varying levels of proficiency, aggregation can be found to be effectual in a number of scenarios.

The wisdom of the crowds effect has traditionally been demonstrated for simple questions for which there is a single answer. For example, Galton (1907) asked a large number of individuals to estimate the weight of an ox. He

found that the median estimate for the weight of the ox was within 1% of the ox’s actual weight. Similarly, Surowiecki (2004) reports that, when polled, the modal answer given by the audience in the US version of the game show “Who Wants To Be A Millionaire” for multiple choice questions is correct more than 90% of the time.

Recently, the wisdom of the crowds idea has also been applied to more complex problems. Steyvers, Lee, Miller, and Hemmer (2009) demonstrated the wisdom of the crowds effect for ordering problems, such as ordering a list of ten states from east to west, ordering the first ten amendments to the U.S. Constitution, or remembering the order of U.S. Presidents. For ordering data, simply taking the mode of individual answers can be problematic because, in many cases, all of the individual orderings are unique. Instead, Steyvers et al. (2009) developed several Bayesian aggregation models that looked at the underlying consistencies in the individuals’ orderings to produce an aggregated solution.

A wisdom of the crowds effect has also been observed recently by Yi, Steyvers, Lee, and Dry (submitted), for a difficult combinatorial optimization problem known as the Traveling Salesman Problem (TSP: see Applegate, Bixby, Chvátal, & Cook, 2006 for a review). In the TSP, the goal is to connect a set of nodes to make the shortest path possible, with the constraints that each node can be visited only once, and the path must end at the same node as it started. The aggregation method developed by Yi et al. (submitted) did not require any spatial information about the locations of the nodes. Instead, the method took advantage of the knowledge of which nodes are connected in individual solutions and selected a solution that maximized the agreement across individuals as to the sequence of nodes visited.

Generating a wisdom of the crowds effect for TSP problems in this way provides an example of a potentially powerful and general approach to aggregating individual knowledge and abilities. The key feature is that all of the aggregation is based on the observed ordering of individuals and their patterns of agreement. No representation was needed of the complex multidimensional TSP stimuli, nor were evaluation measures for individual performance used. For these reasons, the results of Yi et al. (submitted) suggest

Figure 1: An example MSTP solution (a) and its optimal solution (b).

an approach to finding the wisdom of the crowd in challenging real-world situations where the problem space is too large or complicated to represent formally, and there is no clear way to quantify the merits of proposed solutions.

Of course, however, it may be that the TSP result is simply a special or isolated case. Accordingly, in this paper, we explore the possibility of a wisdom of the crowds effect for another complex problem solving task, known as the Minimum Spanning Tree Problem (MSTP). First, as for TSPs, we develop an aggregation method that is based on easily observed features of individual solutions. Then, we apply the method to previously collected data for several MSTPs. We observe a strong wisdom of the crowds effect, in which the aggregate solution is closer to optimal than any individual solution. Finally, we examine how many individual solutions are needed for good aggregation, and discuss how our approach could be extended, modified, and applied to more general problems.

Minimum Spanning Tree Problems

In MSTPs, participants are required to find the shortest possible network that links together a set of nodes in some spatial configuration. An example stimulus and optimal solution for an MSTP is shown in Figure 1. In contrast to the TSP, there is no constraint on the paths that can be formed. Each node can be connected to multiple nodes. The optimal solution is an open, branching path system or tree, in which nodes can be linked to one or more other stimulus nodes.

Finding the optimal solution to MSTPs has an obvious real-world engineering application in regards to finding the minimal length network of cables or pipes needed to join discrete geographical locations (e.g., Borůvka, 1926). However, MSTPs are also of interest from a psychological perspective, providing insight into human decision-making, individual differences in cognitive abilities, and visuo-perceptual organization (e.g., Burns, Lee & Vickers, 2006; Vickers, Mayo, Heiman, Lee & Hughes, 2004). Specifically, the MSTP belongs to a class of difficult visual optimization problems such as the TSP and the Generalized Steiner Tree Problem (GSTP). Despite the apparent difficulty (and in some cases intractability) of these optimization problems, human observers are often able to find optimal or close-to-optimal solutions in a time frame

that increases as a linear function of problem size (e.g., Dry, Lee, Vickers & Hughes, 2006; Graham, Joshi, & Pizlo, 2000).

An important finding from the literature on human solutions to MTSPs is that there are meaningful individual differences (e.g., Burns et al., 2006). As Surowiecki (2004) and others have emphasized, a precondition for the wisdom of the crowds effect is that there is variation between individuals. Intuitively, the hope is that some individuals complete some parts of an MSTP optimally or near-optimally, while other individuals complete different parts well. In this scenario, the aggregation of the individual solutions could potentially improve on both.

Dataset

The data were taken from Burns et al (2006). In that study, as part of a larger battery of optimization tasks and cognitive abilities tests, 101 participants completed 3 MSTPs, with 30, 60 and 90 nodes. The problems were comprised of black nodes on a uniform white background and were presented on color computer monitors.

The participants generated spanning trees by pointing and clicking with the mouse cursor, and were allowed to add or remove links as they saw fit. They were instructed to connect the nodes by making a system of links, using as many links as they felt necessary, under the condition that the resulting system had the minimum overall possible length. The participants worked without time limits and were asked to be as accurate as possible. The results of the empirical solutions are displayed in Figure 2, expressed as the percentage above optimal solution length (PAO = $100 \times [\text{empirical length} / \text{optimal length} - 1]$). Participants provided solutions that were on average around 6% longer than the optimal solution. Importantly however, there were significant individual differences with some individuals providing solutions that were much closer to the optimal solution. Despite the large number of participant solutions available, there was no case in any problem where any participant's solution exactly matched that of another participant.

Figure 2. Mean empirical PAO for MSTP with 30, 60 and 90 nodes; error bars indicate standard deviation of individual performance.

Figure 3. a) Representative subject solutions for the 30-node MSTP, the best subject solution in the upper left with decreasing performance across rows and the worst subject in the lower right. b) Visualization of agreement matrix on problem nodes. Vertices selected by at least one subject are drawn; thicker lines indicate higher agreement.

Aggregation Method

The data for the aggregation method were restricted to the information of which nodes each participant connected in their solutions. In particular, the method was not given any spatial information about the node locations, and so relied solely on the information contained in the participant solutions to create a proposed network. The aggregation method operates under the assumption that vertices between nodes that are better for inclusion in a MSTP solution tend to be selected by more participants. An aggregate solution that maximizes the degree of agreement with participant solutions can therefore be expected to have good performance.

In order to obtain an aggregate solution, we first arranged the solutions of all individuals in an $n \times n$ agreement matrix, where n is the number of nodes in the problem. Every cell a_{ij} in the matrix records the number of participants that connected nodes i and j in their solutions. A visualization of the agreement matrix is depicted in Figure 3b. We then

derived a cost matrix of the same size with cell values $c_{ij} = k - a_{ij}$, where k was the total number of participants; connections with higher agreement would thus have lower costs. This cost matrix is then used as the input to a standard MSTP algorithm to obtain a proposal solution for the aggregate.

The MSTP can be solved optimally in polynomial time through the use of simple greedy algorithms such as Prim's algorithm (Jarník, 1930; Prim, 1957). In Prim's algorithm, a starting node is randomly selected from all nodes. At each step in the algorithm, the vertex with the smallest cost that connects an unconnected node to the already-connected nodes (or starting node, in the first step) is added to the network, until all nodes are connected. Despite the fact that the algorithm is greedy in nature, it is always guaranteed to output the minimum spanning tree depending on the cost metric being used. When the vertex costs are equal to the distances between nodes, Prim's algorithm is guaranteed to produce a spanning tree with the shortest total length. In our research, the vertex costs upon which Prim's algorithm is

Figure 4. Example demonstration of Prim's algorithm on the 30-node MSTP. A random node is selected, shown in white (a.). At each step of the algorithm, vertices with the smallest cost (i.e., highest agreement) that connect an unconnected node (black) to those already connected (white) are added to the network until all nodes are connected (b-d.).

Figure 5. Solution paths for the aggregate method (thin black) and the optimal minimum spanning tree (thick gray) for the a) 30-node, b) 60-node, and c) 90-node MSTPs.

applied are set using the cost matrix based on subject agreement above. The algorithm will still produce a network with minimum total cost, but in this case, the network represents the spanning tree that has the highest agreement with the participant solutions. It is this solution that is selected by the aggregation method. A demonstration of the algorithm is shown in Figure 4.

Optimality of Prim's algorithm can be verified by considering the necessary conditions for a minimum spanning tree. For a solitary node, it is necessary for it to connect to its nearest neighbor using the vertex with the lowest cost. If a spanning tree is created without using such a vertex, and that node is connected to the others via some other vertex, it does not change the connectedness of the network by deleting that other vertex and instead connecting to the nearest neighbor, but it does reduce the total path length. This makes the first step of Prim's algorithm, connecting a random node to its nearest neighbor, a sensible action. The logic can be followed by induction to the sub-networks drawn by Prim's algorithm by treating each sub-network as if it were a single node, thus showing optimality. In cases where multiple potential vertices with the same cost may be selected for addition to the spanning tree, then any of the candidates may be chosen without affecting the solution's optimality.

Figure 6: Ranked performance of subjects and the aggregation method averaged over all problems. Dashed horizontal line indicates mean subject performance.

Results

Figure 5 shows the optimal minimum spanning trees in thick gray lines and solutions selected by the aggregation method in thin black lines while participant and aggregate solution performance is provided in Table 1. Additional performance statistics are noted for the aggregate solutions: the amount of agreement the aggregate solutions had with subject solutions and a count of the number of participants whose performance is better than, worse than, or same as the aggregate. Subject agreement values were calculated as the proportion of subject vertices coinciding with vertices present in the aggregate solution; these can be obtained by noting the value of the aggregate path as measured on the agreement matrix, then dividing by $(n-1)k$, the number of vertices multiplied by the number of subjects. The aggregate

Figure 7: Performance averaged over all problems against mean solution agreement with subject solutions.

Table 1: Subject and Aggregate Method Performance on MSTPs (% network length over optimal)

Problem	subject performance		aggregate method performance				
	subj. best	subj. mean	path length	subj. agreement	# subj. better	# subj. same	# subj. worse
30 nodes	+0.000%	+5.672%	+0.059%	.7856	1	0	100
60 nodes	+0.037%	+6.010%	+1.410%	.8263	21	0	80
90 nodes	+0.235%	+6.533%	+0.310%	.8392	1	0	100
Overall	+0.644%	+6.072%	+0.593%	.8171	0	0	101

method solutions perform quite well, beating the average participant by a large margin. In the 30- and 90-node problems, the performance of the aggregate is bested only by a single participant out of the full set of 101. The aggregate performs relatively worse in the 60-node problem, but still better than most individuals. When performance is averaged over all problems, the aggregate performs better than any individual (Figure 6). Interestingly, the proportion of vertex agreement with participants increased with problem size, and solutions selected by the aggregate did not completely match any single individual on any problem. Figure 7 contains a plot of solution performance against the proportion of agreement with participant solutions averaged equally over all problems for all subjects, the optimal solution, and the aggregate solution. There is a clear correlation between individual performance and the amount of agreement their solutions had with other participants ($r = -.9602$). The optimal solution also has a high rate of coincidence with participant solutions, more than any individual.

Performance of the aggregation method under smaller sample sizes was also investigated. For each sample taken, subjects were selected randomly from the full dataset and aggregate solutions were created for all problems, their performances compared to the subjects in the sample that generated them. In cases where Prim’s algorithm encountered a choice between vertices of the same cost, one was chosen at random to create the proposal solution. Solution performance for selected sample sizes is noted in Figure 8, averaged over 1000 random draws at each sample size. We find that for samples of as small as size 6, the

aggregate is able to obtain performance that is, on average, significantly better than the mean subject and close to that of the best subject in the sample. Averaged over all problems, the aggregate was outperformed by about one participant at all sample sizes investigated. In certain cases for individual problems, the aggregate solution outperformed all participants in the sample; this was much more common for the 30-node and 90-node problems than the 60-node problem.

Conclusions

We have demonstrated a strong wisdom of the crowds effect for the MSTP using a simple aggregation method on participant solutions. The aggregation method was reliant only on the knowledge of which nodes were connected by each participant, requiring no information regarding the spatial characteristics of the problems themselves. In addition, the simple greedy algorithm used to generate solutions required no input parameters to run. The aggregation method solutions generally have performances ranking among the best participants on individual problems, and perform better than any individual when averaged over all problems. Even when the number of available participants was reduced down to as low as 6, the aggregation method was still able to extract enough information to propose solutions that produced performances significantly better than the mean subject and exceeding most or all participants in the sample.

While performance of the aggregation method is quite good, there are potential areas for expanding on the method. It was noted that there was a clear correlation between a

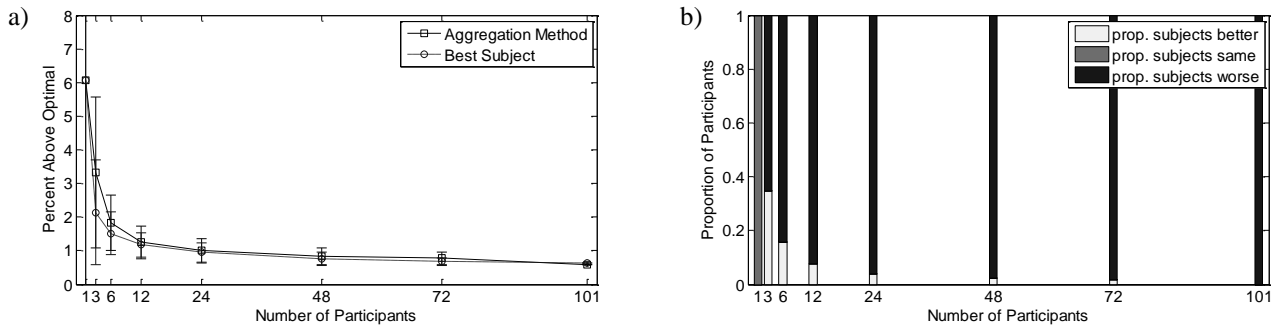

Figure 8. Performance of the aggregate method for selected sample sizes, taken across problems. a) Mean PAO for aggregate and best subject in each sample, error bars indicate standard deviation of individual samples. b) Proportion of subjects with better, same, or worse performance than the aggregate.

participant's performance and the amount of agreement they had with other participants. It may be useful if it were possible to identify 'experts' in the data and weight their responses over that of others. This approach of amplifying expertise may be most useful for when sample sizes are small. Due to the fact that there are so few participant solutions to draw from, there may be many networks that can potentially be chosen by the algorithm that share the same agreement with participant solutions, but carry very different performances in terms of actual distance. If participants can be weighted differently, then there will be less ambiguity. However, with the complexity of the problem structure, it is a difficult problem to create a formal system in which this can be done.

More generally, the results presented here, when coupled with those presented by Yi et al. (submitted) for the TSP, suggests that it may be possible to achieve wisdom of the crowds effects for complicated and only partly defined problems. While the MSTP does have a simple solution algorithm, and the TSP has good approximate solution algorithms for small numbers of nodes, our results show that near-optimal performance can be obtained from simple properties of the sub-optimal sets of solutions produced by a group of people.

In other words, our results show that there is an alternative route to solving these problems, not based on complicated algorithms, detailed stimulus information, and precise performance metrics. Instead, we have shown that the orders people produce can be combined to achieve near-optimality. Of course, for TSPs and MSTPs, there is not much reason to go to the effort of collecting human solutions when good algorithms are available. But our approach will continue to apply for different sorts of difficult problems where, for example, the stimuli or problem space is hard to represent in a formal way. This representational burden is borne by the individual providing solutions, and there is no need for any formal attempt to characterize the problem space. Even more intriguingly, our approach will apply in situations, such as some types of aesthetic judgment, where people agree on what constitutes a good answer once it is produced, but cannot define exactly what metric they are using. Since our aggregation approach just uses the patterns of relationships between individual judgments, and does not need a performance measure, it is equally applicable to these poorly defined problems.

We are currently investigating the use of the wisdom of the crowds approach described in this paper to the "wisdom of the crowds within", the idea that one can aggregate over multiple judgments from a single individual to obtain performance better than the individual judgments alone (Vul & Pashler, 2008). By applying transformations to MSTPs, we can easily test an individual on multiple repetitions of the same problem while minimizing bias from their responses on previous trials. We are also looking at applying the aggregation approach to a less-well defined aesthetic judgment task. Participants were asked in Dry, Navarro, Preiss, and Lee (2009) to connect point stimuli

based off of constellations into perceived structures. It is possible that a structure created by aggregating over individuals is perceived as more aesthetically pleasing than individual patterns. The application of our approach to aggregation to these sorts of challenging problems seems a promising direction for further wisdom of the crowds research.

Abstract

The effects of language on categorization are well documented; however, underlying mechanisms are under debate. According to one account, words facilitate categorization by highlighting commonalities among labeled objects. Although there is some behavioral evidence consistent with this claim, research remains limited for whether labels can direct infants' attention to corresponding visual features. In the current study, adults and infants were presented with 10 different exemplars that were either associated with 10 different labels, the same label, or presented in silence. An eye tracker recorded visual fixations to common and unique features throughout familiarization. Experiments 1 and 2 provide evidence that unique labels can direct infants' and adults' attention to unique features (compared to a silent condition); however, the effect of hearing the same label associated with different objects was less robust in both age groups.

Keywords: Attention; Language; Categorization

Introduction

Beginning at birth, infants must learn to make sense of the world, and the ability to form categories is an important part of this learning. Although very young infants can quickly learn visual categories (Bomba & Siqueland, 1983; Eimas & Quinn, 1994), there is some evidence that words and other types of sounds influence this process. For example, young infants are often better at learning visual categories when category members are associated with the same word than when the same visual stimuli are paired with a nonlinguistic sound (Balaban & Waxman, 1997; Fulkerson & Waxman, 2007; Robinson & Sloutsky, 2007). Exposure to words may also help infants individuate objects. Research demonstrates that infants who hear two different words (but not two sounds) expect two objects to be hidden by an occluder (Xu, 2002). Labels also influence what category structure infants learn. For instance, while looking at the same visual images, infants who heard one word associated with all exemplars learned one category; whereas, infants who heard two words learned two categories (Plunkett, Hu & Cohen, 2008). Finally, although words and sounds often have different effects on categorization and individuation, only a few studies have directly compared infants' performance in label

and sound conditions to a silent baseline. These comparisons illustrate that compared to a silent condition, words and sounds can interfere with categorization of visual input, often with greater interference from sounds than from words (Robinson & Sloutsky, 2007; 2008).

To account for the effect of labels on category learning, several mechanisms have been put forth. First, Waxman and colleagues argue that infants understand the conceptual importance of words and that words (but not sounds) facilitate categorization by highlighting the commonalities among labeled entities (Fulkerson & Waxman, 2007; Waxman, 2003). Given the findings reported by Plunkett *et al.* (2008) and Xu (2002), it is also possible that unique words may also facilitate the formation of multiple categories by highlighting unique features among labeled entities. In contrast, Sloutsky and colleagues argue that infants and young children have difficulty processing multimodal information, with words and sounds often attenuating visual processing (Robinson & Sloutsky, 2004; Sloutsky & Napolitano, 2003). Differential effects of words and sounds stem from sounds interfering with visual tasks more than words (as opposed to words facilitating categorization above a silent control). Thus, according to Waxman and colleagues, hearing common and unique words should increase attention to common and unique features in the early stages of development. In contrast, according to Sloutsky and colleagues, early in development words should have no facilitative effect above a silent condition and may even interfere with visual processing.

The aim of the current set of studies was to explore *how* words might affect visual attention by utilizing eye-tracking technology. Measuring eye movements during experimental tasks provides an online measure of attention. By tracking the gaze of infants and adults during a simple familiarization task, we can investigate whether patterns of visual attention during learning differ with respect to varying language cues.

Overview of Current Studies

To investigate the effect of labels on visual attention, gaze data were collected from both infants and adults while viewing novel stimuli paired with novel labels. Half the features on each stimulus were shared among the

sequentially presented stimuli (i.e., common features); whereas, half of the features were unique. If participants inferred identical labels indicated that images were members of the same object category, it was predicted that participants who heard the same label associated with different images would accumulate more looking to common features than participants in the silent condition. Similarly, if participants inferred different labels indicated that images were members of different object categories, it was predicted that participants who heard different labels associated with different images would accumulate more looking to unique features than participants in the silent condition. Experiment 1 compared adults' attention to common and unique features across familiarization when labels were consistent, varying, or when images were presented in silence. Experiment 2 tested infants with the same three sets of stimuli as presented to adults.

Experiment 1

Method

Participants Thirty-six adults (20 men, 16 women), ranging in age from 18 to 21 years ($M = 18.58$, $SD = 0.79$) were tested, with 12 adults per condition. Adults were recruited from an Introductory Psychology class. Participants provided written consent upon arrival to the laboratory. All adults reported normal or corrected-to-normal vision and normal hearing prior to recruitment.

Apparatus A non-invasive Tobii T60 eye tracker measured eye gaze by computing the pupil-corneal reflection at a sampling rate of 60 Hz (i.e., 60 gaze data points collected per second for each eye). The eye-tracking device, which is integrated into the base of a high-resolution 17-inch computer monitor, was located on a table inside a darkened testing booth, enclosed by curtains. A trained experimenter monitored the experiment on a 19-inch Dell OptiPlex 755 computer located outside of the testing booth. A Sony Network camera was located inside the testing booth to the side of the eye tracker displaying a live feed view of the participant that an experimenter monitored on a 9-inch black and white Sony SSM-930/930 CE television. Two Dell computer speakers were positioned behind a curtain and out of view on either side of the eye tracker.

Stimuli Stimuli included 12 audio-video interleave (AVI) files. Each AVI file combined a static bitmap image with an auditory speech component. The visual images consisted of four uniquely-shaped parts. Two parts were common across all stimuli and two parts were unique across all stimuli. See Figure 1 for example stimuli. The common parts were the same color and shape; whereas, the unique parts varied in color and shape. The auditory input consisted of one-syllable novel labels spoken by a female adult (e.g., *dax*, *bim*, *fep*, *gid*, *jup*, *meb*, *pof*, *raz*, *sop*, and *zot*). All labels were spoken within the context of a simple command (e.g., "Look at the dax."). Speech was recorded using Cool Edit

2000. Each sound file was saved as an audio compression manager waveform at 44.10 kHz, 16 Bit, in stereo. Audio files were then imported into Macromedia Flash, paired with corresponding bitmap images, and exported as Windows AVI files. All AVI files were 6000 ms in duration. The image lasted for the total duration of 6000 ms. The audio occurred with the onset of the image and lasted 2000 ms in duration. The remaining 4000 ms consisted of silence. The stimuli for the silent condition were identical to the label conditions; except, the speech was removed entirely.

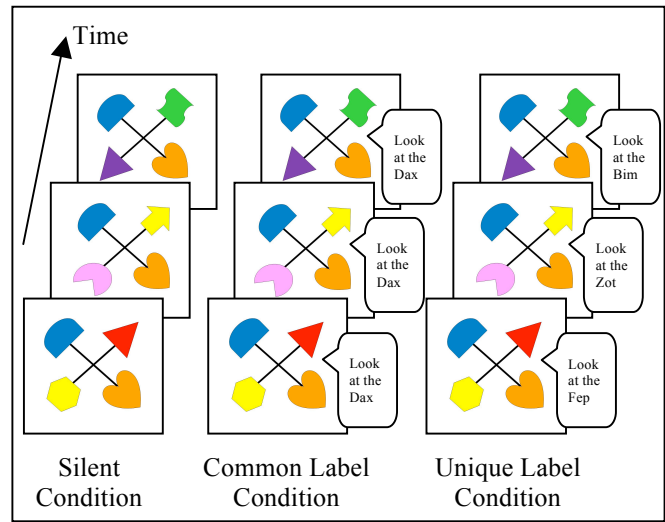

Figure 1: Example stimuli

Design The experiment utilized a between-subjects design. Participants were randomly assigned to one of three experimental conditions (i.e., common label, unique label, or silent). The common condition consisted of 10 different novel images, each paired with the same novel label. The unique condition consisted of 10 different novel images, each paired with 10 different novel labels. The silent condition consisted of 10 different novel images, each presented in silence. The visual input was the same for all conditions and was presented in a random sequence. Only the auditory input differed across conditions.

Procedure Participants sat centered in front of the eye tracker within an approximate viewing distance of 60 cm. Prior to the experiment, participants completed a 5-point calibration sequence lasting less than one minute. The calibration points consisted of a moving red dot appearing in different locations on the screen. The experiment commenced after successful calibration. Participants were asked to pay close attention to the images because they would be asked about them later. All participants were familiarized to 10 stimuli presented one at a time for 6000 ms. Each stimulus was presented subtending an approximate horizontal visual angle of 11° and an approximate vertical visual angle of 11°. A black screen was presented for 1000ms between trials. After training, participants were

tested with four paired preference trials, each trial displaying one old image and one new image presented in silence. Adults were asked to select the new image from the old image. Test stimuli were the same size as familiarization stimuli. Each test trial remained visible until adults made a decision. All gaze data were recorded by the computer using Tobii Studio gaze analysis software.

Results and Discussion

All participants correctly identified the novel stimuli on every test trial; therefore, no one was excluded from the current study. Primary analyses presented below focused on adults' attention to common and unique features during familiarization.

Unfiltered gaze data were exported from the computer using Tobii Studio gaze analysis software. A point of gaze was recorded if a participant made a fixation to pre-determined areas of interests (AOIs). Four AOIs were defined as a rectangle surrounding the four parts of each stimulus image. Gaze data were combined for the two common features and for the two unique features to obtain a measure of looking to unique or common features per refresh rate. These data were used to calculate unique and common feature preference scores based on the proportion of looking time to either unique or common features as compared to the total time looking to all features combined.

Effect of Unique Labels To determine if unique labels pushed adults' attention to unique features, we compared preference for unique features in the unique label condition to preference for unique features in the silent condition.

Gaze data were analyzed using a moving average of participants' attention across time to smooth out temporary fluctuations within a given trial (*i.e.*, 3 trials were averaged per time point such that time point 1 averaged trials 1 to 3, time point 2 averaged trials 2 to 4, and so on). A repeated-measures analysis of variance (ANOVA) was conducted on mean preference for unique features with Condition (unique label vs. silent) as a between-subjects factor and Time Point (1 vs. 2 vs. 3 vs. 4 vs. 5 vs. 6 vs. 7 vs. 8) as a within-subjects factor. Results revealed a significant main effect of Time Point, $F(7, 154) = 6.56, p < .001$, a main effect of Condition, $F(1, 22) = 4.44, p < .05$, and a significant Time Point X Condition interaction, $F(7, 154) = 3.74, p < .01$. Overall, mean preference scores for unique features were significantly greater in the unique condition ($M = .66$) compared to the silent condition ($M = .53$). Specifically, as shown in Figure 2, post-hoc comparisons revealed that mean preference scores for unique features were significantly greater in the unique condition compared to the silent condition at time points 5, 6, and 7, $ts > 2.16, ps < .05$. These results support the idea that unique labels facilitate attention to unique features.

To obtain a better understanding of the dynamics of attention, unique preference scores were averaged across trials and plotted as a function of time. As can be seen in Figure 3, preference for the unique features in the unique

label condition was consistent across the entire 6000 ms trial duration. This attention pattern in adults corroborates evidence for unique labels facilitating attention to unique features.

Figure 2: Adults' mean preference for unique features by time point. (Note: Time points represent moving averages).

Figure 3: Adults' mean preference for unique features over time.

Effect of Common Labels To determine if common labels pushed adults' attention to common features, we compared preference for common features in the common label condition to preference for common features in the silent condition, using the same sample of adults that was previously compared to the unique label condition.

As in the unique label condition, gaze data were analyzed using a moving average. A repeated-measures ANOVA was conducted on mean preference for common features with Condition (common label vs. silent) as a between-subjects factor and Time Point (1 vs. 2 vs. 3 vs. 4 vs. 5 vs. 6 vs. 7 vs. 8) as a within-subjects factor. Results revealed a significant main effect of Time Point, $F(7, 154) = 2.20, p < .05$. Preference for common features attenuated over time for both the common label and silent conditions. However, as shown in Figure 4, mean preference scores for common features were not significantly different between conditions at any point in the course of familiarization.

Figure 4: Adults' mean preference for common features by time point. (Note: Time points represent moving averages).

Furthermore, preference for common features was analogous for the entire 6000 ms trial duration in the common label and silent conditions when preferences scores were averaged across trials and plotted as a function of time (see Figure 5). Therefore, the pattern of attention over time did not suggest that common labels directed adults' attention to common features.

Figure 5: Adults' mean preference for common features over time.

Summary Experiment 1 found a robust effect of unique labels directing attention to unique features and no significant effect of common labels directing attention to common features. Adults presented with varying labels (*i.e.*, unique) compared to silence disproportionately distributed their attention to objects' unique versus common features. In contrast, adults presented with consistent labels (*i.e.*, common) compared to silence did not disproportionately distribute attention to objects' common versus unique features. The purpose of Experiment 2 was to investigate how labels affect visual attention in infancy. Do unique and common labels direct infants' attention to correlated visual features?

Experiment 2

Method

Participants Thirty-six infants, (19 boys and 17 girls), ranging in age from 16 to 24 months ($M = 19$ months, 9 days; $SD = 3$ months, 21 days) were tested, with 12 infants per condition. Ten additional infants were excluded from analyses due to fussiness. Infants were recruited from local birth records. Parents provided written consent upon arrival to the laboratory. All infants were healthy and developing typically.

Materials and Design The apparatus, stimuli, and design were identical to Experiment 1.

Procedure Infants sat on a caregiver's lap and were positioned in front of the eye tracker within an approximate viewing distance of 60 cm. The procedure was identical to Experiment 1 with three exceptions. First, during calibration, rather than a shrinking red dot, infants saw a dynamic kitten image appearing on the screen with a corresponding "bounce" sound. Second, unlike adults, infants were not provided with instructions. Third, a dynamic bouncing ball was presented as an attention-grabbing fixation between trials.

Results and Discussion

Infants in all three conditions (*i.e.*, unique label, common label, and silent) demonstrated a mean novelty preference based on the average looking time to new versus old objects across all four test trials, $t_s > 2.55$, $p_s < .05$. Mean novelty preference scores did not differ among the three conditions. Primary analyses presented below focused on infants' attention to common and unique features during familiarization.

Effect of Unique Labels As in Experiment 1, unfiltered gaze data were exported and combined into looking to common features and looking to unique features. To determine if unique labels directed infants' attention to unique features, we compared preference for unique features in the unique label condition to preference for unique features in the silent condition. As with adults' data, infants' gaze data were analyzed using a moving average of participants' attention across time to smooth out temporary fluctuations within a given trial (*i.e.*, 3 trials were averaged per time point such that time point 1 averaged trials 1 to 3, time point 2 averaged trials 2 to 4, and so on). A repeated-measures ANOVA was conducted on mean preference for unique features with Condition (unique label vs. silent) as a between-subjects factor and Time Point (1 vs. 2 vs. 3 vs. 4 vs. 5 vs. 6 vs. 7 vs. 8) as a within-subjects factor. Results revealed a significant main effect of Time Point, $F(7, 147) = 3.96$, $p < .01$. Although the effect of Condition did not reach significance, as shown in Figure 6, independent *t*-tests revealed that mean unique preference scores were

significantly greater in the unique label condition compared to the silent condition at time point 2, $t(22) = 2.03, p = .05$.

Figure 6: Infants' mean preference for unique features by time point. (Note: Time points represent moving averages).

To obtain a better understanding of the dynamics of attention, unique preference scores were averaged across trials and plotted as a function of time. As can be seen in Figure 7, preference for the unique features was greater in the unique label condition than the silent condition within 1000 ms to 4000 ms. Although, the effect of unique labels was less pronounced in infants than adults, these data provide some evidence for unique labels facilitating infants' attention to unique features.

Figure 7: Infants' mean preference for unique features over time.

Effect of Common Labels To determine if common labels directed infants' attention to common features, we compared preference for common features in the common label condition to preference for common features in the silent condition, using the same sample of infants that was previously compared to the unique label condition. As in the unique label condition, gaze data were analyzed using a moving average. A repeated-measures ANOVA was conducted on mean preference for common features with Condition (common label vs. silent) as a between-subjects

factor and Time Point (1 vs. 2 vs. 3 vs. 4 vs. 5 vs. 6 vs. 7 vs. 8) as a within-subjects factor. Results revealed a significant main effect of Time Point, $F(7, 147) = 9.06, p < .001$. Like adults, infants' preference for common features attenuated over time for both the common label and silent conditions. However, as shown in Figure 8, mean preference scores for common features were not significantly different between conditions at any point in the course of familiarization.

Figure 8: Infants' mean preference for common features by time point. (Note: Time points represent moving averages).

Common preference scores were averaged across trials and plotted as a function of time (see Figure 9). Although results from the ANOVA and t -tests revealed no differences between conditions, preference for the common features in the common label condition exceeded the silent condition for the first and last 1000 ms of the trials. Although not illustrated by adults, this pattern of results revealed that if common labels directed infants' attention to common features, the effects were subtle.

Figure 9: Infants' mean preference for unique features over time.

Summary Experiment 2 found comparable, yet less pronounced results as Experiment 1 with regard to unique labels affecting visual attention. Infants presented with

varying labels (*i.e.*, unique) compared to silence disproportionately distributed their attention to objects' unique versus common features. Effects of common words were less robust, and if they directed infants' attention to common features, these effects are subtle.

Conclusion

The current study reveals several important findings. First, adults, and to a lesser extent, infants, who heard unique labels accumulated more looking to unique features compared to the silent condition. Second, for adults, this effect was robust across familiarization and occurred throughout the entire trial. Third, there was no clear evidence of common labels directing attention to common features for adults or for infants.

Many studies have examined how different types of auditory input affect categorization, as assessed by increased looking to novel categories in a subsequent testing phase (Balaban & Waxman, 1997; Fulkerson & Waxman, 2007; Plunkett, Hu & Cohen, 2008; Robinson & Sloutsky, 2007). The current study, in conjunction with research by Althaus and Mareschal (2010), are the first studies we are aware of that have directly tested the hypothesis that words draw attention to category relevant features for infants. Directly testing this hypothesis (*i.e.*, as opposed to inferring it from infants' looking to the novel category at test) is crucial for understanding possible mechanisms underlying effects of words on category learning.

The findings of the current study are partially consistent with both proposed mechanisms. First, in support of the claim that words direct attention to category relevant information (e.g., Waxman, 2003), there was clear evidence for adults, and to a lesser extent, infants, that unique labels highlight unique features. However, there was little support for the claim that common words highlight commonalities, which may have stemmed from a general tendency to increase looking to novel features across familiarization.

Support for the claim that auditory information can attenuate visual processing (e.g., Robinson & Sloutsky, 2007) is also mixed. Support for this claim primarily comes from the finding that infants in the label conditions did not show better discrimination at test, and there was no robust facilitation across familiarization. However, this account assumes that differential effects of words and sounds stem from sounds attenuating visual processing more than words. A direct test of this account would require a non-linguistic sound condition. At the same time, there was little evidence that words slowed down visual processing. However, studies showing that words interfered with visual processing tested 8- and 12-month-old infants (Robinson & Sloutsky, 2007; Sloutsky & Robinson, 2008), which is younger than the infants tested in the current study.

The current study raises an interesting question. Why was the effect of common labels weaker than the effect of unique labels? One possibility is that adults were told to pay attention to the pictures because they were going to be asked

about them later. These instructions, in combination with habituation to the common features may have biased attention to unique features. Future research will need to systematically manipulate the category structure by changing the proportion of common to unique features. It is possible that effects of words may interact with the structure of the to-be-learned category. It will also be important to test categorization abilities to connect performance at test to training data, allowing for a better examination of individual differences in category learning.

Abstract

This study investigated people's mental representations of diagrams and whether these related to views about diagrams and problem solving performance. The participants were 93 undergraduate students who were asked to complete a questionnaire which included free writing on the topic of diagrams, and problem solving. Analysis of the statements and ideas that the students wrote revealed four categories through which diagrams may be mentally represented: uses/purposes, exemplars, personal opinions, and structure. Personal opinions responses were found to negatively correlate with views about the usefulness of diagrams, and with experiences and confidence in using diagrams. In contrast, responses about the uses/purposes of diagrams positively correlated with confidence in using diagrams. Evidence was also found suggesting that, among students studying math, greater knowledge about the uses/purposes of diagrams facilitated better problem solving performance.

Keywords: Mental representation of diagrams; problem solving; articulation; free writing.

Introduction

Diagrams have many different fields of application (see, e.g., Blackwell & Engelhardt's, 2002, list of academic fields that they identified as having research interest in diagrams), and their use is generally considered as efficacious. In problem solving, for example, Larkin and Simon (1987) explained how diagrammatic representations have distinct advantages over sentential representations because the ways in which diagrams index information can more effectively support useful and efficient computational processes. Hembree (1992) also found that, among the instruction methods he examined in a meta-analysis, training in diagram drawing provided the largest performance improvement in problem solving.

Despite the many reported positive attributes of diagram use, there are numerous problems that have been identified in relation to that use. For example, prior knowledge about diagrams appears necessary for their effective use (see, e.g., Grawemeyer & Cox, 2008; Larkin & Simon, 1987), and student have generally been found to lack spontaneity in using diagrams (see, e.g., Dufour-Janvier, Bednarz, & Belanger, 1987; Uesaka, Manalo, & Ichikawa, 2007). In

essence, these suggest that many individuals probably fail to benefit from diagram use: if they lack sufficient knowledge about how to effectively use them, and – even if they did know how to use diagrams – if they nevertheless neglect to make use of them.

Most of the published research on diagrams have focused on their effects and functions (e.g., Ainsworth & Th Loizou, 2003; Cheng, 2002, 2004; Mayer, 2003), with very few studies that have investigated possible ways of understanding and addressing the problems associated with users noted above. The few studies that have considered issues concerning users of diagrams include Uesaka et al. (2007) which found that lack of confidence and perceptions of difficulty in diagram use, and viewing diagrams more as a strategy that teachers use (rather than a strategy that they themselves can use), were deterrents to students' spontaneous use of diagrams. Uesaka et al.'s findings indicate that how individuals view diagrams influence their use of diagrams – suggesting that understanding the ways in which diagrams can be mentally represented could be key to addressing issues/problems about their use.

There is not a lot in the research literature, however, that deals with how people mentally represent diagrams. Numerous studies have considered mental processes relating to graphical representation: for example, Stern, Aprea, and Ebner (2003) examined the effect of "active" versus "passive" graphical representation (i.e., passive encounter with, as opposed to active construction of, linear graphs) on processing transfer from one subject content area to another. However, such studies have not directly addressed the question of how people might structurally represent diagrams in their minds (e.g., as images and/or propositions, in terms of their functions and/or specific examples?).

Blackwell and Engelhardt (2002) proposed a meta-taxonomy that can be used to analyze and compare existing taxonomic systems of diagrams. Their meta-taxonomy was aimed at facilitating the study of diagrammatic representations, such as assessing the relevance of different representations to specific research questions. One of the taxonomic dimensions they proposed was "cognitive" and, although they did not elaborate on this dimension in any detail, their suggestion of focusing on the nature of the

representation and the ways in which people might differ appears appropriate in any attempt to understand the user perspective in diagrams use.

Perhaps the closest attempt at finding out how people mentally represent diagrams was carried out by Cox and Grawemeyer (2003). They used a card sorting task to assess their participants' semantic knowledge about a wide range of diagrams (that they referred to as "external representations" or "ERs"), and found through cluster analysis 9 major categories of ERs. Furthermore they found that participants differed in the categories they created according to how well they scored on ER reasoning tasks: the group of participants who scored well tended to create fewer categories that were based on semantic distinctions between ERs, while the group who scored lower created more categories that tended to focus more on superficial aspects of ERs (e.g., what the ERs looked like).

Cox and Grawemeyer's (2003) findings revealed some important points about how people mentally deal with diagrams: for example, that those who had (presumably) greater knowledge about diagrams were able to perceive meaning-based commonalities between diagrams that may not look alike, while those who had (again, presumably) less knowledge about diagrams may have had to rely on feature-based processes which in turn may have been based on their recollections of diagrams they had previously encountered. Essentially, this suggests that with greater knowledge about diagrams, a person can perceive meaningful relationships between different forms, and categorize accordingly.

It is questionable, however, whether the categories that Cox and Grawemeyer (2003) identified based on their participants' responses reflect the categories that people normally possess as their mental representations of diagrams (i.e., in normal circumstances, not in response to requests to sort/group diagrams). Would people naturally use such categories in mentally organizing and representing what they know about diagrams? The present authors believe otherwise as the categories that people come up with in response to item sorting tasks would inevitably be influenced by their efforts at incorporating and making sense of items that they either did not know about or had not previously considered as part of the subject in consideration. The categories would also reflect the absence of items they may know about but had not been presented. In other words, the kinds of items presented in the task would unavoidably bias the kinds of categories that are produced.

Furthermore, in the Cox and Grawemeyer (2003) study, the participants' ability to find meaning (e.g., the semantic distinctions) in the task given does not necessarily mean that those meanings previously guided their mental representation of diagrams: the task itself could have facilitated the development of their insight about those semantic distinctions between different ERs. This therefore means that, despite the valuable contributions of the Cox and Grawemeyer study, the question of how people normally represent diagrams in their minds remains largely unanswered.

One method that has been used to gain insights into people's cognitive structures about target "objects" is articulation (see, e.g., Scott, 1966): through the descriptions that participants provide of the target object, the structural properties of their cognition can be inferred (i.e., through the definitions, categorizations, connections, and elaborations they articulate). As information provided with the target object can be restricted, potential biases that can inadvertently be communicated to the participant can be reduced. Steps to reduce the potential for such biases are important when attempting to understand how people normally represent certain concepts in their minds.

Free writing, which can be defined as "a procedure in which students are asked to write down whatever they think of and to keep writing without worrying about quality of ideas" (Hayes & Flower, 1986, p. 1106), is one technique that has been used to facilitate participants' articulation of their beliefs and ideas about target concepts. It has, for example, been used to tap into and understand students' knowledge about, and associations with, basic scientific concepts they were learning (Curtis & Millar, 1988); and to understand the specific content of marital ideals among newly married couples (Knobloch-Fedders & Knudson, 2009).

In the present study, free writing was utilized as a method to facilitate participants' articulation of their thoughts and ideas about diagrams – the aim being to explore and try to understand how people might normally represent diagrams in their minds. A further aim of the study was to find out if such mental representations of diagrams are related to participants' (i) views about the importance of diagrams in teaching and learning situations, (ii) self-assessments of experience and confidence in using diagrams, and (iii) competence in using diagrams in problem solving.

Method

Participants

The participants were 93 undergraduate first-year (freshmen) students in a university of education in Japan (i.e., they were studying to become teachers) who voluntarily participated in completing the questionnaire used in this study. Their mean age was 19.0 years ($SD = .53$ year); 50 were females, and 43 were males.

Materials and Procedure

The questionnaire administered to students was written in Japanese and comprised of three parts. In part 1, after briefly being informed about "free writing", participants were first asked to practice free writing for 1 minute on the topic of "friendship". Following this, they were given 3 minutes to free write on the topic of "diagrams".

In part 2, participants were asked their opinions about diagrams. First, they were asked to indicate on a 5-point Likert-type scale how important they considered diagrams in teaching and learning. They were then asked to briefly write reasons for their response (however, because of space

constraints, analyses concerning the participants' responses to this question have not been included in this paper). Next they were asked to indicate, again on a 5-point Likert-type scale, how much they usually used diagrams, and how confident they felt in using diagrams.

In part 3, participants were asked to solve three problems. Three minutes were allowed for each of the problems, and participants were explicitly asked to try to construct and use diagrams in their attempts to solve them. The first problem required the comparison of heights, and a pictorial depiction of the heights indicated would have been helpful towards solving it. The second problem required working out the circumference following the arrangement of similar-sized pieces of paper; for this, the construction of a table would have been helpful. The third problem concerned applicant placement at a training and employment agency, and for this problem a decision flow chart would have been helpful. (Again, due to space constraints, analyses relating to appropriateness and quality of the diagrams that participants produced have not been included in this paper.)

Results

Categories that Emerged from the Free Writing Task

The participants' responses to the free writing task about diagrams were analyzed initially by looking through these responses and identifying themes or categories of ideas that they conveyed. Understandably, because it was a free writing task and participants were asked to write continuously for the 3-minute duration irrespective of the relevance of the ideas that came to their minds, a large proportion of what they produced appeared unrelated to the topic of diagrams (e.g., single word statements like "compass" and "PC", phrases like "book that has a catchphrase of 'easy to understand'", and sentences like "It keeps appropriate distance."). Apart from these unrelated statements, however, the participants' responses appeared to fall into four broad categories: statements or ideas concerning (a) the uses of diagrams, (b) specific examples of diagrams, (c) personal opinions about diagrams, and (d) the structure of diagrams.

These categories were therefore used to sort and tabulate the participants' responses. The responses were sorted in terms of single, complete 'units of ideas': these could be single words that conveyed a complete idea and appeared intended by the participant to be so (e.g., by being separated from other ideas spatially or through the use of punctuations), complete phrases, sentences, and – in a few cases – diagrams that participants drew.

Table 1 shows the five categories (including the "unrelated" category), the number of ideas or statements that participants wrote in these categories, and the number and percentage of participants who wrote ideas or statements that belonged in these categories.

Under the category of "Uses or purposes" were included statements or ideas that pertained to general or specific uses,

purposes, or functions of diagrams. Examples of general statements/ideas of this kind were: "it can help to summarize" and "promotes understanding". Examples of more specific references to uses, purposes, or functions included: "diagrams are used to represent problems more concretely, as a result people can visualize better and find a hint for finding the solution more easily" and "although mathematics is separate from daily life, many people can reach common understanding by using diagrams".

Table 1: Responses to the free writing task.

Category	No. of ideas/ statements	No./percentage of participants
Uses or purposes	178	69 (74%)
Specific examples	163	52 (56%)
Personal opinions	80	46 (49%)
Structure	17	12 (13%)
Unrelated	470	81 (87%)

The category of "Specific examples" was used when participants simply listed, described, or drew specific kinds or forms of diagrams. Examples included: "graph", "bar chart", "pie chart", and "table".

Included in the "Personal opinions" category were participants' ideas or statements that pertained or related to experiences they have had with diagrams. Examples of statements and ideas placed in this category were: "troublesome ... complicated", "many are difficult to understand", and "I get irritated when I cannot draw them well". Almost all were negative.

Under the "Structure" category were included participants' references to the general or specific ways in which diagrams structure, organize, or present data/information. Examples of the general ways participants mentioned included: "a diagram is a visual representation", and "a different approach from one that uses language". An example of a more specific reference to the way in which diagrams structure data/information included: "something represented line-by-line".

To check the reliability of coding the participants' responses under these categories, another person independently carried out coding on 10% of the participants' responses (10% being the minimum acceptable subsample size recommended by Lombard, Snyder-Duch, & Campanella Bracken, 2008, for such purposes). The inter-rater agreement (Cohen's kappa coefficient) was found to be .63, which was considered as being substantially concordant.

Relationship of Categories to Views About Diagrams

As previously noted, in part 2 of the questionnaire, Question 1 ("Importance") asked participants how important they considered diagrams in teaching and learning situations, Question 2 ("Experience") asked how much experience they had had in using diagrams, and Question 3 ("Confidence")

asked how confident they felt in using diagrams. The participants were asked to respond on 5-point Likert-type scales where 1 was most negative (e.g., not important) and 5 was most positive (e.g., very important).

For the “Importance” question, the mean response was 4.38 ($SD = .59$), indicating that the participants generally viewed diagrams as being very important in teaching and learning situations. For the “Experience” question, the mean response was 3.44 ($SD = 1.04$), indicating that most of the participants had experiences of occasionally using diagrams. And for the “Confidence” question, the mean response was 2.59 ($SD = .84$), indicating that the participants were generally tending toward being doubtful about their ability to use diagrams well.

To find out whether there were any possible relationships between (i) the categories of statements and ideas that participants produced in free writing about diagrams and (ii) their views about diagrams as gauged in part 2 of the questionnaire, correlations between these were examined.

The correlations between the participants’ use or otherwise of the categories, and their responses to the Likert-type scales used in part 2 of the questionnaire, are shown in Table 2.

Table 2: Correlations between participants’ use of the categories and their opinions about diagrams.

Category Used	Importance	Experience	Confid.
Uses or purposes	.043	.109	.212*
Specific examples	.127	.107	.020
Personal opinions	–.195	–.193	–.160
Structure	–.138	.022	–.004
Unrelated	–.081	.009	–.112

* $p < .05$

The significant correlation found here suggests that participants who wrote statements/ideas about the uses of diagrams also indicated greater confidence in being able to use diagrams.

The correlations between the number of ideas/statements that participants wrote under each of the categories, and their responses to the items in part 2 of the questionnaire, are shown in Table 3.

Table 3: Correlations between number of ideas in each of the categories and opinions about diagrams.

Category	Importance	Experience	Confid.
Uses or purposes	.003	.011	.229*
Specific examples	.118	.095	.021
Personal opinions	–.233*	–.255*	–.212*
Structure	–.086	.068	.050
Unrelated	.051	.064	–.009

* $p < .05$

The significant correlation here between “Uses or purposes” and “Confidence” suggests that participants who

wrote more ideas/statements about the uses of diagrams also possessed greater confidence in their ability to use diagrams. In contrast, the significant negative correlations between “Personal opinions” and “Importance”, “Experience”, and “Confidence” suggest that those who wrote more about their personal opinions about diagrams tended to have lesser appreciation of the value of diagrams in teaching and learning situations, and less experience and lower confidence in diagrams use.

Relationship of Categories to Problem Solving Performance

The mean score for the three problems administered to participants in part 3 of the questionnaire was 2.32 ($SD = .80$). Seventy-three percent correctly solved Problem 1 (heights comparison), 76% correctly solved Problem 2 (paper arrangement circumference), and 83% correctly solved Problem 3 (employment agency placement). In general therefore, the problems appeared quite easy for most of the participants to solve and ceiling effects may have been encountered.

No significant and/or meaningful correlations were found between (i) the categories of statements and ideas that participants produced in free writing about diagrams (both whether or not they used the categories, and the number of statements they made in each of the categories) and (ii) the scores they obtained in their attempts to solve the problems given in part 3 of the questionnaire.

However, when participants were differentiated on the basis of their “math involvement” (i.e., whether or not they were in a math course, or were seeking a math teacher’s license), a significant correlation was found between math involvement and problem solving performance ($r = .28, p < .05$). This suggested the possibility that the relationship between math involvement and problem solving performance was mediated by participants’ knowledge about the uses/purposes of diagrams; thus, a mediation effect analysis (Baron & Kenny, 1986) was undertaken. This revealed that when regression analysis on problem solving performance was carried out only with the math involvement variable, the standardized coefficient was significant ($\beta = .208, p < .05$). However, when the same analysis was done with math involvement and participants’ use (or otherwise) of the uses/purposes category as independent variables, the standardized coefficient of math involvement diminished and became non-significant ($\beta = .198, n.s.$). This finding suggests that the better problem solving performance of participants with math involvement was likely due to their greater knowledge about the uses/purposes of diagrams.

Discussion

How Do People Mentally Represent Diagrams?

Through the statements and ideas that participants in the present study articulated via the free writing task, it can be inferred that they viewed or mentally represented diagrams

in terms of their uses, specific examples of them, personal opinions/experiences of them, and their structure. Almost three-quarters of the participants (74%) wrote something about the uses, purposes or functions of diagrams. This high proportion is probably understandable considering that diagrams are tools or strategies that can serve particular purposes: thus the majority of people are likely to mentally represent them in terms of, or in relation to, those purposes they are aware of.

Just over half of the participants (56%) also provided specific examples of diagrams, either on their own or in relation to other categories of statements/ideas they articulated (i.e., uses, personal opinions, structure). This suggests that many people also mentally represent diagrams in terms of, or in relation to, specific kinds of diagrams they know – or exemplars.

Almost half of the participants (49%) wrote statements and ideas that appeared to fall into a category of being about their personal experiences and opinions about diagrams. Again, it probably makes sense that many people would do this when one considers that people make sense of the world around them through their personal experiences and the resulting opinions that they form. Thus, where tools/strategies are concerned, these are likely to be represented in terms of notions like “helpful” or “difficult to use” depending on their experiences of using these.

Finally, a small proportion of participants (13%) referred to the structure of diagrams, suggesting that such structure formed at least part of their mental representation of diagrams. However it should be noted here that the statements/ideas that participants wrote in relation to structure were fairly general and superficial – mostly just expressing that diagrams represent information in visual or pictorial format. They did not refer to more complex and specific structural qualities/portrayals of diagrams like arrays, sequences, notations, and so on.

Only the four categories of uses/purposes, specific examples, personal opinions, and structure were identified in the written data collected in the present study. However, it is possible that other groups of participants would evidence other categories (different from the four identified here) depending on their knowledge about and experiences in the use of diagrams. It would be important to investigate this in future research.

In the present study, only the participants’ responses in terms of their use of the categories identified, and the number of distinct statements/ideas they wrote that belonged to each of those categories, were coded, analyzed, and reported. However, there are a number of other dimensions of the data that, at the time of writing this paper, the authors had not yet examined. These dimensions include the ‘quality’ of the statements and ideas that participants articulated: for example, participants wrote both fairly superficial as well as more meaningful uses/purposes of diagrams that were not differentiated. Also, most of the statements that participants wrote relating to their personal opinions about diagrams were “negative”; very few could be

considered “positive”. Another potentially important dimension is the connectedness of the statements and ideas – both within and between categories. Although outside the scope of the present paper, it would clearly be useful to examine in more detail the possible effects or relationships that may stem from these other dimensions of the data.

Contributions to Cognitive Research

As noted in the introduction to this paper, no prior research had looked into how people might naturally represent diagrams in their minds. The present findings suggest that such mental representations involve categories of uses or purposes of diagrams for the majority of people. Furthermore, approximately 50% of people would have mental representations that incorporate their personal opinions about diagrams and/or specific examples or exemplars of diagrams. A small minority may also have mental representations relating to the structure of diagrams.

Although at first glance the mental representations suggested by these findings may appear completely different from those identified by Cox and Grawemeyer (2003) through their card sorting task, there are possible connections and congruence between these representations. Firstly, the 9 categories identified by Cox and Grawemeyer pertained to the structure of diagrams – both semantic and superficial. Although only a small proportion, some of the participants in the present study did articulate structure-related statements and ideas about diagrams. Categorizing diagrams according to their structure may be a natural response in a task like the one used in the Cox and Grawemeyer study (where structure may appear as the most salient feature of the stimuli presented). However, diagrammatic structure may also be a natural way of mentally representing diagrams for some people: perhaps for those with limited knowledge/experience about diagrams, superficial structures may be the only salient basis for mental representation. Likewise, for those who have greater than average knowledge/experience about diagrams, the semantic structures of diagrams may in fact be a natural way of mentally representing and organizing diagrams.

Secondly, in the same way that the Cox and Grawemeyer (2003) study identified semantic and superficial distinctions in participants’ responses according to their possession of greater or lesser knowledge about diagrams, it is possible that the same semantic-superficial dimension underpins the participants’ responses across the different categories identified in the present study. Thus, for example, the participants’ responses in the personal opinions category may well differentiate those with greater from those with lesser knowledge and skills about diagrams according to whether the opinions expressed are superficial in nature (e.g., basic references to ease or difficulty) or more meaningful (e.g., pertaining to what they have learnt about themselves or about diagrams). One possibility is that the mental representation of diagrams lies along two dimensions – one dimension being the kinds of categories identified in the present study, and the other being

meaningfulness-superficiality. Future research will need to examine this, and whether other strategies/tools may also be represented mentally in a similar manner.

Contributions to Educational Research

There is evidence in the findings of the present study to suggest that mental representations of diagrams could influence students' views about diagrams as well as their problem solving performance. That responses in the personal opinions category negatively correlated with participants' views about the usefulness of diagrams, and their experiences and confidence in using diagrams, is understandable in light of the fact that the majority of statements/ideas written in the personal opinions category were negative. Many of the participants' more positive personal opinions about diagrams were probably expressed as statements/ideas about their uses – thus falling into the uses/purposes category instead.

The finding that responses in the uses/purposes category not only correlated with confidence in using diagrams, but also appeared to mediate the problem solving performance of those studying math, is likely due to two simple explanations (cf. Uesaka et al., 2007). First, greater knowledge about the uses/purposes of a strategy/tool should promote greater confidence in the use of that strategy/tool. Second, greater knowledge about the uses/purposes of diagrams should enable more appropriate use of them in problem solving situations, which in turn should assist toward better problem solving performance. Further research into the mechanisms of these relationships would be helpful toward the development of their applications in classroom instruction.

Acknowledgments

The authors would like to thank Muneyuki Mizutani and Takahiro Komatsu for their assistance in the collection of data for this study.

Metacognitive Judgments of Improvement are Uncorrelated with Learning Rate

Department of Social and Cognitive Sciences, 5200 North Lake Road
Merced, CA 95343 USA

Abstract

Being able to assess one's own learning rate is essential for optimal learning. Can students accurately assess their learning rate, and is the timing of judgments of improvement important? In this experiment, students were to estimate their learning rate on each trial, either before the trial, or immediately after. If students typically make these judgments before embarking on further study, accuracy might be greater in the predictive judgment condition. No evidence was found that students could accurately judge improvement, in either condition. Implications for models of self regulated learning are discussed in light of these findings.

Keywords: metacognition; self regulated learning; metamemory.

Introduction

Judgments of improvement are metacognitive judgments regarding one's speed of learning. These can be thought of as a student's estimation of how quickly he or she is acquiring more knowledge, or put into practical terms, how useful a given amount of study time is likely to be. These judgments are crucial, as the ability to estimate one's learning rate will affect how well students are able to allocate their time optimally during self regulated learning, which then in turn will influence academic achievement. One such example of how these judgments might inform study time allocation is in the proximal learning model (Kornell & Metcalfe, 2006; Metcalfe, 2002; Metcalfe & Kornell, 2005). In this model, it is proposed that decisions seek to maximize the rate of return per time studied, and those regarding when to switch topics or stop studying may rely on judgments of improvement. This way, students can avoid working in vain while not making progress, and instead move on to more fruitful pursuits. The proximal learning model contrasts with an earlier account, the discrepancy reduction model (Thiede & Dunlosky, 1999), which assumed that students focused on the most difficult items first, and stopped when material reached a satisfactorily high level of learning, thus depending on JOL level to determine stopping times. Additionally, Son and Sethi (2006, in press) have derived mathematically that the most optimal behavior is usually to focus on the items with the highest current rate of return, consistent with the proximal learning model. There is some evidence to support this account, which is sometimes referred to as the shift-to-easier-materials effect; this is the finding that under time pressure, students prioritize by studying the easiest (high

rate of return) items first, before moving on to more difficult material (Metcalfe & Kornell, 2003; Dunlosky & Thiede, 2004; Kornell & Metcalfe, 2006).

However, there is not yet evidence to support the idea of using improvement rates to inform decisions, and current research has not shown that students have the ability to make judgments of improvement accurately in any sense. In our previous work (Townsend & Heit, 2010), participants estimated their amount of improvement after completing each study trial, in a repeated series of study trials for a set of verbal materials. Students' judgments of improvement (or JOIs) were not significantly correlated with actual improvement rates, and in some cases were even negatively correlated. The negative correlation occurred when judgments of learning and judgments of improvements were made using different rating scales, which prevented participants from attempting to infer their JOIs from their judgments of learning. Work by Kornell and Bjork (2009) has also shown that students have difficulties estimating how much they will learn during one or more study trials, dramatically underestimating the usefulness of study. They referred to this type of judgment as a prediction of learning, but the concept is the same. Thus, there is reason to be concerned that students are not able to make the metacognitive judgments that would lead to optimal learning.

Students' post-study JOIs showed an interesting shift from underconfidence to overconfidence over the course of learning (Townsend & Heit, 2010), but predictive JOIs that estimate the fruitfulness of further study may or may not show the same pattern. It is important to assess predictions of future learning (predictive, pre-study trial JOI) rather than just a postdictive assessment of learning during a study trial, as decisions regarding study time allocation may depend more on how much is expected to gain from further study, rather than how much was gained from recent study. This experiment was designed to compare the two conditions to evaluate how (or whether) timing affects JOIs. For comparison, we also collected judgments of learning (JOLs, which are predictions of recall test performance) from an additional group of participants, to compare the relative accuracy of JOIs and JOLs. For example, whereas it may be too difficult for students to judge their level of improvement, they still may be able to judge their level of learning in absolute terms.

Experiment

In this experiment, we compared two different rating scales (percentage vs. absolute number of words), as well as different types of improvement judgments. One might expect that judgments in terms of number of words learned would be easier and more successful, due to their simplicity as well as their close nature to other judgments of optimal foraging (Gigerenzer & Hoffrage, 1995). Judgment types were either postdictive (made after a study trial) or predictive, occurring before the next study trial, i.e. “if you were to study this list for another minute, how much do you think you would improve?” “Answer: I think I would learn another ___% of the material”. Predictive JOIs may be more informative than postdictive JOIs for study decisions, and if students do make predictive JOIs (and not postdictive) they should have better accuracy for this kind of judgment. It may be more likely that students would make predictive JOIs, especially if they are determining whether or not further study would be worthwhile. Type of judgment (Predictive JOI, Postdictive JOI, or JOL) and type of scale (percent or number of words) were both manipulated between subjects.

Method

Participants. 171 students from the subject pool at the University of California, Merced, volunteered to participate for class credit. The number of participants in each condition was as follows: 32 making prospective, percent scale JOIs, 31 making prospective, numerical JOIs, 34 making postdictive percent JOIs, 30 making postdictive numerical JOIs, 23 making percent scale JOLs, and 21 making numerical JOLs.

Materials. A list of 50 Swahili – English word pairs was constructed from the Nelson and Dunlosky (1994) norms. These stimuli have been used in much previous metacognitive research. The list of word pairs was constructed to include a range of difficulty.

Design and Procedure. The experiment consisted of six trials, with each trial consisting of a study phase, judgment phase, and test phase. All manipulations were between subjects. The design was 3 judgment types (predictive JOI, postdictive JOI, or JOL) by 2 scales (absolute number or percentage), so each subject only experienced one judgment type and one scale type for a total of 6 different conditions. For the prospective JOI conditions, each trial consisted of judgment – study – test (with the exception of the first trial, which did not include a judgment). Judgments were solicited with the question “if you were to study this list for another minute, how much do you think you would improve? Answer: I think I would learn another ___[% or words] of the material.”

For the postdictive JOI conditions, each trial consisted of study – judgment – test (with the first trial not including a

judgment). These judgments were made after the question “Compared to the previous trial, what percent more of the list will you be able to recall? Answer: I will recall another ___ % of the list” OR “Compared to the previous trial, how many more words of the list will you be able to recall? Answer: I will recall another ___ words of the list”.

The JOL conditions consisted of study – judgment – test. Participants were asked “What percent of the list will you be able to recall? Answer: I will recall ___ % of the list” OR “How many words of the list will you be able to recall? Answer: I will recall ___ words of the list”.

Scoring. Responses on the test trial were marked correct if they matched the target word. No points were deducted for misspellings. Percentage judgments were converted to number of words for the purpose of analysis.

Results

Preliminary analyses revealed that some participants were not successful in learning Swahili-English word pairs. On this basis, 37 participants were removed from analyses due to either not entering any judgments, responding with the same judgment on each trial, not learning more than 5 words after all 6 trials, or technical errors. There were a total of 25 participants in the predictive JOI – percent judgment condition, 23 in the predictive JOI – numerical judgment condition, 25 in the postdictive JOI - percent rating and 25 in the postdictive numerical rating condition. Finally, 15 participants gave percentage JOL judgments, and 20 gave numerical JOL judgments.

Judgments of Learning. Judgments of learning were compared to recall performance, and significant correlations were found for both percentage ($\rho = .61$, $\min = -.58$, $\max = 1.0$, $SD = .56$, $t(15) = 4.38$, $p < .001$) and number rating conditions ($\rho = .42$, $\min = -.88$, $\max = 1.0$, $SD = .68$, $t(18) = 2.67$, $p < .015$). There was no significant difference between the two conditions, $t(33) = .36$, $p = .72$.

Figure 1: Mean JOL values and recall per trial, percent scale converted to number of words.

Confidence Bias. Relative accuracy of JOLs is not particularly informative, since it is reasonable to assume that participants understand that performance generally increases with each trial. For this reason, we examined absolute accuracy of these judgments as well. Absolute accuracy (in terms of bias) was assessed for JOLs by computing the difference between JOLs and actual recall. For percentage judgments, the percentage was converted to number of words. Biases were also analyzed to see if they differed for judgment type. There was a trend toward more underconfidence for percentage judgments, $F(1, 32) = 3.86$, $MSE = 111.22$, $p = .058$, $\eta^2 = .108$. There was a significant effect of trial, $F(5, 160) = 61.33$, $MSE = 44.76$, $p < .001$, $\eta^2 = .657$. Similarly to previous work that included both JOLs and JOIs (Townsend & Heit, 2010), there appeared to be increasing underconfidence with practice, but with a small upturn on the last trials, as seen in Figures 1 (percentage scale judgments) and 2 (numerical scale judgments).

Figure 2. Mean JOL values and recall per trial, numerical scale

Judgments of Improvement. Judgments of improvement were compared with actual improvement, with no significant correlation found for either judgment type or either scale type. For predictive JOIs, neither percentage (average $\rho = .11$, $min = -.89$, $max = .95$, $SD = .50$) nor numerical judgments (average $\rho = .06$, $min = -.98$, $max = 1.0$, $SD = .52$) were significantly different from zero; for postdictive JOIs, percentage (average $\rho = .05$, $min = -.89$, $max = .95$, $SD = .51$) and numerical (average $\rho = .04$, $min = -.89$, $max = .89$, $SD = .52$) judgments were also non-significant.

Changes in JOLs are a possible basis of judgments of improvement. In this experiment, JOIs and JOLs were made between subjects to avoid influencing participants towards inferring JOIs this way. A between subjects repeated measures analysis of variance comparing mean JOIs and mean JOL difference scores by trial suggests that participants may not have been covertly making JOLs and using them to infer JOIs; $F(1, 125) = 13.302$, $p < .001$, $\eta^2 = .096$.

Figure 3. Average JOIs and improvement values per trial, by judgment time.

Figure 4. Average JOIs and improvement values per trial, by scale type.

JOI Bias. Absolute accuracy for JOIs was examined, and no significant differences in bias were found for judgment type or scale type, though there was a significant effect of trial, $F(3.05, 259.51) = 9.13$, $MSE = 25.34$, $p < .001$, $\eta^2 = .097$. Percentage judgments were converted into number of words for the purpose of comparison. There appeared to be increasing confidence with trial, as illustrated in Figures 3 and 4 which corroborates with the results from previous work (Townsend & Heit, 2010) which found that JOIs increased with trial, and in that case, were correlated with JOLs. Average total bias across participants was $-.2872$, $min = -7.10$, $max = 20.0$, $SD = 4.67$.

The low values for JOI biases may lead one to conclude that judged improvement was very close to actual improvement, despite the low correlations. This would be an erroneous conclusion, however, because an examination of the absolute accuracy (Schraw, 2009) of JOIs (average squared deviations between JOIs and improvement) shows a large discrepancy. The average value of absolute accuracy across participants was 45.68 , $min = -78.8$, $max = 897.0$, $SD = 115.21$. No significant differences in absolute accuracy were found for judgment time, $t(96) = -.262$, $p = .091$, or for judgment type, $t(96) = -.45$, $p = .66$.

Discussion

In this experiment, we failed to find a significant correlation between JOIs and actual improvement. The type of scale (percentage or number of words) did not make a difference for judgment accuracy, nor did the time of judgment; predictive JOIs were no more accurate than postdictive JOIs. In comparison, JOLs made before and after a test have been found to differ (Hacker, Bol, Horgan, & Rakow, 2000). One possible reason for why JOL values differ between pre and post test is that students may routinely make JOLs, assessing how well they are likely to do on exams, and then make post test judgments of performance, e.g. "I think I aced the exam!", and there are more cues with which to base posttest JOLs on, as compared to pretest JOLs (e.g. once they've taken the exam, they know what the actual questions were, how quickly the answers came to mind, etc). In contrast, JOIs may be a judgment that is not made very often, without as many informative cues, and is a judgment on which students don't generally get feedback; JOLs do get feedback over time, as students are given grades on assignments and exams (and this feedback may also help savvy students to learn what cues are more informative). To get feedback on a JOI, it would be necessary to test oneself before and after a study session, and then calculate how much more information was known compared to pre-study. This is a cumbersome and unlikely task for a student to perform; more likely, students will rely upon subjective feelings, like how much more fluent the information seems, how answers may seem to come to mind faster, and perhaps even reduced feelings of anxiety about exams—and without feedback, students cannot learn whether or not these feelings are actually informative.

Other research that has looked at JOI predictions also found judgments to be uncorrelated with actual learning. In Kornell and Bjork (2009), they found a large degree of underconfidence in predictions of learning. Participants in their experiment made their predictions on the first study trial, so their results might not predict how learners will feel about the fruitfulness of study if asked beyond that point. For example, if asked initially about how much they will learn in four study trials, they may be incredibly unoptimistic, but if the students were to be asked after two study trials, they may have different predictions, perhaps based on their subjective experience of the task becoming easier. Kornell and Bjork (2009) showed that JOIs were inaccurate, observing that students were incredibly underconfident when it came to predicting future learning beyond one study trial, but they only experienced one trial at the time of judgment, and did not yet have the experience of repeating study (which is the very thing they are asked about). In our experiment, students made their judgments on each study trial, and a different pattern emerged: a shift from underconfidence in early trials, which is consistent with their results, to overconfidence in later trials. Unfortunately it would seem that experience with the task does not improve JOI accuracy at all, but rather shows a more interesting pattern of inaccuracy.

The inaccuracy of these judgments of improvements has significant implications for models of study time allocation that rely on them; specifically, it is highly unlikely that student behavior would approximate optimality by the use of JOIs. The inability to accurately assess the speed at which one is learning means that learners could not accurately make JOIs to reliably know if further study would be made in vain, and when time would be better spent on a different item or task, leading to much wasted time. Even worse, if students do make JOIs and base decisions on them, they may make bad decisions. Students may give up early in the process of learning (as JOIs are underconfident in the beginning of study), and instead work on better-learned material, on which they persist longer than they should due to overconfidence in the later periods of study. This would lead to very inefficient studying, and could have disastrous results- yet many students do manage to achieve reasonable performance in their courses, so this cannot be the whole story. It may be the case that stopping and switching is based not on explicit JOIs but is done implicitly; Reder and Schunn (1996) suggest that much of metacognitive monitoring and control may actually be implicit. Supporting this somewhat, Payne, Duggan, & Neth (2007), found that in a task switching situation where people performed two different tasks (scrabble and word search), they were sensitive to rate of rewards, and able to spend more time in the easier task. This possibility of implicit control will be investigated in future research that more closely resembles a learning situation, rather than tasks in which participants have such obvious successes and failures.

Whether they are informed by explicit JOIs or implicit control, decisions may also be based on other factors: subjective feelings such as frustration and fatigue, idiosyncratic rules (e.g. study for X amount of time, or until I fall asleep, or all day before the exam), JOLs, or on the results of self-testing. It would also be adaptive if students do not simply stop studying low JOI material, because no learning would take place, and that is not always a viable option. In the cases where the item has a low JOI and a low JOL (meaning that the item is not well learned, and is not being learned very quickly), the ideal behavior would be to change strategies, seek other sources of learning, or the guidance of the instructor.

We also leave open the possibility that students could be taught better study habits, and to make more accurate JOIs. In the framework of Stanovich (2009), otherwise intelligent students may act suboptimally because they lack the "mindware" that allows them to reflect on their own level of learning, simulate the possible consequences of further studying, and override their default study strategies. We are hopeful that at least some of these abilities are teachable. Future research will examine these possibilities.

Abstract

In searching for hidden objects, infants younger than 12 months frequently commit “A-not-B errors,” in which they successfully search for an object in one location (A) and then fail to search for it when it is conspicuously hidden in a new location (B). Why do they fail to make the switch and persevere at the first location? Although these errors have often been attributed to cognitive and conceptual limitations, we suggest that the answer is far more basic: in order to search successfully, children must first learn to do so. In what follows, we present an error-driven learning account of “A-not-B” search which suggests that failing to make the switch is an essential part of learning the appropriate searching cues and contextual search strategies. We elaborate the findings of an eye-tracking experiment with 9 month-olds that behaviorally confirms the predictions of our learning model.

Keywords: error-driven learning; search; A-not-B; feedback

It is Monday morning. You haven't seen your car keys since Friday evening. Where do you look for them? In an ideal world, you will go straight to where you last saw them. As an adult, you will have learned from previous experience that keys are not (usually) assigned random locations, and that what best predicts a key's location is the conjunction of a given spot and that spot being the most recent place the keys were seen. In a less than ideal world, however, you may not remember where you last saw the keys; other memories might compete with your specific memories from Friday. Indeed, when you aren't precisely sure where you last saw the keys, you may check the hook where you usually keep them first, because you know that searching at a location where they keys are seen frequently can (on other days) be a successful search strategy.

This story illustrates the task a child faces in learning to find things in the world. A child must learn that some things are most likely found at the location they were *last* seen,

while other things are most likely found they are most *often* seen (while it makes sense to look for keys in the last place you saw them, if you haven't seen your cat for a while, you would be best off looking in the most frequent place the cat is found), and that a successful search will involve weighing these considerations against what the child remembers about the last and most frequent locations of an object. From this perspective, “perseverative errors,” in which a child searches for an object in a most frequent location rather than a most recent, can be seen as a misapplication of what in other circumstances might be a logical strategy.

Piaget (1954) first described what are often called “A-not-B errors” in infants, namely that 8- to 12-month infants will generally search successfully for an object in an initial location (A) and then fail to search for it when it is conspicuously hidden in a new location (B) instead, continuing to search at location A. Subsequent studies have confirmed that in actively searching for hidden objects, infants robustly commit this prototypical A-not-B error, ignoring the last location of an object when they reach for it (see Marcovitch & Zelazo, 1999 for a meta-analysis). In seeking explanations for this reaching behavior, accounts have tended to assume that infants' errors stem from problems associated with implementing a correct search, such as limited working memory and inhibitory control, or from weak memory traces for the object and hiding location (e.g. Baillargeon, Graber, Devos, & Black, 1990; Diamond, 1988; Diamond, Cruttenden, & Neiderman, 1994; Munakata, 1997; Thelen, Schöner, Scheier, & Smith, 2001).

In what follows, we take a slightly different approach to thinking about the prevalence of the perseverative searching behavior. Rather than assuming that a child “knows” how to search, all other things (object concepts, memory, etc.) being equal, we consider what might be expected when children are *learning how* to search. As noted above, in

learning to find objects, children have to figure out which strategy is appropriate in a particular context.

We consider the question of how children learn to discriminate between possible object retrieval strategies in a given context within the framework provided by formal *learning theories* (e.g. Rescorla & Wagner, 1972), which view learning as a process of acquiring information about the relationships between salient events (*outcomes*) in the environment, and the cues that allow those outcomes to be predicted. From this perspective, children's learning to search is a process of trial and error, each iteration of which strengthens or weakens cues depending on how well they predict an outcome (termed *error-driven learning*). While from an adult perspective, children's "perseverative" search may be erroneous, we suggest that from an infant perspective, their behavior is rational in following the often accurate cue of where something has been found most frequently. In the approach of learning theories, A-not-B "errors" are an inevitable, and logical, step along the path to adult search expertise, as infants go through the process of learning which situational cues best predict an outcome.

Mastering Search

In considering perseveration as part of a logical learning strategy, it is interesting to note that it is also evident when infants learn other (novel) relationships between cues and outcomes, and not just in hiding events. Aguiar & Baillargeon (2000), showed that 7-month-old infants perseverated in pulling a towel that had previously had a toy on it, even when the toy was now visibly on a different towel, and Smith, Thelen, Titzer, & McLin (1999) found that directing infants' attention to lids in an A-not-B pattern drew reaching behavior similar to when objects were hidden. These examples suggest that the perseverative response has more to do with the process of learning where to direct an action than particular properties of the objects or hiding events themselves. Munakata (1997) found that perseveration was reduced if the experimenter waved lids at A, but then hid a toy at B, suggesting that infants learn about particular outcomes at particular locations, such that if a *different* outcome is observed at a new location, it is less influenced by prior evidence.

Thus, it appears that A-not-B errors are not only due to prior motor habit (given that infants can switch when a new object is hidden at the new location), or by infants having trouble conceptualizing objects or not being interested in them (given that they search successfully at the first location). Infants appear to "understand" the task, so *why* do they fail to search correctly after a switch in location?

As we noted above, successfully searching for an object involves weighing a number of cues to its likely location: its last location, its usual location, the independent mobility of the object, etc. If a child doesn't know how to weigh those items correctly in search, then in the early stages of learning within a particular context, cues learned when an object is

hidden at location A and then reappears at A may suggest to the infant that location A is the most *likely* location a hidden object will reappear from. When the object is first hidden at location B, the infant will have no experience of objects reappearing at B, and given that the situational cues provided by an object being at A and an object hidden at B overlap, the infant's best guess ought to be that the object will reappear at A. Given only this information, a child thus *ought* to continue to search at location A when the object has first been hidden at location B.

Over time, if we assume that the child in the A-not-B task is capable of learning (e.g., Rescorla & Wagner, 1972), the error resulting from incorrect searches at location A during trials when the object is hidden and retrieved from location B will *weaken* the cues that continue to predict that an object will be at location A. At the same time, cues supporting the prediction that location B is the correct location will *strengthen*. Eventually, the cues predicting that the object will reappear at location B will have more support than those predicting that it will reappear at A, and the infant will slowly come expect the object at B.

Moreover, since the cues supporting the general "search at the most frequent location" response will generate error over time as hiding locations are switched, while conjunctive cues that support searching at the specific place an object was last seen will continue to be accurate, this process will gradually result in conjunctive cues (that favor the most recent location) over cues favoring search at the most frequent location. Thus, the infant will gradually learn to weigh search strategies within a context from the evidence of their success and failure, and will then come to resemble the adult strategies described above.

Further, although we have talked so far about children 'learning to search,' the evidence is that children do not initially appear to learn abstract, generalized "search." While 9-month-old infants succeed in Aguiar & Baillargeon's (2000) towel pulling task, they still fail the standard A-not-B task (Piaget, 1954), even though the tasks are structurally similar. Rather than learning abstract "search," it appears that children may instead learn search and retrieval strategies within particular contexts.

To formally illustrate how children might learn the appropriate search strategy in the A-not-B task, we simulated this process using the Rescorla-Wagner (1972) learning model. In the model the change in associative strength between a cue C_i and a relevant environmental event E_j given a learning trial n is defined to be:

$$\Delta V_{ij}^n = \alpha_i \beta_j (\lambda_j - V_{total})$$

This rule specifies how the associative strength (V) between individual cues (C_i) and an event (E_j) changes as a result of discrete exposure trials, where n indexes the current trial (V_{total} is the sum of the associative strengths between all CSs present on the current trial and US $_j$). The individual saliency of cues can be denoted by a parameter α_i (where C_i $0 \leq \alpha_i \leq 1$), the rate at which cues are learned with respect to an

event is determined by a learning rate parameter β_j (where $0 \leq \beta_j \leq 1$), and the maximum amount of associative strength that an event E_j can support is denoted by value λ_j , such that the *amount learned* by the set of cues on a given trial is the value of $\lambda_j - V_{total}$, modulated by β and α .

simple cues are weakened because they fail to predict the object location as well as the conjunctive cues.

pool, which reflects the properties of the community surrounding Stanford University.

Stimuli Stimuli were movies of colorful keys, accompanied by music. The keys were familiarized in center screen, and were then shown moving across the screen and disappearing into a bucket on one side of the screen. An identical bucket was present on the other side of the screen.

Following the disappearance of the keys, a pinwheel distracter appeared in the center of the screen for three seconds, then disappeared. For the following four seconds only the buckets were visible, while the music that accompanied the keys was played to encourage searching. After the four-second search period, the keys reappeared from the same bucket into which they had disappeared, before moving back towards center screen. The pinwheel animation then reappeared in center screen and remained until infants' attended to it, at which point the next trial began.

Procedure and design Participants sat on a caregiver's lap during testing, facing a 152cm projection screen, which was approximately 180cm from them. An Applied Science Laboratories (ASL) Model 504 corneal reflection eye tracking system collected eye movement data as infants were shown the stimulus displays. A computer script translated the gaze coordinates recorded by the system into gaze durations to regions of interest (ROI) defined around each of the hiding wells during the 4-second search period after each hiding event.

Infants were shown the key-hiding sequence six times: the keys were hidden twice in the bucket on one side of the screen, and then four times in the bucket on the other side of the screen, mimicking the sequence of a typical A-not-B task. Side of initial presentation was counterbalanced across participants.

Results and Discussion Looking-time data are presented as a difference in milliseconds between the amount of looking to the two ROIs, with positive values reflecting greater looking (bias) towards the A-side, and negative values reflecting greater looking (bias) towards the B side, calculated for each participant on each trial.

For data-analysis, the six trials were grouped into three pairs; the first two trials, in which the keys were shown hidden in location A, are labeled 'A trials'; the two subsequent trials, immediately following the switch to the new hiding location B are labeled 'early B trials'; and the last two trials in location B are labeled 'later B trials.' Because not all of the infant participants provided clean data from all six trials, pairing the trial data in this way allowed some missing cells to be filled in. Data was averaged for both trials if available, but if only one trial of the pair had clean data, then this trial was used.

Although the display shown to the infants was intended to mimic the manual A-not-B search task in presentation, the presentation could not be infant-controlled in the same way that manual studies can. In a manual search task, the toys can continue to be hidden at location A until the infant has reached a success criterion for searching at that location, ensuring that the infant has been attending to, and learning about, the hiding events; however, in the current visual search task, we were unable to employ such a criterion accurately in real time. Therefore, the presentation of hiding events continued without any performance-based contingency. Because our visual search task did *not* require success at location A prior to the switch in hiding to location B, we expected that there might be individual differences among the participants in extent of learning about location A, and that this difference might affect later search behavior. Consistent with the design of our model, we would not expect children to learn about hiding events that occurred at a location to which they were not attending.

We considered two possible measures of how much children learned about hiding events at location A. One that is predicted by the model is that infants who attend more to the actual hiding event, as the keys move towards the location in which it will be hidden, learn more about it. However, infants are capable of deploying covert attention, such that gaze does not necessarily imply attention (e.g. Johnson, M.H., Posner, M. & Rothbart, M.K., 1994). Therefore, we decided to use infants' looking behavior during the search period of hiding events at location A as evidence for how much they learned about those events. Following a hiding event at location A, an infant who looks a lot at the ROI for location A, and little at the ROI at location B, demonstrates a greater expectation for the object to be at (and reappear from) location A – the infant has learned something about what to expect about hiding events in the context! As might be expected, there is a correlation in the trials at location A between how much infants attend to the object as it moves towards a hiding location, and how much they look at location A during the search period ($r=.456, p=.005$), but in terms of making predictions about later search expectations, the actual extent of learning demonstrated during trials at location A seems more directly relevant as a measure, which is why we have chosen to focus on that.

Analysis confirmed that infants in the study varied in how much they looked towards location A during the search period of A trials, with 17 infants who (accurately) looked more at location A and another group of 15 infants who looked more at location B during that search period. An ANOVA comparing the searching patterns across the study between these two groups of infants (who searched differently during A trials) revealed the anticipated difference in the patterns of infants' looking across the study, $F(2,90)=34.597, p<.001$. Accordingly, the children were separated for remaining analyses: an 'attenders' group

of children who looked more to A during the initial search trials, and a ‘non-attenders’ group who looked more to B during the initial search trials even though the keys were hidden at location A.

A further omnibus ANOVA, including attending status as a variable, revealed an overall ‘side’ x ‘time’ interaction, $F(1,92)=2.622$, $p=.022$, and a ‘side’ x ‘attending status’ interaction, $F(1,92)=5.435$, $p<.001$ (Figure 2). These results revealed an overall change in where the infants were looking during the search period across trials, and that this change was driven by the attenders, who searched first at location A and then changed their locus of search over time, as more hiding events occurred at location B. Unsurprisingly, the non-attenders did not change their searching behavior throughout the study.

Figure 2: A plot of the difference in looking time to locations A and B across the visual search A-not-B task, (with the first two trials at location A and the remaining at location B) for each of the two groups (those who searched more at location A during the first two trials, attenders, and those who did not, non-attenders).

An analysis of the visual search of the attenders revealed a change in looking bias across the trials, with decreasing looking to location A, $F(1,49)=14.057$, $p<.001$. Despite this trend however, there was still a main effect of side in the study, $F(1,49)=29.468$, $p<.001$, with significantly more looking to A ($M=2038$ ms) than B ($M=1192$ ms), $t(1,50)=4.611$, $p<.001$, even there are twice as many hiding events at B than at A over the course of the experiment. This overall greater searching at location A within the attending group is noteworthy because it demonstrates the same perseverative trend seen in the typical A-not-B task with manual search. Along with the overall perseverative trend, however, the data are also consistent with the learning model presented. Specifically, children’s searching at the formerly correct location gradually lessens as the cues that predict that location are weakened following hiding events in a new location, and the rate of learning to search the alternative location is also slowed until attention shifts away from the initial location. Individual differences among the

attenders elucidate this learning, with a regression showing that the extent of the searching bias A events “predicted” the extent of bias on early B-trials, $p=.018$, a relationship that was not significant for non-attenders.

The non-attenders, who did not learn about location A or the hiding events that occurred there, were not expected to behave in the same way as the attenders. While these non-attenders showed a main effect of side, $F(1,42)=10.979$, $p=.002$, this resulted from more overall looking to location B, $t(1,43)=7.282$, $p<.001$. More distinctly from the attenders, the non-attending infants did not change their looking bias over the course of the trials in different locations, $F(1,42)=.378$, ns. Since the non-attenders failed to notice the hiding events at A, there was no reason that they should later begin to search there. The fact that the non-attenders do not change their bias over time suggests that changes in search do not result simply from regression to the mean (a possible concern, because groups were split based on early search behavior), but reflect different patterns of learning over time in the two groups.

General Discussion

Children who initially learned about an object hidden at one location continued to search visually at that location even after the object was hidden elsewhere, but then showed a gradual shift in their search behavior away from the initial location and towards the new location. This pattern of data is consistent with the idea that learning is a function of experience and the expectations that experience produces (Rescorla & Wagner, 1972; Ramscar, Yarlett, Dye, Denny, Thorpe, in press; Ramscar & Dye, 2009) and suggests that when infants initially learn that objects will appear from A, they will “perseverate” in that response before gradually learning to predict the objects’ appearance at B. The correlation between the attenders’ bias during A trials and the early B trials, but *not* the later B trials, also supports the idea that the initial bias towards A must be unlearned, and that this will happen only as more hiding / appearance events are shown at location B (see also Diedrich, Thelen, Smith, & Corbetta, 2000). This gradual change in looking preference over time supports our hypothesis that search is something children have to learn, and that success or failure at different kinds of search is, to a degree, a matter of contextual experience.

Our results further suggest that infants given the same exposure to a particular hiding location may actually learn differently about it, in part because of the degree to which they attend to training. This variability in attending might not be evident in a reaching paradigm. For example, the results of a recent A-not-B study by Topal, Gergely, Miklosi, Erohegyi & Csibra (2008) are consistent with the idea that the degree to which children attend to hiding events at location A will impact the degree to which they perseverate in search to that location rather than a new hiding location. In their study, Topal et al. found that infants

who were directed to hiding events with the highest level of engagement (both words and gestures) later showed the greatest perseveration to location A, while a group who saw only gestures was more likely to switch successfully to searching at location B. Although the groups had similar rates of searching at location A, that does not necessarily imply equal attention to or learning about hiding events in that location, because any attention drawn to location A should make a reach there more likely than to another location, given the forced-choice single measure outcome. A more continuous measure of attending or learning during trials at location A, such as eye tracking, could have confirmed whether this later difference in perseveration was because attention was actually increased to location A when the experimenter verbally engaged the infants, thereby increasing their learning about that location, and therefore increasing the time it took them to unlearn their response to location A, therefore leading to the observed greater perseveration to location A after the change in hiding location.

While there is much to explain with regards to the development of children's ability to search—and not least how the learning of conjunctive cues over extended trials might impact performance on the A-not-B task—we believe that there is insight to be gained from seeing infants' behavior in the A-not-B task in terms of *learning* to search, and the patterns of behavior that accompany such learning, rather than as a failure to search correctly. Not only does this approach offer an answer to the often puzzling search behavior of children, but we believe that the combination of eye-tracking and computational modeling methods used in the current study provide a useful formal framework for addressing these questions.

The Impact of Collective Opinion on Online Judgment

Yasuaki Sakamoto (ysakamot@stevens.edu)

Center for Decision Technologies

Howe School of Technology Management, Stevens Institute of Technology
Hoboken, NJ 07030 USA

Abstract

Social media are part of our everyday lives. These technologies allow people to share their opinions with others. Here I examine whether the opinions posted online actually change people's perception of the world or they simply serve as anchors when people post their own opinions. Participants rated the interestingness of given stories. In one condition, the stories were presented with invented average ratings of others that matched the rating task. In another condition, the assumed opinions of others mismatched the rating task. Only in the task match condition, people used the opinions of others when rating the stories. The results suggest that the other's opinions are used as anchors when making judgments and do not influence people's perception as much as one may expect. The current work provides insights into cognitive mechanisms underlying collective behavior in online environments as well as a lesson for users and designers of social media websites.

Keywords: Collective opinion; online judgment; social influence; anchoring and adjustment.

Introduction

Many websites allow users to contribute content. Examples include the product reviews on Amazon, the user ratings on eBay, and the votes for stories on Digg. Although these social media websites are used to share information with others (Glushko, Maglio, Matlock, & Barsalou, 2008), little is known about how people process the opinions of others in online environments. In the current work, I examine whether the opinions posted online actually change the way people perceive the world or they simply serve as anchors when people post their own opinions.

Previous offline studies have suggested that people have a strong motivation to compare their opinions with others (Festinger, 1954). People often adopt the decisions of others (e.g., Cialdini & Goldstein, 2004; Deutsch, & Gerard, 1995; Gureckis & Goldstone, 2006) due to their desire to make correct responses under uncertainty (Sherif, 1935) or their desire to be like others (Asch, 1951; 1956).

More recent work has shown that knowing other's decisions also influences people's decisions online. Salganik, Dodds, and Watts (2006) found in an online market study that whereas good music was always downloaded by many and bad music was always unpopular, the popularities of the pieces in between varied depending on whether or not the number of downloads the pieces had was publicly available. Sakamoto, Sadlon, and Nickerson (2008) showed that only a computational model that assumed that users copied other users' decisions could

account for the popularity of stories in an online community. Sakamoto, Ma, and Nickerson (2009) further showed that participants in their online experiments switched their preferences for stories when the assumed numbers of previous supporters were flipped.

These previous studies clearly show that the opinions of others influence decisions. Nevertheless, it is unclear whether the opinions of others change people's mental representations. For instance, when people become aware that many others like a story and decide that they also like the story, (1) are they simply using the opinions of others as anchors for making their response or (2) do the opinions of others actually change their perception of the story? Relevant to this question, Berns et al. (2005) found changes in the activation of the visual regions of the brain when participants conformed to the majority's decisions, suggesting that the decisions of others might actually influence people's perception of what they saw. On the other hand, the anchoring and adjustment heuristic often observed in decision making (Tversky & Kahneman, 1974) has been proposed as a process consumers use to weight information from others when evaluating products (Wooten & Reed, 1998).

To tease apart the two accounts, the current experiment examined how people behave online using materials from real environments. Participants from an online community (Amazon's Mechanical Turk) were asked to rate the interestingness of stories obtained from another online community (Digg). The assumed opinions of others associated with the stories were manipulated. In the task match condition, the opinions of others took the form of previous average ratings, which matched the rating task the participants completed (see Figure 1). In the task mismatch condition, the opinions of others took the form of the number of previous users who found the story interesting, which mismatched the rating task (see Figure 2). The two conditions differed only in the information about collective opinion associated with the stories.

If people use the opinions of others as anchors to make their own judgments, then the participants in only the task match condition will be influenced by the collective opinion. According to this account, when the format of the other's opinions and the format of the task mismatch, people will not be able to use the previous opinions as anchors to complete the task. This account predicts that whereas the stories associated with higher previous ratings will be rated higher in the task match condition, there will be no influence of collective opinion in the task mismatch condition.

Figure 1: Four news stories presented to the task match condition are shown. The information about the collective opinion matches the rating task. The first and third stories have lower previous ratings than the second and fourth stories.

In contrast, if the opinions of others actually change the participants' representations, both the task match condition and the task mismatch condition should show influence of collective opinion. This is because according to this account, knowing the other's opinions lead to actual changes in people's perception, and such changes will transfer across tasks that differ on the surface. In this way, the current work will provide new insights into cognitive mechanisms underlying collective behavior in online environments as well as a lesson for users and designers of websites.

Method

Participants

Two hundred and seven (109 females and 98 males, $M = 31$ years old, $SD = 11$ years) members of Amazon's Mechanical Turk community ([www.mturk.com](#)) completed the experiment. They earned 10 cents for participation.

Figure 2: Four news stories presented to the task mismatch condition are shown. The information about the collective opinion mismatches the rating task. The first and third stories have fewer supporters than the second and fourth stories.

Materials

Six news stories were selected randomly from an online community ([www.digg.com](#)) with the constraints that they (1) were not about exceptional events, (2) were not promoted to the front page, (3) were submitted to the community on the same date, and (4) had between 3 and 5 supporters in the community. These constraints were used to minimize the possibility that participants were already familiar with and had strong opinions about the stories.

Design and Procedure

Table 1 summarizes the manipulation of collective opinion in the current work. There were three conditions: task match, task mismatch, and control. The same six stories were used in the three conditions. To measure any differences in interests among groups, no information about the opinions of others was provided for the same two stories in all groups (Story X and Story Y in Table 1). Collective opinion was manipulated for the remaining four stories (Story 1 – 4 in Table 1). No information about the opinions of others was given in the control group.

Condition		Story X	Story Y	Story 1 (A)	Story 2 (B)	Story 3 (A)	Story 4 (B)
Task match	Low-high	–	–	2	4	2	4
	High-low	–	–	4	2	4	2
Task mismatch	Low-high	–	–	82	2377	85	2412
	High-low	–	–	2377	82	2412	85
Control		–	–	–	–	–	–

Table 1: Manipulation of collective opinion is summarized. Each value represents the average interestingness rating of the story in the task match condition, and the number of people who found the story interesting in the task mismatch condition. A dash indicates that no information about collective opinion was provided. Story X and Story Y were used to measure if the three groups differed in their interests. Stories 1 and 3 are grouped as Story A because they are the same type within each condition. For the same reason, Stories 2 and 4 are grouped as Story B.

In the task match condition, the four stories were associated with the invented average interestingness ratings from previous raters. This information about collective opinion matched the interesting rating task the participants completed. Although the stories selected had similar number of supporters in Digg, suggesting that they are similar in popularity, some stories might be inherently more interesting than others for some participants. To cancel out any effect due to the difference in stories, the assumed information about collective opinion was counterbalanced. In the low-high group in the task match condition, the previous ratings were 2, 4, 2, 4 for the first, second, third, and fourth stories, respectively, as shown in Table 1. In the high-low group in the task match condition, the previous ratings were 4, 2, 4, 2 for the first, second, third, and fourth stories respectively, the flip of those in the low-high group.

In the task mismatch condition, the four stories were associated with the invented number of people who found the stories interesting, which mismatched the rating task. As shown in Table 1, for the low-high group in the task mismatch condition, the number of people who found the stories interesting were 82, 2377, 85, 2412 for the first, second, third, and fourth stories, respectively. In the high-low group in the task mismatch condition, the number of people who found the stories interesting were 2377, 82, 2412, 85 for the first, second, third, and fourth stories, respectively. The first and third stories are grouped as Story A because they are the same type within each condition. For the same reason, the second and fourth stories are grouped as Story B.

The results from previous studies (e.g., Sakamoto et al., 2009) suggest that in the task match condition, whereas the low-high group will provide lower ratings on the first and third stories (Story A) than on the second and fourth stories (Story B), the high-low group will provide higher ratings on Story A than on Story B. Thus, there will be an interaction between Group (low-high vs. high-low) and Story (A vs. B) in the task match condition. Whether this interaction will result in the task mismatch condition is unclear. If knowing the collective opinions of others can indeed change people's internal representations, then there should be an interaction in the task mismatch condition. This is because if knowing

how many people think a story is interesting indeed changes one's perception of the story, this change should influence her responses when she rates the interestingness of the story. Failure to find an interaction in the task mismatch condition suggests that knowing the opinions of others merely anchors people's responses in a task that is compatible with the format of the opinions. The control group's responses will provide the baselines for the interestingness of the stories.

Participants completed the experiment online. They were instructed to read six brief news stories and rate the interestingness of the stories using a 5-point scale. The instruction for the task match condition informed the participants that the previous ratings indicated the average ratings of previous readers. The instruction for the task mismatch condition informed the participants that the number of people indicated how many readers found the stories interesting previously. The instruction for the control group contained no information about the opinions of others. The first two stories were the ones used to measure whether the groups differ in their interests and had no information about the other's opinions in all groups. Then, the participants rated the four stories. Finally they completed the questions asking demographic information.

Results

All participants were included in the analyses. The groups did not differ in their ratings for the first two stories ($F < 1$), suggesting that the groups did not differ in their interests. I first present the results from analyzing the task match condition. One interest is whether the current work replicates previous findings (Sakamoto et al., 2009) that one can influence people's judgment by manipulating the information about the opinions of others. A 3 by 2 Analysis of Variance (ANOVA) was performed on the task match condition's interestingness ratings, with Group (task match low-high vs. task match high-low vs. control) and Story (A vs. B) as independent variables. The main effect of Group approached significance, $F(2, 123) = 2.79$, $p = .07$. As shown in Figure 3, the control group had overall higher ratings than the other groups. Perhaps people tend to use higher end of scales in these tasks, and the invented previous ratings shifted their responses down. Alternatively,

all stories might have been quite interesting to the participants, and the information about the previous ratings could only lower their ratings. There was no significant main effect of Story, $F < 1$. As predicted, there was a significant interaction, $F(2, 123) = 5.75, p = .004$. As can be seen in Figure 3, whether Story A or B was rated higher depended on the type of the Group. As predicted, whereas the low-high group rated Story B higher than Story A, the high-low group rated the rated Story A higher than Story B, $F(1, 83) = 5.96, p = .017$. The participants conformed to the opinions of others.

Further analyses revealed that whereas the high-low group rated Story A significantly more interesting than Story B, $t(41) = 2.03, p = .049$, the difference in the low-high group's ratings on Story A and Story B did not reach significance $t(42) = 1.40, p = .17$. Unexpectedly, the control group rated Story B significantly more interesting than Story A, $t(40) = 2.73, p = .009$. The information about the opinions of others in the low-high group was consistent with the participants' ratings without social influence. Thus the previous ratings might have provided no new information to the participants in the low-high group.

It is surprising that the high-low group in the task match condition shows the opposite pattern from the natural ratings shown by the control group. The participants in the high-low group were willing to rate Story B less interesting than Story A consistent with the invented collective opinions, even though the invented collective opinions went against the true collective opinions suggested by the control group's ratings. This suggests that either the participants did not have strong opinions about these stories, or the desire to conform was so strong that they gave untruthful ratings. The results from the task match condition showed that the participants conformed to the given information about the opinions of others.

Our main interest is whether a similar pattern of results can be found in the task mismatch condition. Figure 4 shows that the pattern of results for the task mismatch condition was rather flat. A 3 by 2 ANOVA was conducted on the task mismatch condition's interestingness ratings, with Group (task mismatch low-high vs. task mismatch high-low vs. control) and Story (A vs. B) as independent variables. There was no significant main effect of Group, $F < 1$. There was a significant main effect of Story, $F(1, 119) = 6.95, p = .009$. Figure 4 shows that collapsing across Group, Story B has overall a higher rating than Story A. However, the effect of Story was mostly due to the control group. Both the low-high group and the high-low group did not differ significantly in their ratings of Story A and Story B, $t(40) = 1.41, p = .17$, and $t < 1$, respectively. As can be seen in Figure 4, there was no significant interaction, $F < 1$. The similar pattern of ratings in the three groups in the task mismatch condition indicates that knowing how many people found the stories interesting had little influence on the participants ratings.

Discussion

In the current study, the participants rated the interestingness of stories with varying information about the opinions of others. In one condition, the information about other's opinions matched the rating task they were asked to complete. In another condition, the information about the other's opinions mismatched the format of the rating task. In this way, I examined whether the opinions of others could actually change the way people perceived the world, or they simply served as anchors when people made their own judgments. The results were consistent with the latter hypothesis. Only when the format of the information about the opinions of others matched the format of the rating task, the opinions of others had significant influence on the participants' judgments.

One might say that perhaps knowing the number of previous readers who found the stories interesting simply do not influence people's judgment. However, previous work showed that information about the number of people who liked a story had significant influence on which of two stories the participant liked better (Sakamoto et al., 2009). Thus, I predict that knowing the number of previous people who have found the stories interesting will influence people's responses on a binary decision task that asks which of the two stories they find more interesting. I further predict that information about the previous ratings will have no significant influence on such binary tasks because the information and the task mismatch in this case. Data from these two groups are being collected right now.

The current work provides insights into cognitive mechanisms underlying collective behavior. Anchoring and adjustment (Tversky & Kahneman, 1974) may be one cognitive mechanism that drives preferential attachment, (Barabási & Albert, 1999), which characterizes the rich-get-richer effect observed in real social networks. Further, the current findings extend existing theories of social influence by suggesting that social influence is not as internal as one may think.

The current results may also have connections to other cognitive theories. The finding that the information about other's opinions must match the task to have influence might be related to the idea of transfer appropriate processing from the memory literature (Morris, Bransford, & Franks, 1977). In transfer appropriate processing, performance is improved not only by the depth of processing but also by the extent that the format of initial encoding of information matches the format of later retrieval. Analogously, the current work suggests a kind of transfer appropriate processing in online social influence: the information about other's opinions needs to match the online judgment task.

Figure 3: The low-high group, the high-low group, and the control group's interestingness ratings in the task match condition are shown for Story A and Story B. Error bars represent the 95% confidence intervals (Loftus & Masson, 1994). The low-high group thought Story A was rated less interesting than Story B. The high-low group thought the opposite. The control group had no information about the previous ratings.

Figure 4: The low-high group, the high-low group, and the control group's interestingness ratings in the task mismatch condition are shown for Story A and Story B. Error bars represent the 95% confidence intervals (Loftus & Masson, 1994). The low-high group thought fewer people found Story A interesting than Story B. The high-low group thought the opposite. The control group had no information about the previous ratings.

The idea of alignability in analogy also has a bearing on the current findings. Two things are alignable when they have common dimensions. For example, knowing that the previous rating of a story is 4 and the task of rating the interestingness of a story using a 5-point scale are alignable. On the other hand, knowing the number of people who found the story interesting and the task of rating the interestingness of a story using a 5-point scale are nonalignable. Work in analogy has shown that alignability plays major roles in memory retrieval (Markman & Gentner, 1997) and preference formation (Zhang & Markman, 1998). The current work suggests that alignability also plays an important role in people's use of other's opinions.

Related to the idea of transfer appropriate processing and alignability, previous studies in social influence have shown that only other's decisions that are relevant have influences on decisions (Cialdini, 1998; Cason & Mui, 1998). Although the social information in both the task match condition and the task mismatch condition was relevant to the interestingness task, perhaps the participants did not regard the number of previous readers who found the stories interesting as appropriate information for the rating task.

The present study also provides useful information for users and designers of websites. Many people use online stores, such as eBay and Amazon, which provide information about collective opinion in the forms of reviews and ratings, and by listing the top selling items or the number of items available in stock. Knowing the responses produced by others can bias people's sampling of information (e.g., Lewandowsky et al., 2009; Stasser & Titus, 1985). The current results show that not all outputs by others influence people's behavior in the same fashion. The information about other's opinions needs to align with the response task to have significant influence on people's response. This is a note for the designers of social media websites, whether they want to encourage or minimize online social influence, as well as for marketers who want to take advantage of social media.

The users of social media websites may also find the current findings useful. Often times, users put too much attention to the opinions of others and too little attention to the actual content of the item (Sakamoto et al., 2009). By doing so they may be creating a trend for an item whose content is not so great. Knowing the present findings, users may be able to focus more on the content and less on what others think.

Perhaps people's desire to attend to the other's opinions survived for a good reason. Observing and imitating others

can allow people to try out solutions that they would not have considered otherwise (Bandura, 1965). Solutions selected by many people are often useful. Collective opinion of a community can be more informative than the opinions of a few experts (Surowiecki, 2004). Learning from the previous outputs of others is considered as a process for the creation of innovative solutions (Kraatz, 1998), the evolution of language (Smith et al., 2003), and the development of culture (Dennett, 1995).

In conclusion, we are surrounded by the opinions of others in online environments. Although online decisions are usually made privately and anonymously, online users influence and are influenced by their opinions as in offline environments. We need to know more about how people process collective opinion in online environments.

Enhancing Acquisition of Intuition versus Planning in Problem Solving

Dawn Chen (sdchen@ucla.edu)

Keith J. Holyoak (holyoak@lifesci.ucla.edu)

Department of Psychology

University of California, Los Angeles

Los Angeles, CA 90095 USA

Abstract

The acquisition of intuition, which guides problem solving by pruning unpromising strategies, is essential to the development of expertise in any domain. Problem-solving intuition may be viewed as analogous to search heuristics in artificial intelligence. One prediction inspired by this analogy is that practicing on subproblems and relaxed problems (versions of a problem with fewer constraints on the goal state and on the possible moves, respectively) may enhance the development of intuition for the full problem. Using the n -puzzle, we found that practice on relaxed problems did promote intuition compared to practice on the full problem, but impaired performance on solving the full problem. More detailed analyses suggest that practice on relaxed problems may discourage planning and encourage reliance on intuition. Planning is slower but more likely to produce optimal solutions if given enough time, whereas relying on intuition is faster but may lead to suboptimal solutions.

Keywords: Problem solving; intuition; planning; learning; heuristic search; n -puzzle.

Introduction

When encountering a problem in an unfamiliar domain for the first time, the novice may feel lost among what seems to be an indefinitely large number of possible actions that seem about equally promising, and end up pursuing some arbitrary path that leads nowhere. But after solving some number of problems from the same domain, the solver will eventually learn to consider only a limited number of approaches, those that are likely to prove effective. In commonsense terms, the learner has acquired *intuition* about the problem domain: an implicit sense of what to do in various types of situations that arise during problem solving (Gobet & Philippe, 2009). How is such intuition acquired through practice?

The standard account of general problem solving is Newell and Simon's (1972) proposal that the problem solver performs search within a problem space. A problem space can be visualized as a graph or tree in which the nodes represent possible states in the problem and each edge represents a legal move transforming one state into another. The legal moves in a problem are defined by its *operators*, or possible types of actions. The problem solver can search the problem space by starting at the node representing the initial state of the problem and moving to adjacent nodes by applying operators, until one of the nodes representing a goal state is reached. The solution to the problem is the successful path that the solver took through the problem-space graph.

Importantly, the problem solver may search the problem space not only by physically manipulating the external representation of the problem state (*external search*), but also by mentally transforming an internal representation (*internal search* or *planning*). During internal search, the problem solver need not always move from the current state to an adjacent node.

For most realistic problems, the problem-space tree is enormous, so that it is terribly inefficient even for a computer to solve the problem by using brute-force search algorithms that traverse the entire tree until a goal state is found. Heuristic search algorithms, on the other hand, are much more efficient because they use domain-specific knowledge to prune branches of the tree that never lead to the goal state or do not do so in an optimal way (i.e., in the minimum number of moves). A search heuristic may guide search by estimating the *distance* (minimum number of moves required) from any state to the goal so that, for example, a search algorithm can always choose to explore next the state that is closest to the goal (i.e., the greedy best-first search algorithm). This form of a search heuristic, commonly used in artificial intelligence, is called a *heuristic function*.

In many ways, the formal concept of a search heuristic is closely related to the commonsense concept of intuition in problem solving. Search heuristics prune branches in the problem-space tree that are unlikely to lead to the goal efficiently, just as problem-solving intuition focuses attention on just those paths that are likely to lead to a solution quickly. Search heuristics are usually fast to compute, but may lead to suboptimal solutions. Similarly, intuitive judgments arise quickly, but are fallible and may result in diminished accuracy or optimality compared to a solution strategy based on systematic analysis or careful planning. Furthermore, just as search heuristics rely on domain-specific knowledge, problem-solving intuition is restricted to a particular domain and is acquired only through multiple experiences with solving problems in that domain. Nonetheless, certain search heuristics are more general than others and apply to several domains with overlapping structure, just as the intuition gained from solving problems in one domain may apply to a related domain (see Hatano & Inagaki, 1986, for a discussion of routine vs. adaptive expertise). Finally, and most importantly for the present study, heuristic functions yield estimates analogous to the intuitive sense of closeness to the goal available to experienced problem solvers. The task we use to assess intuition will be based on subjective judgments of distance to the goal state.

The analogy between problem-solving intuition and search heuristics provides insights into how it might be possible to facilitate the acquisition of intuition in human problem solving. AI researchers have discovered that the solution lengths of *subproblems* and *relaxed problems* often provide good heuristic functions for the original problem (Prieditis, 1993). A subproblem removes one or more constraints on the goal state from the original problem, whereas a relaxed problem removes one or more constraints on the legal moves (i.e., it adds one or more operators). Thus, an instance of the original problem can be solved in fewer moves when translated into a corresponding subproblem or relaxed problem.

Applying the results from AI to the domain of human problem solving, solving subproblems and relaxed problems may facilitate the acquisition of intuition for the original problem. Therefore, learners who practice solving subproblems or relaxed problems may acquire better intuition for the original problem than those who receive the same amount of practice on only instances of the original problem. At the same time, planning may seem less necessary when solving subproblems and relaxed problems. Thus, the kind of learning experience that fosters development of intuition the most may also have a detrimental impact on planning. We will elaborate on these points in discussing our experimental findings.

Method

Participants

Seventy-two undergraduates from the University of California, Los Angeles participated for course credit. Participants were randomly assigned to either the control condition ($n = 24$), the subproblem condition ($n = 24$), or the relaxed problem condition ($n = 24$).

Materials

The n -puzzle Participants solved a computer version of the n -puzzle, which is illustrated in Figure 1. The n -puzzle consists of a square bounded space containing a smaller empty square and n initially misplaced square tiles numbered 1 to n . A legal move consists of sliding any tile into the empty square, and the goal state contains all the tiles in ascending order.

7	8	

goal state

Figure 1: An 8-puzzle with a 5-step solution: Move 4 down, 1 left, 2 up, 5 left, and 6 up.

Subproblems and Relaxed Problems In the subproblems for the n -puzzle, participants were required to move only some of the tiles into their correct places. In the relaxed

problems, participants could swap some of the tiles with adjacent tiles, in addition to sliding any tile into the empty square. These *swappable* tiles were displayed in a lighter color than the non-swappable tiles. Defined in this way, a subproblem that removes k goal constraints requires moving tiles 1 through $n - k$ into their correct places, and a relaxed problem that removes k move constraints contains one empty square and k tiles that can be swapped with neighboring tiles.

Generation of Puzzles All puzzles were generated randomly. The optimal A* search algorithm was used to ensure that each puzzle had the desired minimum solution length.

Procedure

All instructions and stimuli were presented on a computer, and participants responded using a mouse. In each condition, the participant was first given instructions on how to solve the type of puzzles (full, subproblem, or relaxed problem) in that condition. The participant then attempted to solve an initial 8-puzzle of the appropriate type, solvable in a minimum of three moves. An experimenter ensured that the participant understood the instructions and could solve the initial puzzle. In the subproblem condition, the initial puzzle required tiles 1-4 to be moved into place. In the relaxed problem condition, tiles 5-8 were swappable. That is, the number of constraints removed, k , was four for the initial puzzle in both the subproblem and relaxed problem conditions. After solving the initial puzzle, the participant took part in a training phase, a test phase, and finally an intuition assessment phase.

Training Phase The participant was told that more puzzles would now be given for practice, with a time limit of one minute and 30 seconds for each. The participant was told to solve each puzzle in as few moves as possible, and that there would be a penalty for every extra move made. These instructions were designed to discourage external search (the usual strategy for solving n -puzzles) and encourage internal search, which has been shown to enhance learning (O'Hara & Payne, 1998).

The participant then attempted to solve a sequence of 12 8-puzzles. In all conditions, the minimum solution lengths (a measure of difficulty) of the puzzles increased from 4 to 10 (i.e., the puzzles in the experimental conditions were not subproblem or relaxed versions of those in the control condition). In the experimental conditions, k also decreased from four to zero across the puzzles. During the presentation of each puzzle, the minimum solution length and the number of moves the participant had made so far were shown above the puzzle. After the participant solved each puzzle or the time limit expired for that puzzle, a dialog box informed the participant which event had occurred, the number of extra moves the participant made (if the puzzle was solved), and in the subproblem condition, the tiles to

slide into place for the next puzzle. The participant could then take a break and click on a button to start the next puzzle when ready.

Test Phase After all 12 puzzles in the training phase had been presented, participants were told that there would now be a test, with the same instructions as for the practice puzzles. In the subproblem condition, participants were told to slide all tiles into place. Participants in all conditions then attempted to solve the same sequence of 12 full n -puzzles. The first six were 8-puzzles and the last six were 15-puzzles, and all puzzles could be solved in 12 moves. After each puzzle had been solved or had timed out, the next puzzle was presented without any feedback or time to rest. During both the training and test phases, the computer recorded for each puzzle whether it was solved, the solution time, the moves the participant made, the initial latency (the amount of time the participant took to make the first move), and the inter-move latencies (the time to make each subsequent move).

Intuition Assessment Phase After the test phase, participants made a series of 40 *pairwise distance comparisons*. In each comparison, they were presented with two different puzzle states and had to click on the one that they believed was closer to the goal within a short time limit. No feedback was given. The short time limit was designed to elicit a quick, intuitive judgment and prevent participants from solving the puzzles mentally and then counting the number of moves used. Because experts in a domain often have an intuitive sense of how close they are to solving a problem, and heuristic functions estimate the distance of any given state to the goal, this distance comparisons task serves to assess participants' intuition on the n -puzzle.

The first 20 pairs to be compared were 8-puzzles, with 10 seconds each, and the last 20 pairs were 15-puzzles, with 12 seconds each. The true distances of the puzzles ranged from 1 to 28, and the ratio of the shorter distance to the longer distance in each pair was between .2 and .91. For each comparison, which puzzle was chosen and the time taken to make that choice were recorded.

Results and Discussion

Dissociation of Performance on Solving Puzzles and Comparing Distances

The mean percentage of full n -puzzles solved during the test phase in each condition is shown in Figure 2. The relaxed problem group solved a significantly lower percentage of puzzles during the test phase ($M = 57.99$, $SD = 23.25$) than the control group ($M = 69.79$, $SD = 14.08$), $F(1, 69) = 5.18$, $p = .026$, and also the subproblem group ($M = 68.75$, $SD = 15.20$), $F(1, 69) = 4.30$, $p = .042$. The latter two groups did not differ reliably.

However, as shown in Figure 3, the relaxed problem group correctly solved the most problems on the distance comparisons task, which assesses intuition. The percentage

Figure 2: Mean percentage of n -puzzles solved by participants in each training condition during the test phase. Error bars in all data figures represent 1 standard error of the mean.

Figure 3: Mean percentage of comparisons solved correctly on the distance comparisons task in each condition.

of comparisons correct was significantly higher for the relaxed problem group ($M = 68.33$, $SD = 6.94$) than for the control group ($M = 63.44$, $SD = 10.47$), $F(1, 69) = 4.22$, $p = .044$. Performance of the subproblem group on the comparisons task fell between that of the other two groups, but did not differ significantly from either.

To further investigate the difference in performance on the distance comparisons task, we divided the pairwise distance comparisons into an “easy” set and a “hard” set based on the overall performance of the participants on each comparison. For each comparison problem, we calculated the proportion q of participants (over all three conditions) who solved that problem correctly. We then calculated the median value of q over all comparisons. A comparison that

Figure 4: Mean percentage of hard comparisons solved correctly on the distance comparisons task in each condition.

had a q -value higher/lower than the median was assigned to the “easy”/“hard” set. All groups performed about the same on the easy comparisons, but as Figure 4 shows, the relaxed problem group performed the best on the hard comparisons. In particular, the relaxed problem group correctly solved a significantly higher percentage of the hard comparisons ($M = 57.71$, $SD = 10.63$) than the control group did ($M = 49.79$, $SD = 13.47$), $F(1, 69) = 6.00$, $p = .017$. Thus, the relaxed problem group performed very well on the intuition task, especially the harder problems, compared to the control group.

How could participants in the relaxed problem group have apparently acquired such good intuition on the full n -puzzle, and yet perform relatively poorly in actually solving it? A possible explanation is that because planning (internal search) is harder and seemingly less necessary when solving the relaxed problems, participants in the relaxed problem group learned to plan less and rely more on their intuition during the training phase. Thus, even though their intuition became more developed (as evidenced by their performance on the distance comparisons task), their decreased use of planning caused them to perform poorly on solving the puzzles in the test phase. Participants in the control group, on the other hand, learned to rely more on planning and less on their intuition during the training phase, because they were trying to minimize the number of moves they made and it was easier for them to plan. Increased planning led them to perform better on the test puzzles, but their intuition was less developed. We will now present evidence to support each of these claims.

The Relaxed Problem Training Condition Discourages Planning

Planning is Harder on Relaxed Problems This is true for two reasons. First, internally visualizing the move of

swapping two tiles in the relaxed problem imposes a greater working memory load, because the participant must now keep track of the new locations of both tiles, rather than just one tile in the sliding move. Manipulating an internal representation of the puzzle state to reflect a swapping move might take longer as well. Second, the introduction of additional legal moves in the relaxed problem also makes planning harder because participants have to consider more moves at each state (that is, the *branching factor* is higher). In order to plan, participants must also remember more information about which paths they have already mentally explored to some depth and have determined to be unpromising.

The hypothesis that the swapping move consumes more working memory is supported by the finding that the average length of unbroken sequences of backtracking moves during the training phase was significantly lower in the relaxed problem group ($M = 1.34$, $SD = .36$) than in the control group ($M = 1.88$, $SD = 1.11$), $F(1, 61) = 4.66$, $p = .035$, and also the subproblem group ($M = 2.04$, $SD = .82$), $F(1, 61) = 8.93$, $p = .004$. In contrast, no reliable differences among conditions were observed in the test phase. Backtracking for a number of moves requires remembering all those previous moves, and participants solving relaxed problems may have backtracked for fewer moves because they could not remember as many past moves, since storing a single move requires more working memory capacity on average.

Planning Seems Unnecessary on Relaxed Problems

Because relaxed problems have a higher branching factor, the problem-space graphs for relaxed problems are more connected and so there are more ways to reach the goal state. Thus, it may seem unnecessary to plan one’s moves before executing them, since no matter how far away one wanders from the goal, there is always some way to get back onto the right track. In other words, local minima do not exist in the problem space, so a greedy (hill-climbing) search algorithm that always chooses the state with the shortest estimated distance to the goal to explore next cannot become trapped, and is thus sufficient. Accordingly, participants in the relaxed problem group probably learned to use a greedy search algorithm, which does not look ahead and thus requires little effort. Moreover, a greedy search algorithm relies heavily on the heuristic function, so its use would foster development of intuition for participants in this condition.

One piece of evidence that participants in the relaxed problem group planned less than those in the other conditions is that they made extra moves more often during the training phase. The percentage of solved puzzles in the training phase that were solved with extra moves was significantly higher in the relaxed problem group ($M = 49.99$, $SD = 19.76$) than in the control group ($M = 20.92$, $SD = 13.67$), $F(1, 69) = 34.53$, $p < .001$, and also the subproblem group ($M = 25.97$, $SD = 17.43$), $F(1, 69) = 23.58$, $p < .001$. Furthermore, the relaxed problem group had significantly higher average solution times during the

training phase ($M = 35.23s$, $SD = 9.07s$) than did the control group ($M = 27.68s$, $SD = 8.29s$), $F(1, 69) = 9.86$, $p = .002$, and also the subproblem group ($M = 24.64s$, $SD = 7.53s$), $F(1, 69) = 19.41$, $p < .001$. Participants in the relaxed problem condition may have found planning harder and thus took longer on average to plan a single move (when they did plan); in addition, their longer, less optimal solutions took more time to execute. These differences indicate that the relaxed problem participants did not or could not plan as far ahead as did the participants in the other conditions, and tended to meander around the problem space for a while before reaching the goal.

The average initial latency on a puzzle, or the average amount of time a participant spent thinking before making the first move on a puzzle, is a clear indicator of how much a participant plans voluntarily. (While the average inter-move latency is also an indicator of planning, higher inter-move latencies could also indicate that the participant was stuck in the middle of solving a puzzle and was forced to think carefully about what to do next.) The average initial latency was not significantly lower for the relaxed problem group during the training phase, as might be expected if these participants were planning fewer moves ahead; however, the lack of a difference could reflect the offsetting effect of planning each move being harder for the relaxed problems and thus taking longer. During the test phase, when all participants were solving the full n -puzzles, the average initial latency was indeed significantly lower for the relaxed problem group ($M = 10.37s$, $SD = 4.46s$) than for the control group ($M = 14.75s$, $SD = 6.02s$), $F(1, 69) = 7.33$, $p = .009$, indicating that the relaxed problem group continued to plan fewer moves ahead during the test phase.

Increased Planning is Associated with Better Puzzle-Solving Performance

Not surprisingly, increased planning is associated with better puzzle-solving performance. The average initial latency was not correlated with the number of puzzles solved during the training or test phase, perhaps because some participants tended to get stuck at the very beginning and could not solve many puzzles, or were just too slow in general to solve many puzzles. However, average initial latency was negatively correlated with performance measures such as the average number of extra moves made on solved puzzles [$r(70) = -.37$, $p = .002$ for the training phase and $r(70) = -.46$, $p < .001$ for the test phase], and the percentage of backtracking moves [$r(70) = -.26$, $p = .026$ for the training phase and $r(70) = -.31$, $p = .007$ for the test phase]; and positively correlated with the percentage of moves that decreased the true distance of the problem state to the goal [$r(70) = .33$, $p = .005$ for the training phase and $r(70) = .47$, $p < .001$ for the test phase]. These results indicate that the more the participant planned before making the first move, the better the moves the participant made later on.

Recall that on relaxed problems, which do not have many local minima, a greedy search algorithm is sufficient.

However, greedy search may get stuck in local minima on the full n -puzzle, for which the problem-space graph is not as well-connected. Accordingly, if participants in the relaxed problem group did indeed use a greedy search algorithm, they would perform poorly during the test phase. The control group, on the other hand, may have learned to use a more effective search algorithm involving greater look-ahead. Such a search algorithm could achieve an acceptable level of performance with a relatively poor heuristic function. Thus, participants in the control condition would not acquire intuition during the training phase to the degree that those in the relaxed problem group did.

Planning and Intuition are Dissociated

For every participant, we calculated a composite score on the intuition task by summing the values of $1 - q$ for all comparison problems that the participant solved correctly. Recall that for each comparison, q is the proportion of all participants who solved that comparison correctly. Thus, $1 - q$ is the estimated probability of choosing the incorrect response on a given comparison, an empirical measure of its difficulty. Therefore, the composite score on the intuition task gives greater weight to more difficult problems.

We calculated correlations between the composite intuition score and measures of planning for each training condition separately to test whether planning and intuition are dissociated within each group. The following correlations appeared for measures of planning during the training phase: The composite intuition score for the control group was negatively correlated with the average initial latency, $r(22) = -.41$, $p = .047$, as well as the average inter-move latency, $r(22) = -.47$, $p = .021$. For the subproblem group, the composite intuition score had a negative correlation with the average inter-move latency, $r(22) = -.50$, $p = .013$, and a near-significant positive correlation with the percentage of puzzles that were solved with extra moves, $r(22) = .40$, $p = .055$. Finally, for the relaxed problem group, there was a weak negative correlation between the composite intuition score and the percentage of moves that decreased the true distance of the problem state to the goal, $r(22) = -.35$, $p = .098$.

During the test phase, the composite intuition score for the control group had a near-significant negative correlation with the average initial latency, $r(22) = -.39$, $p = .061$, as well as a slight positive correlation with the average number of extra moves, $r(22) = .36$, $p = .082$.

These findings indicate that participants in our study mainly took one of two approaches to solving the puzzles and comparison problems. One was a more analytic or algorithmic approach based on planning, and the other was a more holistic or heuristic approach based on intuition. While the first approach was more effective for solving the full n -puzzles, the second approach was more effective on the task requiring speeded comparison of distances to the goal state. The control training condition encouraged the more analytic problem-solving style, and participants in this

condition developed a more effective search algorithm. In contrast, the relaxed problem training condition encouraged the more intuitive problem-solving style, and participants in this condition developed a more accurate heuristic function.

Conclusions

The present study demonstrates a dissociation between two core mechanisms on which expertise in problem solving depends: internal search (planning) and use of a heuristic function to evaluate locally available moves (intuition). Training on problems with fewer possible moves at each choice point (full n -puzzles) encouraged a more analytic problem-solving style, whereas training on relaxed versions of the same problem type that allow more possible moves encouraged a more intuitive problem-solving style. In the present study, the analytic style led to better performance on actually solving the full n -puzzles, but the more intuitive style led to better performance on a task requiring fast evaluations of how close a problem is to being solved.

Our results should not be construed as evidence that the development of analytical thinking and intuition are mutually exclusive. In fact, true experts in solving problems in complex domains such as chess (Chase & Simon, 1973; Gobet & Charness, 2006) appear to rely heavily on both intuition and planning, with the relative importance of intuition increasing when performance is time-constrained (Gobet & Simon, 1996). The time frame of the present study was far shorter than the years required to develop true expertise (Ericsson, 1996). Even by the end of the experiment, our participants remained novices on the n -puzzle. An expert solver of the n -puzzle would no doubt plan ahead more as well as make better intuitive judgments relative to a novice. The ability to quickly evaluate problem states should allow the problem solver to plan more moves ahead, just as heuristic functions reduce the branching factor and thus allow the search algorithm to search to a greater depth within the same amount of time. In fact, Charness (1981) found that skilled chess players search more deeply than novice players do, indicating that good intuition aids planning in problem solving.

What our findings do indicate is that these two basic approaches to problem solving may not be acquired in lock-step fashion, and to some extent constitute competing problem-solving strategies. Moreover, the two different approaches may be maximally effective for different types of problems. The systematic, analytic approach is slower and places a greater burden on working memory, but is more likely to lead to optimal solutions, and thus may be preferable for problems that can be solved slowly with the assistance of external aids to memory. In contrast, the holistic, intuitive approach is faster and less dependent on working memory, and hence will often be preferable when the problem must be solved under severe time constraints.

One example of this dichotomy is battlefield versus hospital triage. In the hospital, medical personnel may take a more analytic approach, carefully considering the consequences of each possible action. On the battlefield, by

contrast, the need for decisions may be so urgent that the only possible approach is to rely on intuition or “gut feelings.” An important direction for future research will be to determine whether the present findings using the toy example of the n -puzzle in fact generalize to real-world problem solving (cf. Gobet & Philippe, 2008).

Abstract

What makes people help each other? To explore the origin of human altruism, we tested whether 16-month-old infants have an expectation of helping behavior when they observe an interaction between others. Infants watched videos in which one (capable) agent had achieved a goal while the other (incapable) one could not. In a subsequent situation, the capable agent either helped the incapable agent achieve the goal (helping event), or ignored the incapable agent and achieved the goal alone (ignoring event). Infants looked longer at the ignoring event, suggesting that they expected helping behavior rather than ignoring behavior. The results are discussed in terms of infants' understanding of the connection between goals and altruistic behaviors.

Keywords: altruism, helping behavior, violation of expectation paradigm, goal understanding, infants

Introduction

In everyday life, we often help others not necessarily expecting rewards in return. We willingly donate money to charities when we hear news about people on the other side of the earth suffering from hunger and distress due to a tragic natural disaster. We hear about doctors and rescue teams rushing into places of catastrophe to save others' lives. These behaviors cannot be explained from an economic perspective because expending resources without profits could be viewed as irrational. What makes people benevolent toward others? The origin of human altruism has been a major interest of philosophers for a long time. Recently, developmental psychologists have begun to examine infants in order to discover the development of human altruism.

Recent research with toddlers and infants demonstrates that they take some actions to help others under certain circumstances. In Warneken and Tomasello (2006), for example, when 18-month-old children observed that an adult accidentally dropped a marker pen, they picked up the pen and brought it to the adult. Infants do such behaviors

spontaneously without external rewards. Another study showed that children's motivation to help others was in fact *decreased* by material rewards (Warneken & Tomasello, 2008). Meanwhile, it is difficult for younger children to give instrumental aid to others through actions because they have yet to master control of their bodies. Nevertheless, there is some evidence that even 12-month-old infants give relevant information to others by using pointing actions (Liskowski, Carpenter, Striano, & Tomasello, 2006; Liskowski, Carpenter, & Tomasello, 2008).

Infants also discriminate helping behaviors from hindering behaviors (Hamlin, Wynn, & Bloom, 2007; Kuhlmeier, Wynn, & Bloom, 2003). In studies by Kuhlmeier and her colleagues, 12-month-old infants watched a series of computer-animated videos including a social interaction between geometric shapes. In the videos, an agent (e.g., a triangle) helped a circle climb up a hill, whereas another agent (e.g., a square) hindered the circle from climbing the hill. In the following test trials, infants observed scenes in which the circle approached one of the two agents. The looking time of the infants was longer when the circle approached the helper than hinderer. This result indicates that infants are able to make a distinction between a helper and a hinderer. In addition, infants themselves show preference for agents who have helped others over agents who have not (Hamlin et al., 2007).

In summary, infants often show and prefer helping behaviors and distinguish helpers from hinderers. The present study further investigated infants' expectation of others' helping behaviors. More specifically, it asked: Do infants anticipate someone would help another when that other is in trouble or need? For instance, consider the following situation. A person sees another person repeatedly fall down while hiking. We may expect the first person to offer some help to the second person. If the first person simply passes by the second, we may be surprised.

The current research examined what 16-month-old infants expect of an agent when they watch a similar

situation. We employed the violation of expectation paradigm using computer-animated videos as stimuli (see Figure 1). The violation of expectation paradigm measures infants' looking time patterns to evaluate their reasoning about an event, where infants show longer looking times for surprising or unexpected scenes (e.g., Gergely, Nadasdy, Csibra, & Biro, 1995; Onishi & Baillargeon, 2005; Song, Baillargeon, & Fisher, 2005; Woodward, 1998). The infants were randomly assigned to either the experimental or control condition.

In the experimental condition, infants first received familiarization trials in which they watched videos about two agents, a square and a circle. The videos showed that the square was able to achieve the goal of climbing a tall hill whereas the circle was not. During test trials, the infants watched two events. In the helping event, the square helped the circle achieve the goal of climbing the hill by pushing the circle to the top of the hill. In the ignoring event, the square did not help the circle; it simply passed by the circle as if completely ignoring the circle striving to climb the hill. If infants expect the square to help the circle, they should look longer at the ignoring event than at the helping event because their expectation would be violated in the ignoring event.

To rule out the possibility that infants would look longer at the ignoring event than at the helping event simply because the agents' movements are more interesting or perceptually salient in the ignoring event, another group of infants were tested in the control condition. The control condition was identical to the experimental condition except that the circle did not show an intention to climb the tall hill during the familiarization trials. Instead, it simply moved around aimlessly. If infants reason that the circle does not have the goal of climbing the tall hill, and thus that the square does not have to help the circle achieve the goal, infants should look for equal amounts of time at the helping and ignoring events. However, if the ignoring event is simply more interesting than the helping event, infants in both the control and experimental conditions should look longer at the ignoring event than at the helping event.

Experiment

Participants

A total of 31 infants initially participated in the study. However, 7 infants were excluded from the data analyses because of parental interference (1), distraction (1), experimental error (2), and fussiness (3). So, 24 16-month-old infants (12 boys, 12 girls, $M = 16;12$, range 15;8 – 17;22) were kept for data analyses. They were randomly assigned to the experimental condition or the control condition.

Materials and procedure

Figure 1 shows examples of the stimulus videos. In the videos, a red circle and a yellow square-like geometric

shapes climbed small and tall hills. The shapes had some personifying features, i.e., eyes and a nose.

In the experimental condition, the infants received 4 trials during the familiarization phase. In the first two trials, only the square was in the video and infants watched it climb the two hills successfully.

At the beginning of the third and fourth familiarization trials, the square was on top of the tall hill and the circle was at the bottom left corner of the scene. The circle approached the small hill and successfully climbed it. It then tried, but failed, to climb the tall one—it moved up the tall hill until it reached the middle, slid down, and ended up stuck between the two hills. It attempted to climb the tall hill twice more, but continued to fail. The square watched all of these attempts from the top of the tall hill.

In the following test phase, infants received 2 test trials comprising the helping and ignoring events. At the beginning of each trial, infants saw a static scene in which the square was now at the bottom left corner of the scene and the circle was stuck between the two hills. In the helping event, the square pushed the circle up the tall hill and they successfully reached the top together. In the ignoring event, by contrast, the square simply passed by behind the circle and climbed up the tall hill alone, as if ignoring the circle.

In the control condition, the infants watched videos that were identical to those in the experimental condition, with the exception of the movement of the circle in the third and fourth familiarization trials. At the beginning, the circle was at the bottom middle of screen, between the hills. The circle rolled only half up the tall hill, and then reverted to the valley. After that, it moved to the left corner of the scene over the small hill and returned to the original place. The circle stopped at the valley between the two hills. Thus, the circle did not show the intent to climb the tall hill.

The duration of each video was 6 seconds, and these videos were played repeatedly until the end of each trial. Each trial ended if the infants looked away from the monitor for 2 consecutive seconds after watching at least 6 cumulative seconds, or if they looked at the videos for 60 cumulative seconds.

Half of the infants in each condition saw the helping event first, and half saw the ignoring event first. Infants sat on a parent's lap, approximately 45 cm away from a 20-inch computer monitor. The parents were asked to close their eyes and remain silent during the experiment.

Two observers monitored each infant's looking behavior through peepholes in cloth-covered frames on either side of the apparatus. The primary observer's responses determined the end of each trial. Interobserver agreement averaged 93% per trial per infant.

Results

The infants' looking times during the familiarization and test trials were analyzed. Preliminary analyses did not reveal any effect of gender or order of test events

Helping event

Ignoring event

Figure 1: Video stimuli used in the experiment.

(helping event first or ignoring event first) for the looking times during these trials, $F_s(1, 16) < 3.34$, $p_s > .086$. Therefore, these factors were collapsed in further analyses.

During the 4 familiarization trials, the mean looking time of the infants was 23.9 seconds ($SD = 10.4$) in the experimental condition and 23.1 seconds ($SD = 11.1$) in the control condition. A single-factor analysis of variance (ANOVA) with condition (experimental or control) as a between-participants factor demonstrated no main effect of condition, $F(1, 22) < 1$, indicating that the infants in the two conditions did not significantly differ in their mean looking times during the familiarization trials.

The infants' looking times during the test trials were analyzed with a 2 X 2 ANOVA with condition

(experimental or control) as a between-participants factor and event (helping or ignoring) as a within-participants factor (see Figure 2). The results revealed no significant main effect of condition or event, $F_s(1, 22) < 1$. However, the interaction between condition and event was significant, $F(1, 22) = 5.26$, $p < .05$. A planned comparison indicated that the infants in the experimental condition looked reliably longer at the ignoring event ($M = 34.0$ seconds, $SD = 19.6$) than at the helping event ($M = 23.2$ seconds, $SD = 15.7$), $F(1, 22) = 4.77$, $p < .05$, whereas those in the control condition did not show a difference in looking times between the events (ignoring event, $M = 24.3$ seconds, $SD = 18.1$; helping event, $M = 30.2$ seconds, $SD = 19.8$), $F(1, 22) = 1.22$, $p > .2$.

A non-parametric Wilcoxon signed-ranks test revealed the same pattern as above. In the experimental condition, 11 of the 13 infants looked longer at the ignoring event than at the helping event ($Z = 2.13, p < .05$), whereas in the control condition, 4 of 11 infants looked longer at the ignoring event than at the helping event and one of them looked equally at both events, $Z = .66, p > .5$.

Figure 2: Mean looking times of the infants during the test trials. Error bars denote standard error.

Discussion

This study demonstrates that 16-month-old infants expect an agent to be helpful when the agent sees another in need of aid. In the experimental condition, infants looked reliably longer at the ignoring event than at the helping event. This result indicates that the infants expected the competent agent to help the less competent agent achieve the less competent agent's goal.

The infants in the control condition, by contrast, looked for comparable durations at the helping and ignoring events. The results of the control condition confirmed that the results of the experimental condition are not simply due to infants' perceptual preference for movement of the agents in the ignoring event. Note that infants' understanding of basic physics such as *solidity* and *continuity* emerges very early in life (Spelke, 1994). Therefore, the ignoring event could have been more interesting simply because it seems to defy a law of physics, i.e., that solid objects cannot "pass through" one another. However, this possibility was not the case because the infants in the control condition did not show the difference in their looking times between the events. The only difference between two conditions was the motion of the circle during the third and fourth familiarization trials. The circle showed an intention to climb the hill only in the experimental condition. Thus, the infants could have expected that the square would help the circle in the experimental condition, but not in the control condition. The square pushing the circle to the top of the tall hill hence could have been viewed as helping the circle achieve the goal in the experimental condition. In contrast, the same motion in the control condition could not have

been viewed as helpful because climbing the hill was not the circle's demonstrated goal.

The present study thus supports and extends previous studies that investigated infants' understanding and showing of helping behaviors. According to previous findings, infants show spontaneous helping behavior (Warneken & Tomasello, 2006), distinguish helpers from hinderers (Kuhlmeier, Wynn, & Bloom 2003), and prefer helpers to hinderers (Hamlin, Wynn, & Bloom, 2007). In addition, our findings suggest that infants expect an agent to willingly help, rather than neglect, others. In our study, infants expected to see helping behavior even though (1) they did not observe interactions between the agents before the test trials, and (2) they were not informed about the characteristics of the agents beyond the agents' competence to achieve the goal.

Furthermore, our findings extend previous findings that infants of this age can attribute goals to nonhuman agents. Previous research has found that infants are able to notice the goal of a nonhuman agent when several cues to animacy are provided (Biro & Leslie, 2007; Luo & Baillargeon, 2005). In Biro and Leslie (2007), for instance, 9-month-old infants can reason what an object's goal is when it moves freely, as though its movements are being directed by its free will. In our experiment, agents' actions through self-propelled movements and personifying features such as eyes and a nose may have helped the infants detect goals of the agents.

Our results also suggest that infants can infer an agent's goals or intentions even when it fails to accomplish the goal. That is, infants in the experimental condition did not see the circle reach the top of the hill during the familiarization trials, but they were able to infer the goal of the circle. The findings are consistent with previous evidence that infants can infer an agent's goal when observing others' failed actions (Bradone & Wellman, 2009; Hamlin, Newman, & Wynn, 2009).

What do the current findings suggest about the developmental origin of human altruism? Where does the expectation about others' helpful actions come from? On the one hand, the propensity to expect helping behavior could be acquired from interaction with others. Attachment with parents in infancy may especially influence the development of their social models. A recent study suggests that 12- to 16-month-old infants have different expectations of others' behavior in a social context depending on the infants' experiences with their mothers (Johnson, Dweck, & Chen, 2007). On the other hand, the possibility exists that the expectation of helping behavior is an innate tendency since 16-month-old infants are not old enough to have had extensive social interactions in groups. In either case, our findings suggest that the expectation of altruistic behavior emerges in a very early period of human life. To further investigate the root of this altruistic mechanism, future studies can examine the relationship between these results and social factors such as parenting styles, daycare systems, or presence of siblings.

Abstract

Event types (ET) have been widely addressed in linguistic literature, but few studies have dealt with the questions of how they are represented, retrieved and processed in the mental lexicon. We report two experiments in which ET categories were found to give rise to semantic priming effects, both with word and picture stimuli. These effects are argued to provide empirical correlates for ET categories in the mental lexicon not only at the lexical level but also at a deeper conceptual level.

Keywords: Semantic priming; event types; verb processing; verb semantics; psycholinguistics.

Introduction

Event Types

Event types (ET) are an important component of the “event structure template” (Kemmerer & Gonzales-Castillo, 2010) of the verb, and play crucial role in the temporal constitution of the sentence. We refer here to Vendler’s (1967) standard classification of predicates into *states* (STA), *activities* (ACT), *accomplishments* (ACC) and *achievements* (ACH)¹. These categories can be further cross-classified with respect to the features of dynamicity (DYN), durativity (DUR) and resultativity (RES)² (see Table 1).

Table 1: Features of Vendler’s event types

ET	[dyn]	[dur]	[res]
STA	–	+	–
ACT	+	+	–
ACC	+	+	+
ACH	+	–	+

In particular, we focused on ACHs and ACTs, because they contrast with respect to DUR and RES: ACH [–dur, +res] (e.g., *land*, *die*); ACT [+dur, –res] (e.g. *sing*, *walk*).

¹STA denote properties and situations experienced by the subject as being static (e.g. *to know*, *to be tall*); ACT denote non-resultative activities (e.g. *to sing*, *to walk*); ACC denote activities with a clear goal or outcome (e.g. *to write a book*, *to walk to the fence*); ACH denote a change of state (e.g. *to stumble*, *to die*).

²DYN distinguishes among stative events and dynamic events (e.g. *to live*, *to know*, vs. *to run*, *to stumble*). DUR events are events perceived as lasting over time (e.g. *to knit*, *to stir*), non-DUR events are perceived as punctual (e.g. *to fall*, *to die*). RES events entail the existence of a clear outcome or resulting state that has to be reached for the event to be considered completed (e.g. *to land*, *to write a book*, vs. *to fly*, *to talk*).

Empirical Correlates of Event Types

Event types (ET) have been widely addressed in linguistic literature, but few studies have dealt with the questions of how they are represented, retrieved and processed in the mental lexicon. Noteworthy exceptions are: Gennari and Poeppel (2002, 2003); Finocchiaro and Miceli (2002); Heyde-Zybatow (2004); Bott (2008); Bonnotte (2008).

In particular, Bonnotte (2008) shows semantic priming effects of ET for ACTs and ACHs in French, reporting differences between processing of durativity and resultativity: “facilitation was shown on the former with similar and opposite priming, whereas it was shown on the latter only with similar priming”.

Goal of the work

The main goal of the work was the investigation of ETs in the mental lexicon, their representation and retrieval. We report two experiments based on the semantic priming paradigm (see McNamara, 2005, for a review), aimed at providing empirical correlates for ET categories.

Our starting point was the study in Bonnotte (2008), which we replicated for Italian with some crucial design innovations (Experiment 1). This experiment was conducted at a lexical level, using word stimuli. A second experiment (Experiment 2) introduced picture primes, in order to compare lexical semantic priming with non-linguistic priming, with the aim of delving into a deeper conceptual level than word stimuli.

ET categories were found to give rise to semantic priming effects, both with word and picture stimuli, but with a different pattern of results than in Bonnotte (2008): crucial differences were found at the ET level, and not between processing of durativity and resultativity. Priming effects were registered not only at the lexical level but also at a deeper conceptual level.

Experiment 1

Experiment 1 replicated the study conducted for French by Bonnotte (2008). As in Bonnotte (2008), Experiment 1 was designed to explore semantic priming effects of ET categories in Italian.

Nevertheless, two main differences were introduced. First of all, prime-target pairs and ACH-ACT sets were checked and tagged with respect to their semantic class, in order to rule out influences of the semantic class and to isolate effects of features pertaining to ETs, i.e. DUR and RES. Semantic

Table 2: Examples of prime-target pairs in Experiment 1

	target ACH	target ACT
neutral prime	XXX - sparare XXX - <i>to shoot</i>	XXX - dormire XXX - <i>to sleep</i>
opposite prime	ballare - sparare <i>to dance - to shoot</i>	entrare - dormire <i>to enter - to sleep</i>
similar prime	entrare - sparare <i>to enter - to shoot</i>	ballare - dormire <i>to dance - to sleep</i>

classes correspond to WordNet topnodes for verbs (Fellbaum, 1998). The prime and target of each test pair never belong to the same semantic class. Semantic classes were also used as a source of variance in the inferential statistic model. As a further difference with Bonnotte (2008) a slightly longer stimulus onset asynchrony (SOA) was used (300ms), in order to avoid spillover effects with longer stimuli.

Method

Participants 48 native Italian speakers from the University of Pisa and the Scuola Normale Superiore in Pisa volunteered to participate in the experiment and were paid for their participation. All had normal or corrected-to-normal vision.

Materials Two groups of 18 intransitive ACT Italian verbs and 18 intransitive ACH Italian verbs were pair-wise balanced for variables known to affect processing costs, such as length, frequency, syntactic frame frequency, ET polysemy; they were used as targets in the priming experiment.

The average length was 8 characters for ACTs ($SD = 1.5$) and 8 for ACHs ($SD = 1.5$) and did not differ significantly between the two groups (Kruskal-Wallis: $df = 1, \chi^2 = 0, p = 1$). Mean frequency (estimated from ColFis, Laudanna et al., 1995) was 129.5 occurrences per 3 million words for ACTs ($SD = 165.5$), and 88 for ACHs ($SD = 173.5$) and did not differ significantly between the two groups (Kruskal-Wallis: $df = 1, \chi^2 = 1.683, p = 0.2$). Syntactic frame frequencies were estimated from Repubblica corpus (Lenci et al., 2010): all verbs were intransitive and strongly monoargumental; ET polysemy was assessed with pre-test 1.

Each target appeared in one of three prime contexts: after a neutral prime (a string of Xs), after a similar prime (a verb of the same ET), after an opposite prime (a verb of opposite ET). As prime verbs we used different verbs than the target verbs. See examples in Table 2. Each prime-target pair was assigned to one of three lists so that an equal number of pairs per each condition appeared on each list, so that exactly one version of each target appeared on each list and so that each participant saw not more than one version of each target.

Pre-test 1 Italian lacks morphological clues for ET, and verbs tend to be ambiguous with respect to their ET category. Our experiments required non-ambiguous verbs, to be assessed with an inter-annotators pre-test inspired by the one in Bonnotte (2008).

Pre-test 1 was carried out to check our annotation of the verbs according to their ET. Materials for pre-test 1 were 136

predicates (114 transitive VPs - verb + object - and 22 intransitive verbs). Both transitive and intransitive verbs showing all four of Vendler's (1967) ET categories were used, both to have less constrained answers and to have a broader stimuli set for further experiments.

20 native Italian-speaking students performed the test in a web-based format. Per each event, subjects were asked to choose one of four pictures, one representative of each ET:

Figure 1: Pictures used in pre-test 1: the long continuous line depicts a state that lasts in time, the long dashed arrow depicts a process that develops over a certain period of time, the long dashed arrow ending with a vertical dash depicts a process that develops over a certain period of time and leads to a result, the short arrow ending with a vertical dash depicts an event that causes a change of state.

Results showed a mean accuracy of .61, inter-subject observed agreement of .5, inter-subject expected agreement of .25 and a kappa mean value of .33. Kappa was .46 on intransitive ACHs and .34 on intransitive ACTs. Agreement values were above chance and significantly good, since the subjects were naive to linguistics and ET classification. 3 ACHs and 3 ACTs showing low agreement (< 0.19) were ruled out for future experiments.

Procedure Participants were instructed to read the prime and the target and perform a semantic decision task. Half of the subjects were assigned a durativity decision task, the other half were assigned a resultativity decision task. Within the DUR task, subjects were asked:

Does the target denote a process lasting over a period of time?

Within the RES task, subjects were asked:

Does the target denote an event with a clear outcome?

The semantic decision task directly references the manipulated variables, but nevertheless it was preferred over a more neutral lexical decision task for a better comparison with previous results and procedures in Bonnotte (2008). Task choice was later supported by the good accuracy results achieved.

Prime-target stimuli were presented on a screen in white upper-case letters on a black background with an SOA of 300ms. The target was deleted after the response. Participants answered by pressing one of two buttons on a button box, which recorded the decision latencies (DL) to one tenth of ms accuracy. DL were recorded as the time between the target onset and the response. Participants were given a detailed description of the experimental trials and were trained during a special simulation session (9 practice trials) before beginning the experiment.

Design Experiment 1 had a 2x3 within-subjects design (2-levels factor being the ET of the target, and 3-levels factor being the type of prime context) with one between-subjects factor (DUR task, RES task).

Results

The neutral prime level was used as a baseline to evaluate the effect of opposite and similar prime on decision latencies (DL): both primes show smaller mean DL, suggesting a general facilitation effect (see Figure 2, more detailed information on Table 5). A mixed effect model (see Table 3) of DLs³ showed that the difference between the neutral prime and the opposite prime was highly significant, and the difference between the neutral prime and the similar prime was significant; furthermore, it yielded a significant effect of the target's ET.

General accuracy was .86 (.89 for DUR, .82 for RES). A logistic regression analysis performed on errors did not yield any effect of the priming context or of any other factor.

Separate analyses Four separate analyses were conducted, one for each ET (ACH and ACT) within each task (DUR and RES), using four smaller-scale mixed effect models (see Table 4). A significant difference between the neutral prime level and the opposite prime level was found on ACH targets for both DUR and RES tasks. A significant difference between the neutral prime level and the similar prime level was found on ACT targets in the DUR task.

³Fixed effects were prime, task, ET of the target; random effects were subject, target verb, semantic class of the target.

Figure 2: RT means for the different priming contexts in Experiment 1.

In the DUR task, ACTs are able to prime both ACT and ACH targets; on the other hand, in the same task ACHs never prime either ET. This might depend on the fact that ACT are positively marked with the feature of DUR, which is relevant for this task. However, in the RES task, only ACTs have a significant priming effect on ACH targets, suggesting that priming occurs in this case only when the target is positively marked with the feature of RES, activated in this task. Here

it is more the contrast between the [–res] of ACTs and the [+res] of ACHs to produce a priming effect.

Experiment 2

Experiment 1 showed significant priming effects of ET at the lexical level. The aim of Experiment 2 was to delve to a deeper conceptual level, in order to assess if ETs are “pure linguistic” categorizations or if they rather apply also to non linguistic input. With this purpose, a key modification was applied to Experiment 1: picture primes were used instead of word primes.

Method

Participants 42 native Italian speakers from the University of Pisa and the Scuola Normale Superiore in Pisa volunteered to participate in the experiment and were paid for their participation. All had normal or corrected-to-normal vision.

Materials Targets from Experiment 1 were also used as targets for Experiment 2. Each target appeared in one of three prime contexts: after a neutral prime (a pattern of Xs), after a similar prime (a picture depicting an event of the same ET), after an opposite prime (a picture depicting an event of opposite ET). Picture primes were selected from the IPNP database (Bates et al., 2000, see examples in Figure 3) and their association with ET categories was assessed through pre-test 2. Each prime-target pair was assigned to one of three lists so that an equal number of pairs per each condition appeared on each list, so that exactly one version of each target appeared on each list and so that each participant saw not more than one version of each target.

Figure 3: Picture primes: neutral prime, ACH picture (*to break*), ACT picture (*to ski*).

Pre-test 2 Non-ambiguous verb stimuli were selected through pre-test 1; a similar pre-test was conducted to select picture stimuli for Experiment 2. Materials for pre-test were 87 pictures from the IPNP database. Again, all four of

Vendler’s ET categories were used as possible answers. 20 native Italian-speaking students performed the test in a web-based format. Procedure was the same as in pre-test 1.

Results showed an inter-subject observed agreement of .42, inter-subject expected agreement of .26 and a kappa mean value of .21. 12 ACH pictures and 12 ACT pictures showing best agreement were chosen as primes for Experiment 2. Kappa mean value for chosen pictures was .42 (.41 for ACHs, .43 for ACTs).

Procedure Procedure was the same as in Experiment 1, with one difference: picture stimuli required longer times to be processed, and so SOA was set to a higher value (700 ms); SOA was assessed by asking 10 more participants from the same pool as in Experiment 1 and 2 to name the pictures. 700 ms was estimated as the shortest presentation time to allow the participants to identify the picture.

Design Design was the same as in Experiment 1.

Figure 4: RT means for the different priming contexts in Experiment 2.

Results

In contrast with Experiment 1, in Experiment 2 picture primes showed longer mean DL than the neutral prime, suggesting a general inhibitory effect (see Figure 4, more detailed information on Table 5). A mixed effect model (see Table 6) of

Table 6: Experiment 2 - Mixed Effect Model: $\log(dl) \sim \text{prime} + \text{et} + \text{task} + \text{featval} + (1|\text{subj}) + (1|\text{verb}) + (1|\text{sem_cl})$

DLs⁴ showed that the difference between the neutral prime and the similar prime was the only one to reach significance; furthermore, it yielded a significant effect of the target's ET, of the task and of the featural value ([+/-dur], [+/-res]) of the target.

General accuracy was .92 (.94 for DUR, .90 for RES). A logistic regression analysis performed on errors did not yield any effect of the priming context or of any other factor.

Separate analyses Four separate analyses were conducted, one for each ET (ACH and ACT) within each task (DUR and RES), using four smaller-scale mixed effect models (see Table 7). A significant difference between the neutral prime level and the similar prime level was found on ACH targets for both DUR and RES tasks.

A striking difference with respect to Experiment 1 is the absence of priming effects with ACTs, both as target or prime. This fact might be due to the inherently "static" character of picture stimuli, which makes the [+dur] of ACTs less salient.

General Discussion and Conclusions

In line with both our expectations and the study in Bonnotte (2008), our experiments yielded significant priming effects of ET, thus providing evidence to the idea that ETs are indeed relevant for the mental lexicon. This conclusion is further supported by the crucial innovation we introduced in the ex-

periments, i.e. controlling the semantic class of prime and target verbs. The priming effects can thus be related to the more abstract event structure shared by verbs that greatly differ for other dimensions of their meaning.

In addition to this, two different modalities were explored and contrasted: word primes and picture primes. Using picture stimuli is a first but significant attempt to place the study of ETs within a broader frame of study of event meaning in cognition. The Embodied Cognition Framework (Evans & Green, 2006; Haggard et al., 2007; Barsalou, 2008) suggests that semantic representations are not purely amodal, but rather grounded in our sensorimotor perception, and it has been suggested that processing a verb might involve "covertly recapitulating" the event it refers to (Kemmerer & Gonzales-Castillo, 2010).

The effect of facilitation given by the word primes is not surprising; the negative priming which we report for the picture primes is usually explained with a combination of inhibition (an effort of selective attention to avoid a previous stimulus) and memory retrieval (see Tipper, 2001, for a review). Picture primes seem to act at a deeper level than word primes, and it is crucial that the negative priming is found in the similar prime condition: similar primes seem to be more difficult for subjects to ignore.

Moreover, the pattern of results offered by this study suggests a different explanation of such priming effects than the one offered by Bonnotte (2008) (see Table 8). Bonnotte (2008) suggests a crucial difference between processing of

⁴Fixed effects were prime, task, ET of the target, featural value ([+/-dur], [+/-res]) of the target; random effects were subject, target verb, semantic class of the target.

Table 8: Comparison with results in Bonnotte (2008).

Exp 1	opp	sim	opp	–
Exp 2	sim	–	sim	–

durativity and resultativity: “facilitation was shown on the former with similar and opposite priming, whereas it was shown on the latter only with similar priming”. Nevertheless, the pattern emerging from our experiments does not show great differences between processing of durativity and resultativity, but rather suggests a difference at the level of ET categories, which seem to differ with respect to their behavior in both tasks. Differences in priming effects across ET categories can be ascribed to different lexical encodings of their ET features: the [+dur] and [–res] of ACTs is more ductile and subject to contextual adaption, whereas ACHs are more “inherently” [–dur] [+res]. Moreover, ACTs do not seem to be affected by priming with picture stimuli, which might be problematic in conveying the [+dur] [–res] nature of ACTs. In the near future a comparison will be carried out with a similar study of Russian (Batiukova et al., 2010).

The use of videos was also contemplated for this study, but pictures were preferred for a first exploration of the visual modality because the IPNP database provided a convenient standard of stimuli and because picture primes allowed for shorter SOAs. This would not have been the case for video stimuli. Nevertheless, videos have been used in the investigation of event representations (e.g. Gennari et al., 2002) and, since they could provide a better depiction of both DUR and RES, this modality would definitely be of some interest for further work, in order to more thoroughly investigate ET representations in the mental lexicon.

ET categories were found to give rise to semantic priming effects, at both word and picture levels, which, albeit with crucial cross-modal differences, provide empirical correlates for ET categories in the mental lexicon and suggest that ETs are not only a linguistic phenomenon, but relate with our way of conceptualizing events in the world.

Acknowledgments The experiments reported were funded by the Laboratorio di Linguistica of the Scuola Normale Superiore in Pisa. The authors thank Pier Marco Bertinetto, Valentina Bambini, Berry Claus and Pirita Pykkönen for helpful discussions.

Motor Effects in Rating Lines' Length Using a Dichotomous Scale

Lyuben D. Laskin (laskin@mail.bg)

Department of Cognitive Science and Psychology,
New Bulgarian University, 21 Montevideo Street
Sofia 1618, Bulgaria

Abstract

The aim of this study is to demonstrate how the execution of particular task-specific motor movements can influence subjects' ratings of simple stimuli. Sixty-four participants in one control and two experimental groups rated lines of 36 different lengths. Lines appeared on a computer screen and subjects gave their ratings using a standard keyboard. In the experimental groups trials did not change automatically, but subjects had to press a specific button (called the "trial change button"), which was next to one of the response buttons. It was hypothesized that this manipulation would lead to assimilation of the ratings toward the category whose button was next to the trial change button. The results confirmed this hypothesis. Possible explanations of the results are discussed.

Keywords: context effects; scale ratings; grounded cognition; motor actions.

Introduction

According to traditional views in psychology and cognitive science, the role of sensory and motor processes in cognition is only peripheral. Our sensory organs receive information from the outside world and that information is transduced into amodal symbols which represent knowledge. High-level cognition (language, memory, decision making, problem solving, etc.) consists of the interaction of these symbols with each other, the product of which is either the activation of other amodal symbols, or their transduction into motor commands.

Researchers from the field of grounded cognition (Barsalou, 2008) assign a very different role to our sensory and motor systems. According to that view, the brain does not explicitly represent amodal symbols, but rather high-level cognition emerges from the interaction between the brain, the body, and the environment. This can also be stated by saying that high-level cognition is grounded in sensory and motor representations, not amodal, abstract symbols.

An ample amount of empirical results supports the views of grounded cognition. Evidence shows that haptic, visual, auditory sensations, proprioception, as well as execution of motor actions, all influence higher-level cognitive processes, like memory, language processing, visual and motor imagery, and so on (for a review, see Barsalou, 2008).

The aim of this study is to demonstrate how motor actions required for the execution of a particular cognitive task can affect high-level cognitive processes. More specifically, we are going to try to show this by demonstrating how motor actions necessary to perform a scale rating task can influence the ratings.

There already exists a field in psychology which deals with the so-called context effects in scale ratings. There is bountiful experimental literature demonstrating changes in subjects' ratings, influenced by factors like the range of the stimuli, their distribution, the sequence of their presentation, and so on.

Some of the studies demonstrate how context can systematically¹ change the ratings of stimuli evaluated only by one dimension. Examples include judgments of square sizes (Parducci & Perrett, 1971; Sarris & Parducci, 1978), weights (Parducci & Marshall, 1962; Sherif, Taub, & Hovland, 1958), and the length of lines (Kokinov, Hristova, & Petkov, 2004; Petrov & Anderson, 2005).

Other studies demonstrate contextual effects in the ratings of more complex stimuli (stimuli that must be evaluated based on more than one dimension). For example, Cooke & Mellers (1998) asked participants to rate flats' attractiveness based on their rent, number of rooms, and distance from campus. Mellers (1982) demonstrates such effects in equity judgments, and Wedell, Parducci, & Geiselman (1987) show contextual effects in ratings of the attractiveness of female faces.

There are a number of influential theories which try to explain such experimental results. One of the first theories in the field is the **adaptation-level theory** (Helson, 1964). According to that theory, the stimuli a person has rated leave a general impression with which all other stimuli are compared while being assessed. Another powerful theory in this field is the **range-frequency theory** (Parducci, 1965, 1968, 1974). It claims that a stimulus' rating is a compromise between the range and frequency principles. The former refers simply to the lower and higher end of the stimulus material (e.g., the smallest and the biggest square, if the task is to judge the size of different squares). The latter principle is concerned with the distribution of the stimuli (e.g., uniform, positively or negatively skewed, etc). Discussing in detail these and other theories in the field of contextual effects in scale ratings is beyond the scope of this paper.

To our knowledge, there are no studies showing changes in people's ratings of stimuli caused by "peripheral" factors like the specific motor actions executed during the process of rating itself. Furthermore, none of the theories presented

¹ For a change to be considered systematic, it has to be in one particular direction. When the change is in the direction of the context (e.g., when there are more big squares than small squares in the stimulus material and an average square receives a higher rating than normal), the effect is called *assimilation*, whereas when the change is in the opposite direction of the context, the effect is called *contrast* or *compensation*.

above predict any such effects. As was mentioned earlier, the aim of the current study is to demonstrate how task-specific motor actions can influence subjects' performance in the task. Next, we will review some of the literature concerned with how executing particular motor actions affects some cognitive processes which don't seem to be directly related to the motor actions.

Motor Effects in High-Level Cognitive Processes

In this section, we will briefly present empirical results showing how different motor actions can influence high-level cognitive processes. The most commonly used experimental paradigms are described below.

Cacioppo, Priester, & Berntson (1993) use the isometric arm flexion and extension paradigm to trigger the so-called approach and avoidance systems. The authors argue that when these systems are activated, stimuli that people interact with are perceived as more positive or more negative, respectively. In a series of experiments they ask subjects to either place their palms at the bottom of a table and to lift slightly (flexion condition) or to place their palms at the top of the table and to push slightly (extension condition), while at the same time observing Chinese ideographs which they later rate as pleasant or unpleasant. The results show that ideographs observed during arm flexion are later rated as more pleasant, whereas those observed during extension are rated as less pleasant.

Another commonly used method is inducing a smile or a frown by asking subjects to hold a pen or a pencil with their teeth or with their lips, respectively. The muscles activated during these actions are also active during one of the above facial expressions. Using this manipulation, Strack, Martin, & Stepper (1988) showed that holding a pen between the teeth or between the lips leads to evaluating cartoons as funnier or less funny, respectively.

Head nodding or shaking are meaningful gestures in most cultures. They convey agreement/disagreement with or approval/disapproval of someone else's behavior, a witnessed event, etc. Wells & Petty (1980) used the association between the type of head movement and the created mental set toward the currently active concepts to show that making vertical head movements while listening to a message leads to higher agreement with the message, whereas making horizontal movements leads to lower agreement.

For a review of other experiments showing motor influence on high-level cognitive processes, see Briñol & Petty (2008).

Possible Explanations of These Findings

The explanation that most papers provide for the obtained results is related to the existing associations between a motor action and a cognitive response (e.g., nodding associated with agreement). These associations are created during a person's life and influenced by their culture. But how are they created?

Zwaan & Madden (2005) provide one possible mechanism by which such associations can be established. According to their **interconnected experiential traces** theory, all mental representations are experiential, that is, created during some form of interaction with the outside world. They define two types of representations: **referent** and **linguistic**. The former are multimodal memory traces laid down during interaction with the environment. The latter representations are laid down during receiving or producing linguistic information (e.g., talking, listening, writing, etc.). A very important feature of these representations is that they can be interconnected (associated).

The authors propose **co-occurrence** as a possible mechanism for establishing these associations. When two events occur simultaneously or in succession, the neural assemblies which represent those events establish stronger connections with each other (Hebb, 1949). For example, the visual image of a falling glass of water is likely to be associated with the sound of breaking glass. This happens because in a person's lifetime, the experience of a glass falling on the ground from a certain height has almost always been followed by a specific sound (that of breaking glass). Thus, that person develops anticipation for that sound after seeing a falling glass.

Experiment

Likert scales are often used in pilot studies or even as dependent measures in experiments. Researchers exploring contextual effects in ratings have showed that these measures can sometimes be affected by factors other than those being investigated by the particular study (see studies reported in the introduction). However, they have emphasized on "cognitive" factors and have not studied any possible influence of sensory or motor processes on subjects' ratings. The current experiment's goal is to make the first step in filling this gap by demonstrating changes in subjects' ratings influenced by the specific hand movements they make while rating lines of different lengths.

One common feature of the experiments demonstrating motor effects in high-level cognitive processes reviewed in the previous section is that they all exploit associations between different types of representations that have already been formed throughout participants' lives. The current experiment will try a different approach by attempting to *create* new short-term associations between particular motor movements and conceptual categories.

Having in mind the interconnected experiential traces theory of Zwaan & Madden (2005), it can be hypothesized that if the activation of a particular category is repeatedly coupled with the execution of a motor action, a temporary association between the respective category and motor action might be created. After that, the execution of the motor action alone may be sufficient to activate the category with which it was associated.

Hypotheses

In the current experiment, participants’ task was to rate lines’ lengths using a dichotomous scale (a line could be rated as “short” or “long”). If the motor actions (hand movements) required for giving one of the two responses are different in nature this can lead to the creation of a new associative connection between them (i.e., between one of the two categories and the respective hand movement). If, then, one of the motor actions is activated, it should also activate the associated category.

When one of the two categories is more active than the other, this can *increase* the probability of the line being currently rated to receive that particular rating (e.g., a middle-sized red line may be rated as “long” if that category’s base-level activation is higher than usual). This hypothesis was tested using the procedure described below.

Method

Participants 64 New Bulgarian University (26 males, 38 females) undergraduate students volunteered for this study.

Stimuli The stimulus material consisted of 36 lines of different lengths appearing in the middle of a computer screen. The shortest line was 38 pixels and the longest line was 668 pixels, with an increment of 18 pixels. Lines were 2 pixels thick.

Apparatus Lines were presented on a 17” TFT monitor with a resolution of 1024 x 768 pixels. The responses were obtained using a standard computer keyboard. The experimental script was written with the E-Prime 1.1 software.

Design and procedure The experiment was conducted in small rooms with each participant being tested individually. Subjects sat in front of a computer and the instructions were presented to them in written form across the screen, as well as explained to them by the experimenter. In short, the instructions said that subjects would take part in a study concerned with people’s judgment of length and that their task would be to rate different lines presented on the screen as “short” or “long” using the two specified buttons on the keyboard.

The experiment employed a between-subject design with one control group and two experimental groups (see Table 1). In the control group the procedure was the following: after they heard the instruction subjects went through a training session to be familiarized with the experiment. The training session was the same as the experimental session, but only 10 (out of 36) lines were presented in random order. In the experimental session all 36 lines were presented 2 times each, resulting in a total of 72 trials. Figure 1 shows what a single trial looked like.

The procedure in the experimental groups was identical to that of the control group, except for the transition between trials. In the experimental groups, subjects had to press an additional button at the end of each trial (called the “trial change button”) in order to see the next trial (Figure 2). The trial change button was positioned either next to the “short” button or next to the “long” button (see Table 1).

Figure 1: Every trial in the control group started with a fixation cross for 500 ms, followed by a 100 ms inter-stimulus interval, followed by a 3000 ms exposure of the line to be rated, and a 1000 ms inter-trial interval.

Subjects were asked to use only their right index finger to give their responses. Between every two trials they had to put their finger in a neutral position between the response buttons (the black rectangle in Figure 2)². The sequence of actions in every trial (after the line’s appearance on the screen) was: press one of the response buttons – press the trial change button – return to neutral position.

Figure 2: The F4 and F9 buttons were used as response buttons (for responding “short” or “long”), and the F1 and F12 buttons were used as trial change buttons. Both response buttons and trial change buttons were counter-balanced across conditions.

The dependent measure in this study was the response to each line (“long” vs. “short”).

Table 1: The position of the trial change button with respect to the response buttons in the three groups.

	Ex. Group 1	Ex. Group 2	Control Group
TCB next to	“Long” button	“Short” button	No TCB

After the end of the experiment, subjects were debriefed, thanked, and dismissed.

² All other keyboard button functions were disabled, so pressing other buttons accidentally did not affect the experimental procedure. Thus, subjects were instructed to rest their wrists on the keyboard without worrying about accidentally pressing buttons other than those which were part of the procedure.

According to the main assumption in this study, the different types of movements should be associated with one of the two categories. That is, the categories “long” and “short” should be associated with a hand movement to the left or a hand movement to the right (depending on the experimental condition). Since in the two experimental groups the position of the trial change button also requires a hand movement either to the left or to the right immediately before the presentation of the next line to be rated, that movement should activate the respective category more than its rival category and the probability that each line is rated with that category should increase.

Results and Discussion

The expected results following this manipulation were that there is going to be an assimilation of the responses toward the position of the trial change button. That is, if the trial change button is next to the “long” response button, the probability that an arbitrary line is rated as “long” should be higher than in the control group, and if the trial change button is next to the “short” response button, the probability should be lower. The actual results confirmed these expectations (Figure 3).

Figure 3: The probability for every line to be rated as “long” in the three conditions. As was expected, in experimental group 1 more lines were rated as “long” and in experimental group 2 more lines were rated as “short”, in comparison with the control group.

All individual responses (the number of individual responses was *number of subjects * number of trials per subject*) were divided in three groups (the two experimental groups and the control group). “Long” responses were coded as “1”, and “short” responses were coded as “0”. A chi-square analysis was performed in order to test if the results in the three groups differed significantly, $\chi^2(2) = 26.54$, $p < 0.01$. The standard residuals³ are given in Table 2. As can be seen, the two experimental groups were the main contributors for the significance of the results.

Since this analysis had too many individual measures, for a higher certainty in the significance of the results a repeated-measures ANOVA was also performed after

³ Standard residuals are used to determine which cells contribute most for the rejection of the null hypothesis in a chi-square analysis. Absolute values equal to or greater than 2 are considered statistically significant.

aggregating the data for individual lines (that is, one individual measure stood for the percentage of a particular line rated as “long” in one of the three conditions), $F(1, 35) = 68.11$, $p < 0.001$. Three individual t-tests were performed to compare the three groups. The analyses revealed significant results between experimental group 2 and the control group, $t(35) = 4.38$, $p < 0.001$, $ES = 0.73$, also between experimental groups 1 and 2, $t(35) = 4.98$, $p < 0.001$, $ES = 0.83$, and marginally⁴ significant results between experimental group 1 and the control group, $t(35) = -2.3$, $p = 0.027$, $ES = 0.4$.

Table 2: The standard residuals for the chi-square analysis.

	“Short”	“Long”
Control Group	-,9	,8
Ex. Group 1	-2,2	1,9
Ex. Group 2	3,1	-2,7

These results show that the presence of a trial change button always affects subjects’ ratings. However, it is also evident that there is an asymmetry in the difference between the two experimental groups and the control group. That is, when the trial change button is next to the “short” response button the effect is stronger than when it is next to the “long” response button. This and other questions are discussed in the next section.

General Discussion

The results of this study showed that “non-cognitive” factors can also affect “cognitive” processes like judgment and categorization under certain circumstances. We think these results contribute to both the field of embodiment and grounded cognition, as well as to the field of context effects in scale ratings. The two main findings are: (1) task-specific motor actions can potentially affect subjects’ ratings in a scale rating task, and (2) temporary associations between referent and/or linguistic representations can be established even for a short period of time.

Of course, there still remain a lot of open questions. In relation to the first finding, one thing that needs to be explored empirically is whether the same results can be obtained with a larger scale (e.g., a 7-point Likert scale). One might argue that the task in the current study was not scaling at all, but rather simple categorization.

⁴ Due to the increasing probability of making a type I error when performing more than 1 t-test on overlapping statistical data, the acceptable level of significance was not 0.05, but was set to $\alpha = 1 - \sqrt[3]{(1 - 0.05)} = 0.017$. For that reason $p = 0.027$ is considered a marginally significant result.

Another open question regarding the first finding is concerned with the observed asymmetry between the two experimental groups. All performed statistical analyses showed that the assimilation is stronger when the trial change button was next to the “short” response button than when it was next to the “long” response button. A possible explanation for this result can be found in the linguistic notion of **markedness** (Andrews, 1990). This term was coined by the Russian linguist Nikolai Trubetzkoy. Even though he used it to explain some phonological phenomena, other authors later extended the notion to other linguistic fields, including semantics. An unmarked form of a concept is a basic and natural form, whereas a marked form is one that is derived from the unmarked form. For example, lioness is the marked form of lion, since lion can refer to both male and female lions, whereas lioness only refers to female lions. Since, as was mentioned earlier, the task that subjects received in this experiment can be considered categorization, some markedness effects can also be observed. When talking about the size of a line, it is more natural to think about its “length”, rather than its “shortness”. This suggests that “long” is the unmarked category, and “short” is the marked category⁵. That might be the reason why the experimental manipulation was weaker for the experimental group in which the trial change button was next to the “long” response button. Subjects are simply more confident in responding “long” than in responding “short”. However, this clearly is a *post-hoc* explanation and needs further confirmation.

It has also been brought to our attention that the results could be explained by assuming that subjects press the button closer to the TCB in order to save time and effort and not because of the activated referent or linguistic representations. This is a valid point and needs to be addressed in future studies.

Regarding the second finding in this study, the open questions are concerned with the exact mechanisms underlying these associations. Zwaan & Madden (2005) propose a sound theory, but it is not specified in enough detail.

Returning to the current study, one interesting question is related to the exact representations that are associated. Throughout this paper, it was assumed that the semantic category (“long” or “short”) is associated with the particular type of movement (hand movement to the left or to the right). A second possibility is that it is the visual image of a button that is associated with the respective category. In that case, every time subjects have to press the trial change button, their attention is directed toward the respective response button too, and that activates its category. The

results of the current experiment are unable to disambiguate between these possibilities.

Future Studies

It is clear that there are a lot of open questions that need to be investigated empirically. In this section, we will propose two experiments that might clarify some of them.

The first one is a natural extension to the current study. Namely, can the same results be obtained if there are more than two responses, that is, if a larger scale is used? The procedure in that study is going to be the same, but there are going to be more than two response buttons (e.g., 7 buttons for a 7-point scale) and again the trial change button is going to be placed at one side of the scale. If our hypothesis is correct, the same assimilation effect should be observed.

The second proposed experiment is aimed at answering the question of whether or not the obtained results are simply due to the fact that subjects’ attention is being directed towards a particular response button every time they press the trial change button (see the discussion in the previous section) or if the results are due to a time/effort saving incentive. The proposed procedure is the following.

There are going to be three experimental sessions. In the first session, subjects will have the same rating task as in the current study (i.e., rating lines’ lengths). However, instead of “long” and “short”, the available response categories are going to be “big” and “small”. If the assumptions made in this paper are correct, during this session these categories should be temporarily associated with the hand movements required for giving these responses.

In the second session, subjects will have a task whose goal will be to make them press one of the two response buttons more frequently than the other (e.g., a circle will appear on the left or on the right side of the screen and the subjects’ task will be to press the respective button on the keyboard; the circle will appear more frequently in the right or in the left, depending on subjects’ experimental condition). Again, if the assumptions made in this paper are correct, this should make the movement that has been executed more frequently more active than the other movement, and that would make the associated category more active as well.

In the third experimental sessions, subjects will have a task identical to that of the first session, but the stimuli will be different (e.g., rating squares, instead of lines), but again using the same categories for responses (“big” and “small”). If one of the two categories is more active than the other (because of the manipulation in the second experimental session) this should lead to a higher probability of responding with that category. Since in no part of this procedure is there any trial change button, the “attention” and time/effort saving explanations of the results can safely be ruled out.

Both proposed experiments are going to be performed in the near future.

⁵ Results from the control group support this hypothesis. About 60% of the lines were rated as long, and only 40% as short, $\chi^2(1) = 45.93$, $p < 0.001$ (this difference would not be expected if subjects have no bias toward either category). It seems that subjects find it more natural to call a middle length line “long”, rather than “short”.

Conclusions

This study showed effects of motor actions on the process of rating lines as “long” or “short”. The results are considered to contribute to both the field of grounded cognition and the field of context effects in scale ratings (or even to fields like psychophysics, if the effects of the methodology of measuring subjects’ perceptions for different stimuli are to be taken seriously).

There are still many open questions which must be further explored. Despite all uncertainties however, these results show that it is quite likely that sensory and motor processes can be significant factors in the process of scaling (a finding that is not predicted by the main theories explaining contextual effects in scaling).

Acknowledgments

I would like to thank Armina Janyan, Boicho Kokinov, Encho Gerganov, Georgi Petkov, Ivan Vankov, and Stefan Mateev for the fruitful discussions. I would also like to thank my thesis advisor Penka Hristova for her advice, support, and encouragement without which my first publication would not have been the same. And last but not least, I want to thank Meryl Varadinov for helping me in fixing many small but significant details in this paper.

Abstract

A synesthetic metaphor (e.g., “*sweet touch*”) is a metaphor that results from a combination of a modifier and a head, where they express different perceptual qualities. Most of the existing studies examine how the acceptability of synesthetic metaphors can be explained by the pairing of adjective modifier’s and head noun’s modalities. However, little attention has been paid to how people comprehend synesthetic metaphors. This paper explores how people comprehend Japanese synesthetic metaphors. In our psychological experiment we collected 10388 words associated with 62 synesthetic metaphors and classified them into the following four kinds of features: common (features listed for the metaphor, the vehicle and the topic), vehicle-shared (features listed for both the metaphor and the vehicle, but not listed for the topic), topic-shared (features listed for both the metaphor and the topic, but not listed for the vehicle), and emergent (features listed for the metaphor, but not listed for either the vehicle or the topic). The result showed that there were significantly more emergent features than the other kinds of features in the comprehension of synesthetic metaphors. This result suggests that we do not so directly comprehend synesthetic metaphors based on salient features of the vehicle or the topic. In this paper we focus on event knowledge which is assumed to play a crucial role in comprehending synesthetic metaphors. We analyzed how many words associated with synesthetic metaphors could be classified into those based on event knowledge. The results showed that there were significantly more words based on event knowledge than those which could not be classified as words based on event knowledge. This result suggests that event knowledge play an important role in comprehending synesthetic metaphors.

Keywords: synesthetic metaphors; Japanese language; event knowledge; words association; emergent features.

Introduction

Synesthetic metaphors such as “*sweet touch*” or “*sweet voice*” are one kind of adjective metaphor, in which an adjective denoting the perception of some sense modality modifies a noun’s modality. Metaphor studies in the domain of cognitive science have paid little or no attention to adjective metaphors. Many existing studies have paid much attention to nominal metaphors such as “*My job is a jail*” (e.g., Bowdle & Gentner, 2005; Glucksberg, 2001; Jones &

Estes, 2006; Utsumi, 2007) and predicative metaphors such as “*He shot down all of my arguments*” (e.g., Lakoff & Johnson, 1980; Martin, 1992).

Many studies focusing on synesthetic metaphors, including Werning et al. (2006), have examined how the acceptability of synesthetic metaphors can be explained by the pairing of adjective modifier’s and head noun’s modalities. Ullmann (1951), in a very early study on synesthetic metaphors, proposes a certain hierarchy of lower and higher perceptual modalities. He claims that qualities of lower (e.g., tactile) senses should preferentially occur in the source domain (i.e., adjective), while qualities of higher (e.g., optic) senses should be preferred in the target domain (i.e., noun). After Ullmann, Williams (1976) makes a more differentiated claim of directionality, in which a similar order of sense modalities is proposed. Werning et al. (2006) explores the factors that enhance the cognitive accessibility of synesthetic metaphors for the German language. Very few studies, however, have attempted to explore how people comprehend synesthetic metaphors.

Utsumi & Sakamoto (2007a) is one of the few studies to have explored how people comprehend synesthetic metaphors. They proposed a two-stage categorization theory and argued that the comprehension process of adjective metaphors including synesthetic metaphors could be explained as a two-stage categorization process. The intuitive idea behind two-stage categorization is that correspondences between the properties literally expressed by the adjective and the properties to be mapped onto the noun would be indirect, mediated by an intermediate category. In the case of “*red voice*”, for example, the adjective “*red*” first evokes an intermediate category “*red things*,” to which “*blood*,” “*fire*,” “*passion*,” “*apple*” and “*danger*” typically belong. Then exemplars relevant to the noun “*voice*” are selected and they evoke a final abstract category of property like “*scary*,” “*screaming*” and “*dangerous*.” However, they did not mention the relationship between the intermediate category and the noun and the detailed process in which certain exemplars are selected as those relevant to the noun was left unexplored.

In this study we focus on experience-based event knowledge to explain how people comprehend synesthetic metaphors.

Event knowledge has been recognized to be important for metaphor comprehension process by many scholars. For instance, Lakoff & Johnson (1980) argue that metaphors like HAPPY IS UP as in “*She is in high spirits*” and ANGER IS HEAT as in “*boil with anger*” are grounded in correlations in our experience. The HAPPY IS UP metaphor is grounded in the experience that a person in a positive emotional has an erect posture, and the ANGER IS HEAT metaphor is grounded in the experience that the angry person feels hot.

As for synesthetic metaphors, Taylor (2003) argues that they cannot be reduced to correlations. He argues that synesthetic metaphors are based on perceived similarity across different domains. Unlike Taylor (2003), Sakamoto & Utsumi (2008) point out that there are a number of synesthetic metaphors which seem to be based on correlations in experience. For example, a metaphor “*sweet smell*” (“*amai nioi*” in Japanese) is based on correlations in experience. “*Sweet smell*” is the smell you feel when you eat something sweet. A metaphor “*delicious autumn*” (“*oishii aki*”) is also based on correlations in experience because you can eat lots of delicious meals in autumn (especially in Japan). However, Sakamoto & Utsumi (2008) did not verify their argument based on psychological experiment.

To sum up, we propose the following comprehension process: an intermediate category is evoked by the adjective to which various things belong. Then exemplars correlated in experience with the noun are selected as those mapped onto the noun and they evoke a final abstract category of property. The experience-based event knowledge plays an important role in the process of relating the intermediate category evoked by the adjective to the concept expressed by the noun.

Experiment

Participants

Participants were recruited through Macromill, Inc., an organization that maintains a panel of more than 533579 people who have agreed to participate in web-based online survey research. 3266 Japanese males and females, aged 20-78, agreed to participate in our experiment.

Materials

Materials used for our experiment (i.e., 62 Japanese synesthetic metaphors) were made by combining 24 Japanese adjectives with 5 Japanese nouns. The adjectives were “*light*” (“*karui*” in Japanese), “*hot*” (in temperature) (“*atsui*”), “*cold*” (“*tsumetai*”), “*hard*” (“*katai*”), “*soft*” (“*yawarakai*”), “*tasty*” (“*oishii*”), “*sweet*” (“*amai*”), “*sour*” (“*suppai*”), “*bitter*” (“*shibui*”), “*hot*” (in taste) (“*karai*”), “*fragrant*” (“*koubashii*”), “*smelly*” (“*namagusai*”), “*sweet-smelling*” (“*kaguwashii*”), “*stinking*”(1) (“*kusai*”), “*stinking*”(2) (“*kinakusai*”), “*red*” (“*akai*”), “*blue*” (“*aoi*”),

“*yellow*” (“*kiroi*”), “*white*” (“*shiroi*”), “*black*” (“*kuroi*”), “*quiet*” (“*shizukana*”), “*noisy*”(1) (“*urusai*”), “*noisy*”(2) (“*yakamashii*”), “*noisy*”(3) (“*sawagashii*”). The nouns were “*color*” (“*iro*”), “*touch*” (“*tezawari*”), “*voice*” (“*koe*”), “*taste*” (“*aji*”), “*smell*” (“*nioi*”).

Procedure

3266 participants were classified into 20 groups. 3-8 linguistic expressions were assigned to each group. The linguistic expressions assigned to one group were randomly assigned to each participant in that group (e.g., linguistic expressions assigned to group 1 were randomly assigned to each participant belonging to group 1).

Participants of group 1-4 were each assigned 7-8 adjectives or nouns, and the remaining 16 groups were assigned 3-4 metaphorical expressions per participant. They were asked to list 3 words associated with each linguistic expression.

Japanese is written with a mixture of hiragana, katakana, and kanji. Hiragana, katakana, and kanji of the same concept (e.g., rose can be written as “*ばら*,” “*バラ*,” or “*薔薇*”) were regarded as the same feature. This feature combination procedure was completed by three judges. Features regarded as the same by at least two judges were unified into one expression, and we got 8594 features. After this combination procedure, all features listed by at most 1 participant were dropped. The following analyses were based upon these amended feature lists.

Analysis 1

According to Becker (1997), when a person interprets a novel metaphor such as “*A child is a sponge*,” that interpretation has the potential to contain information from four logically possible sources. The first is a feature which is salient only for the vehicle (i.e., “*sponge*”). Thus, this feature appears in the interpretation for the vehicle and the metaphor. She refers to such a feature as a “*vehicle-shared feature*.” The second is a feature which is salient only for the topic (i.e., “*child*”). Thus, this feature appears in the interpretation for the topic and the metaphor. She refers to such a feature as a “*topic-shared feature*.” The third is a feature which is salient for both the vehicle and the topic. Thus, this feature appears in the interpretation for the vehicle, the topic and the metaphor. She refers to such a feature as a “*common feature*.” The fourth is a feature which is not salient either for the vehicle or for the topic. Thus, this feature appears in the interpretation only for the metaphor. She refers to such a feature as an “*emergent feature*.”

Becker (1997) conducted a psychological experiment for “*A is a B*” metaphors. Participants were divided into two groups. One group of participants listed features of metaphors. The other group of participants listed features of the topic or the vehicle presented alone. Features from metaphor interpretations were compared with features listed for vehicle interpretations and topic interpretations in order to identify the four kinds of features: common, vehicle-

shared, topic-shared, or emergent. These features are shown in Table 1.

Table 1: Features.

features	detail
common	features listed for the metaphor, the vehicle and the topic
vehicle-shared	features listed for both the metaphor and the vehicle, but not listed for the topic
topic-shared	features listed for both the metaphor and the topic, but not listed for the vehicle
emergent	features listed for the metaphor, but not listed for either the vehicle or the topic

The result of her experiment showed that metaphor interpretations contained larger numbers of vehicle-shared and emergent features than either common or topic-shared features. In Particular, there were significantly more vehicle-shared features than the other kinds of features. Furthermore, she found that altering a metaphor’s vehicle produced greater changes in emergent content than did altering the topic and suggested that emergent features were influenced primarily by salient features of the vehicle.

In Analysis 1 we compare what Becker (1997) says for the comprehension of nominal metaphors with the comprehension of synesthetic metaphors.

Features listed by participants were classified into one of the four kinds as in Table 1. For each metaphor, the frequency of each of the four kinds was counted. Features were counted both as types (i.e., counted only once no matter how often the feature was listed) and as tokens (i.e., counted as often as the feature was listed). The result was 1198 types and 10388 tokens.

The mean value of common, vehicle-shared, topic-shared, and emergent features are presented in Figure 1 (type counts) and Figure 2 (token counts).

Figure 1: The mean value of the four kinds of features (type counts).

Figure 2: The mean value of the four kinds of features (token counts).

As can be seen from the two figures, regardless of whether one counts features as types or as tokens, participants produced more emergent features than the other kinds of features.

Analyses of variance (ANOVAs) among the four kinds (common, vehicle-shared, topic-shared, emergent) were conducted for both type and token counts. The type count analysis revealed a significant feature type main effect, $F(3, 183) = 456.82, p < .001$. Post hoc analyses (Ryan’s method) to explore the interaction revealed that significantly more emergent features were produced than the other kinds of features ($p < .05$) and significantly less common features were produced than the other kinds of features ($p < .05$). The token count analysis also produced a significant main effect, $F(3, 183) = 74.79, p < .001$. Post hoc analyses (Ryan’s method) to explore the interaction revealed that significantly more emergent features were produced than the other kinds of features ($p < .05$) and significantly less common features were produced than the other kinds of features ($p < .05$). In the type count analysis significantly more vehicle-shared features were produced than topic-shared features ($p < .05$), but in the token count analysis this difference was not significant.

These results are different from the results of Becker (1997) which analyzed nominal metaphors. According to Becker (1997), in the interpretation of nominal metaphors there were significantly more vehicle-shared features than the other kinds of features, and nominal metaphors were influenced primarily by salient features of the vehicle. Our results show that in the interpretation of synesthetic metaphors there were significantly more emergent features than the other kinds of features. Thus, our results suggest that we do not so directly comprehend synesthetic metaphors based on salient features of the vehicle or the topic.

Analysis 2

If, as shown in Analysis 1, synesthetic metaphors were not so directly comprehended by salient features of the vehicle

or the topic, where do the emergent features come from? We address this question based on the assumption that the influence of salient features of the vehicle or the topic in the comprehension process of synesthetic metaphors is indirect, mediated by experience-based event knowledge. As we described in the introduction, Sakamoto & Utsumi (2008) suggest that synesthetic metaphors such as “sweet smell” (“*amai nioi*” in Japanese) is based on correlations in experience. Thus, in Analysis 2 we explore whether features listed for synesthetic metaphors could be explained by experience-based event knowledge.

Considering experience-based event knowledge and the fact that the vehicle and the topic of a synesthetic metaphor are an adjective and a noun, respectively, we can elaborate the claim of Sakamoto & Utsumi (2008) as follows:

[Hypothesis]

Synesthetic metaphors are interpreted based on event knowledge in which we typically perceive a property denoted by the vehicle (i.e., adjective) and an object denoted by the topic (i.e., noun) simultaneously.

According to this hypothesis, words associated with synesthetic metaphors reflect the process shown in Figure 3; we understand the metaphorical expression as “an object of perception readily evoked by an event in which an entity characterized by the adjective figures prominently.” Then we evoke a concrete event in which we typically perceive a property denoted by the adjective and an object denoted by the noun simultaneously. Therefore, words associated with the synesthetic metaphor reflect the evoked concrete event. That is, words associated with the synesthetic metaphor are either feature 1 (hereafter, F1), feature 2 (F2) or feature 3 (F3) in Figure 3.

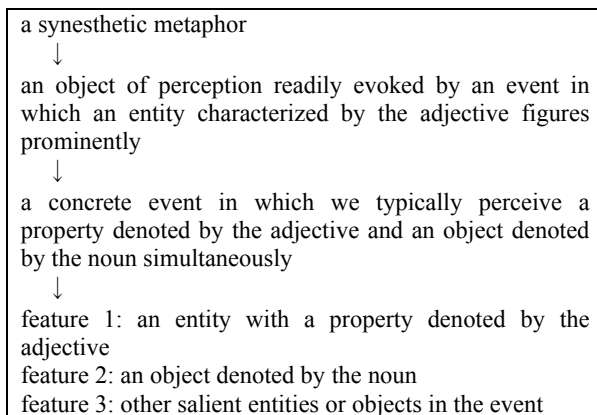

Figure 3: comprehension process of synesthetic metaphors

For example, in the comprehension of “red taste” (“*akai aji*” in Japanese), as shown in Figure 4, an event in which we eat chili peppers is evoked as an event in which we perceive “red” and “taste” simultaneously. This comprehension process is verified when features such as

“chili peppers (F1),” “hot (F2)” and “sweat (F3)” are listed for “red taste” in the experiment.

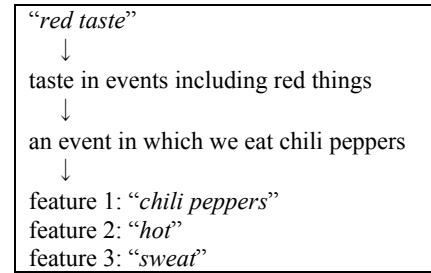

Figure 4: comprehension process of “red taste”

If this hypothesis is valid, the ratio of features corresponding to either F1, F2 or F3 against all the features collected in the experiment will be very high. Therefore, in Analysis 2, we explore the ratio of features corresponding to either F1, F2 or F3 against all the features collected in the experiment. This exploration is based on the following procedure.

Step 1: Labeling features

This step is a preparation for Step 2 and Step 3. Step 2 and Step 3 are procedures for identifying features corresponding to either F1 or F2.

In this step, features satisfying either of the condition shown in Table 2 are labeled either X or Y. This labeling procedure is conducted based on majority decision of three judges. Hereafter, WXs denote features labeled X and WYs denote features labeled Y. For example, features such as “chili peppers” or “tomato” listed for “red taste” are WXs, and features such as “hot” listed for “red taste” are WYs.

Notice that at this step we cannot yet determine whether WXs and WYs correspond to either F1 or F2.

Table 2: Labels and Conditions.

label	condition
X	an entity with a property denoted by the adjective
Y	an object denoted by the noun

Step 2: Identifying F1

One situation (hereafter, S1) in which we perceive properties denoted by the adjective (hereafter, PA) and objects denoted by the noun (hereafter, ON) simultaneously is one situation in which there is an entity satisfying both a PA and an ON. In S1, if an entity satisfying both a PA and an ON is a WX, the expression “the ON of a WX” is natural. For example, since “chili peppers” for “red taste” is a WX, “the ON of a WX” is “the taste of chili peppers.” This expression is natural.

In this step, therefore, the three judges mentioned in Step 1 consider whether “the ON of a WX” is natural for each synesthetic metaphor. If two or more judges find this

expression natural, the WX is regarded as F1. So, “*chili peppers*” for “*red taste*” is regarded as F1.

Step 3: Identifying F1 and F2

If an entity satisfying both a PA and an ON is evoked as shown in Step2, a possibility, in which our participants will very likely list not only WXs but also a concrete ON of a WX as a feature, is very high. Features corresponding to concrete ONs of WXs are WYs.

Another situation in which we perceive a PA and an ON simultaneously (hereafter, S2) is one situation in which an entity with a PA is different from an object of a category ON. In S2, if an entity with a PA is listed as a feature, the entity is a WX. In S2, if an object of a category ON is listed as a feature, the object is a WY.

If a synesthetic metaphor evokes S1 or S2 for our participants, that will indicate that WXs are strongly connected with WYs. This in turn will make it easy for the three judges mentioned in Step 1 to imagine a concrete event based on the closely associated WXs and WYs.

In this step, the three judges combine all WXs with all WYs for each synesthetic metaphor. If two or more judges can easily imagine concrete events, a WX and a WY comprising the combination are regarded as F1 and F2 respectively.

For example, the features “*chili peppers*” and “*hot*” are listed for “*red taste*.” “*Chili peppers*” and “*hot*” are a WX and a WY respectively. The judges make a pair “*chili peppers, hot*.” Then, they consider whether they can easily imagine an event on the basis of the pair. Since they can imagine an event easily (e.g., eating chili peppers), “*chili peppers*” and “*hot*” are regarded as F1 and F2 respectively.

Step 4: Identifying F3

In this step, we identify F3. Features unlabeled in Step 1 may correspond to F3. If unlabeled features correspond to F3, concrete events are most likely to have already been evoked. Thus, there is a strong possibility that F1 and F2 are included in the features listed by our participants.

In this step, based on this line of reasoning and the rationale presented in Step 3, we conduct the following procedure; the three judges mentioned in Step 1 combine features regarded as either F1 or F2 in Step 2 and Step 3 with unlabeled features. If two or more judges can imagine concrete events easily, the unlabeled feature included in the combination is regarded as F3.

For example, “*chili peppers*”, “*hot*” and “*sweat*” are listed for “*red taste*.” “*Chili peppers*” and “*hot*” are F1 and F2, respectively, in Step 3. Thus, the judges combine “*sweat*” with the pair “*chili peppers, hot*.” Since the judges can imagine an event easily (e.g., eating chili peppers), “*sweat*” is regarded as F3.

Result of Analysis 2

All the features regarded as either F1, F2 or F3 are those based on experience-based event knowledge. Table 3 shows the total number of token counts and the mean value of

token counts when the features are classified into either those based on event knowledge or those not based on event knowledge. The proportion of the token counts classified as the features based on event knowledge was significantly higher than those which could not be classified as the features on event knowledge, $\chi^2(1, N = 10388) = 804.01, p < .01$. Furthermore, the T-test using the mean value of token counts revealed that there were significantly more features based on event knowledge than those which could not be classified as features based on event knowledge, $t(61) = 3.28, p < .01$.

This result shows that synesthetic metaphors tend to be understood based on event knowledge.

Table 3: Classification Result.

	event knowledge	not event knowledge
total	6639 (63.91%)	3749 (36.09%)
mean	107.08	60.47

General Discussion

Indication for the theory of metaphor

Analysis 1 showed that in the interpretation of synesthetic metaphors there were significantly more emergent features than the other kinds of features. The result of Analysis 1 suggests that we do not so directly comprehend synesthetic metaphors based on salient features of the vehicle or the topic.

Utsumi & Sakamoto (2007a, 2007b) proposed a two-stage categorization theory. In the two-stage categorization theory, correspondences between the properties literally expressed by the adjective and the properties to be mapped onto the noun would be indirect, mediated by an intermediate category. Utsumi & Sakamoto (2007a, 2007b) tested their argument by means of computer simulation in which the meanings of adjective metaphors including synesthetic metaphors are computed in a multidimensional semantic space. In the simulation, three theories for adjective metaphor comprehension, i.e., two-stage categorization theory, categorization theory (Glucksberg, 2001; Glucksberg & Keysar, 1990) and comparison theory (Bowdle & Gentner, 2005), were compared in terms of how well they mimic human interpretation of adjective metaphors. The simulation result was that the two-stage categorization theory is a more plausible theory of adjective metaphors than the other kinds of theory.

As for the fact that we do not so directly comprehend synesthetic metaphors based on salient features of the vehicle or the topic, the result of Analysis 1 is consistent with the two-stage categorization theory. Thus, our results support the arguments by Utsumi & Sakamoto (2007a, 2007b). Furthermore, while Utsumi & Sakamoto (2007a, 2007b) left unsolved the detailed process in which certain exemplars are selected as those relevant to the noun, the result of Analysis 2 showed that experience-based event knowledge played an important role in that process.

Importance of Event Knowledge

We showed that experience-based event knowledge play an important role in the comprehension process of synesthetic metaphors. How we use knowledge to interpret new experiences is an important topic in cognitive science. Since 1970's many studies have been conducted based on the concepts of "frame" (Minsky, 1975), "schema" (Rumelhart, 1980) and "script" (Schank & Abelson, 1977). Recent studies such as Bicknell & Rohde (2009) also argue the important role of real-world event knowledge in processing linguistic expressions. Our study showed that experience-based event knowledge also play an important role in the comprehension process of metaphorical expressions.

Conclusion

This paper explored how people comprehend synesthetic metaphors, to which previous studies had paid little attention. The results of psychological experiments showed that there were significantly more emergent features than the other kinds of features. This suggests that we do not so directly comprehend synesthetic metaphors based on salient features of the vehicle or the topic. We argued that experience-based event knowledge played an important role in the comprehension process of synesthetic metaphors.

In our future work we are planning to confirm this finding by different psychological experiments. Since the tendency of synesthetic metaphors to evoke negative images was pointed out by Sakamoto and Utsumi (2009), it would also be interesting for further work to investigate how those negative images were evoked in the comprehension process of synesthetic metaphors using experience-based event knowledge.

Abstract

Two experiments demonstrate the impact of the self-performed actions during the encoding phase on the amount of the learned information. People memorized more items if they had touched the stimuli during learning. The experiments differ from many of the classical studies testing embodiment of human memory in two main respects:

First, the performed actions are completely unrelated to the essence of the learned stimuli, thus the results can not be explained by pure association-based facilitation. Second, the actions are performed during the encoding phase only, thus the results may be directly linked to the nature of the encoded representations. The possible mechanisms that may underlie the observed influence are discussed shortly.

Keywords: embodiment; memory encoding; representations

Introduction – embodied cognition

The classical AI theory of manipulations of abstract symbols had been reconsidered during the last decades. Very influential in the field of the so-called embodied view of cognition are the books of Lakoff and Johnson (Lakoff & Johnson, 1980, 1999). They argue for a massive cross-domain interrelation of various structures that map each other. Furthermore, the authors claim that maybe the whole cognition is ground in the body. The growing theory of embodied cognition rejects in its extreme version even the very idea of representations: “What you get underlying our representations of the world - the kinds of things we formulate, for instance, in declarative sentences - is not further representations but rather a certain grasp of the world that we have as agents in it” (Taylor, 1987, p. 432).

The relation between the sensory-motor and the conceptual system was widely explored from different perspectives. O'Regan & Noë, (2001) focus on the dynamic interrelation of all cognitive systems – the perceptual one, the action one, and in turn the conceptual one. The fundamental base for the view that perceptual signals lie at the core of the conceptual representations is enriched by the works of Barsalou (1999) and Brooks (1987). According to the Barsalou's perceptual symbol system, the representations of all concepts, even the abstract ones, are based on associations with huge number of perceptual and motor neural signals. A wonderful theoretical analysis of the philosophical view of embodiment had been made by Anderson (2003), as well by Shepard (1984), Glenberg (1997), and Varela et al. (1991).

At the same time, many empirical studies gave additional support for the idea of embodiment. Sinai et al. (1998) and

Proffitt et al. (2003) demonstrated how physical difficulties may change abstract judgments of people. For example, people judge a certain distance as longer if they stay with a heavy rucksack on their back. Myung et al. (2006) performed an experiment to show that recognition of the action, for example, typing on typewriter, is facilitated by the context of a piano just because of the common typical finger movements performed on both objects. In addition, not only the performed actions influence perceptions, but also the perceived objects influence directly some motor commands. Thus, in a series of experiments Tucker and Ellis (Tucker & Ellis, 1998; Ellis & Tucker, 2000), as well as Richardson et al. (2001) demonstrated this opposite effect – the perceived objects automatically and immediately activate certain action responses.

Evidence supporting the embodiment view on cognition can be found also in brain imaging researches (Hauk, Johnsrude & Pulvermüller, 2004; Damasio, 1999). Even the mirror neurons (Rizzolatti & Craighero, 2004) often are speculatively related to this view.

Together with the interdependency between perceptions and actions, the relationship between language and constraints of the body is explored widely by the scientists. For example, people prefer to say that a given umbrella is above the man's head if the umbrella protects the man from the rain even if the real position of the umbrella is at 45 degrees according to the head (Coventry et al., 2001). The claim that language is grounded in our bodies and actions is supported by a huge number of empirical evidences (Glenberg & Kaschak, 2002; Pecher et al., 2003; Solomon & Barsalou, 2001; Spivey et al., 2000; Stanfield & Zwaan, 2001; Zwaan et al., 2002). Catrambone et al. (2006) demonstrated that an irrelevant touch of the objects may facilitate relatively abstract analogy-making. Maybe babies first ground the meaning of verbs that are closely related to the body parts (Tardif & Wellman, 2000).

Actions – Massively associated with the representations or essence of the memorized knowledge

However, most of the empirical studies can not answer whether there are pure symbolic representations of objects in our mind that are massively associated with the action and perceptual representations or indeed the body actions and perceptions are the very essence of the memory traces. Many classic theories in the field of memory and learning assume that learning can be improved if the target

information is processed from different modalities. For example, The Levels of Processing Theory (Craik & Lockhart, 1972), which is deeply based on representational view of memory, is grounded exactly on the interaction between memory and vision (Craik & Lockhart, 1972), memory and hearing (Fletcher et al., 1998; Srinivas et al., 1997), memory and touching (Srinivas et al., 1997), and memory and smell (Schab, 1991). Dual-coding theory (Paivio, 1986) also assumes that the visual and auditory information are processed separately but nevertheless claims for a deep relation between them (Anderson & Bower, 1973). Thus, many empirical data that support embodied view on memory are actually arguments for the relationship between perceptions, actions, and conceptual system but do not contradict in any way to a possible existence of pure symbolic representations of the concepts.

In most of the experiments that test embodied effects on human behavior, the performed actions are closely associated to the respective test items. For example, recognition of a typewriter is faster in the context of a piano (Myung et al., 2006). However, this does not mean that the concrete movements of fingers are inseparable part of the representation of the typewriter. Instead, maybe there are huge number of associative links between the symbolic representation of the concept ‘typewriter’ and many concrete situations in which a typewriter has been used. Furthermore, maybe the representation of these concrete situations is linked (again associatively) to the representation of the concrete finger movements.

Thus, we decided to conduct an experiment in which the manipulated action is not associatively linked to the essence of the tested items in any way. More concretely, we decided to test whether simple pointing to a colour sample may improve actor’s memory of this sample.

In addition, we wanted to ensure that the effect of action should not be manifested during the test phase. With other words, we attempted to avoid the possible explanations that actions and movements may influence the process of retrieval. Thus, we ask participants to perform or not certain actions during the phase of memorizing only. Then people from both acting and not-acting groups were tested in the same way – by asking them to write on a sheet of paper what do they remember.

Experiment 1: The role of the own action

Method

Design

One-factorial between-subject design was used. People from both the control and the experimental group were asked to memorize the colours of twelve small rectangles, placed at different positions on the screen. People from the experimental group were asked to open the rectangles themselves by touching different parts of the touch-screen. When any of the rectangles on the screen was touched a colour appears on its place. Participants from the control

group observed the same procedure of opening the colours without touching the screen. The dependent variable was the number of correctly recognized colours on the respective positions.

Stimuli

Six different colours, each of them used twice, were randomly placed on a 4x3 table. The exact positions of each colour, as well the predefined order for their exposure, are shown on table 1. Initially all colours are “closed”, i.e. the rectangles were gray.

Table 1: The order of opening and the colour of each rectangle.

6. red	3. blue	8. green	11. orange
10. yellow	12. black	1. red	7. blue
9. green	4. orange	5. yellow	2. black

Procedure

A 4x3 table with 12 gray rectangles was placed at the middle of a touch-screen monitor. When a fixation cross appeared within a certain rectangle, participants from the experimental group touched it and the rectangle changed its colour from gray to one of the six target colours (i.e. red, green, yellow, orange, black and blue). The duration time for the colour presentation was fixed to 1500ms than the rectangle became gray again. One second later the fixation cross appeared on a different location and the procedure was repeated until all twelve rectangles were seen.

Participants from the control group did not touch the screen. Two seconds after the fixation cross the rectangle changed its colour alone for 1500ms and then turned into gray again. Thus, the control participants were only permitted to observe the same procedure as participants in the experimental group but were not actively involved in it.

The order of presentation of the rectangles, as well the position of the colours, was randomly assigned at the beginning of the experiment and was the same for all participants.

The memory test for both groups was performed five minutes later, at which time the participants looked a short movie. Each participant received a sheet of paper with a 4x3 empty table graphed on it. Then he/she was asked to fill the table with the colour labels that he/she can memorized. For each participant the number of positions filled with correct colour labels was counted.

Participants

53 students from New Bulgarian University (26 in the experimental and 25 in the control group) took part as volunteers in the experiment. The range of their age was from 19 to 32 years; 24 of them were males and 29 were females, randomly assigned to both groups.

Results

Nobody had memorized correctly eleven or twelve colours; everybody had memorized at least one; one person had memorized correctly only one colour.

The mean number of correctly recognized colours for the control group was 4.33, st. dev. 1.94. People from the experimental group had recognized correctly mean 5.96, st. dev. 2.60 (see figure 1). The difference was significant: $t(51) = -2.59$, $p = 0.012$; the size effect (Cohen's d) was 0.725.

Figure 1. The results from the first experiment - mean number of positions, filled with correct colours during the memory test for both groups. The error bars show 95% CI for the means.

Discussion

The results from the experiment demonstrated that people memorize better when they use their own hand for touching the stimuli during learning. These results differ from most of the empirical data supporting the idea for embodiment of our memory traces because the memorized items were completely unrelated to the specific hand action and because the action was performed during the encoding phase only, but not during the test phase. Thus, the results are in favor of the hypothesis that concrete situated actions, performed by people, are important part and key factor of the representation of relatively abstract and in some sense purely symbolic items.

However, two alternative explanations of the experimental results may arise: First, maybe memories of people from the experimental group are richer because a representation of a movement is added to the representation of each colour position. Thus, because the overall amount of information for the experimental group is larger, maybe the respective memory traces are more accessible. Second, it could be that participants from the control group were less motivated and less involved in the task.

Thus, a second experiment had been performed. The amount of the information that maybe encoded was controlled. In addition, the experiment was performed in an ecological environment by a trained experimenter who tried to keep the attention of people from both groups.

Experiment 2: Control of the amount of information

This experiment differs from the first one in three aspects:

First, a manually made cardboard was used instead of a computer touch-screen. Second, the experimenter opened and closed the covers of the coloured rectangles for the control group. This ensured that for both groups somebody's movements can be encoded. Third, the experimenter was trained on several things: to keep the motivation and attention of the participants; to know the exact order of opening the covers; and to keep the time for exposition of the colours as equal as possible.

Method

Design and stimuli

The design of the second experiment followed exactly the respective one from the first experiment. However, the stimuli used differed significantly. A 4x3 cardboard was manually modeled and each of the twelve rectangles was differently coloured. The pattern of the colours followed exactly the respective pattern from the first experiment (see table 1). Twelve gray covers that could be opened were stuck in one side of the rectangles.

Procedure

The experimenter touched one of the covers till the respective participant attended it. Then in the control group she opened the cover for about one and a half second and then closed it. Participants from the experimental group were instructed to open the cover that was pointed from the experimenter themselves and after one and a half second they closed the cover. The order of presentation of the stimuli was the same as in the first experiment (see table 1).

After the presentation of the twelve stimuli, all participants watched a five minutes movie on a portable computer screen. After that all of them received a graphed sheet of paper and were asked to fill the positions with the colours they remember. Thus, the overall procedure was the same as in the first experiment.

Participants

40 persons (20 women and 20 men) took part as volunteers in the experiment. The range of their age was from 18 to 35 years. All they were randomly assigned to one of the two groups.

Results

Everybody had memorized at least one colour position; two persons had memorized correctly just one; one of the participants had filled correctly all twelve colours.

The mean number of correctly recognized colours for the control group was 4.50, st. dev. 2.37. People from the

experimental group had recognized correctly mean 6.45, st. dev. 2.69 (see figure 2). The difference was significant: $t(38) = -2.43$, $p = 0.020$; the size effect (Cohen's d) was 0.77.

Figure 2. The results from the second experiment - mean number of positions, filled with correct colours during the memory test for both groups. The error bars show 95% CI for the means.

Discussion

During the second experiment the time of colour exposition was not controlled but the amount of the exposed information was equalized for the two groups, i.e. someone's hand opened and closed the covers. At the same time, in the first experiment, any possible influences from the exposure time or from the behavior of the experimenter were eliminated. Nevertheless, similar pattern of results was observed in both experiments. Moreover, although during the ecological experiment people memorized a bit more in both groups, the size effect was almost the same in the two experiments. Thus, the effect of the authentic actions on the amount of the memorized information seems to be stable enough.

Models that can account to the experimental results

Often the phenomena of the embodiment cognition are related to the constructive processes of cognition. Thus, the models of constructive memory like the CHARM model (Metcalf, 1990), the TODAM2 model (Murdock, 1995), the Trace synthesis model (Nystrom, McClelland, 1992) and the Complementary Learning Systems (CLS) model (McClelland, McNaughton, & O'Reilly, 1995) can account to many of the empirical data that support the embodied view. All these models are based on massively interconnected associative networks. Thus, they can explain the influence of the performed actions to the perceptions (for example, the contest of a piano may facilitate the recognition of a typewriter). They can explain as well the opposite relationship – the perceived objects may automatically activate motor commands.

However, the results from the two experiments can not be explained satisfactory from this type of models. The main reason is that the associative links can be excluded as a possible reason for the effect, because people did not make any movements during the recognition phase.

A second possible explanation of the experimental results can arise from the encoding of the information that comes from proprioception. As it was mention during the discussion of the first experiment, maybe people from the experimental group have richer representations, because their own pointing is an additional portion of information. This was one of the reasons for conducting the second experiment, in which somebody's hand movement can be encoded in both groups. However, the information that comes from the proprioception still is available for the people from the first group only. Unfortunately, there are not any memory models that take into account this type of information.

Ballard and colleagues (Rao, Ballard, 1995, Ballard et al., 1997) propose their model, based on the idea for deictic pointers. According to the authors, eye-fixations and the attention serve for creation and manipulation of pointers to the objects in the environment. The pointers, instead of the representation of the objects can be encoded in the memory. If necessary, it is easy to use these pointers for finding the objects and to encode from them the necessary information. From one hand, the deictic codes model proposes a way for a drastic decreasing of the necessary calculations for performing tasks in a 3-D environment. From other hand, they answer to the question why people are limited for the amount of information that can process simultaneously.

The paradigm of the proposed experiments seems very close to the deictic codes view. Maybe pointing to the objects with a hand is an additional source for creating such deictic pointers. Thus, it seems natural why people from the experimental group have better memories – they can just use more deictic pointers.

Unfortunately, the model that Ballard and colleagues propose is still not enriched with mechanisms for creation, manipulation, and retrieval of memory traces from the long term memory. Thus, the relation between the deictic codes view of the embodiment and the results from the two experiments seems promising but still speculative.

Finally, maybe pointing to the objects has additional social value that in turn can influence memory. (Nathan, in press) proposes various examples how gestures may enrich the listener's understanding as well as the speaker's one during a conversation. Thus, people from the experimental group point to the colour samples and they point not only for themselves but to the experimenter too. Maybe this is the reason for their better memory.

Conclusion

The theory of embodiment of memory and cognition opposes in its extreme versions the classical representational based view. Many empirical data support the close relationships and interdependencies between our conceptual system and the sensory-motor inputs and outputs. However, it is still an open question whether actions and perceptual signals lie at the very core of the memory traces or it is just a massive associative interconnection between the separate conceptual and sensory-motor systems.

The two related experiments, presented here, tried to highlight more this question. People memorized better colour samples if they touched them instead of just observed them. The same effect of the action of touching has been observed both during the controlled laboratory experiment and during the more ecological second experiment.

It is demonstrated that the simple touching influences what people had learned even if the respective touching is not related in any way to the essence of the information, required to be learned. Thus, the results are in support of the hypothesis that the movements that we perform maybe are a substantial part of the representation of the things we learn during these movements. This hypothesis is supported additionally by the fact that the observed effect is caused by what is actually encoded, not by any influences of the actions during the recall phase.

The experiments, however, do not highlight any possible mechanisms that may underlie the observed effect. It is not clear whether the concrete touching influences the attention, the way of encoding, both, or something else.

Nevertheless, the observation that simple touching can influence the rate of memorizing of relatively abstract items seems promising for further investigations.

Abstract

Many theories in cognitive science assume that people possess a repertoire of strategies or a "toolbox" from which they choose depending on the situation. This approach suffers from the problem that the number of assumed strategies is often not constrained and may be extended post-hoc to improve the fit to the data. This makes it difficult to rigorously test and compare strategy repertoire models. To prevent this "strategy sprawl", a criterion is necessary to decide how many strategies a toolbox should include. Here, Bayesian statistics provide a powerful tool to evaluate toolboxes of different sizes based on their marginal likelihoods. The present work illustrates how such a Bayesian approach can be implemented and demonstrates its applicability by means of parameter recovery studies. Our approach also makes the novel contribution of showing how Bayesian statistics allow testing the strategy repertoire theory against alternative decision theories.

Keywords: Strategy repertoire theories, Bayes factor, model selection, simulation, Bugs.

The problem of strategy sprawl

A common assumption within many research areas in cognitive science is that people possess a repertoire of cognitive strategies to solve the problems they face. For example, people use different strategies for making consumer decisions (Payne, Bettman, and Johnson, 1993), for organizational memory tasks (Coyle, Read, Gaultney, & Bjorklund, 1998), for estimations of frequencies (Brown, 1995), for categorization problems (Patalano, Smith, Jonides, & Koeppel, 2001), for the development of mathematical skills (Siegler, 1991), or for inference problems (Gigerenzer, Todd, and the ABC Research Group, 1999). The strategy repertoire approach provides a fruitful way to explain intra- and inter-individual differences in cognitive processes. This approach has also been described by the metaphor of an adaptive toolbox according to which individual decision makers select between different cognitive strategies to solve specific tasks just as a craftsman selects tools from a toolbox.

Despite its undisputed success in explaining a wide range of human behavior, the idea of a toolbox raises the question of how many different strategies the mental toolbox should contain in the first place. A larger number of possible strategies will always lead to a better description of the data

but not necessarily to greater insight. For example, by assuming a specific tool for each possible task, the toolbox should provide a good description of observed behavior due to its great flexibility. Along the same lines, Dougherty, Thomas, and Franco-Watkins (2008) criticized that in a situation in which no strategy out of a set is able to describe a person's choices, an unconstrained toolbox could be enlarged by a new strategy to describe the data. On the other hand, if the toolbox is restricted to only a few or to a single strategy it would lose its ability to describe different cognitive processes.

In the following, we outline a possible solution to the question of how many tools a toolbox should contain based on a Bayesian approach. Having a criterion for determining how many strategies to include keeps strategy sprawl at bay and is also a necessary pre-condition for rigorously comparing different toolbox models with competing cognitive theories that do not assume different strategies but rely on the idea of an "all-purpose" process (Newell, 2005).

Example of a cognitive toolbox

As an illustrative example of a cognitive toolbox, imagine a situation in which a person tries to determine which of two used cars is a better deal. To make this decision, a person could use different pieces of information (i.e., cues) such as mileage, number of previous owners, or accident history of the cars. In such a situation, each single cue provides a hint of which car might be better, but none of the cues provide an indisputable prediction, because it could be that a car with many previous owners still turns out to be superior overall. In other words, the cues are probabilistically related to the criterion, so that even an object with positive cue values for all cues could sometimes be inferior compared to an object with negative cue values. Probabilistic inferences can be complicated because it is not always clear which information is relevant and how and whether the different pieces of information should be combined.

To make probabilistic inferences, such as choosing the better of two cars, people may choose from a variety of cognitive strategies, that is, from their adaptive toolbox (Gigerenzer, Todd & the ABC Research Group, 1999). For instance, when choosing between two options, people could use a simple non-compensatory decision strategy called take the best (TTB) that only focuses on the single most important or valid cue that discriminates between the two

options. If the most valid cue discriminates between the alternatives, TTB chooses the object with the positive cue value. Only in cases where the most valid cue does not discriminate does TTB then consider the second most valid cue, and so on. An alternative strategy in the toolbox could be a weighted additive (WADD) rule. This model adds up all available cue values weighted by their respective validities and then selects the alternative with the largest score. The WADD rule is compensatory because a highly valid cue may be compensated for by a number of other cues that point to the opposite choice.

This example illustrates that different decision strategies can be applied to make a choice between two options that are described by several attributes. Here, proponents of a toolbox approach could argue that people use either TTB or WADD depending on the decision situation and the characteristics of the decision maker.

Preventing strategy sprawl

When examining how people solve an inference problem researchers aim to identify the model that best describes the cognitive processes, that is, the one that most likely generated the observed data. Under the assumption that people have a repertoire of strategies, the goal is to identify the strategy that a person has selected. Possible strategies are not known a priori. Therefore, a researcher may add more and more strategies to the toolbox to increase chances that one strategy provides a good fit to the data. From a model comparison perspective, a given toolbox becomes more flexible and complex when more strategies are added. Accordingly, it is not surprising when it provides a better description of the observed data. Therefore, the question of how many strategies to include in the toolbox essentially becomes a trade-off between the complexity of the toolbox and its fit in describing observed data. Adding another strategy is only justified if it increases the fit substantially. Bayesian techniques offer a valuable theoretical framework to make this trade-off and to identify a toolbox that fits the data well. More precisely, the probability of a specific dataset given a specific toolbox model (referred to as the evidence or marginal likelihood of that model) can be used as a criterion of how many tools to include.

Bayes' theorem

In a Bayesian framework, the marginal likelihood $p(D)$ is a measure of how well a given model M describes the observed data D across all possible parameter values of that model (Kass & Raftery, 1995; Shiffrin, Lee, Kim, & Wagenmakers, 2008):

$$p(D) = \int p(D|M) \times p(M) \, dM \quad (1)$$

where $p(D|M)$ is the likelihood of the observed data given the model and $p(M)$ is the prior probability of the model. The evidence provides a viable metric to compare different models against each other. However, to eventually apply this criterion the possible toolbox models and the strategies

within each toolbox need to be specified in a Bayesian framework. In particular, this requires the specification of prior distributions and likelihood functions.

In the following, we lay out the necessary specifications in detail. To illustrate the basic principle behind this approach, we start with the simple example of comparing two toolboxes consisting of only one strategy each, before proceeding to the more complex case of comparing toolboxes of different sizes.

Model specification for a simple toolbox

As a first step, we compare two toolboxes that only consist of one single strategy each. For illustrative purposes, we assume that the first toolbox consists of TTB, described above. In its basic form, TTB is a deterministic strategy that assumes people make no errors. This is a rather unrealistic assumption because if someone uses TTB but occasionally makes an error, strictly speaking the resulting choice data would contraindicate the application of the strategy. Therefore we allow for the possibility of inconsistent choices due to application errors or “unsystematic noise”. We extended the deterministic model with a simple error theory, so that a parameter α_{TTB} indicates the probability that a decision maker will chose the alternative that was not predicted by TTB in a pairwise choice. In the following, we refer to this probabilistic version of TTB as TTB_a . Other deterministic choice strategies such as WADD can be extended by similar error terms, in an analogous manner.

Specifying the prior distribution

In the case of a toolbox that only consists of TTB_a as a single strategy, the only free model parameter is the application error α'_{TTB} . A reasonable prior on α'_{TTB} may be to assume an average application error of about 10%. Of course, other values are also possible. In any case, the application error will probably vary depending on the situation and the type of experiment. Therefore, a moderate degree of uncertainty concerning the prior distribution seems justified. As α'_{TTB} may fall within a range from 0 (no implementation error) to 1 (100% implementation error), we choose the prior to be beta distributed. For illustrative purposes, we set the rate and shape parameters of this beta distribution to 1 and 9, resulting in a mean of 0.1 and a standard deviation of 0.09.

$$\alpha'_{\text{TTB}} \sim \text{beta}(1, 9) \quad (2)$$

Specifying the likelihood function

Next, a likelihood function needs to be defined that indicates the probability of the observed data given the model. The predictions of a deterministic choice model like TTB are readily available as long as the attributes of options in the experiment are known. In this case, the likelihood is just a function of the implementation error α . If a single choice between a pair of options is in line with the deterministic predictions of the model for that pair, then likelihood of that choice equals $1 - \alpha$, otherwise, the

likelihood equals α . Hence, the likelihood of a series of N choices in an experiment is the product of likelihood values for all pairwise choices:

$$p(D|M) = \prod [d_n \times (1 - \alpha) + (1 - d_n) \times \alpha] \quad (3)$$

where d_n is 1 if the decision for the n^{th} pair of options is in line with the deterministic prediction of the model for that pair and 0 otherwise.

For illustrative purposes, suppose a participant in an experiment made z pairwise choices that were inconsistent with TTB's deterministic prediction and $N - z$ choices that were consistent with it. Following Equation 3, the likelihood of this data can be expressed as a Bernoulli function:

$$p(D|TTB_\alpha) = \alpha'^{\text{TTB}}_{}(z) \times (1 - \alpha'^{\text{TTB}}_{})(N - z) \quad (4)$$

Deriving $p(D)$ for a single strategy

Once the prior and the likelihood function of a model are specified, the evidence for the observed data $p(D)$ can be estimated. In the present case of a single strategy with one free parameter α , a closed-form solution exists:

$$p(D) = B(a + z, b + N - z) / B(a, b) \quad (5)$$

where B is the beta function, a and b are the rate and shape parameter of the beta distribution that defines the prior, and z quantifies how many out of a total of N choices are in line with the prediction of the deterministic model.

Specification for WADD

The outlined approach for TTB_α can be conveyed to other deterministic strategies like WADD. Like TTB, WADD can be extended with a similar beta-distributed error term leading to $WADD_\alpha$. The prior distribution and likelihood function for $WADD_\alpha$ can be specified analogously to TTB_α with the only difference being different deterministic predictions of WADD.

Comparison between two simple toolboxes

Now that two toolboxes are specified, they can be compared with regard to a given set of data. This case is analogous to a model selection task in which an individual decision maker can be classified as a TTB_α or $WADD_\alpha$ user.

To lay out the approach in a concrete way, we assume a hypothetical decision experiment in which a single participant made 40 choices among pairs of options described on a number of attributes, as in the used-car example outlined in the introduction. We further assume that the options were chosen to differentiate TTB from WADD, such that both strategies would make opposing predictions. In this example, a decision maker chooses option A 30 times and B 10 times. If we set the prior as $\text{beta}(1,9)$ for both models, we can calculate the respective marginal likelihoods according to Equation 2. For TTB_α , this yields $p(D) = 2.8 \times 10^{-11}$ for TTB_α as compared to

$p(D) = 2.5 \times 10^{-14}$ for $WADD_\alpha$. The ratio of the marginal likelihoods, also known as the Bayes factor (Kass & Raftery, 1995), is 1118:1 in favor of TTB_α . Therefore, Bayes' rule clearly indicates that the decision maker should be classified as a TTB_α user.

Next, we outline how this procedure can be extended to toolbox comparisons that include more than one decision strategy.

Specifying toolboxes with more than one strategy

The concept of a cognitive toolbox relies on the idea that decision makers have several decision strategies available to them. To account for this assumption, we extend the Bayesian approach to toolboxes that contain more than one strategy. Again, precise model specifications are required so that Bayesian techniques can be applied.

Model specification

For illustrative purposes, we assume toolbox $TB_{TTB, WADD}$ contains two strategies, TTB_α and $WADD_\alpha$. We further assume that an individual decision maker who uses this toolbox will choose according to TTB_α with probability β and according to $WADD_\alpha$ with the complementary probability $(1 - \beta)$. Thus, $TB_{TTB, WADD}$ has three free parameters: The implementation error for TTB in the toolbox (α_{TTB}), the implementation error for WADD in the toolbox (α_{WADD}), and the probability of selecting TTB_α (β). The likelihood function of this toolbox is simply a function of the likelihood for each single strategy weighted by the probability of selecting it:

$$p(D|TB_{TTB, WADD}) = \beta \times p(D|TTB_\alpha) + (1 - \beta) \times p(D|WADD_\alpha) \quad (6)$$

Next, a prior distribution for each of the three parameters needs to be specified. Without any prior knowledge about the probability of selecting TTB_α over $WADD_\alpha$ all possible values between 0 and 1 seem equally likely a priori. Accordingly, we assume that the prior on β is uniformly distributed:

$$\beta \sim \text{uniform}(\min = 0, \max = 1) \quad (7)$$

Likewise, in this example we do not make any a priori assumptions about the probability of particular implementation errors. Thus, we assume priors for α_{TTB} and α_{WADD} are uniformly distributed. Based on these specifications, the marginal likelihood of $TB_{TTB, WADD}$ can be estimated by integrating out all three parameters in the model analogous to Equation 1:

$$p(D) = \iiint p(D | \alpha_{TTB}, \alpha_{WADD}, \beta) \times p(\alpha_{TTB}, \alpha_{WADD}, \beta) | d\alpha_{TTB}, d\alpha_{WADD}, d\beta \quad (8)$$

While this approach is conceptually similar to the case with only one free parameter, it becomes more elaborate to

estimate the integral of Equation 1 as the number of free parameters increases.

MCMC methods to estimate the evidence

Fortunately, a closed-form mathematical solution, is not mandatory to estimate marginal likelihood because all that is needed is a representative sample from the integral of Equation 1 that is large enough to draw reliable conclusions on the shape of the distribution. Such a sample may be obtained by means of Monte Carlo Markov Chain (MCMC) methods for which statistical packages are readily available (Gilks, Richardson, & Spiegelhalter, 1996). For the present analysis, we utilized the *OpenBugs* software implemented in the *BRugs* package, version 0.51, that can be integrated into the statistics software *R*.

Similar to the mathematical solution outlined above, the implementation in *BRugs* requires the specification of prior distributions and likelihood functions. Provided it is properly implemented, the software returns the evidence as well as a representative sample of the full posterior distribution across all parameters.

Comparison between a small and a large toolbox

To illustrate the principle of comparing toolboxes that differ in the number of cognitive strategies they contain, we will compare a simple toolbox TB_{TTB} that only consists of TTB_a as a single strategy to a more complex toolbox $TB_{TTB,WADD}$ that contains both TTB_a and $WADD_a$. Thus, TB_{TTB} is nested within $TB_{TTB,WADD}$.

Transdimensional prior

Instead of calculating the evidence for both toolboxes separately, we directly compared the two models by means of a transdimensional prior θ . This prior acts like a model indicator, controlling which of two models most likely generated the observed data. Thus, θ immediately informs us which of the two toolboxes best describes the choices of an individual decision maker. The parameter θ is Bernoulli-distributed with a prior that assigns equal probabilities to both models (Han & Carlin, 2001; Shiffrin, et al., 2008). Like any other estimated parameter in the model, θ is updated during the course of MCMC simulation. The Bayes factor (BF) is simply the odds ratio of this probability, that is, $BF = \theta / (1 - \theta)$. Figure 1 graphically depicts the model's implementation in *OpenBugs*. The graph follows the notation used by Lee and Wagenmakers (2009) and Shiffrin et al. (2008).

Figure 1: Graphical representation of the model comparison. TTB_i and $WADD_i$ depict the deterministic predictions for each choice i out of N choices. The notation c indicates the actual choice (A or B) and π depicts the probability of choosing A over B as predicted by the particular model.

Model recovery

To test this approach, we set up a model recovery simulation based on 1,000 pairs of options described on 30 attributes to ensure that the results would not be influenced by an extreme constellation of binary attribute values that were randomly drawn from a Bernoulli distribution with $p = .5$. The importance weights for each attribute were set to increase linearly from the least to the most important attribute. Next, we simulated hypothetical decision makers who repeatedly chose among the pairs of options according to either TTB_a or $WADD_a$ (i.e., β was set to either 1 or 0). The implementation error α for both decision strategies varied from 0 to 0.5 in steps of 0.1 across decision makers. For each value of α in the simulation, we estimated θ by sampling from three separate MCMC chains in *OpenBugs* that were run for 2,000 steps each with a thinning of 10.

For $TB_{TTB,WADD}$ the priors were set to uniform distributions ranging from 0 to 0.5 for α_{TTB} and α_{WADD} and from 0 to 1 for β . For TB_{TTB} , the prior on α'_{TTB} was set to a uniform distribution ranging from 0 to 0.5.

Predictions

If a comparison based on Bayesian evidence is a feasible way to solve the problem of strategy sprawl, the method should assign more evidence to the model that generated the data. Thus, if the data was generated by choices according to TTB_a , the evidence for a simple toolbox TB_{TTB} should be higher than that of a toolbox $TB_{TTB,WADD}$ even though the latter one contains TTB_a as a special case.

Results

The samples from the three estimated chains in OpenBugs provided representative samples as indicated by a visual inspection of the trace plot, the autocorrelation and the Gelman–Rubin statistic. The results clearly indicate that the marginal likelihood for a smaller toolbox can indeed be higher than that for a larger toolbox. Figure 2 plots the actual implementation error α_{TTB} for choices based on TTB_α (Figure 2a) and the actual implementation error α_{WADD} for choices based on WADD_α (Figure 2b) against the estimated θ . Here, θ indicates the probability of the more complex $\text{TB}_{\text{TTB}, \text{WADD}}$ over TB_{TTB} . As can be seen from Figure 2a, θ increases as α_{TTB} increases. This indicates that a decision maker who uses TTB_α with a small implementation error is better described by TTB_α as compared to $\text{TB}_{\text{TTB}, \text{WADD}}$. Likewise, a decision maker who chooses according to WADD_α is clearly better described by $\text{TB}_{\text{TTB}, \text{WADD}}$ even if the implementation error α_{WADD} is large. This relationship seems plausible because the larger toolbox contains WADD_α whereas the smaller toolbox does not.

For an α of 0.5, which indicates random choice, Bayes' rule tells us to favor TTB_α , because in the case of very noisy data a simpler model is favored over a more complex one. Together, the results show that a small toolbox with only one strategy should be preferred over a more complex one provided that the small toolbox contains the appropriate tool to describe the initial decision-making process.

Figure 2: Plot of θ against the implementation error α_{TTB} (Figure 2a) and α_{WADD} (Figure 2b) used in the simulation. θ indicates the evidence in favor of $\text{TB}_{\text{TTB}, \text{WADD}}$ relative to TB_{TTB} .

Parameter recovery

The results so far show that Bayesian methods can be fruitfully applied to solve the question of how many strategies a toolbox should contain. However, we have implicitly assumed that the estimation methods accurately estimate the free parameters of the choice models within the toolboxes. To test if this condition really holds, the actual parameters used in the choice simulation can be compared with their respective posterior estimates. Figure 3a shows the marginal of the posterior distribution for α_{TTB} in the toolbox plotted against the actual parameters used in the simulation. As can be inferred from Figure 3, the posterior distributions of α_{TTB} match the actual values of α_{TTB} used in the simulation quite well. The parameter recovery for the α_{TTB} parameter of the simple TTB_α model appears similar.

Figure 3b shows the estimated β values plotted against α_{TTB} parameters used in the simulation. For low values of α_{TTB} , estimated β values are high. As β indicates the probability of using TTB_α over WADD_α within the toolbox, this relationship also seems plausible.

Figure 3 also shows the actual values for α_{WADD} from the choice simulation plotted against the posterior of α_{WADD} (Figure 3c) and β (Figure 3d) in the toolbox. Again, the estimated values match up with the actual values, indicating that the parameters were recovered across the whole parameter space. For high values of α_{WADD} the Bayesian model slightly underestimates the implementation error. Presumably this is the case because the prior distribution constrains the parameter space between 0 and 0.5. If the prior distribution is extended to range from 0 to 1, the estimated parameters match more closely.

Figure 3: Parameter recovery $\text{TB}_{\text{TTB}, \text{WADD}}$ for choices according to TTB_α (Figure 3, a & b) and WADD_α (Figure 3, c & d). Error bars indicate the 95% highest probability density region of the posterior distribution.

Discussion

Due to higher degrees of freedom, a cognitive toolbox that includes many strategies will always provide a better fit to the data, but it will not necessarily provide the highest evidence or marginal likelihood. The results of our analyses indicate that the marginal likelihood within a Bayesian framework can be fruitfully used to determine the number of tools to include in a toolbox. Thus, Bayesian statistics are well suited to prevent strategy sprawl.

As outlined above, the marginal likelihood can only be estimated with regard to a specific set of choice data and to precisely defined cognitive strategies. Thus, the number of tools to include may vary depending on cognitive strategies included in the toolbox. Yet, within these boundaries, the approach indicates that a small toolbox may be preferred over a large toolbox if the small toolbox contains a tool that describes the data well—even if the small toolbox is nested within the larger one.

The reason why the marginal likelihood provides a common comparison metric is because it implicitly accounts for differences in model complexity. This happens because the prior probability of each possible combination of parameters decreases with an increase in parameters. This carries over to the marginal likelihood that weights the likelihood of the data by the probability of each combination of possible parameter values. Thus, even though the likelihood of the data can be expected to increase with more free parameters, this increase is counteracted by a lower prior probability for each possible combination of parameters.

A comparison of the prior distributions of TB_{TTB} and $TB_{TTB,WADD}$ illustrates this mechanism. The prior probability of TB_{TTB} follows a beta-distribution around a single parameter α . On the other hand, the prior probability of the parameters in $TB_{TTB,WADD}$ embrace a total of three parameters. As prior distributions are probability distributions, they must integrate to 1. With more parameters in the model, the probability of each specific combination of parameter values should decrease because parameter space is more spread out.

Limitations and future research

Here we demonstrated that the Bayesian approach provides a powerful statistical tool for comparing and evaluating cognitive toolboxes that contain rather few strategies. In principle, the same approach can also be used for more complex scenarios. The only constraint of this methodology lies in the potential difficulties of implementing efficient MCMC sampling for vastly more complex models. As long as these computational challenges are met, the approach is not constrained to comparing toolboxes but can also be extended to compare different toolboxes against alternative cognitive models that do not conform to the notion of a repertoire of strategies.

Acknowledgments

We would like to thank Eric-Jan Wagenmakers for helping us implement the Bugs code.

Meaning Representation in Natural Language Categorization

Trevor Fountain (t.fountain@sms.ed.ac.uk) and

Mirella Lapata (mlap@inf.ed.ac.uk)

School of Informatics, University of Edinburgh

Abstract

A large number of formal models of categorization have been proposed in recent years. Many of these are tested on artificial categories or perceptual stimuli. In this paper we focus on categorization models for *natural language concepts* and specifically address the question of how these may be represented. Many psychological theories of semantic cognition assume that concepts are defined by features which are commonly elicited from humans. Norming studies yield detailed knowledge about meaning representations, however they are small-scale (features are obtained for a few hundred words), and admittedly of limited use for a general model of natural language categorization. As an alternative we investigate whether category meanings may be represented *quantitatively* in terms of simple co-occurrence statistics extracted from large text collections. Experimental comparisons of feature-based categorization models against models based on data-driven representations indicate that the latter represent a viable alternative to the feature norms typically used.

Introduction

Considerable psychological research has shown that people reason about novel objects they encounter by identifying the category to which these objects belong and extrapolating from their past experiences with other members of that category. This task of *categorization*, or grouping objects into meaningful categories, is a classic problem in the field of cognitive science, one with a history of study dating back to Aristotle. This is hardly surprising, as the ability to reason about categories is central to a multitude of other tasks, including perception, learning, and the use of language.

Numerous theories exist as to how humans categorize objects. These theories themselves tend to belong to one of three schools of thought. In the *classical* (or Aristotelian) view categories are defined by a list of “necessary and sufficient” features. For example, the defining features for the concept BACHELOR might be *male*, *single*, and *adult*. Unfortunately, this approach is unable to account for most ordinary usage of categories, as many real-world objects have a somewhat fuzzy definition and don’t fit neatly into well-defined categories (Smith and Medin, 1981).

Prototype theory (Rosch, 1973) presents an alternative formulation of this idea, in which categories are defined by an idealized prototypical member possessing the features which are critical to the category. Objects are deemed to be members of the category if they exhibit enough of these features; for example, the characteristic features of FRUIT might include *contains seeds*, *grows above ground*, and *is edible*. Roughly speaking, prototype theory differs from the classical theory in that members of the category are not required to possess *all* of the features specified in the prototype.

Although prototype theory provides a superior and workable alternative to the classical theory it has been challenged by the *exemplar* approach (Medin and Schaffer, 1978). In this view, categories are defined not by a single representation but rather by a list of previously encountered members. Instead of maintaining a single prototype for FRUIT that lists the features typical of fruits, an exemplar model simply stores those instances of fruit to which it has been exposed (e.g., apples, oranges, pears). A new object is grouped into the category if it is sufficiently similar to one or more of the FRUIT instances stored in memory.

In the past much experimental work has tested the predictions of prototype- and exemplar-based theories in laboratory studies involving categorization and category learning. These experiments tend to use perceptual stimuli and artificial categories (e.g., strings of digit sequences such as 100000 or 0111111). Analogously, much modeling work has focused on the questions of how categories and stimuli can be represented (Griffiths et al., 2007a; Sanborn et al., 2006) and how best to formalize similarity. The latter plays an important role in both prototype and exemplar models as correct generalization to new objects depends on identifying previously encountered items correctly.

In this paper we focus on the less studied problem of categorization of *natural language concepts*. In contrast to the numerous studies using perceptual stimuli or artificial categories, there is surprisingly little work on how natural language categories are learned or used by adult speakers. A few notable exceptions are Heit and Barsalou (1996) who attempt to experimentally test an exemplar model within the context of natural language concepts, Storms et al. (2000) who evaluate the differences in performance between exemplar and prototype models on a number of natural categorization tasks, and Voorspoels et al. (2008) who model typicality ratings for natural language concepts. A common assumption underlying this work is that the meaning of the concepts involved in categorization can be represented by a set of features (also referred to as properties or attributes).

Indeed, featural representations have played a central role in psychological theories of semantic cognition and knowledge organization and many studies have been conducted to elicit detailed knowledge of features. In a typical procedure, participants are given a series of object names and for each object they are asked to name all the properties they can think of that are characteristic of the object. Although feature norms are often interpreted as a useful proxy of the structure of semantic representations, a number of difficulties arise

when working with such data (e.g., Sloman and Rips 1998; Zeigenfuss and Lee 2009). For example, the number and types of attributes generated can vary substantially as a function of the amount of time devoted to each object. There are many degrees of freedom in the way that responses are coded and analyzed. It is not entirely clear how people generate features and whether all of these are important for representing concepts. Finally, multiple subjects are required to create a representation for each word, which limits elicitation studies to a small number of words and consequently the scope of any computational model based on these feature norms.

Even when the stimuli in question are of an abstract or linguistic nature, the features elicited are assumed to be representative of the underlying referents. As an alternative we propose to model the categorization of linguistic stimuli according to their distribution in corpora. Words whose referents exhibit differing features likely occur in correspondingly different contexts; our question is whether these differences in usage can provide a substitute for featural representations.

The idea that words with similar meaning tend to be distributed similarly across contexts is certainly not a novel one. *Semantic space* models, among which Latent Semantic Analysis (LSA, Landauer and Dumais 1997) is perhaps known best, operationalize this idea by capturing word meaning *quantitatively* in terms of simple co-occurrence statistics (between words and paragraphs or documents). More recently, *topic models* (Griffiths et al., 2007b) have arisen as a more structured representation of word meaning. In contrast to more standard semantic space models where word senses are conflated into a single representation, topic models assume that words observed in a corpus manifest some latent structure — word meaning is a probability distribution over a set of topics (corresponding to coarse-grained senses). Each topic is a probability distribution over words whose content is reflected in the words to which it assigns high probability.

In this work we investigate whether semantic representation models based on the statistical analysis of large text collections can provide a viable alternative to feature norms for natural language categorization. Specifically, we compare categorization models that represent concepts by features against LSA, Latent Dirichlet Allocation (LDA, Griffiths et al. 2007b; Blei et al. 2003), a well-known topic model, and a semantic space that takes syntactic information into account (Padó and Lapata, 2007). These semantic representations are used as input to two well-established categorization models, namely Nosofsky's (1988) generalized context model (GCM) and a prototype model derived from the GCM. We evaluate the performance of these models on three adult categorization tasks — category naming, typicality rating, and exemplar generation — which have been previously modeled using exclusively feature norms (Storms et al., 2000). Our results indicate that LSA-based meaning representations outperform more sophisticated alternatives across the board, whilst lagging behind feature norms only by a small margin.

Meaning Representation

In this section we briefly describe the feature norms used in our experiments. These were based on an existing general purpose database (McRae et al., 2005) which we augmented in several ways to suit our categorization tasks. We also de-

scribe three corpus-based models of meaning representation, highlight their differences, and motivate their selection.

Feature Norms

As mentioned earlier, many behavioral experiments have been conducted to elicit semantic feature norms across languages. One of the largest samples for English has been collected by McRae et al. (2005). Their norms consist of 541 basic-level concepts (e.g., DOG and CHAIR) with features collected in multiple studies over several years. For each concept several annotators were asked to produce a number of relevant features (e.g., *barks*, *has-four-legs*, and *used-for-sitting*). The production frequency of a feature given a particular concept can be viewed as a form of weighting indicating the feature's importance for that concept. A spatial representation of word meaning can be extracted from the norms by constructing a matrix in which each row represents a word and each column a feature for that word. Cells in the matrix correspond to the frequency with which a feature was produced in the context of a given word. An example of such a space is shown in Table 2 (a) (the numbers correspond to production frequencies, e.g., 12 participants thought *has-legs* is a feature of TABLE).

Unfortunately, McRae et al.'s (2005) norms do not include any explicit relational information. Because we are interested in using the norms in a model of categorization it was necessary for us to augment the concepts with category labels (e.g., 'dog' is an ANIMAL) and typicality ratings (e.g., 'dog' is a typical ANIMAL whereas 'Snoopy' isn't). We collected this information using Amazon Mechanical Turk¹, an online labor marketplace which has been used in a wide variety of elicitation studies and has been shown to be an inexpensive, fast, and (reasonably) reliable source of non-expert annotation for simple tasks (Snow et al., 2008).

We obtained category labels as follows. We presented each participant with twenty unrelated, randomly selected concepts from McRae et al.'s (2005) data set and asked them to label each with the category to which it best belonged. Responses were in the form of free text, i.e., participants were asked to key in a label rather than select one from a list. Each concept was labeled by ten participants; concepts were then grouped according to the resulting categories. Because annotations collected from Mechanical Turk can be noisy we then discarded those categories containing fewer than five unique concepts, leaving 41 categories for 541 exemplars. These category labels are listed in Table 1. To fully integrate them into the norms it was necessary to collect semantic features for them. To do this, we replicated the norming study of McRae et al. (2005), again using Mechanical Turk. Participants were presented with a single concept (drawn from the set of category labels collected in our previous study) and asked to generate ten relevant features. Instructions and examples were taken from McRae et al. (2005). For each category label we collected features from 30 participants, resulting in a large number of features per item. These features were then mapped into the features already present in the norms; as in McRae et al. (2005) this mapping was performed manually.²

Table 1: Category labels with most typical exemplars produced by participants in category naming and typicality rating study.

This augmented dataset could be used as-is to evaluate a model of categorization on either a category naming or an exemplar generation task (we describe these tasks in detail in the following section). We further wished to use typicality rating as an additional means for evaluation (Voorspoels et al., 2008). We therefore elicited typicality ratings again via Mechanical Turk. Participants were presented with a single category (e.g., FRUIT) along with twenty randomly selected exemplars belonging to the category (e.g., ‘cherry’, ‘apple’, and ‘tomato’) and asked to rate the typicality of each exemplar among members of the category. Typicality ratings for each exemplar-category pair were collected from 20 participants and an overall rating for each exemplar was computed by taking their mean. The highest rated exemplar for each category is shown in Table 1.

We assessed the quality of the data obtained from Mechanical Turk by calculating their *reliability*, namely the likelihood of a similarly-composed group of participants presented with the same task under the same circumstances producing identical results. We split the collected typicality ratings randomly into two halves and computed the correlation between them; this correlation was averaged across three random splits. These correlations were adjusted by applying the Spearman-Brown prediction formula (Storms et al., 2000; Voorspoels et al., 2008). The reliability of the ratings averaged over 41 concepts was 0.64 with a standard deviation of 0.03. The minimum reliability was 0.52 (INSTRUMENT); the maximum was 0.75 (FURNITURE). Reliability on the category naming task was computed similarly, with an average of 0.72, a maximum of 0.91 (INSTRUMENT), and a minimum of 0.13 (STRUCTURE). These reliability figures may seem low compared with Storms et al. (2000) who perform a similar study. However, note that they conduct a smaller scale experiment; they only focus on eight common natural language concepts (whereas we include 41), and 12 exemplars for each concept (our exemplars are 541).

Data-driven Approaches

In addition to feature norms, we obtained semantic representations for categories and exemplars from natural language corpora. We compared three computational models: Latent Semantic Analysis (LSA; Landauer and Dumais 1997), Latent Dirichlet Allocation (LDA; Griffiths et al. 2007b; Blei et al. 2003), and Dependency Vectors (DV; Padó and Lapata 2007). LSA has historically been a popular method of extracting meaning from corpora, and has been successful at explaining a wide range of behavioral data — examples include lexical priming, deep dyslexia, text compre-

hension, synonym selection, and human similarity judgments (see Landauer and Dumais 1997 and the references therein). LSA provides a simple procedure for constructing spatial representations of word meanings. The same is true for dependency vectors where co-occurrence statistics are computed between words attested in specific syntactic relations (e.g., *object-of*, *subject-of*). The assumption here is that syntactic information provides a linguistically informed context, and therefore a closer reflection of lexical meaning. LDA, in contrast, imposes a probabilistic model onto those distributional statistics, under the assumption that hidden topic variables drive the process that generates words. Both spatial and topic models represent the meanings of words in terms of an n -dimensional series of values, but whereas semantic spaces treat those values as defining a vector with spatial properties, topic models treat them as a probability distribution.

Latent Semantic Analysis To create a meaning representation for words LSA constructs a word-document co-occurrence matrix from a large collection of documents. Each row in the matrix represents a word, each column a document, and each entry the frequency with which the word appeared within that document. Because this matrix tends to be quite large it is often transformed via a singular value decomposition (Berry et al., 1995) into three component matrices: a matrix of word vectors, a matrix of document vectors, and a diagonal matrix containing singular values. Re-multiplying these matrices together using only the initial portions of each (corresponding to the use of a lower dimensional spatial representation) produces a tractable approximation to the original matrix. This dimensionality reduction can be thought of as a means of inferring latent structure in distributional data whilst simultaneously making sparse matrices more informative. The resulting lower-dimensional vectors can then be used to represent the meaning of their corresponding words; example representations in LSA space are shown in Table 2 (b) (vector components represent tf-idf scores).

Dependency Vectors Analogously to LSA, the dependency vectors model constructs a co-occurrence matrix in which each row represents a single word; unlike LSA, the columns of the matrix correspond to other words in whose syntactic context the target word appears. These dimensions may be either the context word alone (e.g., *walks*) or the context word paired with the dependency relation in which it occurs (e.g., *subj-of-walks*). Many variants of syntactically aware semantic space models have been proposed in the literature. We adopt the framework of Padó and Lapata (2007) where a semantic space is constructed over dependency paths, namely

sequences of dependency edges extracted from the dependency parse of a sentence. Three parameters specify the semantic space: (a) the *content selection function* determines which paths contribute towards the representation (e.g., paths of length 1), (b) the *path value function* assigns weights to paths (e.g., it can be used to discount longer paths, or give more weight to paths containing subjects and objects as opposed to determiners or modifiers.), and (c) the *basis mapping function* creates the dimensions of the semantic space by mapping paths that end in the same word to the same dimension. A simple dependency space is shown in Table 2 (c) (vector components represent co-occurrence frequencies).

Latent Dirichlet Allocation Unlike LSA and DV, LDA is a probabilistic model of text generation. Each document is modeled as a distribution over K topics, which are themselves characterized as distribution over words. The individual words in a document are generated by repeatedly sampling a topic according to the topic distribution and then sampling a single word from the chosen topic. Under this framework the problem of meaning representation is expressed as one of statistical inference: give some data — words in a corpus, for instance — infer the latent structure from which it was generated. Word meaning in LDA is represented as a probability distribution over a set of latent topics. In other words, the meaning of a word is a vector whose dimensions correspond to topics and values to the probability of the word given these topics; the likelihood of seeing a word summed over all possible topics is always one. Example representations of words in LDA space appear in Table 2 (d) (vector components are topic-word distributions).

Implementation All three models of word meaning were trained on the British National Corpus. For the LSA model we used the implementation provided in the Infomap toolkit³, with words represented as vectors in a 100-dimensional space; for the DV model we used the implementation⁴ of Padó and Lapata (2007) with dependency paths up to length 3 and a length-based path value function that assigns each path a value inversely proportional to its length, thus giving more weight to shorter paths corresponding to more direct relationships. We obtained dependency information from the output of MINIPAR, a broad coverage dependency parser (Lin, 2001). Infrequent dependencies attested less than 500,000 times in the BNC were discarded. The LDA model used the implementation⁵ of Phan et al. (2008) with 100 topics. Inference in this model is based on a Gibbs sampler which we ran for 2,000 iterations. Additionally, LDA has two hyperparameters α and β which were set to 0.5 and 0.1, respectively.

Categorization

Models

The semantic representations described above served as the input to two categorization models, representative of the exemplar-based and prototype-based approaches. In the generalized context model (GCM, Nosofsky 1988; Medin and Schaffer 1978) categories are represented by a list of stored

exemplars and inclusion of an unknown item in a category is determined by the net similarity between the item and each of the category’s exemplars. Specifically, the similarity $\eta_{w,j}$ of a novel item w to the category c is calculated by summing its similarity to all stored items i belonging to c :

$$\eta_{w,c} = \sum_{i \in c} \eta_{w,i} \quad (1)$$

To calculate the inter-item similarity $\eta_{w,i}$ we compute the cosine of the angle between the vectors representing w and i :

$$\eta_{w,i} = \cos(\theta) = \frac{v_w \cdot v_i}{\|v_w\| \|v_i\|} \quad (2)$$

Following Vanpaemel et al. (2005), we can modify Equation (1) into a prototype model by replacing the list of stored exemplars with a single ‘prototypical’ exemplar c_j :

$$\eta_{w,c} = \eta_{w,c_j} \quad (3)$$

For the category prototype c_j we use the representation of the category label, e.g., the prototype for the category FRUIT is the semantic representation of the word ‘fruit’. The similarity between an item and a category thus reduces to the cosine distance between the item and prototype representations.

Tasks

We evaluated the performance of our models on three categorization tasks introduced in Storms et al. (2000): category naming, typicality rating, and exemplar generation.

In *category naming* the model is presented with a previously unencountered word and must predict the most appropriate category to which it belongs, e.g., the exemplar ‘apple’ would be most correctly identified as a member of the category FRUIT, or (with lesser likelihood) FOOD or TREE. In the exemplar model (see (1)), we measure the similarity $\eta_{w,c}$

Figure 1: Performance of exemplar model using feature norms and data-driven meaning representations.

Figure 2: Performance of prototype model using feature norms and data-driven meaning representations.

of the novel word against all previously encountered exemplars and select the category with the highest *net* similarity between its exemplars and the word in question; for the prototype model (see (3)) this is the category with the highest similarity between the word and the category’s label. Performance on the category naming task was determined in a leave-one-out fashion: a single exemplar was removed from the training examples and then categorized. This was repeated for each exemplar in the training set. The latter consisted of 41 subject-produced category labels each with an average of 30 exemplars.

In a *typicality rating* task the model is presented with both an exemplar and label of the category to which it belongs, and must predict the degree to which it is common amongst members of that category. For the category FOOD, for example, ‘pizza’ or ‘bread’ would be considered highly typical exemplars, while ‘lutefisk’ or ‘black pudding’ would likely be considered much more atypical. The predicted typicality rating for a word and a category is simply the similarity between the two. In the exemplar model this is the sum similarity between the word and each of the category’s exemplars; in the prototype model this is the similarity between the category’s label and the word. Performance on the typicality rating task was evaluated by computing the correlation between the models’ predicted typicality ratings and the average value predicted by the participants of our rating study. The dataset included typicality ratings for 1,228 exemplar-category pairs.

In an *exemplar generation* task the model is given a category label and must generate exemplars typical of the category, e.g., for FOOD we might generate ‘pizza’, ‘bread’, ‘chicken’, etc. Given a category the model selects from the exemplars known to belong those that are most typical; typicality is again approximated by word-category similarities as determined by the model-specific $\eta_{w,c}$. We evaluate perfor-

mance on the exemplar generation task by computing the average overlap (across categories) between the exemplars generated by the model and those ranked as most typical of the category by our participants.

Results

Figure 1 summarizes our results with the exemplar model and four meaning representations: McRae et al.’s (2005) feature norms (Norms), Latent Semantic Analysis (LSA), Latent Dirichlet Allocation (LDA), and Dependency Vectors (DV). Results are shown for category naming (Figure 1(a)) typicality rating (Figure 1(b)) and exemplar generation (Figure 1(c)). We examined performance differences between models using a χ^2 test (category naming and exemplar generation) and Fisher’s r -to- z transformation (to compare correlation coefficients for the typicality rating task).

On category naming the exemplar model performs significantly better with the feature norms than when using any of the three corpus-derived representations ($p < 0.01$); however, LSA performs significantly better ($p < 0.05$) than DV or LDA. On typicality rating there is no significant difference between the feature norms and LSA. The norms are significantly better ($p < 0.01$) than either DV or LDA, while LSA surpasses both of the other two corpus-derived representations ($p < 0.01$). Additionally, LDA performs significantly better than DV ($p < 0.05$). On the exemplar generation task the feature norms are significantly better ($p < 0.01$) than any of the corpus-based representations; similarly, LSA performs significantly better than LDA or DV ($p < 0.01$), while LDA again outperforms the dependency space ($p < 0.05$).

Our results with the prototype model are shown in Figure 2 and broadly follow a similar pattern. On category naming the feature norms outperform any of the corpus-based representations ($p < 0.01$), LSA is significantly better than LDA which

in turn is better than DV ($p < 0.05$). On typicality rating there is no significant difference between the feature norms and LSA; the difference between LSA and either of the other two representations is significant ($p < 0.01$). On the exemplar generation task feature norms significantly outperform all other representations ($p < 0.01$); LSA is significantly better ($p < 0.01$) than LDA or DV.

Discussion

In this work we have quantitatively evaluated feature norms and alternative corpus-based meaning representations on three natural language categorization tasks. Perhaps unsurprisingly our results indicate that feature norms are more accurate representations when compared to corpus-based models. As feature norms rely on explicit human judgment, they are able to capture the dimensions of meaning that are psychologically salient. Corpus-based models on the other hand learn in an unsupervised fashion and require no human involvement or external sources of knowledge.

Overall we find LSA to be a reasonable approximation of feature norms, superior to both LDA and the syntactically more aware dependency vectors. This result is consistent across models (exemplar vs. prototype) and tasks. Importantly, the LSA model is language-independent and capable of extracting representations for an arbitrary number of words. By contrast, feature norms tend to cover a few hundred words and involve several subjects over months or years. Albeit in most cases better than our models, feature norms themselves yield relatively low performance on all three tasks we attempted using either an exemplar or prototype model (see Figures 1 and 2). We believe the reasons for this are twofold. Firstly, McRae et al.'s 2005 norms were not created with categorization in mind, we may obtain better predictions with some form of feature weighting (see Storms et al. 2000). Secondly, the tasks seem hard even for humans as corroborated by our reliability ratings.

The differences in performance between LSA, LDA, and DV can be explained by differences between the notion of similarity implicit in each. Closely related words in LDA appear in the same *topics*, which are often corpus-specific and difficult to interpret; words belonging to different categories may be deemed similar yet be semantically unrelated. By contrast, the poor performance of the DV model is somewhat disappointing. Our experiments used a large number of dependency relations; it is possible that a more focused semantic space with a few target relations may be more appropriate.

Finally, our simulation studies reveal that an exemplar model is a better predictor of categorization performance than a prototype one. This result is in agreement with previous studies (Voorspoels et al., 2008; Storms et al., 2000) showing that exemplar models perform consistently better across a broad range of natural language concepts from different semantic domains. This finding is also in line with studies involving artificial stimuli (e.g., Nosofsky 1992).

Directions for future work are two-fold. Firstly, we wish to explore alternative meaning representations more suited to the categorization task. A potential candidate is the feature-topic model (Steyvers, 2009; Andrews et al., 2009), in which documents are represented by a mixture of learned topics in addition to predefined topics derived from feature norms.

Secondly, we expect that developing specialized models for natural language categorization that are tailored to data-driven meaning representations would improve performance.

Temporal Chunk Signal Reflecting Five Hierarchical Levels in Writing Sentences

Abstract

Previous research on the temporal chunk signal has focused on the use of pauses in behaviour to probe chunk structures in working memory. On the basis of some of these studies, a hierarchical process model has been proposed, which consist of four hierarchical levels describing different kind of pauses. In this model, the lowest level consists of pauses between strokes within letters. On higher levels, there are pauses between letters, words, and phrases. Each level is associated with a larger amount of processing when retrieving these chunks from memory. The main aim of the present study is to test whether the temporal chunk signal can distinguish a fifth level, the sentence level. A secondary goal is to replicate the findings which were used to construct the hierarchical process model in a manner that overcomes some of the limitations of the earlier experiments.

Keywords: Temporal chunk signal, graphical protocol analysis, writing, working memory, sentences.

Introduction

Chunks have a fundamental role in information processing in the human cognitive architecture. Chunks are individual pieces of information grouped into larger units that increase our information retention (Carroll, 2004). It is widely accepted in Cognitive Science that the hierarchical storage and processing of chunks in working memory provides a fruitful basis for explaining a substantial range of the behavioural phenomena, such as recall from long-term and working memory and expert performance. This acceptance comes in part from various established methods that have been developed to infer the particular structure of chunks possessed by individuals from their behaviours. Such methods have made an important contribution to developing accounts of cognition in complex tasks. One method is computational modelling. Another method, on which this research focuses, provides information about the structure of chunks in memory by measuring pause lengths that occur in verbal or motor actions, the inter response latency. Chase and Simon's (1973) work on chess expertise and Reitman's (1976) work on Go experts are classic examples of the uses of pause lengths during the recall of a board containing chess pieces or Go discs. There are many other studies that have also exploited pause lengths in actions in order to define chunks. In one of the earliest studies using this approach, McLean and Greg (1967) studied the chunking of arbitrary letter sequences. Later on, Buschke (1976)

examined the gradual acquisition of chunks comprising clusters of every day words originally presented in unstructured lists. Egan and Schwartz (1979) showed how electronics experts chunked components of electrical circuits in terms of their functioning. In all these studies, the duration of a pause preceding an action that generated an element of the domain (in these studies letters, words, and components respectively) is taken as an indication of whether the element is within a putative chunk or at the boundary between chunks. The term *temporal chunk signal*, TCS, is used in order to refer to the basic phenomenon that underpins the use of pause lengths to probe chunk structures. Typically, the TCS is often used in a binary fashion, which includes setting some threshold (e.g., 500 ms) as a criterion upon which to classify successively produced elements as intra-chunk if the pause length is less than the threshold, or as inter-chunk if the pause length is greater than the threshold.

The present experiment is a continuation of our studies on the nature and application of the TCS that is manifest in the process of writing and drawing, or more general graphical production. We call our general approach to using the TCS to study chunk related behaviour in writing and drawing tasks, *graphical protocol analysis*, GPA. A standard graphics tablet is used to record pen strokes. Pause lengths are computed by finding the difference in time between the lift of the pen from the tablet at the end of one stroke and the time at which the pen touches the tablet at the beginning of the stroke of interest: $\text{pause}_{\text{item}} = \text{time}_{\text{pen-down-current-item}} - \text{time}_{\text{pen-up-previous-item}}$. In our previous experiments, tasks with known hierarchical structures have been used, such as 'to be or not to be', so that each pause could be coded as intra-chunk or inter-chunk. For sentences and language-like stimuli identified pauses have included: intra-chunks pauses between strokes within a letter (e.g., second stroke of a 't', level 0 or L0); inter-chunk pauses between letters within a word (e.g., between 't' and 'o', L1); and inter-chunk pauses between words within a phrase (e.g., between 'to' and 'be', L2).

Our previous experiments have shown that the TCS is a richer source of information about chunk structure than just a binary signal. We consider that TCS within GPA has potential to be used as general technique for the study of various cognitive phenomena. In the domain of copying mathematical formulae, the TCS was able to distinguish

participants who had four different levels of expertise in mathematics (Cheng & Rojas-Anaya, 2007). The TCS has also been used to distinguish between children with and without dyslexia (van Genuchten et al., submitted). Cheng, McFadzean, and Copeland (2001) have shown that the TCS reflects three distinct levels of processing when drawing geometric figures. That experiment showed the TCS to be present when drawings are made with pen on paper or with a mouse on a computer screen. Obaidellah and Cheng (2009) used the TCS to reveal the role of perceptual chunks and spatial schemes in different modes of drawing complex abstract diagrams. In Cheng & Rojas-Anaya (2005) participants wrote number sequences that had been memorized with different chunk structures. The TCS showed the existence of three levels corresponding to: pauses between strokes within a digit (e.g., second stroke in '7', L0, ≈ 90 ms); digit level chunks (e.g., between '1' and '2', L1, ≈ 280 ms); and digit group level chunks (e.g., between '111' and '222', L2, ≈ 440 ms). In Cheng & Rojas-Anaya (2006) the TCS again showed the existence of the same three levels of pauses when writing familiar and jumbled sentences (≈ 90 , ≈ 270 , ≈ 400 ms respectively). Finally, moving beyond three hierarchical levels, Cheng & Rojas-Anaya (2008) devised an artificial sentences copy task with four hierarchical levels (e.g., 'ITH* ITH* ITH*',

ITH* ITH* ITH*') and found the same pattern of stroke, letter, word and phrase level pauses (≈ 90 , ≈ 250 , ≈ 440 and ≈ 600 ms respectively). On the basis of these studies, a hierarchical process model has been proposed (see Figure 1) to explain these patterns in terms of the depth first serial processing. In this model, the hierarchical structure of chunks corresponds to the amount of processing associated with different branch lengths of the hierarchy, with longer branches indicating longer pause lengths.

The main aim of the present experiment is to test whether the TCS can distinguish more than four hierarchical levels, by adding a fifth level of pauses between sentences, and thereby extend the previous findings. Is it simply the case that this fifth level in the chunk hierarchy will merely result in an additional amount of processing and a corresponding increment of pause duration? If so, will the increase in magnitude of the pause length be linear as is the case between the other levels? A secondary goal of the experiment is to replicate the previous findings in a manner that overcomes some of the limitations of the earlier experiments. In particular, the found significant effects existed at the level of individuals using pairwise comparisons of the pauses between levels, but typically involved relatively small numbers of participants. Hence, a subsidiary aim of the present experiment is to test whether

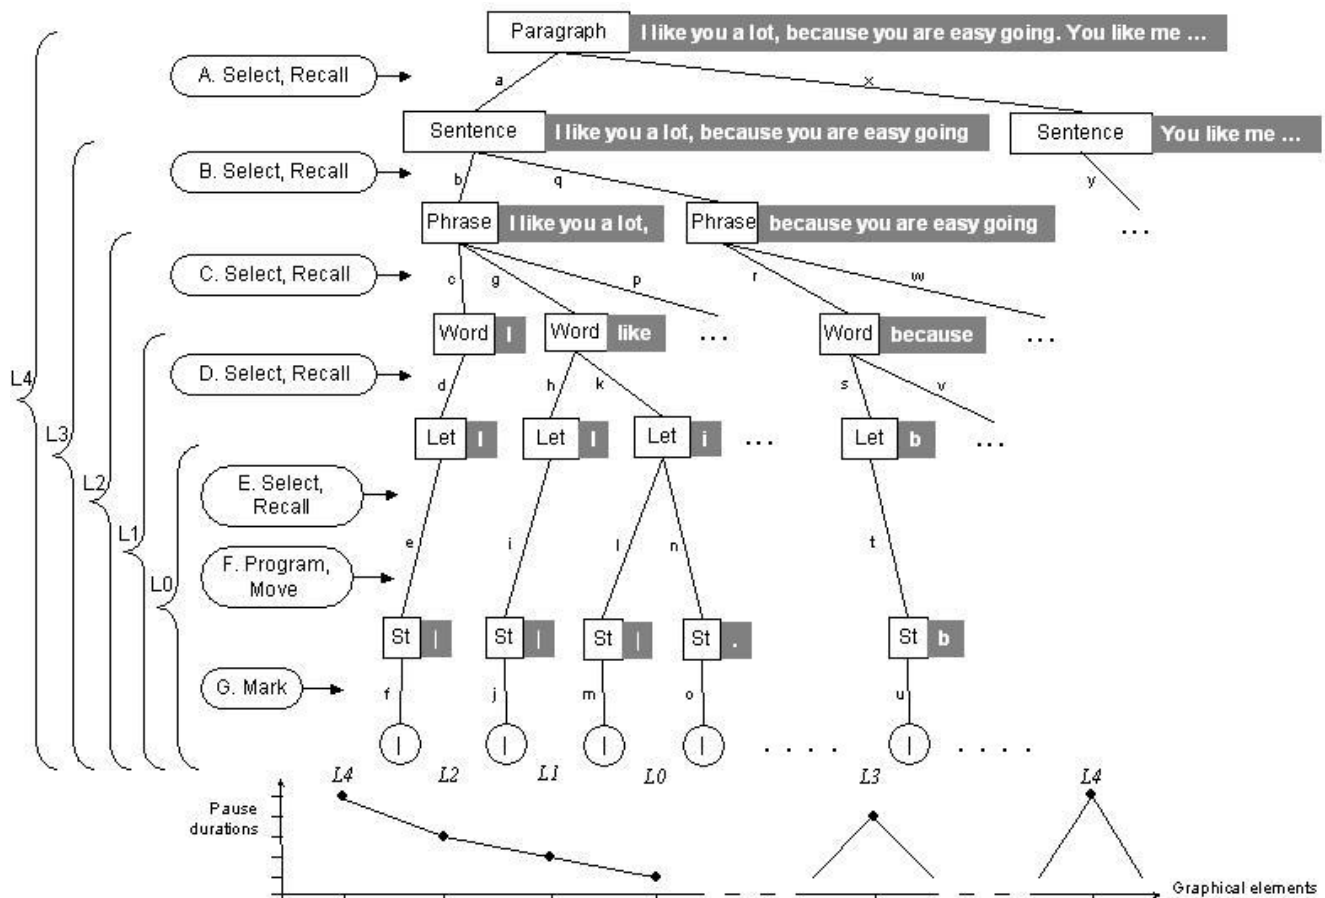

Figure 1: Hierarchical process model including the sentence level, reflecting relations between chunk structure, processing steps, and pause levels (adapted from Cheng & Rojas-Anaya, 2008).

the differences between the hierarchical levels is a robust effect by using multilevel analysis to simultaneously compare all the levels from the data of a large number of participants.

Method

Participants

Participants in this study were 32 adults, 19 female and 13 male, between 18 and 33 years old, working or studying at a large university in the UK. The participants ($M = 22.99$ years, $SD = 3.98$ years) were all native English speakers.

Measures and Materials

In order to answer the research question, pause lengths between sentences, phrases, words, letters, and strokes in paragraphs were compared. These five measures were calculated for each stimulus. The eight English sentence stimuli were specially written to obtain these five hierarchical levels. Each stimulus comprised of three or four sentences (L4), which were made up of two or three phrases (L3), which in turn were comprised of between 4 and 8 words (L2), which contained letters (L1) that may have required more than one stroke (L0) to write. This hierarchical structure was emphasized by including punctuation marks (periods between sentence and commas between phrases). Example stimuli are:

‘You just signed up for a trip, from your favourite society, because you like visiting different places. You paid with some money, which you got from your mum, because you did shopping for her. You have never been to Holland, so you would like to visit Amsterdam, and have a great time.’ (3 sentences, 3 phrases)

‘We like swimming, in the pool next door. You like to cycle, to towns far away. They like to play football, on the top of the hill. As they play all day, they should eat enough.’ (4 sentences, 2 phrases)

The median per level was calculated in order to reduce the

influence of outliers, which could only occur in the direction of longer pause lengths, and which would consequently severely distort the mean, rendering it unsuitable as a measure in this study (Stavig & Gibbons, 1977).

All sentences were written on a piece of paper attached to a graphics tablet containing horizontal rows of rectangles. One letter had to be written in each rectangle (width: 6 mm, height: 8 mm), so that participants were encouraged to lift their pen from the paper and to put it down again for the next letter, and allowing the distance between each letter to be approximately equal (see Figure 2). The equal distance between rectangles rules out the possibility that differences in hand movements account for the different pause lengths. Therefore, pauses between the last letter of a line and the first of the next were ignored, because of increased hand movement.

Design and Procedure

The administering of the test had a duration of 45 to 75 minutes per participant. A quiet room was used to minimize disturbing background noises. The session began with an acclimatization period which allowed the participants to become familiar with writing on a tablet by having them write their names on the tablet. The actual experiment did not start until the participant was considered to have followed all instructions. Participants were asked not to write any punctuation in order to make sure that increased pause lengths were not due to writing an extra symbol. The task itself consisted of remembering and writing down the eight visually presented target stimuli.

All stimuli were presented in turn in random order. After presenting a stimulus, participants were allowed to apply any strategy and take as long as needed to rehearse the stimulus. When participants finished rehearsing, the experimenter tested recall accuracy by asking participants to recite the stimulus sentences without errors twice. Once this was accomplished, participants were allowed to start writing. A hash (#) had to be written at the beginning of each sentence to ensure that the writing process was well underway before the first letter was generated (Cheng & Rojas-Anaya, 2006).

<i>Deviance</i>	19846		19146		19146	

Notes: ^a The constant has been left out of the model with predictors, because a complete set of dummy variables was used.

^b Robust standard errors were used, because the assumption of linearity of residuals was not met.

* $p < .001$.

Data and Analysis

A specially written program, TRACE, was used to record the writing actions and to extract the pen positions, times of points and pause lengths (Cheng & Rojas-Anaya, 2003). All files generated by TRACE were analysed using a specialized computer programme (Pause Level Extraction Tool, PLET, van Genuchten, 2009). Automatic detection of letters and automatic calculation of pause lengths had to be applied, because of the large amount of data (at least 1200 measures per participant). This involved identifying the horizontal position of strokes making up a letter within a rectangle and the horizontal separation between these strokes between rectangles. The written input was specified for each stimulus, so that errors (e.g., wrongly spelled or omitted words) were taken into account. Only in those cases where no automatic detection of letters was possible (e.g., when strokes of subsequent letters were written relatively close together), manual calculation of the pause lengths was applied.

To test whether there were differences between pause lengths of different pause types, a multilevel analysis was performed. On the lowest level, data of pause lengths of each stimulus for each pause type were used as predictors and were measured within participants. This data was gathered on the highest level, the participant. It is expected that the correlation between measures is higher within a participant than between participants. By performing a multilevel analysis, the dependency between data measures within individuals is controlled. Dummy variables were created for each of the five pause types.

Results

The comparison between the model-fit of the one-level and two-level intercept only models, indicates that there is

significant variance at the participant level ($\chi^2(1) = 41.78$, $p < .01$). This means a two-level multilevel analysis is appropriate. Parameter estimates for the intercept only model and model with predictors are presented in Table 1.

A difference between the different pause types was expected, which was confirmed by the model with predictors. However, plots of standardized residuals against normal scores indicated that the assumption of linearity of residuals was not met. Therefore, robust standard errors were calculated using the Sandwich method (Hox, 2002). The resulting model indicates that a distinction can be made between pause lengths on the basis of pause type. Specifically, the regression coefficients show that pause lengths between sentences are longest, and that pause lengths become successively shorter when considering pauses between phrases, words, letters, and strokes (sentences: $B = 1134$, $SE = 96.0$, $p < .001$; phrases: $B = 567$, $SE = 41.3$, $p < .001$; words: $B = 374$, $SE = 19.8$, $p < .001$; letters: $B = 273$, $SE = 13.6$, $p < .001$; strokes: $B = 90$, $SE = 3.1$, $p < .001$). This means that pause lengths can be very well predicted when it is known which type of pause is concerned.

Discussion

One aim of the present experiment was to replicate the findings of previous experiments concerning the temporal chunk signal, TCS, using a more rigorous methodology. These earlier studies showed that the TCS reflects a hierarchical chunk structure as increasing durations of pause lengths between written elements. In this research, differences between every pause level within this structure were also found to be significantly different in a single multilevel statistical test. Although the outcomes of the previous experiments had to be carefully qualified, it does

Table 2: Pauses (ms) for various stimulus levels over different stimulus types (rounded to 10 ms).

Experiment	Stimuli	L0	L1	L2	L3	L4
Cheng & Rojas-Anaya (2005)	Number sequences	90	280	440		
Cheng & Rojas-Anaya (2006)	Familiar and jumbled phrases	90	270	400		
Cheng & Rojas-Anaya (2008)	Artificial sentence	90	250	440	600	
Present	Natural language paragraphs	90	270	370	570	1130

appear that the effects found are genuine, because of the consistency with the present experiment.

Regarding the primary aim of this experiment of adding a fifth level to the structure, the results show that when a rehearsed stimulus that possesses five hierarchical levels is written, the TCS, which is based on the pauses between written elements, reflects the ordering of the levels. The stroke level pause lengths are the shortest and the duration increases for each successive increment of level, through letter, word, phrase and sentence level. The increase of the pause with the addition of the fifth sentence level is consistent with the proposal that in graphical production of well rehearsed stimuli each successive chunk level requires specific processing to deal with the particular information associated with that level (Cheng & Rojas-Anaya, 2008).

The direct comparison of the approximate absolute values of the pauses associated with each level for this and the previous experiments reveal some interesting patterns (see Table 2). The three prior experiments noted in this table involved graphical production using the same experimental task methodology: specifically, the writing of sequences from memory after rehearsal with one character in one rectangle. The experiments differ in the important respect that each used a different type of stimulus, as indicated in Table 2. The similarity of the absolute values of the pauses over each level across the different experiments is noteworthy, because it suggests that the same underlying processes are responsible for the pattern of pauses irrespective of the nature of the stimulus. The differences between the pauses on successive levels range between 100 and 200 ms, with mean values of $L1-L0=178$, $L2-L1=145$ and $L3-L2=180$ ms. Taking Newell's (1990) estimate of the time scale for elementary deliberated operations as circa 100 ms, this suggest that there is at least one additional operation occurring when preparing to graphically produce an element that is one level higher in the hierarchy. One such operation will be a process to select the next chunk at a particular level. At the beginning of a new phrase this will involve selection of a phrase, a word, a letter and a stroke. The increase in time suggests that this selection occurs serially and is therefore consistent with the predictions of the hierarchical process model (Cheng & Rojas-Anaya, 2008).

The increase in pause length up to the sentence level from the phrase level is more than three times greater than the increase between any of the other levels. As this is new data from just one experiment, some caution must be taken with its interpretation. It seems to suggest that additional operations that occur at this level do not occur at the levels below. The additional time may be an indication that

working memory is fully loaded when complex stimuli comprising multiple sentences with several sub phrases are being processed. Furthermore, the additional time may indicate that retrieval from long-term memory is required as the complete stimuli cannot all be held in working memory despite the rehearsal. As there are approximately ten times as many letters in each of the present stimuli as there were in the stimuli of the previous experiments and as the number of chunks is larger than Miller's magical number 7 ± 2 (Miller, 1956), this is a likely interpretation. In future research, verbal working memory measures, such as the digit span task (Wechsler, 1985) and the listening span task (Daneman & Carpenter, 1980), could be used to gain insight into how pause lengths are related to working memory capacity and the possible involvement of long-term memory. However, it should be noted that as there were 19 pauses on the sentence level at the most, the actual value might be less robust than for the other levels, because outliers have a larger influence with a small number of measurement points. For comparison, there were 33 phrase level, 238 word level, and about 1148 letter level pauses (the number of strokes depended on whether cursive or block letters were used).

Another possible interpretation of this large increase in pause length is that, in addition to retrieving a sentence, inhibiting processes take place to suppress the inclination of writing punctuation. A possibility to overcome this problem is to require participants to write punctuation in a separate rectangle. However, in this case, it is unclear whether the pause between the last letter of for example, the sentence and the period (full stop) or the pause between the period and the first letter of the next sentence, should be taken as an indication of pause length. An alternative for future experiments would be to require participants to write punctuation marks in the same rectangle right after the last letter of the sentence or phrase.

In summary, other processes than selection and retrieval processes might also underpin this pattern of pause lengths. Therefore, empirical and modelling studies are conducted to unravel which processes contribute to the increase in pause length accompanied with each level.

Irrespective of the precise explanation for the increase in duration between each hierarchical level, the results of this experiment reconfirms the claim that there is a temporal signal. This signal may be associated with chunking processes and is a source of high resolution information concerning participants' task performance. With appropriately designed tasks, the TCS could provide valuable evidence to probe the relations among the sub-processes that underpin cognitive phenomena.

A logical next step is to investigate whether a sixth level, the paragraph level, can be added to the hierarchical process model. However, as the demands on working and long-term memory will increase even more, such an experiment has to be designed carefully in order to be feasible.

Acknowledgements

We would like to thank Keith Smith of the University of Sussex for his assistance with the recruitment of participants for this study. We would also like to thank Cora Maas of Utrecht University for her assistance in performing the multilevel analysis.

Emotion in Good Luck and Bad Luck: Predictions from Simplicity Theory

Jean-Louis Dessalles (dessalles@telecom-paristech.fr)

Abstract

The feeling of good or bad luck occurs whenever there is an emotion contrast between an event and an easily accessible counterfactual alternative. This study suggests that *cognitive simplicity* plays a key role in the human ability to experience good and bad luck after the occurrence of an event.

Keywords: Kolmogorov complexity; simplicity; emotion; luck; probability; unexpectedness.

Good Luck and Bad Luck

Situations spontaneously associated with good luck or bad luck are an important source of emotion. They are frequent in daily life: missing (or catching) the train by five seconds, forgetting one's cell phone the very day one is late for an important appointment, finding a banknote on the ground, etc. They are heavily used in popular fiction, precisely to arouse emotion: the gun gets jammed just at the right (or bad) time, the heroine defuses the bomb just before it explodes, etc. Regarding oneself or someone else as lucky or unlucky on specific occasions may induce gratitude or guilt, and for those who downplay the role of chance, intense feelings of good or bad luck may strengthen supernatural beliefs (Teigen & Jensen, *in press*). Reasoning about good luck and bad luck may also significantly influence rational judgment (Roese, 1997; Wohl & Enzle, 2003).

The feeling of having good or bad luck is a clear-cut phenomenon. Different individuals have consistent views of which situations can be regarded as bad or good luck (what the present study will confirm). This ability therefore gives rise to a well-posed problem, worth investigating. Previous studies have identified various parameters that control the feeling of luck. These include physical or temporal closeness (Kahneman & Varey, 1990; Teigen, 1996; Roese, 1997; Pritchard & Smith, 2004), deviation from norms and expectations (Kahneman & Miller, 1986), mutability of causes (Kahneman & Miller, 1986; Byrne 2002, 2007) and controllability (Roese, 1997).

Many authors have acknowledged the prime importance of counterfactuals in any situation that generates a strong feeling of good or bad luck. Individuals systematically go through thoughts such as "If only..." or "I almost..." when regarding situations as (un)lucky. The theoretical treatment of counterfactuals in general, and in emotional situations in particular, remains however complex, as a multitude of determining factors seem to be involved.

The purpose of the present study is to propose a new perspective on the phenomenon, imported from two other scientific domains. One is the study of narrative relevance (Dessalles 2008a). Spontaneous conversations are replete with stories about (un)lucky episodes, and the laws of interestingness seem to apply to them. The other import is the mathematical notion of complexity, which is involved in several important cognitive phenomena (Chater 1999; Chater & Vitányi, 2001).

After mentioning existing attempts to capture the good/bad luck phenomenon formally, I will briefly present the Simplicity Theory and its first predictions concerning our problem. I will then present a study that seems to corroborate those predictions. Then, I will consider situations in which individuals adopt causal thinking. The results and the scope of the theory will be discussed in a last section.

Formal accounts of luck

Various determining factors have been identified that control the intensity of luck. One of them is the low probability of the (un)lucky event s . According to Rescher (1995:211), the intensity of luck is given by $L = E(1-p)$, where E measures the difference that the occurrence of s makes for the interests at stake, and p is its probability. This formula has two major drawbacks. First, contrary to intuition, it does not distinguish moderately unlikely outcomes from highly unlikely ones, as both would provide emotion roughly equal to Δu . Second, as pointed out by Teigen (2005), it fails to capture the crucial presence of a counterfactual. As shown by Teigen in various studies, the amplitude of (un)luck is controlled by the 'distance' to an alternative outcome that would have provided an emotional contrast. Teigen (2005) represents these effects through the formula: $L = \Delta u / D$, where Δu is the difference in 'utility' between the counterfactual s_2 and the actual situation s_1 , whereas D represents the 'distance' between s_1 and s_2 .

This formula makes predictions that are much closer to observation, and thus represents a significant progress in comparison with Rescher's initial proposal. It has, however, its limitations. First, the influence of low probability, as identified by Rescher, is lost. The problem is illustrated in figure 1, where the feeling of unluck after missing the winning sector (in color) in a wheel of fortune game is stronger in (b) than in (a). Second, the notion of 'utility', imported from economics, does not account for situations of pure surprise ('I almost got six on all dice'). Third, the

notion of distance is not properly defined. Sitting next to a lottery winner doesn't make you feel unlucky; you might however feel unlucky to have played her winning numbers, but a week to soon. Lastly, Teigen's formula fails to capture one property of counterfactual s_2 that contributes to (un)luck, namely its simplicity. In figure 1(c), the winning sectors (in color) of the wheel of fortune occupy the same area as in (a) and the distance to the landing site is the same in both cases. Judgment of bad luck is, however, stronger in (a) than in (c). This phenomenon, due to the greater complexity of the counterfactual in (c), is not predicted by Teigen's formula.

Figure 1: Three examples of near miss

We will propose an alternative account, based on Simplicity Theory. It can be formulated in an informal way:

(Un)lucky events are situations that occurred despite of simple, easily accessible alternatives.

Simplicity Theory

Simplicity Theory (ST) (formerly called 'Complexity Drop Theory') has been developed to predict how people select events worth to tell. It has applications in the study of spontaneous conversations, of narratives, of news, and in the definition of subjective probability (Dessalles, 2006; 2008a). ST's main principle can be stated:

Interesting situations are those which are 'too' simple.

ST uses the notion of cognitive complexity, which is a slightly modified version of the mathematical notion known as Kolmogorov complexity.

The complexity $C(s)$ of a situation s is the size of the ideal minimal description of s that is available to the observer.

(the last restriction is crucial for the notion to be useful in cognitive science). The concept is much less trivial than it seems at first sight, and has given rise to a growing literature since its definition in the years 1960.

ST uses two notions of complexity. The second notion is *generation complexity*.

$C_w(s)$ is the minimal size of the parameters to be set for the 'world' w to generate situation s .

To compute $C_w(s)$ of a lottery draw, for instance, one adds up the descriptions of all drawn numbers, as the 'world' (in this case, the lottery machine) had to 'choose' them independently. Note that the notion refers, not to any

objective world, but to the observer's perception of the world. ST's central notion is unexpectedness, noted $U(s)$.

$$U(s) = C_w(s) - C(s) \quad (1)$$

A situation is unexpected if it is 'too' simple, *i.e.* simpler to describe than to generate. In the lottery example, a 'remarkable' lottery draw such as 22-23-24-25-26-27 is unexpected, since C is much smaller than C_w . It only requires to instantiate 22 and to mention that it is a continuous series. C thus spares five instantiations by comparison with C_w . Hence a strong feeling of unexpectedness if such a draw actually occurs (Dessalles 2006). This definition of unexpectedness accounts for various cognitive abilities, such as the perception of coincidences (Dessalles, 2008b) and of interestingness (Dessalles, 2008a; Dimulescu & Dessalles, 2009) (see details on www.simplicitytheory.org). It is consistent with the observation that 'contrast' (what we call unexpectedness) is more relevant than (standard) probability to explain surprise (Teigen & Keren, 2003).

Complexity is usually linked to probability p_0 thanks to the following formula $p_0 = 2^{-C_{w_0}}$, where w_0 is a blank world (Solomonoff, 1978). This formula is, however, unsatisfactory, as it assigns a virtually zero probability to most situations of daily life, as they depend on a huge quantity of parameters. If we replace the blank world w_0 by the observer's model w of the actual 'world', we get $p_w = 2^{-C_w}$, which corresponds to the usual definition of 'objective' probability. In a lottery, for instance, p_w is the same for all draws. ST (Dessalles 2006) defines *subjective* probability p by subtracting cognitive complexity C from C_w . We get:

$$p = 2^{-U} \quad (2)$$

Hence the statement about unexpected events being 'too' simple. In ST's framework, the concept of probability is a derived notion and should be replaced by the notion of unexpectedness to account for many aspects of cognition.

To account for good luck and bad luck, we must say how emotion is related to simplicity (Dessalles, 2008a). Let's call $E(s)$ the (always positive) intensity of the emotional experience caused by situation s .

$$E(s) = E_h(s) + U(s) \quad (3)$$

$E_h(s)$ is the hypothetical emotional intensity attached to the occurrence of s . It corresponds to a not unexpected experience (when $U = 0$). In many cases, $E_h(s) = V(s)$, where V is a utility function. Events that were complex for the world to produce (C_w large) arouse more intense emotion when they occur, as they are more unexpected. Using (2), (3) can be rewritten: $e(s) = e_h(s)/p(s)$, where e_h and e stand for non-logarithmic emotions. The cognitive complexity $C(s)$ decreases $E(s)$ in (3). It acts like an emotional 'tax' paid for considering the event.¹

¹ In (2), U must remain positive. In (3), U may be negative, but E must be positive. These constraints can be used to define the *relevance* of events (Dessalles, 2008a).

If s is not an event, but an anticipated situation, the expected emotion can be expressed using utility function V :

$$E_h(s) = V(s) - U(s) \quad (4)$$

The perspective of a situation that is complex for the world to produce (C_w large) arouses less emotion. In the non-logarithmic domain, equation (4) reads $e_h(s) = v(s) \times p(s)$.

In causal reasoning, we suppose that expected emotion propagates through causal links (Dessalles 2008). If a known emotional situation s is believed to result from situation s' , then $E_h(s) = E_h(s')$. Using conditional complexity, we may write:

$$U(s) = U(s') + C_w(s/s') \quad (5)$$

By adding $E_h(s)$ to both sides, we get:

$$E(s') = E(s) - C_w(s/s') \quad (6)$$

ST's Predictions

In the absence of any precise counterfactual, as when one's house is struck by lightning, (3) provides a definition of luck, in line with (Rescher 1995):

$$L_1 = E_h(s_1) + U(s_1) \quad (7)$$

To assess the expected emotion $E_h(s_1)$ in such case, individuals may recall a known situation s of lightning on a house (or imagine it), and consider $E_h(s_1) = E_h(s) = L_1(s) - U(s)$.

In wheel of fortune situations, the expected emotional intensity $E_h(s_+)$ of winning corresponds to landing on a winning site s_+ . The colored segment in figure 2 represents the winning sector in a linear version of the wheel of fortune. The complexity of landing on s_+ is $C_w(s_+) = \log_2 l_0$. This is the number of bits required by the 'world' to choose a landing position. According to (4), the maximum value of $E_h(s_+)$ is obtained for typical, *i.e.* maximally complex s_+ : $C(s_+) = \log_2 l_2$. This is the number of bits required to discriminate among all winning positions. We get:

$$\max E_h(s_+) = V(s_+) - \log_2 l_0/l_2$$

This corresponds to the classical expected utility in the non-logarithmic domain.

Figure 2: Discrete bounded near miss

When playing with a wheel of fortune, individuals acknowledge that the probability of landing in various sectors of the roulette is constant, but that landing close to a winning sector involves more intense bad luck (Teigen,

1996). Let us considered a linear version of the problem (figure 2).

After the draw, possibly for (self-)narrative purposes, individuals pick the situation s that maximizes emotional intensity $E(s)$. It may be the actual situation s_1 , as in (7), or a counterfactual one s_2 . Individuals are supposed to opt for the computation that gives the more intense emotion. In the counterfactual case, s_1 is seen as an intermediary step toward s_2 . (3) and (6) give a new value for $E(s_1)$: $E_c(s_1) = E_h(s_2) + U(s_2) - C_{wc}(s_2/s_1)$. Luck is measured by the emotional gap between both emotions for s_1 :

$$L_2 = E_h(s_2/s_1) + U(s_2) - C_{wc}(s_2/s_1) \quad (8)$$

Conditional $E_h(s_2/s_1)$ means that the expected emotional intensity is assessed using the actual emotional intensity of s_1 as baseline. The counterfactual nature of s_2 requires the introduction of a fictitious world wc that is able to keep a memory of s_1 to generate s_2 . The term $C_{wc}(s_2/s_1)$ is the minimal price to pay for the 'If...'. It represents the size of the minimal parameter modifications that the observer can imagine for the 'world' to have generated s_2 instead of s_1 .

In the case of figure 2, $E_h(s_2/s_1) = V(s_+)$, and $C_{wc}(s_2/s_1) = 1 + \log_2(\delta + \eta)$, which is the amount in bits needed to indicate the (non zero) targeting shift to the right toward s_2 . On the other hand, $C_w(s_2) = \log_2 l_0$ and $C(s_2) = 1 + \log_2(1 + \eta)$ (one bit to choose the left edge of the winning region, plus the representation in bits of the (possibly null) shift to reach s_2). We get: $L_2 = V(s_+) + \log_2 l_0 - \log_2(\delta + \eta)(1 + \eta) - 2$. Taking $\eta = 0$ to maximize the intensity of unluck:

$$L_2 = V(s_+) + \log_2 l_0/\delta - 2 \quad (9)$$

The experience of bad luck in this near miss experience is an increasing function of the missed opportunity $V(s_+)$ and of the number l_0 of possibilities, and a decreasing function of the miss δ .

If the counterfactual is assessed against the expected emotion, here $\max E_h(s_+)$, instead of s_1 , we get:

$$L_3 = V(s_+) + \log_2 l_2/\delta - 2 \quad (10)$$

This model accounts for the fact that when s_2 is more complex, as in figure 1(c), the intensity of (un)luck is smaller. We have $C(s_2) = \log_2 k + 1 + \log_2(1 + \eta)$, where k is the number of winning regions. The intensity of luck is thus diminished by $\log_2 k$.

The extension to the continuous case is straightforward (figure 3). We suppose that the space is bounded to the left but not to the right. If we call α the landing precision, then $C_w(s_2) = \log_2(l_0/\alpha)$, as we need that number of bits to decide where to stop.² As previously, $C_{wc}(s_2/s_1) = \log_2(\delta + \eta)/\alpha$, and $C(s_2) = \log_2(1 + \eta/\alpha)$. After taking the best choice $\eta = 0$, we get:

$$L_2 = V(s_+) + \log_2 l_0/\delta - 1 \quad (11)$$

² This supposes that there is a way to delimit numbers in the algorithm.

(the one-bit difference with (9) comes from the fact that the winning region has only one edge). Equation (11) accounts for emotions described by the expression: “fall short of the goal”.

Figure 3: Continuous unbounded near miss

Equations (9) and (11) define the intensity of luck, but not only. They predict what the counterfactual situation s_2 will be (what many models of counterfactual thinking omit to do). Individuals pick the alternative s_2 that realizes the best compromise between high emotion $E(s_2)$ and low counterfactual complexity $C_{wc}(s_2/s_1)$.

Nine Stories

The following experiment was conducted to validate the predictions of the model. We tested 61 participants who accepted to pass the test on a Web site (www.dessalles.fr/expe/histoires). All contacted individuals had a high level of academic education, though in domains different from psychology or language sciences (mainly students in engineering). Nine short stories were presented to them (see Table 1). Each involved two or three choices. Instructions invited participants to choose options that made emotion maximal. Some choices irrelevant to the present study (such as the age of the victim in story S9) have not been exploited. Answers given after less than 20 sec. of reading were automatically discarded (median answering time per story was 90 sec.), which leaves us with a minimum of 56 answers per story. Presentation order (stories and options) was randomized.

Table 1: Abridged translation of the stories (originals on www.dessalles.fr/expe/histoires).

S1- René is a railway worker. He works at the border, at a place where signals must be manually transmitted between the two networks. There is single-track line at **[9 (71*) / 23 (21) / 15 (7)]** km from René's post. That day, René forgot to send the signal as a train crossed the border. He eventually did, but **[ten (59*) / fifty (21) / thirty (20)]** seconds before that, another train had entered the single-track line. The collision killed one of the two drivers.

S2- Lucas was heading for the metro station. At **[30 (71*) / 100 (20) / 800 (9)]** m from the station, he stopped to lace up his shoe. As he arrived on the platform, the doors of the train closed in front of him. He had to wait **[25 (89*) / 15 (9) / 6 (2)]** minutes for the next train.

S3- Michèle has been playing lotto every week for **[6 (84*) / 4 (11) / 2 (5)]** years. On December **[19 (70*) / 3 (18) / 12 (12)]**, she told **[two (60*) / four (32) / three (9)]** friends of hers that she would stop playing. They persuaded her to bet for the special Christmas draw, on December 26. She did and won 62 000 Euros.

S4- Jacques was badly injured at his workplace by a defective machine on November 7. The defect had been previously notified and the machine was planned to be repaired on **[November 8 (75*) / November 17 (12) / December 18 (12)]**.

S5- Florence works in a biology lab. Her two-**[year (84*) / month (11) / week (5)]** experiment on cell cultures was ruined by a student who knocked over a shelf. This broke **[all boxes containing (35) / a bottle of formalin that fell on (45) / the automatic device nourishing (20)]** the cell cultures. Florence was furious. She discovered that the student was the son of **[her neighbor (67*) / her former PE teacher (15) / the piano teacher of her sister (18)]**.

S6- A young writer is admitted to Magalie's emergency department at the hospital. Her condition deteriorates. **[8 (66*) / 4 (21) / 6 (14)]** infectious agents may explain the illness. Magalie sends samples to the lab and tests are conducted in parallel. It takes **[seven (79*) / three (16) / five (5)]** hours to get the result and the patient is saved at the last minute. Magalie remembers that she saw the name of the virus in **[the media, as well-know singer recently died of it (52*) / the record of another patient (28) / a specialized journal (21)]**.

S7- For **[four months (76*) / two months (21) / two weeks (3)]** I was thinking of changing my cell phone. I eventually went to SFR Thursday at 1pm. I had to pay part of it because I was lacking 1000 points. **[Thursday (74*) / Friday (21) / Tuesday (5)]** evening, I received an offer: “change your phone, SFR offers you **[1500 (55) / 4000 (38) / 500 (7*)]** points”.

S8- Ms Tsuda's daughter had invited **[two friends (71*) / all girls in her class (17) / four friends (12)]** to her house. One of them was late. She had left her own house long ago. Ms Tsuda walked toward the girl's house and arrived at a level crossing, located at **[200 (55*) / 500 (24) / 900 (21)]** m from Ms Tsuda's house. There was indeed an accident involving a young girl. It turned out that the invited girl was not involved and was late because of a detour caused by the accident.

S9- Helen, retired teacher, fainted as she was walking in the woods. She was found by **[a retired couple (49) / a colleague teacher (26) / a member of her bridge club (25)]** who called the rescue team. Helen would not have survived if she had reached the hospital **[half an hour (77*) / one hour (16) / one hour and a half (7)]** later.

Note: Choices irrelevant to the present study are not shown here. Numbers in parentheses indicate percentages. Asterisk indicates significance ($p < 0.001$). Underlined numbers indicate model predictions.

As shown in Table 1, most results were significant and 19 of the 21 majority choices are congruent with the model's predictions.

Analysis

Some results are commented now in the light of the theory.

Emotions: The intensity of the actual event, $E(s_1)$, was tested in story S2 (Lucas's waiting time), and in story S5 (duration of Florence's lost experiment). Unsurprisingly, majority choices make $E(s_1)$ maximal. In story S7, the third choice (number of points offered) influences $E_h(s_2)$: option “500”,

which would lead to a smaller value of $E_h(s_2)$, was discarded by participants.

Counterfactual simplicity: In story S8, counterfactual s_2 corresponds to the invited girl (G) being involved in the accident ('it could have been her'). Both majority choices in S8 tend to make s_2 simpler, in agreement with equation (8). Participants clearly preferred that the invited girl (G) be one among 2 (71%) instead of one among 5 (17%) or 30 (12%), thus making the minimal description of G smaller by $\log_2 n - 1$ in comparison with $n = 5$ and $n = 30$. Similarly, by choosing the closest location (200m (55%)) instead of 500m or 900m for the counterfactual accident, they saved bits on $C(s_2)$ ($\log_2(500/200)$ and $\log_2(900/200)$).

Duration before near miss: In story S7, participants judged important that the hero hesitated four months (76%) instead of two months or two weeks before buying her/his telephone. We are in a case of unbounded near miss, and as predicted by equation (11), participants preferred the largest value for L . The same phenomenon explains the strong preference for the fact that Michèle has been playing for 6 years (84%) in story S3 (in this case, the winning 'sector' is s_1 and it is reached, but the computation is identical).

Proximity in near miss: Equation (11) predicts that emotion is maximum when one ends up close to the border between 'winning' and 'loosing' sectors (δ small). Several stories represent near miss situations. In S1, the train accident would have been prevented if the signal had been sent $k \times 10$ sec before ($k = 1$ preferred (59%)); In S4, the worker would not have been badly injured if the accident had occurred k days later ($k = 1$ preferred (75%)); in S7, the cost would have been saved if the purchase had been made k days later ($k = 1$ preferred (74%)); in S9, Helen would have died if her admission had been delayed by $k \times 30$ min ($k = 1$ preferred (77%)).

Causal Thinking in Good or Bad Luck

When confronted with events they perceive as (un)lucky, people tend to construct causal explanations for why these events happened (Pritchard & Smith, 2004). Causal thinking may produce counterfactuals by negating causes of the actual event, but also by enabling conditions for the counterfactual (Byrne, 2007). In what follows, we show how causal thinking can be accounted for within the ST framework.

Suppose that a cause s_3 can be found to explain s_1 . If we use (5) together with (7), we get:

$$L_1 = E_h(s_1) + U(s_3) + C_w(s_1|s_3) \quad (12)$$

This relation shows that unexpected causes ($U(s_3)$ large) and materially complex causal links will tend to increase the feeling of (un)luck in the non-counterfactual case.

If s_4 is a counterfactual alternative to s_3 that would have led to s_2 , we can compute L_2 from s_3 . Using (8):

$$L_2 = E_h(s_2/s_3) + U(s_2) - C_{wc}(s_2|s_3)$$

We may decompose $C_{wc}(s_2|s_3)$:

$$L_2 = E_h(s_2/s_3) + U(s_2) - C_w(s_2|s_4) - C_{wc}(s_4|s_3) \quad (13)$$

The term $C_{wc}(s_4|s_3)$ measures the mutability of s_3 (Byrne, 2007). Equation (13) can be used to find a cause that people will be likely to select as mutable. Let us check these predictions against the experimental results.

Cause simplicity: Relation (12) predicts that simple causes ($C(s_3)$ small) will augment emotion since they are more unexpected. This is verified in story S5, where participants preferred the student responsible for the damage to be a neighbor's son (67%) instead of more complex individuals. In story S6, they preferred the virus to have been mentioned in the media (52%), rather than in a medical journal or a medical record where it would have been more complex to discriminate. Story S9 was also designed to test causal simplicity. We expected participants to reject option 'a retired couple', as these individuals would be more complex to discriminate than in the two other options ('a colleague teacher' and 'a member of her bridge club'). However, participants did not show the expected preference (49% vs. 26%+25%).

Causal link complexity: Relation (12) predicts that materially complex causal links ($C_w(s_1|s_3)$ large) are more unexpected and thus will augment emotion. Story S6 has been designed to check this point. Participants did prefer Magalie's eventual success to go through a seven hour (79%) test to decide between 8 (66%) infectious agents, rather than easier alternatives.

Causal link simplicity: Relation (13) conversely predicts that in counterfactual thinking, simple causal links will be preferred ($C_w(s_2|s_4)$ small). In story S1, participants chose the shortest distance between the railway worker's faulty action and its effect (71%); in story S2, they preferred Lucas to lace up his shoe close to the station (71%). In both cases, the material simplicity of the causal link diminishes the counterfactual complexity from the cause ('if he had sent the signal...', 'if Lucas had not paused to lace his shoe...') to the counterfactual effect. We failed to show the same effect in story S5, where we expected participants to chose the simpler causal mechanism ('broke all the boxes') instead of more complex ones ('broke a bottle of formalin'; 'broke the nourishing device'). The probable reason is that a simple causal link is preferable if one adopts Florence's counterfactual thinking, whereas a complex causal link is preferable if we only consider the newsworthiness of the story, what some participants seem to have done despite the instructions.

Discussion

The strong point of this study was to show the relevance of the notion of complexity in the study of the perception of luck. Many judgments about (un)lucky situations are not explained by variations of probability (even perceived probability) (Teigen, 1996). However, they vary in a

systematic way according to variations in complexity. We tried to connect people's attitude toward luck with predictions from Simplicity Theory, with some positive results.

Another positive aspect of the study is to highlight several intervening factors that have gone unnoticed in previous studies, such as the simplicity of the counterfactual situation (story S8), the fact that proximity is measured on a relative scale (stories S3, S7), or the simplicity of causes (stories S5, S6). The model also provides quantitative laws, e.g. for the wheel of fortune near miss.

We had two negative results in the experiment (story 5, choice 2 and story 9, choice 1). Note, however, that both consist in qualitative choices, which are more prone to complex interpretations by participants. The failure in S5 is likely to result from the bad design of the story; the failure in story 9 remains a mystery (perhaps the association due to word 'retired' being used twice is sufficient in rapid readers to make the rescuers seem simple).

In its current state, this theory of luck is not as simple as it should be. There are still some conceptual connections to be done that will make the link between equations and the processing of emotional intensities more transparent. The present account is meant as an attempt to depart from mere lists of factors and to outline an integrated model of the human ability to perceive luck in events.

The research, initiated in the recent years, on the cognitive role of descriptive complexity has already produced valuable results. The model presented in this paper is meant as a contribution to this enterprise. The sensitivity to complexity differences, which is central to ST, seems to be a general law, which applies across modalities and at all levels of abstraction. Its importance in the processing of some emotions that are involved in decision processes, such as the feeling of being (un)lucky after the occurrence of an event (Loomes & Sugden 1982), should encourage further investigation in this domain.

Scan Patterns on Visual Scenes predict Sentence Production

Moreno I. Coco (M.I.Coco@sms.ed.ac.uk) and

Frank Keller (keller@inf.ed.ac.uk)

Abstract

A range of cognitive modalities are involved in everyday tasks, which raises the question to which extend these modalities are coordinated. In this paper, we focus on two particular aspects of this coordination: linguistic structure and visual attention during sentence production, based on the hypothesis that similar scan patterns are associated with similar sentences. We tested this hypothesis using a dataset from an eye-tracking experiment in which participants had to describe photo-realistic scenes. We paired each sentence produced with the corresponding scan pattern, and computed a range of similarity measures for both modalities. Correlation and mixed model analyses confirmed that trials involving similar scan patterns also involve similar sentences productions. This was true for all pairs of linguistic and scan pattern similarity measures we investigated. The result holds both before and during sentence production, and for within-scene and between-scene analyses.

Keywords: scan patterns; sentence production; eye-tracking; sentence similarity.

Introduction

Everyday tasks demand the coordination of a range of cognitive modalities. If the task is to make tea, for example, then motor actions (e.g., arm-hand movement) and visual attention (e.g., looking at the pot) have to be coordinated (Land, 2006). This implies that if two different persons perform the same task, they will do so in a similar way. It follows that the sequence of scan patterns, i.e., eye fixations across spatial locations in temporal order (Noton and Stark, 1971) as well as the sequence of motor actions, will be similar across participants (Land, 2006).

In this paper, we investigate whether a similar evidence of cross-modal coordination can be found when vision and language have to be coordinated. In particular, we focus on the similarity between scan patterns and linguistic structures in a language generation task.

In the visual cognition literature, similarity of scan patterns has not received much attention, mainly because of the high variability across participants (Henderson, 2003). There are some results, however, that point toward a range of visual factors that can trigger similarity. Often, these factors are related to the task (Castelhano et al., 2009) and to the degree of cross-modal interactivity required to perform it.

In tasks with a low level of interactivity, i.e. free viewing, visual attention is mainly guided by **exogenous** factors like *saliency* (Itti and Koch, 2000): a measure of visual prominence based on low-level features (color, intensity and orientation). A free viewing task does not require visual attention to interact with knowledge-based (top-down) information. The low interactivity of free viewing means the visual

responses are driven by exogenous visual mechanisms while minimizing the need for cross-modal coordination.

Different patterns of visual attention emerge in other visual tasks, such as *memorization* or *imagery* (Humphrey and Underwood, 2008), where participants are asked to memorize images in preparation for a recall phase. In the recall phase, despite the absence of the original stimuli (preventing bottom-up effects), scan patterns on a blank screen were more similar across participants within the same scene than across different ones (Humphrey and Underwood, 2008). In this case, the task requires an **endogenous** control of visual attention through top-down knowledge, i.e., scene layout, contextual information, and even semantic relations between objects (Hwang et al., 2009). Thus, exogenous bottom-up effects are overridden by endogenous contextual guidance effects.

These results, consistent with similar findings from visual search studies (Yang and Zelinsky, 2009), suggest that in tasks requiring endogenous control, categorical and semantic information is activated. It seems plausible that this endogenous access to categorical information is activated during daily actions (Land, 2006); e.g., categorical knowledge about the tea pot (i.e., it has a handle to grasp) is necessary to allow cross-modal coordination between visual attention and motor action.

It is important to notice that this information has a direct link with language processing. Categorical information, in fact, is typically expressed verbally, and drives linguistic tasks such as scene description. It seems likely that the same mechanism, based on categorical information, which allows coordination between motor-action and visual attention might also underlie the coordination between language processing and visual attention.

Previous research has looked at the interaction between vision and language principally using the visual world paradigm (VWP, Tanenhaus et al. 1995), an eye-tracking paradigm which has demonstrated clear links between the processing of certain linguistic constructions and the access to visual contextual information (Knoeferle and Crocker, 2006). Research in this field suggests a tightly coupled relation between vision and language, but previous works has largely focused on specific psycholinguistic phenomena (e.g., attachment ambiguity), rather than uncovering the shared mechanisms by which this interaction takes place. We explain this coupled relation assuming a categorical interface which coordinates the cross-modal, visual and linguistic, interaction.

In this paper, we investigate the extent to which visual and

Cue - Animate: "Man"

Cue - Inanimate: "Suitcase"

Figure 1: Example of scene and cues used as stimuli for the description task

language processing are synchronized when participants perform a task viz., scene description in a visual context, which requires endogenous interaction between linguistic and visual processing. Our main hypothesis is that scan patterns and sentences are correlated, i.e., if two trials involve similar scan patterns, then the sentences produced in these two trials will also be similar.

Experimental Setting

In this section, we discuss how the data was collected and processed, and explain how we computed the measures of scan pattern and linguistic similarity.

Data Collection and Pre-processing

In an eye-tracking language production experiment (Coco and Keller, 2010), we asked participants to describe photo-realistic indoor scenes after being prompted with cue words which referred to visual objects in the scenes. The cue words were either animate or inanimate (e.g., *man* or *suitcase*) and were ambiguous with respect with the scene (see Figure 1 for an example trial). Participants' eye-movements were recorded using an Eyelink II eye-tracker with a sampling rate of 500 Hz on a 21" screen (1024 x 768 pixel resolution), while the speech of the participants was recorded with a lapel microphone. We collected a total of 576 sentences produced for 24 scenes which were drawn from six different scenarios (e.g., bedroom, entrance). The sentences were manually transcribed and paired with the scan patterns that participants followed when generating the sentences. We removed two pairs because the sentences were missing.

The data varies across participants and scenes both in terms of the complexity of the sentences (i.e., *one man waits for another man to fill out the registration form for a hotel* vs. *the man is checking in* for Figure 1) and in the length of

the scan patterns produced both in preparation for production (min = 800 ms; max = 10205 ms) and during production (min = 2052 ms; max = 18361 ms). Both types of variability have to be taken into account when developing metrics for sentence and scan pattern similarity.

Similarity Measures

Before quantifying the association between scan patterns and sentence productions, we measure similarity within each modality. We defined two similarity (or equivalent, dissimilarity) measures for both modalities. Applying more than one measure makes it less likely that our results will be an artifact of the type of measure used.

Sentence Measures We define two similarity measures on sentences: Feature Dissimilarity (FD) and semantic similarity computed using Latent Semantic Analysis (LSA). We preprocess the sentences produced by the participants using an automatic part of speech (POS) tagger (Toutanova and Manning, 2000), whose reported accuracy is 96.8% on the Penn Treebank. The POS tags make it easy to extract relevant information from a sentence.

For FD measure, we represent each sentence as a vector, each element of which represents a feature of the sentence. We include semantic and syntactic features, as well as contextual information derived from the scenario a scene belongs to. (In the result section, we also report correlation coefficients obtained when excluding the contextual features.)

Syntactic features include (1) the length of the utterance, which is a general indicator of complexity while also reflecting the total number of visual referents, and (2) the presence of coordination, which reflects disambiguation strategies. As **semantic features** we include (1) the verb frame and (2) semantic similarity between verbs. The verb frame encodes the arguments the verb can take, obtained from WordNet (e.g., transitive or intransitive); semantic similarity is computed using Jiang and Conrath's (JC) synset path-distance (Budanitsky and Hirst, 2006). This distance measure is based on the number of nodes from one verb to another in the WordNet database. We calculate pairwise JC distance on all pairs of unique verbs in our corpus of sentence productions; we then apply hierarchical clustering to group together similar verbs. Cluster membership is the feature value included in the FD vector.

The **contextual features** include (1) the animacy of the cue word, useful to discriminate between different descriptive routines and, (2) the scenario in which the sentence was produced (e.g., bathroom, entrance). Notice that the contextual features are not scene specific; each scenario is represented by four different scenes.

After converting each sentence into a vector of features, we calculate FD between all pairs of sentences by applying Gower distance (Gower, 1971), which can be used when the data is both numerical and categorical.

LSA measures the similarity between words based on the co-occurrence of content words within a collection of docu-

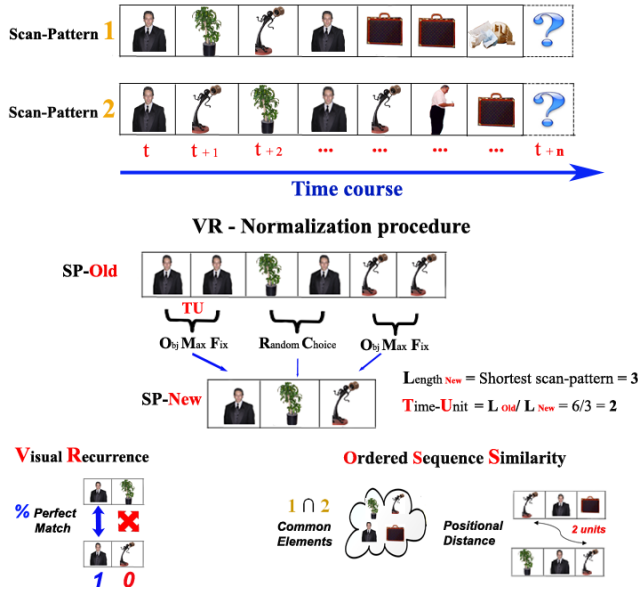

Figure 2: Example of how scan patterns are represented and normalized (for VR only); and how measures of scan pattern similarity are computed

ments (in our case the British National Corpus). It indicates how likely two words are to occur in the same document. Different from Hwang et al. (2009) where LSA is calculated between individual words, we implemented a version of LSA generalized to compute the similarity of sentences (Mitchell and Lapata, 2009). We compute an LSA vector for each content word in the sentence (context window of size five; low frequency words are removed) and then combine these vectors using addition to obtain a sentence vector (an alternative discussed by Mitchell and Lapata 2009 would be vector multiplication). Similarity between sentence vectors is measured using cosine distance.

Scan Pattern Measures We use two measures to compute the similarity between scan patterns: Visual Recurrence (VR) and Ordered Sequence Similarity (OSS, Gomez and Valls 2009).

We consider scan patterns as temporally ordered sequences of fixated target objects. Each trial is therefore encoded as a sequence of discrete time points, each annotated with the object fixated at that time, encoded numerically (see Figure 2). VR is a percentage measure of scan pattern similarity that counts the frequency of looks to the same objects during the same time points between two scan patterns relative to its total length. For example, in Figure 2, we have two matches on a total of seven time points, i.e., 25.87% agreement between the scan patterns.

VR can only compare scan patterns equal in length. We therefore normalize each scan pattern (SP_{old}) by mapping it onto a normalized time course of fixed length (SP_{new}). The length of SP_{new} is set on the basis of the shortest eye-movement sequence found across all participants. For each

SP_{old} , we obtain the number of time-points corresponding to a time unit of SP_{new} by simply dividing the length of SP_{old} with the length of SP_{new} . Over the SP_{old} time-points, we look for the object which has received the highest number of looks and map it into the corresponding time-unit of SP_{new} . The final result is a normalized scan-pattern of fixed length containing the objects most likely to be fixated.

The second method used to compare scan patterns is Ordered Sequence Similarity (note that despite its name, OSS is in fact a dissimilarity measure). Its main advantage is that it can be used with sequences of different lengths, and has shown to be more effective than established measures such as edit distance (Gomez and Valls, 2009). OSS is based on two aspects of sequential data: the elements the sequence is composed of, and their positions. When comparing two sequences, it takes into account the number of common elements and their relative order. The first step is to find target objects that occur in both scan patterns. For example in Figure 2, four objects are shared by the two scan patterns (man, plant, statue, suitcase). For each common element, we calculate the distance between the two sequences, e.g., statue of scan pattern 1 is two units distant from statue in scan pattern 2. Distances are then summed and normalized on the basis of sequence lengths (for details refer to Gomez and Valls 2009).

All four measures of similarity are computed pairwise, i.e., every trial (sentence and scan pattern) is paired with every other trial. This resulted in a total of 164,164 pairs for each region of analysis, i.e., Before and During production.

Analysis

To analyze the correspondence between sentences and scan patterns, we divide the data into two regions: *Before* speech onset, and *During* production. The *Before* region provides evidence about the process of utterance planning and visual information retrieval, whereas *During* is informative about linguistic encoding and the utilization of visual information during this process. We perform two types of analysis: descriptive and inferential.

In the descriptive analysis, we investigate the data at two levels: (1) globally, i.e., by performing comparisons between all pairs of trials in the full data set, and (2) locally, i.e., by comparing only the trials that pertain to a given scene (24 in total). These two forms of analysis make it possible to test whether the correspondence between sentences and scan patterns is scene specific. For comparison, we also report a baseline correlation (Humphrey and Underwood, 2008) that is obtained by pairing sentences and scan patterns randomly (rather than pairing the scan patterns with the sentences they belong to).

We quantify the strength of the correspondence between similarity measures by computing Spearman's ρ for all pairs of measures. We do not report coefficients for the baselines, as they are not significant across all combined measures: $\rho \approx 0.002$; $p > 0.1$. For the correlation analysis, we also con-

sider a variant of the Feature Dissimilarity measure for which we remove the contextual features (FD-C). This makes it possible to investigate the contribution of scenario and animacy of the cue word to the correspondence between scan pattern and sentence similarity.

The distinction we made between global and local similarity has implications for the nature of correspondence. A correlation found globally (across all scenes) would imply that scan patterns are partially independent from the precise layout of the scene, i.e., position of the objects, etc., as these factors varied across scenes, but rather dependent on the categorical structure shared, i.e. the visual referents common across scenes. A correlation found at the local level would be consistent with well-known scene-based effects, both bottom-up and top-down, which guide visual attention (Itti and Koch, 2000; Humphrey and Underwood, 2008).

In the inferential analysis, we apply linear mixed effects modeling (LME) (Baayen et al., 2008) using the R-package lme4. We use scan pattern similarity as the dependent variable (fitting a separate model for OSS and VR) and sentence similarity (FD and LSA) as predictors. The region of analysis (before or after) is also included as a factor. As random effects, we included participants and trials.¹ All fixed factors were centered to reduce collinearity. The models are built following a forward step-wise procedure. We start with an empty model, then we add the random effects. Once all random effects have been evaluated, we proceed by adding the predictors. The parameters are added one at time, and ordered by their log-likelihood improvement of model fit: the best parameter goes first. Every time we add a new parameter to the model (fixed or random), we compare its log-likelihood against the previous model. We retain the additional predictor if log-likelihood fit improves significantly ($p < 0.05$). The final model is therefore the one that maximizes fit with the minimal number of predictors.

Results and Discussions

Figure 3 plots the linguistic similarity measures LSA and FD against the scan pattern similarity measure OSS², computed globally, i.e. across all scenes. We bin the data on the x-axis and include 95% confidence intervals. The plots also include the random baseline.

For both linguistic measures, we observe a clear trend between sentence and scan pattern: when LSA similarity increases, scan pattern dissimilarity decreases; when feature dissimilarity (FD) increases, OSS also increases. This effect is observed both Before and During region, but not in the random baseline.

We also observe a difference in the intercept between the Before and During region. In the Before region, there is less dissimilarity between scan-patterns overall. This could indicate a higher degree of coordination between the two modal-

¹Similarity is calculated pairwise. Thus, we need to include as random variables two participants and two trials for each pair.

²For reason of space, VR is shown only in the LME results.

Figure 3: Correlation between LSA similarity, Feature dissimilarity (FD) and Ordered Sequence Similarity (OSS)

ities during sentence planning, compared to sentence encoding. During planning, visual attention integrates the categorical information of the scene with the linguistic referents selected as arguments of the sentence. When production starts, detailed information is sourced from the visual processor to drive encoding, thus triggering more specialized routines of visual information retrieval.

Figure 4 plots local similarity values, i.e., values computed separately for each scene (OSS against LSA)³. Generally, the

³Again, for space limitation, we can show only one pair of combined measures, OSS/LSA. However, we observe a similar trend for all the other pairs.

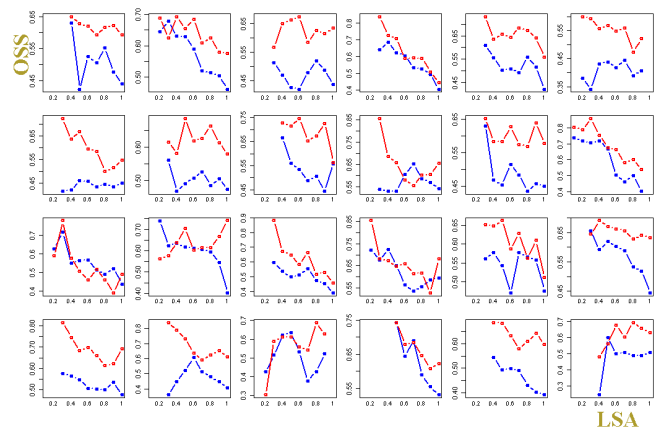

Figure 4: Scan pattern dissimilarity (OSS) as a function of the Linguistic Similarity (LSA) across all 24 scenes

Table 1: Correlations (Spearman ρ) between the different similarity measures. *Before* and *During* aggregated

Measures	VR	OSS	FD	LSA
OSS	-0.63***			
FD	-0.07***	0.15***		
LSA	0.15***	-0.10***	-0.06***	
FD-C	-0.02**	0.01*	0.86***	-0.10***

Table 2: Minimum and Maximum correlations (Spearman ρ) across different scenes between the different similarity measures

Measures		VR	OSS	FD
OSS	min	-0.10		
	max	-0.56		
FD	min	-0.01	-0.02	
	max	-0.55	0.44	
LSA	min	0.01	-0.001	-0.52
	max	0.33	-0.30	-0.79

trend previously observed at the global level is confirmed, both for the *Before* and the *During* region, though there is some variation in the degree of association between scan patterns and linguistic similarity across scenes.

Table 1 lists the correlation coefficients for all pairs of similarity measure. There are weak but significant correlations across all measures. In particular, both VR and OSS are significantly correlated with both FD and LSA in the direction expected, i.e., positively in case of dissimilarity and negatively in the case of similarity. Between the two scan pattern measures (OSS and VR), we observe a strong correlation, whereas the association between the two linguistic measures (FD and LSA) is weak. We also observe that FD-C, the measure obtained by removing contextual information from FD is highly correlated with FD, but the removal of contextual information weakens the correlation with the scan pattern measures. On the other hand, FD-C is somewhat more strongly correlated with LSA than FD is. It seems that the contextual information, even if at the level of the scenario, prominently contribute to the prediction of scan pattern similarity.

In Table 2, we show the minimum and maximum values of the correlation coefficients for similarity measures observed locally, i.e. computed trials aggregated by scene. As expected from the plots in Figure 4, correlation coefficients vary across scenes for all pairs of measures. The context of the individual scenes modulates the correspondence between scan patterns and linguistic productions. Compared to the global coefficients, the most noticeable difference is a strengthening of the correlation between the two linguistic measures FD and LSA. It seems that in a scene context, the semantic information expressed by LSA more directly matches the information in FD, which also includes verb semantics and scenario information.

Figure 5: Predicted values of the linear mixed effects model: linguistic similarity predicted by scan pattern similarity

Table 3: LME coefficients. The dependent measures are: *OSS* and *VR*. The predictors are: *Region* (contrast coding: *Before* = -0.5; *During* = 0.5) and the Linguistic Measures (LM) *FD* or *LSA*. Each column shows which linguistic/scan pattern similarity measure is compared

Predictor	FD/OSS	FD /VR	LSA/OSS	LSA/VR
Intercept	0.0879***	18.95***	0.639***	18.97***
Region	0.062***	-0.907***	0.062***	-0.906***
LM	0.087***	-6.151***	-0.104***	5.953***
LM:Region	-0.083***	4.866***	n.sig.	-2.687***

Turning now to the inferential analysis, Figure 5 plots LME predicted values calculated globally for all pairs of measures. The models closely follow the empirical patterns in Figure 3. Table 3 lists the coefficients of the mixed models; we find a significant main effect of scan pattern similarity for both FD and LSA, for both the OSS and the VR model. Moreover, we observe a main effect of region across all combined measure: for the *Before* region, sentence similarity is more strongly related to scan pattern similarity, compared to the *During* region.

Furthermore, we observe an interaction of region of analysis and linguistic similarity: for *Before* region, the similarity between sentence and scan pattern has a steeper change, compared to *During*. In linguistically driven visual planning, we retrieve the referents going to be encoded. Thus, if two sentences are going to be very different, the set of referents chosen during visual planning is also going to be very different. During encoding instead, the visual system is already sourcing detailed information in a sentence specific way, thus the magnitude of change is smaller compared to planning.

General Discussion

A range of cognitive modalities are involved in everyday tasks, which raises the questions to which extend these modalities are coordinated. In this paper, we focused on two particular aspects of this coordination: linguistic structure and visual attention during sentence production. Our main hy-

pothesis was that similarity of scan patterns predict the similarity of sentences.

We tested this hypothesis using a dataset from an eye-tracking experiment in which participants had to describe photo-realistic scenes. We paired each sentence produced with the corresponding scan pattern, and computed similarity measures for both modalities. We used Visual Recurrence and Ordered Sequence Similarity to compare scan patterns, while for sentences we used a semantic similarity measure based on LSA and a feature dissimilarity measure that combines syntactic, semantics, and contextual information.

Both descriptive and inferential analysis confirmed our hypothesis: if two trials involve similar scan patterns, then the sentences produced in these two trials are also similar. This was true for all pairs of linguistic and scan pattern similarity measures. Furthermore, we subjected the data to a global analysis (i.e., we computed similarity across different scenes) and a local analysis (i.e., we only compared scan patterns and sentences within the same scene). Significant correlations were found in both cases, which suggests that the correspondence between sentences and scan patterns cannot be explained as a simple mapping between individual scene content and the objects mentioned in the corresponding sentence. This conclusion is confirmed at the level of individual scenes, where the variability observed suggests the presence of different visual and linguistic factors modulating the strength of the correspondence.

An important point emerged during our analysis regarding the role of contextual information in predicting similarity. When contextual features were removed from the linguistic measure, the strength of the correlation was reduced (but was still significant). Even though our contextual features were not scene specific, but rather pertained to more general scenarios, they were still helpful in predicting scan patterns.

Within the broader context of cognition, our results indicate that in tasks demanding the interaction of vision and language, where endogenous control plays an essential role, they synchronize processing through coordination over a shared categorical interface.

Ongoing work is currently investigating the sequential and temporal aspects of the correspondence using alignment techniques borrowed from bio-informatics. Preliminary results show that the inclusion of temporal information together with a more stringent analysis of sequential data increase correlation between sentences and scan patterns.

Finally, in future work we plan to investigate a range of linguistic features separately, thus enabling us to establish which aspects of scan patterns predict syntactic, semantic, or contextual aspects of sentence production.

Modulation of motor-meaning congruity effects for valenced words

Abstract

We investigated the extent to which emotionally valenced words automatically cue spatio-motor representations. Participants made speeded button presses, moving their hand upward or downward while viewing words with positive or negative valence. Only the color of the words was relevant to the response; on target trials, there was no requirement to read the words or process their meaning. In Experiment 1, upward responses were faster for positive words, and downward for negative words. This effect was extinguished, however, when words were repeated. In Experiment 2, participants performed the same primary task with the addition of distractor trials. Distractors either oriented attention toward the words' meaning or toward their color. Congruity effects were increased with orientation to meaning, but eliminated with orientation to color. When people read words with emotional valence, vertical spatio-motor representations are activated highly automatically, but this automaticity is modulated by repetition and by attentional orientation to the words' form or meaning.

Keywords: Automaticity, Metaphor, Motion, Space, Valence

Introduction

Do some abstract concepts depend, in part, on mental representations of physical space? According to theories of metaphorical mental representation, linguistic metaphors like 'a rising price', 'a sliding scale, or 'a long engagement' suggest that many of our abstract ideas are grounded in representations of *motion* and *space*. These are, in turn, grounded directly in perceptuo-motor experiences (e.g., Clark, 1973; Lakoff & Johnson, 1999; Talmy, 1988). Although initial arguments for metaphor theory were based on descriptive linguistic data, psychological experiments provide evidence for important links between spatio-motor representations and mental representations in more abstract domains like *power* (Schubert, 2005), *happiness* (Meier & Robinson, 2004), *time* (Boroditsky, 2000), *number* (Dehaene et al., 1993), and *similarity* (Casasanto, 2008). Yet researchers are just beginning to specify what roles spatial representations may play in abstract thought.

Debates about metaphorical representation have focused on two theoretical possibilities outlined by Murphy (1996), which were impossible to distinguish based on observational linguistic data, alone. On the Strong View, representations in metaphorical source domains (e.g., space) are necessary for conceptualizing target domains (e.g., time). According to Lakoff and Johnson (1999), activating

source-target mappings is obligatory: without them, "abstract thought is virtually impossible." On the Weak View, however, source domain representations make an optional contribution to people's understanding of target domains. Boroditsky (2000) tested whether spatial representations are necessary for understanding temporal language, and concluded that "spatial schemas are *useful*, but *not necessary*" (italics added).

Framing experiments in terms of the necessity of source domain representations for understanding target domains (and for understanding target-domain language in particular) helped to transform a question that was long the province of linguists and philosophers into a question that is tractable using the psychologist's toolkit. Yet continuing to test a Strong-Weak dichotomy seems unlikely to lead to further new discoveries.

On nearly any theory of metaphor, source domain representations are hypothesized to be *part* of a more complex mental representation or word meaning: on the Strong View, a necessary part. The idea that there are *necessary parts* (i.e., features) of concepts or word meanings, however, is difficult to maintain. Wittgenstein (1953) famously exploded the notion that even a simple, relatively concrete word like *game* has any features that are necessarily present in all of its instantiations. It seems unlikely that more abstract words like *value* or *justice*, whose meanings are notoriously fluid, would have any necessary parts. This suggests the necessity question should be reframed in terms of functionality: What causes source domain representations to be activated, and what functional roles do they play in understanding target domains?

Psychologists have also raised a related question about metaphor (e.g., Meier & Robinson, 2004; Meier, et al., 2007): Are source domains activated *automatically* when people understand target domains? Automaticity is of interest because it is taken as evidence against the possibility that source-domain representations are only activated strategically (perhaps consciously) when people need to communicate about abstract ideas, or in response to task demands (Meier, et al., 2007). Curiously, however, automaticity has been treated as binary; source domains either *are* or *are not* activated automatically. Yet for most aspects of concepts and word meanings, it seems unlikely that activation is fully automatic – not in the same sense that people automatically perceive the lines in the Müller-Lyer illusion to be of different lengths. As classic studies of 'semantic flexibility' suggest, context can modulate the

activation of even those aspects of a word's meaning that might seem to be indispensable (e.g., Barclay, et al., 1974). Notions of automaticity that are well-suited for characterizing aspects of perceptual and motor processes may not be appropriate for characterizing aspects of meaning: meaning is not a reflex.

Traditional notions of necessity and automaticity must be tailored to fit questions about metaphor (and about meaning, more broadly). Rather than asking whether source domains are necessary for understanding target domains, it may be more fruitful to ask 'what functional roles do source-domain representations play in understanding target domains?' Rather than investigating *whether* source domain representations are activated automatically, it may be useful to ask 'to what extent is their activation automatic, and under what conditions is their activation increased or diminished?' We take up these latter questions of automaticity here, assuming automaticity to be a continuum.

Emotional valence is an abstract domain that people often talk about using metaphors from space and motion: when people are optimistic they're *looking up*, and when they're sad they're *feeling down*; hopes can *rise*; morale can *drop*; spirits can *soar* or *plummet*. Behavioral studies suggest these linguistic metaphors correspond to mental metaphors: non-linguistic associative mappings from representations of motion or space to the representations of emotional valence. Stroop-like experiments show these mappings are activated when people process language with positive or negative valence, even when they're not using any linguistic metaphors.

In one study (Meier & Robinson, 2004), participants were faster to judge words like *polite* and *rude* as having positive or negative valence when positive words were presented at the top and negative words at the bottom of a computer screen (Experiment 1). Furthermore, judging words to be positive directed attention to the top of the computer screen, and judging them to be negative directed attention to the bottom (Experiment 2). Yet based on these experiments it would be premature to conclude that space-valence associations are 'automatic'. For one thing, the spatial variation from trial to trial was highly salient in Meier & Robinsons' experiments (in fact, impossible to ignore), and for another, participants made explicit judgments about the valence of the words. Thus, the tasks strongly focused attention on both the source and target domains.

To address these concerns, Casasanto (2008) adapted a spatial interference task of Zwaan & Yaxley's (2003) for use with valenced words. Participants saw pairs of words, one above and the other below fixation, and made speeded synonym-antonym judgments. Target word pairs were antonyms, one with positive and the other with negative valence. Participants were fastest to classify the pairs as antonyms when the positive word appeared above the negative (e.g., *wealthy* above *poor*). In a second experiment, participants were faster to make lexical decisions on positive-valence words (e.g., *brave*, *ethical*) when they were presented above non-word distractors, and on negative-

valence words (e.g., *failure*, *hate*) when presented below non-word distractors. This was true even though neither the spatial position of the words, nor their valence, nor any other part of their meaning was relevant to the task.

In a third experiment, Casasanto (2008) presented positive and negative words in the center of a screen, in either red or blue letters. On the right and left of the screen there were three large boxes. The top box was red and the bottom box was blue (or vice versa). The middle box was white, and was filled with marbles. Participants were instructed that as soon as each word appeared, they should move one marble with each hand into the box corresponding to the color of the word's font, as quickly as possible. They moved marbles fastest when the direction of movement was congruent with the spatial schema suggested by the word's valence. This was true even though movements were cued only by the words' colors: not only was their meaning irrelevant, the tasks did not even require participants to process the words *as words*.

These Stroop-like congruity effects suggest that spatial representations are activated with a considerable degree of automaticity when people read valenced words. The goal of the present study was to test the limits of this automaticity. In Experiment 1, we tested whether repeating stimuli modulated the magnitude of the space-valence congruity effect. Casasanto's (2008) marble-moving task was adapted for use with button presses, to automate response coding. Stimuli were presented twice, in successive blocks, and reaction times were compared across blocks. In Experiment 2, we tested whether attentional orientation influenced the magnitude of space-valence congruity effects. We used a Task Set Inertia manipulation (Allport & Wylie, 2000). Distractor trials oriented attention during the target trials toward either semantic or perceptual aspects of the target words.

Experiment 1: Does repetition modulate motor-meaning congruity effects?

Experiment 1 tested whether motor-meaning congruity effects observed in previous studies would be modulated by repetition of the same stimulus words.

Methods

Participants Native English-speaking UC Berkeley students (N=20) participated in exchange for course credit or payment.

Materials

Two lists of 48 English words were created, one with positive and the other with negative valence (e.g., *wealthy*, *poor*, *virtuous*, *evil*, *joy*, *disgust*, etc.), totaling 96 stimuli. The words were nouns and adjectives that have no literal spatial meaning, but which subjects in a previous norming study spatialized consistent with their metaphorical associations (e.g., placing *wealthy* above *poor*; *virtuous* above *evil*, etc.) Positive and negative words did not differ

in frequency ($p=0.70$), number of syllables ($p=0.60$), or number of letters ($p=0.12$), by two-tailed t -tests.

Stimuli were presented on a CRT monitor with a refresh rate of 60 Hz. A standard QWERTY keyboard was mounted vertically directly underneath the monitor, and participants responded using three of the keys: top (the A key), bottom (the apostrophe key), and middle (the H key). The top and bottom keys were colored green and purple, and the assignment of colors to keys was counterbalanced across participants. The middle key was always colored white.

Procedure All 96 words were presented one at a time in random order in block 1, and again in a new random order in block 2. Half of the words were in green letters and half in purple letters. The assignment of colors to words was the same for both blocks within-subjects, and counterbalanced between subjects.

Participants began each trial by holding down the middle (white) key with the pointer or middle finger of the dominant hand. A fixation cross appeared for 1000ms-1500ms on a rectangular distribution (to prevent anticipatory releases of the middle key). When the fixation disappeared, a word appeared in the center of the screen for 2000 ms in lowercase, bold 28-point Arial font (purple or green), on a black background. Participants were instructed to release the white key and press the key matching the color of the text as quickly as possible. Only the color of the word was relevant to the response: the word's meaning was irrelevant, and the direction of the response was incidental. But because the purple and green keys were positioned vertically, one above the other, each key press required the participant to make either an upward or a downward movement. After pressing the colored key, participants returned their finger to the white key. Pressing the white key initiated the next trial.

The color of the words was orthogonal to their valence. Therefore, for half of the trials the direction of the correct response was congruent with the valence of the word (e.g., if the word *joy* appeared in green and the green key was on top), and for the other half of the trials direction and valence were incongruent (e.g., if the word *joy* appeared in purple and the purple key was on bottom).

Participants received warning messages, displayed for 2500 ms, if they released the middle key too early (less than 200 ms after word onset) or too late (more than 1000 ms after word onset). Participants performed 16 practice trials prior to the first block. Halfway through each block, they were given a rest, and chose when to continue.

Results and Discussion

Accuracy

Participants pressed the correct button for over 99% of trials. Accuracy did not differ as a function of congruity or block (t -values <1).

Reaction Times

We collected two reaction times: Release Time (measured from the onset of the word to the release of the middle white

key), and Press Time (measured from the onset of the word to the press of the colored key). From these we computed Travel Time (Press Time - Release Time). Trials for which Press Time was more than two standard deviations from the participant's mean were excluded from further analysis (143 out of 3840 trials, 3.7%).

Release Times Mean Release Times are given in fig 1a-b. Omnibus $2 \times 2 \times 2$ ANOVAs showed a 3-way interaction of Direction (upward, downward), Valence (positive, negative), and Presentation (first, second), both by subjects ($F_1(1,19)=5.95$, $p=.03$) and by items ($F_2(1,94)=5.83$, $p=.02$). The predicted motor-meaning congruity effect would be indicated by a 2-way interaction of Direction \times Valence. There were no significant 2-way interactions in the data from both presentations, combined (all F 's <1), so separate 2-way ANOVAs were conducted to test for this effect within each block.

Presentation 1 showed the predicted Direction \times Valence interaction ($F_1(1,19)=4.67$, $p=.04$; $F_2(1,94)=3.26$, $p=.07$). Presentation 2 showed a slight trend in the opposite direction, but the Direction \times Valence interaction did not approach significance ($F_1(1,19)=1.60$, ns ; $F_2(1,94)<1$, ns).

Press Times Mean Press Times are given in Figure 1c-d. Omnibus $2 \times 2 \times 2$ ANOVAs showed a 3-way interaction of Direction (upward, downward), Valence (positive, negative), and Presentation (first, second), by subjects and by items ($F_1(1,19)=9.17$, $p=.007$; $F_2(1,94)=3.72$, $p=.06$).

Presentation 1 considered alone showed the predicted Direction \times Valence interaction ($F_1(1,19)=4.43$, $p=.05$; $F_2(1,94)=3.32$, $p=.07$). Presentation 2 showed a slight trend in the opposite direction, but the Direction \times Valence interaction did not approach significance ($F_1(1,19)=2.84$, ns ; $F_2(1,94)<1$, ns).

Overall, there was a strong main effect of direction for Press Times ($F_1(1,19)=131.62$, $p=.0001$; $F_2(1,94)=764.76$, $p=.0001$), which was not present for Release Times. This effect appears to be an artifact of kinematic differences between top and bottom key presses, which used different muscle groups due to the positioning of the keyboard. This main effect is not relevant to the predicted motor-meaning congruity effect.

Travel Times Neither the omnibus 3-way ANOVAs nor the separate 2-way ANOVAs testing relationships between Direction and Valence in Presentation 1 and Presentation 2 showed any interactions that approached significance. This suggests that congruity effects arise during action planning rather than action execution.

In summary, we found the predicted Direction \times Valence interaction only during the first presentation of the stimulus words. This motor-meaning congruity effect was absent when words were presented a second time (in Block 2). To test the effect of repetition directly, we compared the magnitude of the congruity effect (incongruent trials -

congruent trials) across blocks, both for Release Times ($t_1(19)=2.46$, $p=.02$; $t_2(95)=2.37$, $p=.02$) and Press Times ($t_1(19)=3.02$, $p=.007$; $t_2(95)=1.95$, $p=.05$). Repetition significantly reduced the effect of congruity between movement direction and valence.

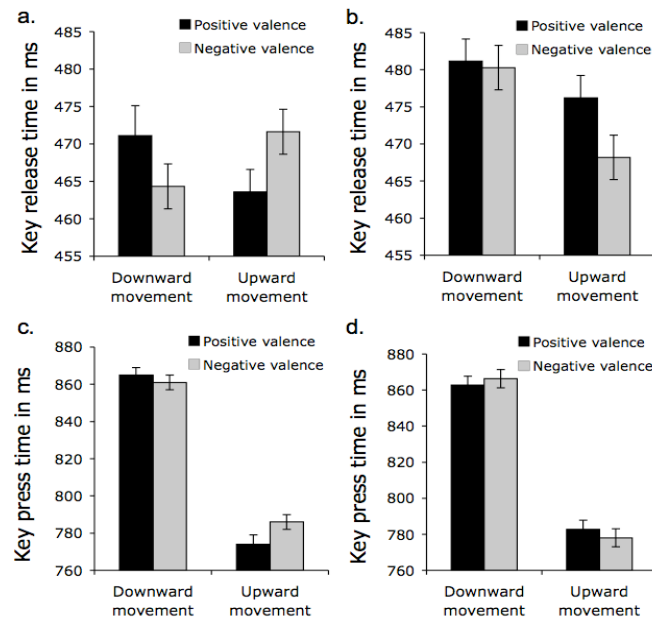

Figure 1. Results of Experiment 1. Top: RT measured from the release of the middle key for Presentation 1 (1a) and Presentation 2 (1b). Bottom: RT measured from the press of the colored key for Presentation 1 (1c) and Presentation 2 (1d). Error bars indicate s.e.m.

Experiment 2: Does attentional orientation modulate motor-meaning congruity effects?

What accounts for the disappearance of the congruity effect when words are repeated? On one possibility, participants may have become so efficient at performing the task that there was no opportunity to detect any interference from irrelevant dimensions of the stimuli: a ceiling effect. Yet an increase in efficiency should result in an overall decrease in reaction times from Presentation 1 to Presentation 2. Since we found no main effect of Presentation, this explanation is not well supported.

Alternatively, it may be that with practice, participants are better able to attend to the relevant dimension of the stimuli (their color) as opposed to irrelevant dimensions (their valence, and more generally their meaning). To test this explanation, for Experiment 2 we adapted Allport & Wylie's (2000) Task Set Inertia paradigm. Target trials were the same as in Experiment 1, but distractor trials were added. For one group of participants, the distractor trials oriented attention toward the meanings of the target words. For the other group, distractors oriented attention toward the target words' colors. We compared reaction times across groups to determine whether attentional orientation modulates the magnitude of space-valence congruity effects.

Methods

Participants Native English-speaking UC Berkeley students ($N=48$) participated for course credit or payment.

Materials and Procedure

The experimental apparatus for Experiment 2 was the same used in Experiment 1. The primary task was identical to Presentation 1 of Experiment 1, except that 48 distractor trials were added, randomly intermixed with the 96 target trials, for a total of 144 trials. Participants were assigned to perform one of the two versions of the task, one with distractors designed to orient attention to the Meaning of target words, and the other to the Color of target words. Responses to these distractors were not recorded.

Stimuli in the Meaning Orientation condition were 24 concrete nouns, half referring to animate and half to inanimate objects. Whereas target words were shown in purple or green letters, distractors were in white letters. Participants performed a go/no-go animacy judgment, releasing and then re-pressing the middle white button to indicate the distractor word named something animate. In the Color Orientation condition, a 2×2 grid of grey squares appeared. On half of the trials the grid was empty, and on the other half an unsaturated red "X" appeared in one of the squares, balanced across the 4 positions. Participants performed a go/no-go X-detection judgment, re-pressing the middle white button to indicate that a red X was present.

Only one block of trials was performed, and brief rests were provided twice, after the first 48 trials and then after the next 96 trials.

Initially, 16 participants were assigned to each of the distractor conditions. Upon preliminary analyses, the predicted congruity effect was present in the Meaning Orientation condition but not in the Color Orientation condition. Sixteen new participants were added to the Color Orientation condition, to ensure that the absence of a congruity effect was not due to lack of statistical power. Since results for the second cohort did not differ from results in the first, data from both cohorts were combined for the analyses reported here.

Results and Discussion

Accuracy

Participants correctly pressed the button corresponding to the color of the word for 100% of target trials. Performance on distractor trials was not analyzed.

Reaction Times

Omnibus $2 \times 2 \times 2$ ANOVAs showed no significant 3-way interaction of Direction (upward, downward), Valence (positive, negative), and Distractor Type (Meaning, Color). The Press Time data showed the predicted 2-way interaction of Direction and Valence in the Meaning Orientation condition ($F_1(1,15)=6.12$, $p=.03$; $F_2(1,94)=4.23$, $p=.04$), but not in the Color Orientation condition ($F_1(1,31)=.11$, ns ; $F_2(1,94)=.55$, ns). A slight trend toward the same Direction \times Valence interaction in the Meaning Orientation condition

was found for Release Times ($F(1,15)=1.61$, $p=.22$; $F(2,94)=1.57$, $p=.21$) and Travel Times ($F(1,15)=4.81$, $p=.05$; $F(2,94)=.82$, $p=.37$). The absence of a significant effect on Release Times was unexpected, given the results of Expt. 1. This may have been the result of noise introduced into the early phase of target responses when participants were required to task-switch following distractor trials.

To test the predicted effect of attentional orientation on Press Times directly, we compared the magnitude of the congruity effect (incongruent trials - congruent trials) across conditions. According to a Wilcoxon signed rank test, the congruity effect was greater in the Meaning Orientation condition (15.1 ms) than in the Color Orientation condition (1.7 ms; difference of means=13.4 ms, $W=176$, $p=.04$, one-tailed). Orienting attention toward Meaning or toward Color during distractor trials modulated the size of the motor-meaning congruity effect observed during target trials.

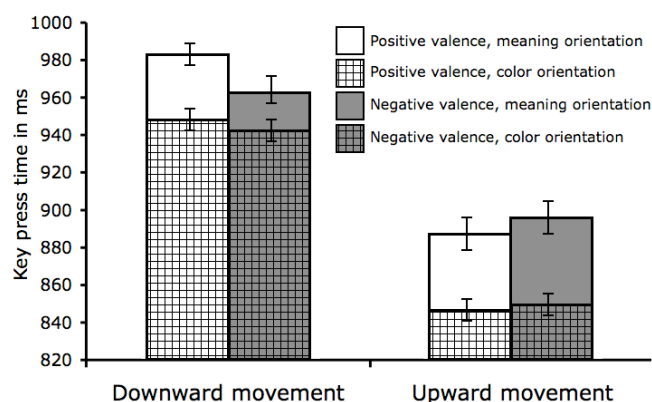

Figure 2. Results of Experiment 2. Space-valence congruity effects were found for target trials when distractors oriented attention to word meaning but not to word color. Error bars indicate s.e.m.

General Discussion

In two experiments, we show effects of congruity between the valence of a word and the spatial direction of the response it cued. In both experiments participants responded only to the color of the target words, pressing the button that matched in color. The spatial directions of the responses were task-irrelevant, as were the meanings of the words. Still, participants responded fastest when the direction of the response and the valence of the word were in agreement: upward movements for positive-valence words, and downward for negative-valence words. The presence of space-valence congruity effects even during shallow, incidental processing of both space and valence suggests that the spatial component of the words' meanings was activated with a high degree of automaticity.

Both experiments also illustrate that automaticity has its limits. In Experiment 1, the motor-meaning congruity effect was found only during the first presentation of the stimuli, but not upon their repetition. Since there was no overall reduction in response times between Presentation 1 and

Presentation 2, the extinction of the congruity effect does not appear to be a ceiling effect.

Experiment 2 tested an alternative explanation for the effect of repetition: perhaps with practice, participants became more adept at focusing on the task-relevant dimension of the stimuli (their color) rather than the task-irrelevant dimension (their meaning). Consistent with this proposal, when distractor trials oriented participants to the meaning of the target words, a strong congruity effect was found. By contrast, when distractor trials oriented participants to the color of the target words the congruity effect disappeared.

It is possible to interpret both the repetition effect (in Expt. 1) and the Task Set Inertia effect (in Expt. 2) as effects of attention. During the initial presentation of the words in Expt. 1 and in the Meaning Orientation condition of Expt. 2, participants failed to fully disregard the task-irrelevant meanings of the target words, one component of which is a spatial (or spatio-motor) representation with a certain direction. During the second presentation in Expt. 1 and the Color Orientation condition of Expt. 2, participants more successfully attended to the target words' colors. In Expt. 1, this was because the participants became better at restricting attention to the task-relevant dimension of the stimuli, as a result of practice. In Expt. 2, this was because of attentional 'inertia' from the colored-letter-detection distractor task.

Although this standard interpretation may be valid, there is a potential alternative that does not rely on the construct of attention ("psychology's Weapon of Mass Explanation", according to Vincent Walsh (2003)). Implicit in the attentional account is an assumption that reading a word activates *its meaning*. On standard psycholinguistic theories, *the meaning* of a word is retrieved from the mental lexicon, much the way a definition can be looked up in a dictionary. Then attention determines how strongly the word's meaning is activated, and which aspects of the meaning are highlighted.

On alternative accounts of the mental lexicon, however (e.g., Elman, 2004), words don't have meanings; rather, words are cues to activate stored information. The particular constellation of information that gets activated in any instance depends both on the cue, *per se*, and on the context in which the cue is encountered. As a consequence, a word's meaning is unlikely to ever be the same over successive experiences (see James, 1892/2001). 'Meaning', then, is nothing more (or less) than the effect that the word-in-context has on the representations formed in the mind of its reader (or hearer).

On this dynamic view of word meaning, our stimulus words cued the activation of spatio-motor representations in some contexts more than in others. The results of the first block of Expt. 1 suggest that the target words typically cue upward or downward spatio-motor representations such that these representations were activated even though they are irrelevant to the task at hand. But the same words serve as weaker cues for activating such task-irrelevant

representations in contexts where the participant's experience (either with the preceding block of target trials or with the intermixed distractor trials) has adjusted the cue validity of the words' color relative to validity of other pieces of information associated with the words, such as their valence.

Ordinarily, for the words we used as stimuli, valence has high cue validity and the color of the ink has low cue validity: reading that someone is *a hero* is normally a valid cue that the reader should construe the referent positively, regardless of the color *hero* is printed in. But the typical cue validity of words' color and valence is reversed in our tasks, because of the tasks' goals. Seeing a word in green letters is a valid cue that the item should be construed as a member of the category of "up-words" (or "down-words"), regardless of the word's valence or other aspects of its meaning. The weights that participants assign to Color and Meaning as cues, it seems, can be adjusted by the experience of doing the primary task repeatedly, or by the addition of distractor trials that require either color processing or meaning to be processed exclusively.

The present data may be equally consistent with the first proposed account (that words have meanings and attention determines which parts of their meanings get activated) and with the second (that words are cues, and the same cues activate different sets of information depending on the contexts in which they are encountered). Arguably, the second view is preferable on grounds of parsimony: the appearance and disappearance of space-valence congruity effects can be explained based on contextual modulation of retrieval cue weights, alone, rather than on retrieval dynamics *and* the intervention of attention. Distinguishing these accounts definitively will require further experiments.

Conclusions

Some versions of metaphor theory propose that source domain representations are activated automatically when people process words or concepts in target domains (Lakoff & Johnson, 1999). Experimental results have been interpreted as evidence for this automaticity (e.g., Meier & Robinson, 2004). Here we show that, indeed, spatio-motor representations are activated with a surprising degree of automaticity when people read words with positive or negative emotional valence. Space-valence congruity effects are found even when both space and valence are processed shallowly and incidentally.

The present results make clear that automaticity has its limits. The magnitude of space-valence congruity effects was modulated both by repetition of the valenced words and by a Task Set Inertia manipulation (Allport & Wylie, 2000). Spatio-motor representations may be activated by default when people read valenced words, but their activation is also context-dependent. These results are consistent with dynamic views of mental metaphor and of meaning construction, more broadly (Elman, 2004; Evans, 2009; Feldman, 2006).

Does micro-variability make models more complex? A comparison between diffusive and linear evidence accumulation

Abstract

Most theories of how decisions are made assume that the accumulation of evidence from the environment is a noisy process. Recently, models have been proposed which do not have this micro-variability, and as a result are simple in the sense of being analytically tractable. We use a global model analysis method called landscaping to show that in terms of flexibility, simply removing micro-variability does not necessarily make a model more simple. Our landscaping also highlights an experimental design which might be helpful in discriminating between different response models.

Keywords: response time models; complexity; landscaping

A wide range of experimental psychology tasks involve a decision between two alternatives. Which alternative is chosen and the time taken to make that choice has been the subject of intense investigation. The most successful theories for the decision process usually come from a class of evidence accumulation (or sequential sampling) models. Evidence accumulation models assume that participants collect information from the environment to use as evidence as to which potential response is correct. Evidence is accumulated until there is enough to indicate that one of the responses should be given. This response is then made and the time taken for evidence accumulation makes up the decision time component of observed reaction time (RT). Though there are many models which follow this basic framework, the particular assumptions about evidence accumulation that each model makes varies considerably.

Historically, the collection of evidence from the environment has been modeled as a stochastic process (e.g. Ratcliff & Tuerlinckx, 2002; Usher & McClelland, 2001), such that how much evidence there is for a response varies randomly from moment-to-moment. For example, in a random walk process, the amount of evidence accrued between any two moments in time is a sample from a normal distribution.

A small number of recently proposed models, however, have demonstrated that it is not necessary to explicitly model the micro-variability in evidence accumulation (e.g. Reddi & Carpenter, 2000; Reeves, Santhi, & Decaro, 2005). Brown and Heathcote's (2008) Linear Ballistic Accumulator (LBA) model assumes that while a decision is being made, evidence accumulates at a fixed linear rate. Despite this lack of micro-variability the model provides a full account of benchmark choice and response time phenomena.

Brown and Heathcote (2008) proposed the LBA as a simple model of choice and RT because it makes few, and relatively basic, assumptions about how evidence accumulation occurs. Here we investigate a slightly different question, whether or not the LBA, with its lack of micro-variability, is a functionally simpler model. More generally, we aim to examine whether the addition of micro-variability necessarily increases the complexity of a model. Since Occam's Razor says that we should prefer the simplest and complete description of data, and models both with and without micro-variability have been shown to account for empirical data, our investigation may shed light on whether decision models need to necessarily assume micro-variability. We will use a technique called landscaping (Navarro, Pitt, & Myung, 2004) to assess complexity. First, however, we provide an overview of the diffusion and LBA models.

Overview of Models

The Diffusion Model

Consider a recognition memory task in which participants have been asked whether or not a stimulus currently presented was either previously studied, "old", or not studied, "new". A diffusion model account of this choice assumes that participants sample information continuously from the stimulus. Each sample of information counts as evidence for one of the two responses and is used to update an evidence counter, shown by the irregular line in the right panel of Figure 1. Total evidence begins at some starting point and evidence that favors an "old" response decreases the evidence counter and evidence for a "new" response increases the counter. Evidence accumulation continues until the counter reaches one of the response boundaries, the horizontal lines in Figure 1. The choice made depends upon which boundary was reached, the top barrier for "new" and the bottom barrier for "old". The observed RT is the time taken for accumulation plus a non-decision time component made up of things such as encoding time and the time taken to make a motor response.

A key feature of the diffusion model is its micro-variability, such that the amount of evidence accumulated varies from moment-to-moment according to a normal distribution whose mean we call the *drift rate*. On top of this within-trial variability, there are typically three forms of between-trial variability added to the diffusion model. Drift rate and start point

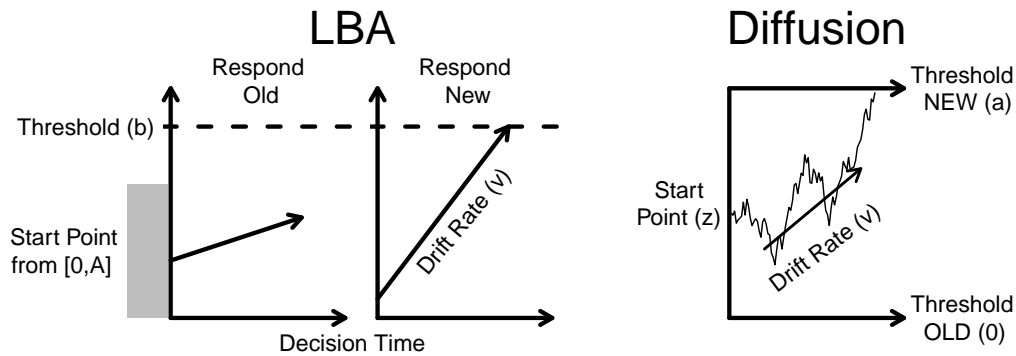

Figure 1: Overview of the diffusion and LBA models (left and right panel, respectively)

are generally assumed to vary from trial-to-trial according to a normal and uniform distribution, respectively. Finally, Ratcliff and Tuerlinckx (2002) included between-trial variability in non-decision time in the form of a uniform distribution.

The LBA Model

In the LBA there are separate accumulators gathering evidence for each of the “new” and “old” responses. As indicated by the straight lines in the left panel of Figure 1, these accumulators accrue evidence linearly and without micro-variability. Accumulation begins at some start point and continues until evidence in one accumulator reaches a response boundary. The accumulator which reaches the boundary first selects its associated response and predicted RT is accumulation time plus non-decision time. As in the diffusion model, the LBA also features between-trial variability. Like the diffusion model, drift rate and start point are assumed to vary between-trials according to normal and uniform distributions, respectively. Unlike the diffusion model, the LBA typically does not require between-trial variability in non-decision time to fit empirical data.

The Complexity of the Models

The LBA was considered by Brown and Heathcote (2008) as a relatively simple model because of its simpler assumptions about variability, and hence fewer parameters. However, recent work has demonstrated that the complexity of a model is not determined simply by the number of parameters in a model, but by how the parameters of the model interact within the model architecture to produce different patterns of predictions – also known as the functional form complexity of a model (e.g. Myung, 2000; Shiffrin, Lee, Wagenmakers, & Kim, 2008). Functional form complexity differs among models when they are able to produce differing ranges of predictions, even when they share the same number of parameters. In this way an overly complex model can provide an excellent fit to data, but not because the model gives a good account of the underlying process, but simply because of the

model’s flexibility. In particular, a more complex model can “overfit” the data by explaining the noise specific to a particular sample, as well as the structure due to the underlying processes. Because only the structure re-occurs in new data, overfitting limits the model’s ability in terms of prediction.

There are many techniques for analyzing the complexity of a model (see Shiffrin et al., 2008 for a review). We will focus on one particular method proposed by Navarro et al. (2004) called *landscaping*. This method is highly related to parametric bootstrap methods proposed by Wagenmakers, Ratcliff, Gomez, and Iverson (2004). *Landscaping*, as a means of determining model complexity, is based on the idea that a more flexible model will be better able to mimic the predictions of an alternative model. *Landscaping* is used to compare the relative flexibility of any two models, and for our purpose these will be models with and without micro-variability (a diffusion and an LBA model, respectively). Note that *landscaping* tells us about a specific form of local, relative flexibility, rather than the model’s general flexibility. In particular, *landscaping* tells us about how flexible one model is relative to another model, specifically for the regions of the parameter space in which we observe real data. In what follows we will refer exclusively to this local flexibility.

Landscaping

To do *landscaping* we generate data from one model, say model A, and fit these data with both models, i.e. model A and the alternative model, say model B. We then repeat the process with model B as the data-generating model. How well model B can fit the data generated by model A, and vice versa, gives insight into the relative flexibilities of both models. We will focus on two measures of model flexibility, the first is the difference between how well model B fits model A’s data compared to model A, and the second is how often model B can better fit model A’s data. The first measure tells us how flexible model B is compared to model A, i.e. if model B gives better fits to data from model A than vice versa, then model B is more flexible. The second measure tells us how distinguishable, or confusable, the two models are, i.e. how

often we expect to have model B fit data better than model A when model A is actually the true model.

In all of our landscaping analyses we simulated 3200 data sets from each model. For each data set a random sample of parameters was chosen from uniform distributions whose ranges were determined by previously observed parameters estimated from real data. In particular, Matzke and Wagenmakers (2009) identified the range of parameter values previously estimated across all previous applications of the diffusion model to data. Donkin, Brown, Heathcote, and Wagenmakers (2009) used these values to identify a range of parameters values for the LBA which spanned the same range of data space. Note that parameters are sampled from each distribution independently and so may not reflect the correlations between parameters in real data.

Table 1: Range of parameter values used to generate data sets. Parameters not previously defined are as follows: T_{er} is non-decision time in both models, s and η represent between-trial standard deviation in drift rate in their respective models, and s_z and s_t represent the ranges of between-trial variability in start point and non-decision time in the diffusion model, respectively.

Model		$b - A$	A	T_{er}	s	ν	
LBA	Min	0	.15	.1	.15	.5	
	Max	.5	.45	.4	.35	1	
		a	T_{er}	η	s_z	s_t	ν
Diffusion	Min	.06	.3	.01	.01	.01	.01
	Max	.25	.6	.25	.08	.3	.5

Landscaping is known to depend on the design of the data simulated. Here we selected two commonly used designs, one in which only the difficulty of the task was manipulated, and one in which both difficulty and response caution were manipulated. To simulate a difficulty manipulation we used three conditions (easy, medium and hard) across which only the drift rate parameter of the model could change. In practice this meant that the distribution of drift rates shown in Table 1 was divided evenly into three smaller distributions, with the ease of the task increasing with drift rate. To simulate a caution manipulation we used the same procedure to create two conditions (speed emphasis and accuracy emphasis) across which only the response boundary parameter could change, i.e. boundary parameter distributions were divided in two and two values were sampled.

Micro-variability

In these first set of analyses we aim to investigate whether the micro-variability of the diffusion model makes it more flexible than a model without micro-variability, the LBA model. The models, however, differ in more ways than just micro-variability. In an attempt to make the models more similar, and hence make the effect of micro-variability more salient, we use a slightly simplified version of the standard diffusion

model (cf. Ratcliff & Tuerlinckx, 2002) in which there is no between-trial variability in non-decision time. The models now share the same assumptions about between-trial variability – it is in both drift rate and start point of accumulation (but see the General Discussion for talk of other key differences between the models).

Difficulty Manipulation To create our landscape we first simulated data from both the LBA and the diffusion model. The data were simulated with all parameters except for drift rate fixed across three difficulty conditions, with 200 observations simulated per condition. We used 200 observations per condition because this amount is standard in applications of choice RT models. Both models used seven parameters for both simulating and fitting data – the diffusion model: a , T_{er} , η , s_z , v_{easy} , v_{medium} , v_{hard} , and the LBA: b , T_{er} , s , A , v_e , v_m and v_h . The simulated data were summarized using five quantiles (.1, .3, .5, .7 and .9) and both models were fit using quantile maximum probability estimation (Heathcote, Brown, & Mewhort, 2002) as the objective function and simplex as a search algorithm.

Figure 2: Difference in log-likelihood values between the data-generating model and the alternative model. The black and gray lines represent the diffusion and LBA as the generative models, respectively. The dotted line represents the point at which the data-generating and alternative models give equal quality fits, negative values indicate cases in which the alternative model fits better than the generative model. In this plot the simulated data come from a difficulty manipulation and the models used make the same assumptions about between-trial variability.

Figure 2 shows the difference in quality of fit between the generating and alternative model when the diffusion was the generating model (black histogram) and when the LBA was the generating model (gray histogram). Positive values indicate that the data-generating model fits better than the alternative model, and negative differences indicates that the alternative model is fitting the generating model's data better than the generating model itself. Two things are apparent from

the figure: the gray histogram is generally more positive than the black histogram, and neither histogram has much mass in the region of negative differences. The first observation tells us that when the LBA was the generating model the diffusion tended to fit worse than how well the LBA fit when the diffusion was the generating model. In other words, the diffusion model appears to be less flexible than the LBA model in terms of how closely it can resemble the other model's data. The second observation tells us that neither model is very capable of better fitting the other model's data – the LBA fit data generated from a diffusion model better than the generating model in only 3.2% of the 3200 data sets, and the diffusion model better fit data generated from an LBA only 0.8% of the time.

Visual inspection of the fits suggested that the predictions of both models matched the simulated data closely, regardless of which model the data had come from. Indeed, in all but the most extreme cases, the models appeared to be mimicking each other closely. This suggests that the differences in log-likelihood we observe in Figure 2, and in all other figures, are not simply due to the models occupying completely separate data spaces, but reflect differences in the ability of one model to better fit the other model's data (i.e., what we define as model flexibility).

Caution and Difficulty Manipulations To create the landscape for a design in which both caution and difficulty were manipulated we simulated data in which all parameters except for drift rate were fixed across the three difficulty conditions and all parameters except for response boundary were fixed across the two caution conditions. Fits were as in the previous landscape except that each model now had eight parameters – the diffusion: a_{speed} , $a_{accuracy}$, T_{er} , η , s_z , v_e , v_m , v_h , and the LBA: b_s , b_a , T_{er} , s , A , v_e , v_m and v_h . Landscapes were created using both 200 observations per condition (as in the previous landscape), as well as 100 observations per condition (since twice as many conditions meant that total sample size was twice that of the previous landscape). Sample size had little effect on the pattern of results, but the smaller sample size did lead to slightly more confusion between the models. We present, therefore, the results of the landscape using the smaller sample size (i.e. where total sample size was equated across landscapes).

A quick look at Figure 3 suggests that the current landscape is similar to the one where only difficulty was manipulated. Closer inspection, however, reveals two differences: Firstly, the histograms in Figure 3 show a larger mean and variance than those in Figure 2, and secondly, the histograms show even less mass below zero. The first observation suggests that when both caution and difficulty are manipulated that both models are not as good at accounting for the alternative model's data. Note, however, that the relative position of the black and gray histograms continue to suggest that the diffusion model has less flexibility than the LBA. The second observation implies that the models are even more distinguishable when both caution and difficulty manipulations

Figure 3: Difference in log-likelihood values between the data-generating model and the alternative model. The data come from a caution and difficulty manipulation, and the models make the same assumptions about between-trial variability.

are made – in 3200 data sets, the LBA never better fit data generated from a diffusion model, while the diffusion model better fit data from an LBA only 0.4% of the time.

Discussion Our first measure of flexibility, the relative shapes and positions of the histograms in our figures, suggest that the LBA is capable of getting better fits of data generated from a diffusion model than vice versa. We take this to mean that the LBA model is more flexible than our simplified version of the diffusion model (i.e. one without non-decision time variability). Since the models were equated on assumptions about between-trial variability, we also take this result as evidence against the idea that the micro-variability in the diffusion model makes the model more flexible than the model without micro-variability, the LBA. Indeed, there may be evidence to suggest the opposite – that micro-variability reduces the functional form complexity of a model. We do not mean our results as conclusive evidence of such a result, however, particularly because micro-variability is not the only difference between the LBA and diffusion models. We direct the reader to our General Discussion for suggestions of how the effects of micro-variability could be more investigated more specifically.

Our second measure of flexibility, how often the alternative model can better fit data from the generating model, gives a less clear result. This is largely because both models seem relatively incapable of better capturing the other model's data, at least for the sample size we use. When we repeated our landscaping analysis with a greatly reduced sample size (just 20 observations per condition) we observed an interesting result, consistent with our first measure of flexibility – the LBA better fit diffusion data in almost one in ten samples, while the diffusion still only better fit LBA data in less than one in two hundred samples. The results reported in Figure 3, however,

suggest that the two models are distinguishable based on fit alone for the types of sample sizes typically used. In other words, in the unlikely case that one of the two models was truly responsible for empirical data, then our results suggest that the alternative model would rarely be mistakenly chosen as the best fitting model, provided at least 100 observations were recorded per condition. However, this result is not very useful since we do not believe that a diffusion model without between-trial variability is appropriate. We now repeat our landscaping using a diffusion model *with* between-trial variability in non-decision time, paying particular focus as to whether or not the models remain distinguishable.

Comparing the LBA and the Full Diffusion

The method for creating the following two landscapes was the same as for the previous two landscapes, however, between-trial variability in non-decision time was assumed for the diffusion model (but not the LBA).

Difficulty Manipulation Figure 4 suggests that a full diffusion model may be slightly more flexible than the LBA when only difficulty is manipulated. In particular, though largely overlapping, the grey histogram looks like a slightly left-shifted version of the black histogram, suggesting that the difference between quality of fit for the data-generating and alternative models was smaller when the LBA generated the data. In other words, the diffusion model was slightly better able to fit LBA data than vice versa. When we look at just the cases in which the alternative model fits better than the data-generating model we see that the same pattern continues, the LBA model better fits data simulated from a diffusion model in 6% of simulated data sets, while the diffusion model better fits LBA data 10% of the time.

Figure 4: Difference in log-likelihood values between the data-generating model and the alternative model. The data come from a difficulty manipulation, and the diffusion model makes the additional assumption that non-decision time has between-trial variability.

Figure 5: Difference in log-likelihood values between the data-generating model and the alternative model. The data come from a caution and difficulty manipulation, and the diffusion model makes the additional assumption that non-decision time has between-trial variability.

Caution and Difficulty Manipulations The landscape in which both caution and difficulty were manipulated was created using 200 simulated data points in each of the six conditions. From Figure 5 it is not clear which of the full diffusion model or the LBA is more flexible. In particular, the grey histogram has more mass than the black histogram at both very small and very large positive values, suggesting that the diffusion model fit LBA data both very well and very poorly. In terms of how often the alternative model fit better than the data-generating model, when the diffusion model was the generative model then the LBA never fit better, while the diffusion model fit LBA data better in only 0.8% of the simulated data sets.

Discussion The first two landscapes we created suggested that the LBA and the diffusion models were distinguishable, such that each model was relatively incapable of better fitting the other model's data. These second pair of landscapes looked at whether these results extended to the full diffusion model (with between-trial variability in non-decision time). The first landscape we created suggested that this might not be the case. When data came from a design in which only difficulty, i.e. drift rate, varied then both models displayed some reasonable mimicry, such that the LBA looked more like a diffusion model in 6% of the simulated data sets and the diffusion model looked more like an LBA 10% of the time. These proportions are not overly large, but they do suggest that if one of the models actually was the true model, that we would observe the alternative model fitting data better for about one in ten to twenty participants.

The results of our fourth and final landscape suggest that the models become highly distinguishable when both difficulty and caution are manipulated. Indeed, the results suggest that if one of the two models were the true model then the al-

ternative model would be mistaken as the best fitting model for fewer than one in a hundred participants. The difference in distinguishability between these two final landscapes is remarkable, however it is possible that the difference occurs because there are twice as much data under the design with both caution and difficulty manipulations. Equating total sample size using a simplified diffusion model, however, had little effect on distinguishability – doubling sample size meant that the largest confusion occurred 0.4% of the time instead of 0.2%. We expect, therefore, that it is something about the design rather than sample size which causes such a large change in distinguishability. Consistent with this idea, Donkin et al. (2009) showed that the boundary parameters of the LBA and diffusion model do not have a similar effect on model predictions. These results further cement the idea that the key to distinguishing between these two models may lie in the differential effect of manipulating the response boundary parameter in each of the models.

General Discussion

We compared the flexibility of the LBA model, which contains no micro-variability in evidence accumulation, with a simplified version of the diffusion model, which does contain micro-variability. Our results suggest that micro-variability does not necessarily make a model more flexible than one without micro-variability. We can not, however, confidently conclude that micro-variability does not increase flexibility at all. This is because the LBA and the diffusion model, even a simplified version without between-trial variability in non-decision time, do not have identical frameworks. In particular, the LBA has multiple, independent, accumulators while the diffusion has a single accumulator, which implies that evidence for one response is perfectly negatively correlated with evidence for the alternative response. Without further investigation, we can only confidently conclude that a ballistic multiple-accumulator framework gives the LBA more flexibility than a stochastic single-accumulator framework gives the diffusion. Further investigation into the effects of micro-variability might directly compare a multiple accumulator framework with and without micro-variability (e.g. the LBA compared to a simplified version of Usher and McClelland's, 2001, model). Such a study will be more difficult than that carried out here because analytic expressions do not exist for Usher and McClelland's model.

Our final two landscapes compared the relative flexibility of the LBA model and the full Ratcliff diffusion model. Most impressive here was the increase in distinguishability which arose out of the inclusion of a caution manipulation. This increase is quite remarkable, when only difficulty was manipulated the models show the largest overlap of any landscape we analysed, but when caution is added there are almost no cases in which a model fit data better than the data-generating model. The distinction between models may arise because the effect of changing caution (i.e., boundary separation parameters) is different for the two models (Donkin et al., 2009). In

particular, micro-variability in processing means that some responses will terminate quickly regardless of the position of response boundaries. Without this micro-variability, however, increasing caution will slow down even the fastest responses. This means that changing caution in the diffusion model effects the speed of the fastest responses much less than in the LBA. Regardless of the cause, our results suggest that whichever model can better account for a combined caution and difficulty manipulation is probably closer to the true model, and unlikely to be due to model mimicry.

Abstract

This research has aimed to debate some decision making theoretical principles, in particular the bounded rationality concept. The conceptions of cognition subjacent to this concept, its main limitations for understanding the human decision process and the possible contributions from two other theoretical perspectives- the self-organization process and the embodied cognition concept have been methodologically analyzed. The concluding comment claims that: a. other forms to conceive the human cognition are still necessary to better understand the cognitive basis of human making decision process; b. the Self-Organizing and Embodied Cognition Theories, as understood here, might constitute themselves as relevant contributions to the development and reflection concerning the making decision process and the Bounded Rationality concept.

Keywords: decision making; bounded rationality; self-organization; embodied cognition.

Introduction

Electing perspectives for acting and making decisions are critical aspects of the human life and theoretical explanations about these topics could be retraced to the Greek Antiquity. A common characteristic to several of these explanations is concerning the conception that the decision making is essentially a logical-rational process, in which utility principles are prevalent. This conception has become historically stronger and influenced by four sources: the Illuminist thought from XVII century, the probabilistic mathematical theories elaborated from XVIII century, the Utilitarian philosophical-economic theories from XVIII century, and the Neoclassic Economic theories, developed from XIX century on (Buchanan & O’Connell, 1996; Taleb, 2007; Glimcher, Camerer, Fehr & Poldrack, 2009). Since the middle of XX century the approaches that conceive the decision making process under the *expected utility* premises - like those that have been derived and influenced by F. Ramsey, von Neumann e Morgenstern (1944), L. Savage (1954) e R. Jeffrey (1956) works - have obtained a wide and important diffusion. These theories have constituted an important scientific advance for understanding the human decision process, presenting for the first time questions about the decision maker preferences, the capacity to order

among several variables and rationally choice the *best decisional option*. They have thus created conditions to think more deeply and systematically about the role of the decision maker subjectivity to the decision process. However since the last years from XX century the Expected Utility Theory has been the target of a strong criticism, mainly concerning: a restrictive conception of the human cognition, understanding it basically as an “algorithmic machine”, b. the idealization of the decision maker as a super-rational agent, omniscient and omnipotent within the decision process and c. the concept of information on which this theory relays, quantitative and syntactic, making the relation between the informational input and the value attribution to the decisional variables a paradox¹. These critics have stimulated other theorizations characterized by reconsidering two principal questions: the optimized reason principle and the Maxim Expected Utility principle.

The Bounded Rationality Concept: cognitive presuppositions

H. Simon when contesting the conception of rational/optimized decision considered its substitution for the concept of satisfactory decision; founded on three main issues: a) the human beings are cognitive and perceptually restricted, never being able to fully apprehend the environmental complexity, b) these restrictions impact the decision making process, generating a “cost”, compelling the decision maker to find alternative actions that satisfy the decision requirements at other levels (“satisficing” principle) and c) the difficulties and restrictions found in making a decision disclose and clarify its significance, making the process to find satisfactory alternatives adjustable to the decision maker limitations and to the environmental parameters.

These statements sustain the bounded rationality concept developed by H. Simon and formalized in *A Behavioral Model of Rational Choice*, in *Models of Man*, 1957. In Simon’s definition this is the term used “to designed rational choice that takes into account the cognitive limitations of the decision maker- limitations of both knowledge and computational capacity” (1997, p. 291).

¹ See Kahneman & Tversky, 1979; Simon, 1989, Juarrero, 1999; Gigerenzer & Selten, 2001.

The bounded rationality concept is widely used at present and has been employed in several areas “to relax” the strong rational view (decision optimized paradigm) concerning the Classical Decision Theories. Despite that, the comprehension about the *nature* of human cognition upholds the same principles in both approaches, mainly: a. the appeal to the symbolic-normative reasoning, b. the ontological and epistemological gap between subject/object and c. a tight relation among the conception of rationality, truth criteria and a necessary coherence (consistency) between the decision maker and their purposes.

In an article from 1993 A. Vera and H. Simon explained the conception of cognition underlying to the bounded rationality concept. The reasoning process is understood as a sequential and symbolic (internal) computational processing of information, recursively operating within this basis: input - processing of information - output (reply/behavior). Symbols, on this perspective, are patterns: “(...) when we say that symbols are patterns, we mean that pairs of them can be compared (by one of the system's processes) and pronounced alike or different, and that the system can behave differently, depending on this same/different decision.” (Vera&Simon,1993,p.03).

The information/symbols processing is thus conceived: a) inputs are received from the exterior environment as patterns of sensorial stimulations and codified by perceptual processes in symbols; b) these symbols are indexed and stored in the long term memory; c) the elicitation of the meaning denoted by the symbols is made by another symbol, used as input, to get access to a referring object stored in the memory, to affect it or to be affected by it.

It is observed that this conception is, essentially, the same used for computational mind theories²; that have not been satisfactorily successful to explain the plasticity and flexibility of the human cognitive – and decision making- process. Simon and Vera (1993) have added contributions from the Behavioral Psychology to this conception of computational mind, relaxing thus some of the hardest cognitivist arguments. This Behaviorist basis can be especially observed when the authors argued for a semantical basis in their conception of computational cognition³: the patterns received/perceived for a system are already abstracted, represented and stored with an aggregated meaning. This meaning, not being universal, which would be opposite to the concept of bounded rationality, would follow the material and cultural surroundings in which the (symbolic) system is inserted. In such a way it would –circularly- justify, for example, the different attributions of meaning that exist among/within distinct cultures.

² See also Argyris, 1973; Walczack, 1998 e Patokorpi, 2008.

³ See Rastier, 1996; Floridi, 2004.

Simon had aimed during his academic life to understand *how* human cognition and decision making process really *work*. But does the juxtaposition of elements of two theories (computational mind theory and Behavior Psychology) both of that understanding the cognition and the behavior in terms of causal or functional relations, based in input/output or stimulus/response, appropriately elucidate the human cognitive processes? Or the making decision process? Does the human cognition really “operate” on a computational-representational model? Could the information, at least in the scope of the living beings, still continue to be narrowly understood as a “data flow”?

The concept of bounded rationality, while circumscribing the rationality and decision process limits, situating them as context-time dependents, modified the general comprehension about the human decision-making process. But this “new” focus does not seem yet satisfactory to *really* understand the human cognition; at least not under the behaviorist-rationalist perspectives that remain underlying to it. For a more “realistic” theoretical approach about the decision and cognitive human processes other ontological and epistemological bases are fundamental. We discuss that these bases must be searched in a conception of embodied cognition, which conceives the cognition as a vital self-organizing process.

Cognition: an embodied self-organizing process

The self-organization concept is intended as concerning to the natural process of trends ordering observed in complex systems, both artificial and natural (Debrun, Gonzales & Pessoa, Jr., 1996; Haken, 2000; Piers, Muller & Brent, 2007). It was a term “coined in the 1940s to label processes in which systems become more highly organized over time, without being ordered by outside agents or by external programs” (Shalizi et. al., 2004). A concept strongly attached to this is that of emergence, here understood as the appearance (materialization) of qualities not yet observed in a system from its self-organizing interaction and that cannot be understood by the analysis (on an individual basis) of the relations or elements of the system⁴.

Within the scope of this paper both concepts the one about self-organizing process and the one about emergence are relevant for representing by which the organization of a system modifies itself; reaching other levels of complexity. This complexity alteration that enables a system to diversify its surrounding coupling is the definition here conceived to the embodied cognition concept, or “vital cognition”. In the core of this conception (and following Hutchins, 1995, Clark, 1997, Zunda, 1999, Wheeler & Clark, 2007, Calvo & Gomila, 2008), the cognitive process is qualified by some undissociated attributes: it's situated, social and

⁴ See Bissoto, 2007, 2008; Halley & Winkler, 2007.

distributed. It's observed that within this conception it is not necessary to dichotomously disembodify the affective/rational attributes from the human cognition. As embodied beings situated and embedded in a physical circumstantiality, whose comprehension is semantically and socially constructed, reason and emotion/affection are imbricated, mutually influencing themselves, being not possible to disentangle one from the other.

Some theoretical approaches between the bounded rationality and the embodied cognition concepts are possible. The (behavioral) premise of the first concept implies in an interactive relation system/environment and in a situated and embodied action - in the sense that there is a material "body", natural or artificial, acting in a determined time/space. However there is a fundamental difference between both the proposals concerning to *how* the system-environmental interaction occurs.

The bounded rationality concept, when epistemologically considered, can be described as a meaning-sign appropriation one. The system is always acting to apprehend the reality "really" existent in the exterior world, generating diachronically a response/a behavior resulting of the symbolic decoding. When understanding the embodied cognition as a self-organizing movement of a system the main epistemological assumption is that the interrelation system/surrounding is an *interpretative* one. Although it does not discard the assumption of an existent materiality that sustains, displays and sets parameters for the embedding system/environment, there is not in the embodied cognition concept the comprehension that this materiality contains any meaning that could *objectively* be abstracted by a system. According to these considerations signs - and information - are not entities that "carry" an aggregated meaning. They are rather material elements that arise modifications: they provoke the formation of an interpretation, implying in a systemic attribution of value and in changing perspectives for the interacting system. There is not, in this optics, incomplete or badly-structuralized information: everything that can be perceived/selected and meant/interpreted as relevant, from the vital dynamics of each system, comes to be meaningful; guiding the action of this system in the space-time of its surroundings⁵.

The making decision process

Decision, within the embodied cognition perspective as here understood, is the *choice* executed by a system concerning to its adaptative efforts. This adaptative process is, by the way, understood as integration, as relational adjustment to the changing environment, rather than forced behavior of adequateness. It is a process to make the world meaningful⁶ and must address the

dynamical self-organizing system "health" and not just looking for a satisfactory or excellent platform of stability. A "good" decision is one that prepares the system to get energy and informational resources, which will lead it to other (richer, in the system's optics) possible organizing openings.

Socially, the decisor's choices still within the embodied cognition perspective are understood as enlargement/disclosure of other interactive horizons which will impulse the enaction of new meaning attributions and therefore the institutions self-organizing vitality; rather than the statement of decisions that aims narrowly a prompt and short-termed efficiency of certain functions of those institutions.

In this scope the bounded rationality concept might be understood considering the perception and action limitations inherent to a determined system in the circumscription of the possibilities for the embedding of this system resulting of order parameters: those boundaries that once emerging from the system/surrounding coupling work as attractors, "forming"/enacting a decision pattern. The analysis of these order parameters by the system itself (or by an observer) can "materialise" for this system an *interpretative* understanding of this dynamics, causing it to be less "evanescent" and allowing the system to disclose which will be the next organizational parameters to be configured, making a dialogue with its trajectory possible.

Understanding the decision making processes under this embodied-self-organizing cognitive perspective is relevant for considering: a. that the "utilities" or preferences of the system are dependents from the historical of interactions system/surroundings already constituted for a system, b. how this system has been successful to perceive other organizing horizons and c. to make possible to think the decision making process as a decentralized one, systemic and surrounding distributed and not circumscribed to the logic-cerebral rationality. The "not-rational", "irrational" or the "bad" decisions are not conceived as errors but as tied within the organizing perspectives of a system, any evaluation of that could just be thought *a posteriori*, and for the observer's perspective.

The actions assumed for a system (a decision maker) within the incessant informational and energetic flow that this access, are conflicting. Any decision attends to the certain states of the system, ignoring others. There is a momentary "pacification" of the system although a state of "unsated" is always latent, which pressures the system to levels of criticality. From these levels the system could organize itself in new relational situations. But it can be "crystallized" or also "paralyzed" when not obtaining informational and energetic resources that allow it to foment or to choose other organizing routes; which would stimulate the emergence of other systemic configurations. Furthermore a system could reach so high disorder levels

⁵ See C.S.Peirce, 1972.

⁶ See von Uexküll, s/d; Skarda & Freeman, 1987; Johnson, 1999; van Dijk et. al., 2008.

(from inherent reasons, like a disease, or from surroundings reasons, like a catastrophic event) that its decision acts would attend just minimal organizational requirements, and its organizational continuity would become impracticable.

Concluding Comments

The decision making theories, including those that follow the bounded rationality principles, have traditionally supported the idea of a decisor agent that controls a data flow – received from the outside- by rational/intellective cognitive process, obtaining therefore a better decisional management. Nevertheless, other decision making process conceptions are possible, mainly when one considers that the decisor system/environmental relation involves more than the creation of syntactic mental models - or, still, as defended by the bounded rationality principles, a (weakly) semantic model.

Kunreuther & Meyer's research (2001) show us information relative to a survey about complex making decisions, which are referents to important aspects of our daily life like health, family, security and financial decisions. The authors analyzed the contrast between how this kind of decision should be made and how they are made (Kunreuther & Meyer, 2001, p. 05). The concluding comments claim that the human complex decision making are characterized for not adequately considering the available information about the probability of an event to occur, fail when differentiating these probabilities, in terms of relevance, attitudes showed for thoughts like “these things will not happen with me”; are strongly influenced by normative social rules, the social *status quo*, the present situation- “I'd better not think about this ever”, emotions and affects, failing to learning from other decisional situations.

These remarks also allow us defend the assumption that the research for others ways to comprehend the human making decision process is still a strong scientific requirement. As has been discussed in this paper the embodied concept and the self-organization theory are serious theoretical alternatives for another understanding of the human cognitive and decision making process. The decision making process, as understood here, is closely cohesive within the system/surroundings embedding, in the scope of an embodied and self-organizing cognition.

Some theoretical decision-making perspectives have been incorporating both of the concepts here approached. The Embodied Cognition Theory has been employed in the Consumer Decision-Making Research (Malter, 1996), in the studies on Cognitive-Decision Making (Stewart, 2006) and Neuroeconomics (Hardy-Vallée, 2007) and the Self-Organizing Theory has been thought in the analysis of the collective making-decision (Johnson et. al., 1998) and on the decentralization in (economical) social networks (Roy, Nair & Venema, 2009). Despite of these new branches about the decision making process, the

main focus of the Decision-Making field still “targets” the human cognition rational aspects.

In the perspective of this paper further researches could analyze if under this theoretical bases we could increment the human decision process a. debating alternative ways to theorize what is information and its role in the decisional process; b. understanding the cognitive process as “using” the information interpretatively, when this “usage” is nestled in a systemic organization and not relying just on rational capacities and c. widening the interpretative universe of a system, searching to better comprehend *how* the social and distributed cognitive attributes would favor to this system “disclose” organizing alternatives.

The Role of Inhibition in Theory of Mind Performance: Evidence for a Non-Modular View of Theory of Mind

Abstract

As the modularity of Theory of Mind continues to be debated, the present study sought to investigate the relationship between inhibitory control and performance on a linguistic Theory of Mind (ToM) task. Performance on ToM tasks that relied on inhibitory control was contrasted with performance on ToM tasks that did not rely on inhibitory control. In addition, a range of executive function tasks were administered to all participants. It was hypothesized that if Theory of Mind shares resources with the executive process of inhibition, performance on the ToM task would diminish when inhibition demands were high. Results indicated that performance on the ToM task was significantly lower when participants were required to inhibit superficial discrepancies in the Theory of Mind stories. Moreover, performance on the ToM task correlated with the ability to resist non-linguistic interference. These findings challenge the modular views of Theory of Mind, and suggest that Theory of Mind and executive functions may rely on common cognitive resources.

Keywords: Theory of Mind; inhibition; executive function; modularity.

Introduction

Human beings, as the most social of primates, rely heavily on complex social knowledge or social cognition (Adolphs, 1999). Social cognition has been described by Adolphs (1999) as “the processes that subserve behavior in response to other individuals of the same species...especially those higher cognitive processes subserving the extremely diverse and flexible social behaviors that are seen in primates.” Social cognition, as a high-order cognitive process, relies on several cognitive functions for appropriate interaction including goal-directed planning, emotional control and recognition, arousal, vigilance, and memory integration, (Adolphs, 2009). One aspect of social cognition, Theory of Mind (ToM), allows humans to understand that others have mental states and to use reason about these mental states in order to predict the behavior of others (Fletcher, et al., 1995; Frith & Frith, 1999). While the importance of the Theory of Mind for successful social functioning is not debated, there is controversy surrounding the degree to which the development and use of Theory of Mind relies on domain-general cognitive processes. A modular approach views Theory of Mind as a specific and independent cognitive module (Frith & Frith, 1999). A domain-general approach

sees Theory of Mind as a skill that relies on executive function (EF) – a collection of complex cognitive processes that includes inhibitory control (or the ability to resist interference), updating (or working memory), and task switching (e.g., Miyake et al., 2000; Smith & Jonides, 1999; Zelazo, Craik, & Booth, 2004).

The modular view is supported by clinical data, with certain clinical impairments, such as autism or schizophrenia, characterized by marked difficulty with Theory of Mind tasks in the face of relatively spared intellect (e.g., Frith & Frith, 1999; Happé, 1994). The modularity of Theory of Mind has also been evaluated in individuals with traumatic brain injury (TBI), a population commonly found to demonstrate impairments in Theory of Mind (Bibby & McDonald, 2005; Channon, Pellieff, & Rule, 2005; Turkstra, Dixon, & Baker, 2004). For instance, Bibby and McDonald (2005) found that individuals with TBI exhibited impairments in Theory of Mind tasks and that these difficulties could not be accounted for by inference abilities or language skills. As further support for the modular view, functional neuroimaging techniques have identified specific brain regions that are selectively active during Theory of Mind tasks (e.g., Adolphs, 2009; Amodio & Frith, 2006; Fletcher et al., 1995).

In contrast to domain-specific views of Theory of Mind, it appears that other cognitive domains, most notably the executive functions (Leslie, German, & Polizzi, 2005; McKinnon & Moscovitch, 2007), may influence Theory of Mind performance. For example, McKinnon and Moscovitch (2007) used a dual-task experiment to examine whether Theory of Mind and working memory relied on the same resources. Dual-task experiments assume that when two cognitive processes compete for shared resources, performance will be diminished for one or both tasks. McKinnon and Moscovitch (2007) found that adults' performance on a Theory of Mind task was significantly worse when participants were required to simultaneously perform a working memory task. This finding suggested that both the working memory and Theory of Mind tasks rely on common cognitive resources. In another dual-task study, Theory of Mind performance was shown to decrease in both older and younger adults when the executive function demand of the task was increased by requiring participants to also reason about approach or avoidance

beliefs (German & Hehman, 2006). Similarly, Carlson, Moses, & Claxton (2004) found that children's performance on inhibitory tasks was significantly related to their performance on Theory of Mind tasks.

The current study sought to evaluate the relationship between adults' performance on a linguistic Theory of Mind Task and inhibitory control – a component of the executive function. Previous work on the relationship between ToM and executive function either focused on very young children (e.g., Leslie et al., 2004), used dual-task methodology (e.g., McKinnon & Moscovitch, 2007), or used a purely correlational approach (e.g., Carlson & Moses, 2001). In the current study, the relationship between inhibitory control and ToM was examined in two ways. First, we manipulated the executive function demands of the ToM task itself. Second, we administered a battery of Executive Function tasks to all the participants, being particularly careful to index inhibitory control in both the linguistic and the non-linguistic domain.

The ToM task designed for the current study presented participants with pairs of short stories that either matched or mismatched in the ToM Structure (see Table 1 for examples of stories). Stories described human behavior that required understanding of people's intentions and beliefs (including engaging in white lie, using sarcasm, etc.). Stories that matched in ToM structure described situations that shared the underlying intent (e.g., both were stories about white lies). Stories that mismatched in ToM Structure described situations that diverged in the underlying intent (e.g., one story was about a white lie and another story was about sarcasm). Participants were asked to make same/different judgments on pairs of stories that either matched or mismatched in ToM structure based on the underlying intentions of the story characters. The key manipulation involved the Surface Structure of the stories. Half of the stories matched in superficial contextual elements (characters had the same names, actions took place in the same location, etc.), while half of the stories mismatched in superficial contextual elements (characters had different names, the actions took place in different locations, etc.). This design yielded four conditions: Stories that matched in both the ToM Structure and Surface Structure; stories that matched in ToM Structure but differed in Surface Structure; stories that matched in Surface Structure but differed in ToM Structure; and stories that mismatched in both the ToM and the Surface Structures. The logic was that making a "same" decision on stories that matched in ToM but that mismatched in Surface Structure would require inhibition of attention to superficial discrepancies. Similarly, making a "different" decision on stories that mismatched in ToM but that matched in Surface Structure would require inhibition of attention to superficial similarities. Conversely, performance on stories that either both matched or both mismatched in ToM and Surface Structure would not require inhibitory control. We hypothesized that if performance on ToM tasks relies on executive function, then participants should be less accurate and slower making

judgments of similarity on the conflicting stories than on the non-conflicting stories, since performance on conflicting stories would require inhibitory control. If, on the other hand, performance on ToM tasks relies on domain-specific mechanisms that are separable from executive function mechanisms, then participants should show similar performance on conflicting and non-conflicting stories.

In addition to embedding inhibitory-control manipulation within the ToM task itself, we also examined the relationship between executive function and Theory of Mind by administering a range of executive function tasks to the participants. We hypothesized that if ToM relies on executive function, then adults' performance on the ToM task would correlate with performance on executive function measures. Since executive function is a complex construct that subsumes a number of dimensions, finding that performance on the ToM task correlates with some executive function measures, but not others would be informative with regards to the specific executive function mechanisms that may underlie performance on Theory of Mind Tasks in adulthood. Because the ToM task designed for the current study was linguistic in nature, we were especially interested in examining the relationship between ToM performance and performance on linguistic vs. non-linguistic executive function tasks.

In summary, the goal of the present study was to examine the modularity of Theory of Mind in adults by testing the relationship between ToM and inhibitory control. We theorized that if performance on ToM tasks requires inhibitory control, then participants should perform less well on ToM tasks that place increased demands on the inhibitory control mechanism. We also theorized that if performance on the ToM tasks is related to executive function, then measures of executive function should correlate with ToM performance.

Methods and Procedures

Participants

Twenty-two participants were recruited for this study. Participants ranged in age from 18.9 to 22.8 years, and all were native speakers of English. Each participant scored within the normal range on English receptive vocabulary as measured by the Peabody Picture Vocabulary Test-III (Dunn & Dunn, 1997) (*Mean* = 108.57; *SD* = 7.00), and on reading ability as measured by the Reading Fluency subtest of the WJ III Tests of Achievement, (Woodcock, McGrew, & Mather, 2001a) (*Mean* = 110.41 *SD* = 8.28). Participants also scored in the normal range on the non-verbal intelligence measure (Visual Matrixes subtest of the Kaufman Brief Intelligence Test, Second Edition, K-BIT2; Kaufman & Kaufman, 2004) (*Mean* = 101.76, *SD* = 11.87).

Materials and Procedure

Each participant was tested in one two-hour session. Theory of Mind tasks, executive function tasks, language ability tasks, and a non-verbal IQ test were administered in random order.

Table 1: Examples of Stimuli in Four ToM Conditions

	ToM Match		ToM Mismatch	
	Story A	Story B	Story A	Story B
Surface Match	Ann and her husband left their home for work on a gloomy, rainy day. Ann said, "What a bright cheery day."	Ann and her husband left their home for work on a gloomy, rainy day. Ann said, "It's a good thing I packed my sunglasses today."	Dan attempted to cook dinner for his sister's birthday, but burnt everything to a crisp. His sister's friend Kristy said, "You're quite the chef, Dan."	Dan attempted to cook dinner for his sister's birthday. His sister's friend Kristy said, "Your dinner was great, I just wasn't very hungry tonight."
Surface Mismatch	Jacob's history professor assigned six chapters of reading for the following day's class. On the way out of class, Jacob said to his friends, "We'll have plenty of free time tonight, huh?"	Joan had to stay late at work for the next week while her boss was out of town. Her coworker John said, "Aren't you the lucky one this week?"	Ben and Ryan were walking to class when Ben said, "Did you see John's shoes at track practice today? They were awful." Just then Ryan turned around and said, "Oh hi John, I didn't see that you were behind us."	Karen really wanted to try out a new café in town but didn't want to go alone. Karen said to her best friend, Joanne, "I'll probably try out that new café, but I suppose I'll have to go alone since no one will go with me."

Theory of Mind Task The ToM task in this study evaluated participants' ability to identify Theory of Mind inferences in the face of varying inhibitory control demands. The ToM task presented participants with 40 pairs of short stories to be read silently from a computer screen (see Table 1). Stories ranged from two to four sentences in length and were constructed using vocabulary and syntax at the sixth grade level. Five story types, each requiring Theory of Mind for accurate interpretation were included in the task. Story types included white lie, deception, faux pas, sarcasm, and persuasion. Participants were not informed of the story types. Executive function demands were manipulated through variation in the Surface Structure or context of each story. In the low executive function conditions, the story context and the ToM inference were both similar or both different across stories. In the high executive function conditions, the stories either shared the ToM inference, but differed with regards to story structure or shared story structure, but differed with regards to the ToM inference. Participants first completed two practice trials, each of which was followed by an explanation of the correct response. The order of presentation of story pairs was randomized. Participants first saw a screen with only a black vertical line bisecting the screen at the midline, and then were presented with one story (Story A) on the left side of the screen. After reading the story, participants pressed the space bar and Story A disappeared and Story B was presented on the right side of the screen. After reading story B, the participant again pressed the space bar and both stories appeared on the screen, separated by the vertical black line. This procedure was implemented in order to minimize the effect of reading times and of working

memory demands on ToM performance. While both stories were available on the screen for review, the participant chose whether the stories required the same inference, (e.g., both stories included a faux pas situation) or if they required different inferences, (e.g., one story included faux pas and one demonstrated sarcasm). Participants indicated their decision by pressing the forward slash key if the inferences were the same across stories, or the "z" key if the inferences were different across stories. Both accuracy and reaction times were recorded. Reaction time measurements began as both stories were presented simultaneously and ended as soon as a decision key was pressed. Participants were instructed to respond to each stimulus as quickly as possible while maintaining response accuracy.

Executive Function Tasks Tasks measuring distinct EF components were administered to each participant. *Linguistic inhibitory control* was measured via the Color-Word Interference Task (a version of the Stroop task, Stroop, 1935), where participants were asked to name ink colors and inhibit the more automatic processing of print (Delis, et al., 2001). *Non-linguistic inhibitory control* was measured via the Simon task (Simon & Rudell, 1967), where participants were presented with either red or green circles in the center, or on either the left or the right side of the computer screen and were required to press a left key when they saw a green circle and a right key when they saw the red circle. On incongruent trials, the location of the colored circle conflicted with the response key, and participants had to inhibit the automatic spatially-based response. *Complex problem solving and planning* were measured via The Towers Task (Delis, et al., 2001), where participants were presented with disks of different sizes and

three rods, and were required to achieve the target arrangement of disks on rods in as few moves as possible. *Working Memory* was measured using the Numbers Reversed subtest of the Woodcock Johnson III Tests of Cognitive Abilities, (Woodcock, McGrew, & Mather, 2001b), where participants heard increasingly-long sequences of digits, and were required to repeat each sequence in the reverse order.

Results

Accuracy and Reaction Time data were analyzed using 2 x 2 Repeated-Measures ANOVAs, with ToM Structure (matching vs. mismatching) and Surface Structure (matching vs. mismatching) as within-subjects independent variables. A-priori follow-up paired-samples comparisons were conducted to examine (1) whether surface mismatch impaired participants' ability to identify similar ToM structure in the stories, and (2) whether surface match impaired participants' ability to differentiate distinct ToM structures in the stories. Finally, correlation analyses were conducted to examine the relationship between ToM performance and Executive Function measures. Here, we were especially interested in comparing the relationships between ToM performance and language-based EF tasks and the relationship between ToM performance and non-linguistic EF tasks.

For accuracy, a 2 x 2 ANOVA with ToM Structure and Surface Structure as within-subjects Independent Variables yielded a marginally-significant interaction between the two independent variables, $F(1, 20) = 3.23, p = 0.09, \eta_p^2 = 0.14$. The interaction of ToM and Surface Structure variables indicates that performance on the ToM task was influenced by superficial contextual information, and suggests that the inhibitory-control demands mediated ToM performance. For RTs, a similar analysis yielded a main effect of ToM structure, $F(1, 19) = 8.10, p = 0.01, \eta_p^2 = 0.30$, indicating that conditions in which ToM matched required shorter response time than those in which ToM differed.

A-priori pair-wise t-tests were conducted to determine whether accuracies and reaction times differed across high and low inhibitory control conditions. For accuracy, a significant difference was observed between performance on stories where both ToM and Surface Structure matched and stories where ToM matched but Surface Structure mismatched, $t(20) = 2.03, p = 0.06$. However, there were no differences in performance on stories where ToM and Surface Structure both matched and stories where ToM mismatched but Surface Structure matched, $t(20) = 0.83, p = 0.42$. Figure 1 displays average accuracy for each condition.

For RTs, a significant difference was observed between performance on the condition in which both ToM and Surface Structure matched, and the condition in which ToM Structure differed but Surface Structure Matched, $t(19) = -2.21, p = .04$. Figure 2 displays average RTs for each condition.

Figure 1: Performance Accuracy on ToM Task

Figure 2: Performance RTs on ToM Task

Pearson Correlation analyses were conducted to examine the relationship between participants' accuracy and RTs on the ToM task and their performance on the executive function tasks.

Performance on the Digits Reversed task did not correlate with any of the performance measures. This indicates that the ToM task in the current study did not tax working memory capacity. Performance on the Stroop task was positively correlated with accuracy on the ToM task where both ToM and Surface Structure differed ($r = 0.45$). The finding that only one condition of the ToM task correlated with Stroop performance was unexpected, especially because this ToM condition did not require inhibition. It may be that the lack of association was due to the fact that the Stroop task demanded inhibition of an irrelevant perceptual dimension (conflicting color word) while the ToM task required inhibition of an irrelevant response dimension (response based on surface structure). It may also be that the lack of association was due to differences in response modality across the two tasks, with the Stroop task requiring vocal responses, and the ToM task requiring button-press responses.

Unlike the Stroop findings, performance on the Simon task was associated with ToM performance. To measure non-linguistic inhibitory control, a difference score was calculated where participants' RTs on the incongruent Simon trials (requiring inhibition) were subtracted from the

neutral Simon trials. Small difference scores indexed successful conflict resolution, and thus, superior inhibitory control. This measure of conflict resolution was correlated with ToM performance in each of the four conditions, and only one analysis yielded a significant correlation. Namely, successful conflict resolution on the Simon task was associated with higher accuracy on the ToM task in a condition where two stories shared the underlying ToM structure but diverged in Surface Structure ($r = -0.51, p = 0.02$). This finding suggests that non-linguistic inhibitory control was associated with ToM performance only in a condition where participants had to select the “match” response and inhibit the “mismatch” response based on non-overlapping superficial structural characteristics.

Interestingly, accuracy scores on the Towers Task were inversely correlated with accuracy on the ToM condition in which both ToM and Surface Structure matched ($r = -0.55$), and the total time taken to complete the Towers Task was inversely correlated with RTs for all conditions in the ToM task (correlation coefficients ranged from -0.51 to -0.58). It is difficult to interpret these correlations since it is unclear what cognitive abilities the Towers Task indexes. In our data, performance on the Tower task did not correlate with any other executive-function measure, indicating that the skill(s) it was indexing may not have been related to executive function. It is possible that these inverse relationships between performance on the Tower task and performance on the ToM task are due to the different modalities tapped by each task: visuospatial in the Towers and linguistic in the TOM task.

Discussion

Questions regarding the degree to which higher-order cognitive tasks rely on domain-general processes permeate every aspect of cognitive science. The goal of the current study was to inform the debate surrounding the modularity of Theory of Mind by examining the relationship between performance on the Theory of Mind task and inhibitory control. The results indicated that performance on the linguistic ToM task was associated with inhibitory control function. This conclusion was supported by three main findings.

First, higher accuracy was observed on the condition with similar ToM and Surface Structure compared to the condition with similar ToM Structure but differing Surface Structure. Because the condition with divergent Surface Structure required more inhibitory control than the matching condition, we interpret this pattern of results to suggest that ToM and inhibitory control draw on common cognitive resources.

Second, participants were significantly quicker to respond to trials in which both ToM and Surface Structure were similar than when the ToM Structure differed, but the Surface Structure was similar. This finding suggests that the inhibitory-control demands imposed by the incongruent ToM and Surface Structure resulted in prolonged response times.

Finally, performance on an executive function measure as assessed by the Simon task correlated with ToM performance, particularly for the condition where participants had to detect matching ToM across two structurally-distinct stories. This finding suggests that performance on the linguistic ToM task (especially one that involved inhibition) was associated with performance on the non-linguistic inhibitory-control task.

While this study included a small sample size and all participants scored very high on measures of receptive English vocabulary, the findings of a link between ToM and executive function support the non-modular view of the Theory of Mind (e.g., Carlson, et al., 2004; McKinnon & Moscovitch, 2007). It appears that Theory of Mind performance in adulthood may in fact draw on the same complex cognitive processes as inhibitory control. However, the findings are also consistent with the view of Theory of Mind proposed by Leslie, Friedman, & German (2004). Leslie et al. (2004) argued that Theory of Mind is comprised of an innate, modular ‘Theory of Mind mechanism’ that generates alternate interpretations of social situations, and an executive selection process that chooses one interpretation from those suggested by the Theory of Mind mechanism. According to this view, the selection process is inhibitory in nature. This theory has been tested previously using a false belief task, in which the participant must correctly identify that a character in the task has a belief that is different from the actual state of reality (Leslie, et al., 2004; Leslie, et al., 2005). In the case of a false-belief task, Leslie (2004) argued that the Theory of Mind mechanism generates several possible beliefs with the reality of the situation being the default selection. In a false-belief task, however, because the character’s belief is false, the selection process must inhibit the default interpretation in favor of a belief that is different than the reality of the situation.

When considering the findings of the present study, it could be argued that in the condition in which the ToM and surface structure are incongruent, the irrelevant surface structure information must be inhibited in favor of the deeper ToM structure. Therefore, the present data may in fact support the view of Theory of Mind that construes performance on ToM tasks as a process that consists of mechanisms specific to the Theory of Mind, and domain-general inhibitory control mechanisms.

Whatever the interpretation of the findings, it is intriguing that only one ToM condition was taxing for the participants – the condition with similar ToM and differing surface structure. The opposite condition, in which the ToM structures differed, but the surface structure matched did not seem to incur higher inhibitory demands. Perhaps suppressing a “no” response requires more inhibitory control than suppressing a “yes” response, although it is unclear why this may be so. The degree to which different ToM tasks require inhibitory control is therefore a crucial area of further research.

This study provides evidence that performance on Theory of Mind tasks may rely on domain-general inhibitory control mechanisms, and more broadly provides insight into the non-modularity of processes associated with high-order cognition. It is possible to increase inhibitory-control demands of the ToM task by pitting similarities in the underlying intentional structure of the stories (ToM) against superficial similarities in the linguistic structure of the stories. Requiring participants to make decisions about ToM similarities while ignoring structural differences imposes inhibition demands on performance. Crucially, performance on the linguistic ToM task correlated most highly with a measure of non-linguistic inhibitory control, pointing to an association between ToM and executive function in particular, and linguistic and non-linguistic performance in general. This pattern is in line with non-modular views of Theory of Mind, that construe performance on social cognition tasks as drawing on the same basic cognitive mechanisms that underlie performance on complex planning tasks, i.e., executive function.

Acknowledgments

The authors thank Dr. Lyn Turkstra for helpful discussions of this work. This research was made possible by the training fellowship to Lindsey Frederixson Byom from the University of Wisconsin-Madison Department of Communicative Disorders T32 Interdisciplinary Research Training Grant.

An ACT-R List Learning Representation for Training Prediction

Michael Matessa (mmatessa@alionscience.com)

Alion Science and Technology

Felton, CA 95018 USA

Abstract

This paper presents a representation of training based on an ACT-R model of list learning. The benefit of the list model representation for making training predictions can be seen in the accurate a priori predictions of trials to mastery given the number of task steps. The benefit of using accurate step times can be seen in the even more accurate post-hoc model results.

Keywords: Training; prediction; list length; ACT-R.

Introduction

Numerous studies have documented operational and training problems with the modern autoflight systems, in particular the flight management system (FMS) and its pilot interface, the control display unit (CDU). During the last few years, more attention has been given to the limitations of current autoflight training methods. Many studies have concluded that current training programs are inadequate in both depth and breadth of coverage of FMS functions (Air Transport Association, 1999; BASI, 1998; FAA Human Factors Team, 1996).

Matessa and Polson (2006) proposed that the inadequacies of the programs are due to airline training practices that encourage pilots to master FMS programming tasks by memorizing lists of actions, one list for each task. Treating FMS programming skills as lists of actions can interfere with acquisition of robust and flexible skills. This hypothesis of the negative consequence of list-based representation was validated by Taatgen, Huss, and Anderson (2008), who show poorer performance for list-based representation compared to a stimulus-based representation.

This paper extends the table-based training time predictions of Matessa and Polson (2006) by presenting a computational model that represents procedure training as list learning. The model is meant to describe training programs where to-be-learned procedures are formally trained, and trainees must demonstrate mastery before they can go on to more advanced, on-the-job training. Airline transition training programs are examples of this paradigm. The model takes as input the number of steps in a procedure and the time per step, and it generates estimates of the training time required to master the procedure. Predictions of the model are compared to human data and show the benefit of the number-of-steps and step-time parameters.

Model

Novice pilots lack an organizing schema for memorizing lists of actions and so the actions are effectively represented as nonsense syllables (Matessa & Polson, 2006). Therefore, the list model does not represent the actual information to be learned, but instead as an engineering approximation represents the training as learning a list of random digits. The model is motivated by the table-based list model of Matessa and Polson (2006), but is implemented in the ACT-R cognitive architecture (Anderson, 2007).

Table-Based List Model

The following description from Matessa and Polson (2006) shows how procedure learning can be represented as list learning, and a table-based prediction of training time can be created based on procedure length. A representation of a task must encode both item (actions and parameters) and order information. Anderson, Bothell, Lebiere, and Matessa (1998) assumed that item and order information is encoded in a hierarchical retrieval structure incorporated in their ACT-R model of serial list learning shown in Figure 1. The order information is encoded in a hierarchically organized collection of chunks. The terminal nodes of this retrieval structure represent the item information. The model assumes that pilots transitioning to their first FMS-equipped aircraft master a cockpit procedure by memorizing a serial list of declarative representations of individual actions or summaries of subsequences of actions. It is assumed that each of these attempts to learn the list is analogous to a test-study trial in a serial recall experiment.

Figure 1: The List Model representation for a list of nine digits (from Anderson et al., 1998).

An interpretive process uses the list to perform the procedure. This process incorporates the knowledge necessary to understand each step description and to execute actions necessary to perform each step. Thus, an item such as “Press the LEGS key” would generate the actions required to locate the Legs key on the CDU keyboard and press it. A parameter such as a waypoint identifier would be represented in working memory as a sequence of letters. The interpretative process would generate the keystrokes necessary to enter the identifier into the scratch pad.

The list actions representation is a consequence of pilots’ decisions to treat the task of mastering FMS procedures as learning serial lists of actions. The retrieval structure shown in Figure 1 is generated by processes that adults use to memorize any arbitrary serial list of items. It is assumed that a novice representation of a FMS procedure with nine actions would be represented by replacing the terminal-node chunks with chunks representing individual actions in the procedure. The retrieval structure only encodes order information and supports access to the chunks representing individual actions. The groupings of the actions imposed by this structure have no relationship to the underlying task structure. Because these retrieval structures are unique to each task, they block transfer of training.

The following figure is a possible list describing an FMS procedure for the Boeing 777 for responding to the following hold clearance that would be generated by a pilot with limited glass-cockpit experience.

“NASA 1: Hold west of Haden on the 270 degree radial. Right turns. 10 mile legs. Expect further clearance at 2130 z.”

1. Press HOLD Function/Mode Key.
2. Press LSK 6L, if a holding pattern is in the route.
3. Line select waypoint identifier for Haden to scratchpad.
4. Press LKS 6L.
5. Enter the quadrant and the radial, W/270.
6. Press LSK 2L.
7. Enter the turn direction into the scratchpad, R.
8. Press LSK 3L.
9. Enter the leg distance into the scratchpad, 10.
10. Press LSK 5L.
11. Enter expect further clearance time, 2130.
12. Press LSK 3R.
13. Verify the resulting holding pattern on the ND.
14. Press EXECUTE.

Figure 2: A possible novice representation of a FMS procedure for responding to a Hold clearance.

This probably looks like a list of nonsense syllables to you, as it does to novice pilots. Pilots do not receive an explicit instruction on how to encode FMS procedures in memory early in training and lack organizing schemas that would help in memorizing instructions. Catrambone (1995) has shown that novices tend to describe problem solutions in terms of actions used to solve the problem. In the case of

FMS programming skills, this process leads to long lists that are very difficult to memorize.

The list shown in Figure 2 has undesirable properties and would be difficult to memorize. It is long—14 items—and it is organized as a linear sequence of actions that cannot be directly stored in memory (Anderson, et al., 1998). Some kind of idiosyncratic organization would have to be imposed on it to break it up into sublists before it could be successfully memorized. Furthermore, the representation of the procedure for programming a hold shown in Figure 2 is specific to a particular clearance. It would be relatively easy to generalize this representation to clearances with identical parameters but with different values. However, generalizing this procedure to cover the entry of any hold clearance requires numerous nontrivial inferences.

The Savings Paradigm The list model assumes that learning a FMS procedure is analogous to memorizing serial lists of nonsense syllables for a pilot with limited FMS experience. Training times can be estimated using results of an experimental paradigm initially developed by Ebbinghaus (1888/1913, Chapter 8). On the first day of the experiment, participants learn a serial list of items to a criterion of mastery of one perfect recitation of the list. Performance is measured as the number of trials to mastery. Participants return to the laboratory 24 hours later and relearn the list to the same criterion of mastery. Training stops on the first day that participants perform perfectly on the first presentation of the list after a 24-hour retention interval.

Table-based Prediction Matessa and Polson (2006) developed a table that presents the number of retentions on each successive day and the number of days of training required to be able recall a list perfectly after 24 hours. The numbers in the table were derived by synthesizing the results of several experiments from the list-learning literature starting with the data from Ebbinghaus (1885/1913, Chapter 8). The numbers are extrapolations generated by fitting power functions to Ebbinghaus’s results and then adjusting them to account for the fact that he used a very rapid presentation rate.

Training time is estimated by calculating the amount of time it would take to administer N repetitions of a procedure of length L during one session in a fixed-base or full-motion simulator. The model’s description of the training processes has three time parameters: session setup time (SST), repetition setup time (RST), and step time (ST). SST is the time required to set up a simulator to begin training a specific procedure. RST is the time required to set up the simulator for the next repetition, and ST is the time required for a trainee to perform a step and receive feedback from the instructor if necessary. These values are then summed over days to generate a training-time prediction for a given procedure.

The time devoted to training a procedure on one day = $SST + N \cdot RST + N \cdot L \cdot ST$.

The values for N, the number of repetitions on a day, are taken from the table. Values for SST and RST were set to 120 seconds, and ST was set to 5 seconds. Current fixed-based and full-motion simulators were found to be ill-suited to this kind of training; they are designed to simulate the execution of complete missions.

Numerous studies have shown that PC-based, part-task simulators can be used successfully to train skills such as performing FMS procedures (e.g., Salas, Bowers, and Prince, 1998; Salas, Bowers, and Rhodenizer, 1998; and Polson, Irving, and Irving, 1994). The lesson planners incorporated into commercially developed simulators can be programmed to deliver the necessary repetitions while minimizing the SST and RST (Aerosim Technologies, www.aerosim.com; Tricom Technologies, www.tricom-tech.com/products.htm; CAE, www.Cae.com; and Wicat, www.wicat.com). Use of such a trainer was modeled by reducing the values of SST and RST to 5 seconds.

ACT-R List Model

This paper presents a computational list model developed in the ACT-R cognitive architecture (Anderson, 2007). ACT-R includes a subsymbolic level of representation where facts have an activation attribute which influences their probability of retrieval and the time it takes to retrieve them. The activation A_i of a chunk i is computed from two components – the base-level and a context component. The base-level activation B_i reflects the recency and frequency of practice of the chunk. The equation describing learning of base-level activation for a chunk i is

$$B_i = \ln\left(\sum_{j=1}^n t_j^{-d}\right)$$

where n is the number of presentations for chunk i , t_j is the time since the j th presentation, and d is the decay parameter. The equation for the activation A_i of a chunk i including context is defined as:

$$A_i = B_i + \sum_j W_{ji} S_{ji}$$

where the base-level activation B_i reflects the recency and frequency of practice of the chunk as described above. The elements j in the sum are the chunks which are in the slots of the chunk in module k . W_{kj} is the amount of activation from source j in module k . The strength of association, S_{ji} , between two chunks is 0 if chunk j is not in a slot of chunk i or is not itself chunk j . Otherwise it is set using the following equation:

$$S_{ji} = S - \ln(m)$$

Built into this equation is the prediction of a fan effect (Anderson, 1974) in that the more things associated to j the less likely any of them will be, on average, in the presence of j . That is, if there are m elements associated to j their average probability will be $1/m$.

The current model is an ACT-R 6.0 model based on the ACT-R 4.0 list learning model developed by Anderson et al. (1998) and can account for phenomena such as length and serial position effects. Figure 3 plots the probability of correctly recalling a digit in position as a function of serial position in input. There is considerable variation in recall of items both as a function of list length and input position. These variations are predicted by the model as a reflection of the changes in activations of the elements being retrieved. These activations increase with rehearsal (base-level activation), decrease with time (base-level activation), and decrease with list length (associative activation). As the list is longer, there will be greater interference because there will be more associations from the list element and less associative activation to any member of the list.

Figure 3: List model showing length and serial position effects.

In order to approximate training, the current model differs from the Anderson et al. (1998) model by not implementing its rehearsal strategy. In this way, presentation rate represents task step time (ST). As a consequence, longer presentation rates produce poorer performance, in contrast to findings from studies that allow rehearsal.

The model also uses the Pavlik and Anderson (2005) version of memory decay that accounts for spacing effects. They developed an equation in which decay for the i th presentation, d_i , is a function of the activation at the time it occurs instead of at the lag. This implies that higher activation at the time of a trial will result in the gains from that trial decaying more quickly. On the other hand, if activation is low, decay will proceed more slowly. Specifically, they propose

$$d_i(m_{i-1}) = ce^{m_{i-1}} + a$$

to specify how the decay rate, d_i , is calculated for the i th presentation of an item as a function of the activation m_{i-1} at the time the presentation occurred, with

$$m_n(t_1 \dots t_n) = \ln\left(\sum_{i=1}^n t_i^{-d_i}\right)$$

showing how the activation m_n after n presentations depends on the decay rates, d_i s, for the past trials.

These equations result in a steady decrease in the long-run retention benefit for additional presentations in a sequence of closely spaced presentations. As spacing gets wider in such a sequence, activation has time to decrease between presentations; decay is then lower for new presentations, and long-run effects do not decrease as much.

The model is run inside code that simulates the savings paradigm in order to determine trials to mastery. The model uses the same parameters as Anderson et al. (1998) except that the rate of presentation (representing step time) and repetition setup time are both set to 5 seconds, as in Matessa and Polson (2006). The activation retrieval threshold is set to -0.85 in order to match the predictions of the trials to mastery table found in Matessa and Polson (2006).

Experiment

In order to gather data for an experimental interface, Boeing conducted experiments with a PC-based, part-task simulator to compare the new interface to the current 777 interface (Prada, Mumaw, Boehm-Davis, & Boorman, 2007). Results from these experiments can be compared with model predictions to show the usefulness of the list modeling approach.

Boeing Pilot Performance

Boeing gathered performance data on flight tasks in a medium-fidelity, setting to get feedback on proposed interface improvements and to generate performance data comparing the 777 design to the proposed design (Prada et al., 2007). Two desktop computer simulations of the 777 and proposed automatic flight control panels and associated displays were created. The simulations provided appropriate feedback, including mode changes, as controls were manipulated. However, the aircraft remained frozen in time and space until advanced by the experimenter. Participants controlled the simulation using a standard two-button mouse. For this paper, only data from the 777 interface is considered.

Participants The participants consisted of twelve FMC-naïve subjects who were male Boeing employees. All were general aviation pilots with instrument rating. Six had commercial certification and four were not instrument current. They had no previous exposure to the 777 FMC.

Procedure Twenty training tasks were selected to capture tasks that are difficult on each interface and to provide a representative set of functions. In the training tasks, for each action (click) on the interface, the location and time were collected. Also collected were overall task time, number of steps correct, and trials to mastery.

Results The number of steps in the tasks ranged from two steps to thirteen steps. For this paper, tasks are grouped into those with an average of two, four, seven, and thirteen steps. Trials to mastery increased with the number of steps in the task (Figure 4).

Model Performance

The original list model of Anderson et al. (1998) made predictions for lists with three items up to twelve items. The current model retains this range, and so, for analysis, tasks with two steps are compared to lists with three items and tasks with thirteen steps are compared to lists with twelve items (four steps are compared directly, as are seven).

Results Model runs with the step time of 5 seconds used by Matessa and Polson (2006) show trials to mastery increasing with the number of steps in the task. The difference in trials to mastery between the model and subjects averaged 1.5 trials (Figure 4, model-pre).

A post-hoc analysis used the actual average step time from subjects as input to the model. For tasks with an average of two, four, seven, and thirteen steps, the average step time was 15.2, 8.1, 8.0, and 6.5 seconds, respectively. The difference in trials to mastery between this model run and subjects averaged 0.8 trials (Figure 4, model-post).

Figure 4: Trials to mastery for model and subjects.

Conclusions

The benefit of the list model representation for making training predictions can be seen in the accurate *a priori* predictions of trials to mastery given the number of task steps. The benefit of using accurate step times can be seen in the even more accurate post-hoc model results.

Ideally, the list model would be given an accurate estimate of step times without seeing the data ahead of time. To this end, the list model is currently being integrated with CogTool (John, Prevas, Salvucci, & Koedinger, 2004). CogTool takes as input a demonstration of an interface task and returns a zero-parameter prediction of task performance time based on ACT-R primitives. With this information, the number of steps in the task and average step time can be fed into the list model in order to make training predictions. A number of open issues remain, such as the level of abstraction of a "step". Does a step to push a button include the visual search for that button, or is that a separate step? More empirical work is needed to determine in what situations the list model representation can be useful in training prediction.

Abstract

In this study eye movements were recorded for participants under three different conditions. All three conditions consisted of a perception phase and a mental imagery phase. The imagery phase was similar for all conditions: i.e., participants looked freely at a blank white screen. The perception phase was different for each condition. In the control condition, participants looked freely at a complex picture. In the first experimental condition, they looked at another complex picture but maintained fixation at the center of the picture. In the second experimental condition, they maintained central fixation while listening to a verbal scene description. The results revealed that despite central fixation during the perception phase under the two experimental conditions, participants' eye movements were spread out during the imagery phase, reflecting the spatial positions and directions within the picture or scene. These results contradict the theory that eye movements during mental imagery are reenactments of perception.

Keywords: Eye movements, mental imagery, spatial cognition, visual attention, scene description.

Introduction

Since the late Nineties, several eye-tracking studies have reported that spontaneous eye movements occur with mental imagery and that these eye movements closely reflect the content and spatial relations from an original picture or scene (e.g., Brandt & Stark, 1997; Holsanova, Hedberg & Nilsson, 1998; Laeng & Teodorescu, 2002; Gbadamosi & Zangemeister, 2001; Altmann, 2004; Johansson, Holsanova & Holmqvist, 2006; Humphrey & Underwood, 2008). A similar effect has been found for spatial relations and scenes that are verbally described (e.g., Demerai & Cohen, 1998; Spivey, Tyler, Richardson, & Young, 2000; Spivey & Geng, 2001; Johansson et al, 2006). It has further been shown that this effect is equally strong irrespective of whether the original elicitation was visual or verbal (Johansson et al., 2006). Additionally, an eye movement effect of this kind has also been found during problem-solving tasks (e.g., Yoon & Narayanan, 2004; Freksa & Bertel, 2007) as well as with visual motor imagery (Heremans, Helsen & Feys, 2007; Gueugneau, Crognier & Papaxanthis, 2008). From this large body of research, it appears that eye movements

play an important role in visual imagery and in the construction of mental models. However, what role these eye movements have, and why they appear, are issues of debate (cf., Johansson et al., 2006; Ferreira, Apel, & Henderson, 2009; Richardson, Altmann, Spivey & Hoover, 2009).

Hebb (1968) suggested a *functional* role for eye movements during mental imagery, and proposed that they are necessary to assemble and organize "part images" into a whole visualized image. This functional view has gained strong support from a study by Laeng and Teodorescu (2002). In their study participants inspected visual stimuli of two kinds: 6x6 grid patterns with 5 black filled cells or a small fish in various locations on the screen. One group was instructed to maintain fixation onto the screen's center and another group was free to inspect the stimuli. In a subsequent imagery phase, both groups were instructed to 'build a visual image of the figure' they had just seen and were then allowed to move their eyes freely while looking at a blank screen. The results revealed that those who maintained their gaze centrally in the perception phase did the same, spontaneously, during the imagery phase, while those who inspected the original stimuli freely had eye movements during the imagery phase which, to a high degree, resembled those in the perception phase. Laeng and Teodorescu (2002) argued that this implied eye movements are stored along with a visual representation of the scene, and are used as spatial indexes to properly arrange the parts of a mental image. They concluded that eye movements during mental imagery are *re-enactments* of perception and have a necessary and functional role in "constructing" the mental image. However, the question can be raised whether the instruction to 'build a visual image', in combination with the relatively simple stimuli, might necessarily lead to spatial scanning of the mental image.

As discussed in Johansson et al. (2006), the task and the complexity of the stimuli are important when the scene is recalled during mental imagery. For instance, it is possible that the mental image is only covertly scanned or is not scanned at all. Thomas and Lleras (2009) have shown that shifts in covert attention can produce identical results in a

problem-solving task to overt eye movements. It is however less likely that shifts in covert attention, or lack of scanning altogether, would be sufficient when recalling scenes that are rich in detail and contain many objects: i.e., visualizing highly complex scenes would increase the cognitive load such that more internal operations would be needed to construct the parts of the image and then tie them together and place them into a context.

The purpose of the present study is to investigate whether Laeng and Teodorescus' (2002) 'central gaze effect' occurs even for visual scenes of high complexity. To ensure that spatial scanning is actually employed, the experimental design and method from Johansson et al. (2006) was used. In this method the imagery task is to orally describe the scene from memory, which introduces a great need for spatial scanning. Additionally, by including two types of stimuli – visual scenes and verbal descriptions – we can investigate mental imagery for scenes that have never been seen in the first place.

Experiment

The experiment consisted of three conditions: a *control* condition, a *fixed-picture* condition and a *fixed-verbal* condition. All three conditions consisted of a *perception* phase and a *mental imagery* phase. The imagery phase was similar for all conditions: i.e., participants looked freely at a blank white screen. The perception phase was different for each condition. In the control condition, participants looked freely at a complex picture. In the fixed-picture condition, they looked at another complex picture but were instructed to maintain fixation at the center of the picture. In the fixed-verbal condition, they were instructed to maintain central fixation while listening to a verbal description of a scene.

Participants

Twenty students at the University of Lund – ten females and ten males – participated in the experiment. All subjects reported either normal vision or vision corrected to normal (i.e., with contact lenses or glasses). All participants were native Swedish speakers. The mean age of the participants was 21.4 years (SD = 1.9).

Apparatus and stimuli

The participants were seated in front of a computer screen at a distance of 600-700 mm. (The distance varied slightly because of the subjects' freedom to move their head and body.) The eye tracker used was the SMI iView RED250, which has a sampling frequency of 250 Hz and a precision of 0.02°. The data was recorded with the iView X 2.4 software. The eye-tracking data was analyzed with BeGaze 2.4 and in-house MatLab programs.

The visual stimulus in the experiment was presented using Experiment Center 2.4 on a 480 mm. x 300 mm. computer screen with a resolution of 1680 × 1050 pixels. The auditory stimulus was a pre-recorded description (one minute and 38

seconds long). An English translation of the scene description follows:

"In the center, right in front of me, I see a large, green spruce. At the top of the spruce, a bird is sitting. To the left of the spruce – to the far left – there is a yellow house with a black tin roof and with white corners. The house has a chimney on which a bird is sitting. To the right of the large spruce – to the far right – there is a tree as high as the spruce. The leaves of the tree are colored yellow and red. Above the tree a bird is flying. Between the spruce and the tree is a man in blue overalls, raking leaves. Below the spruce, the house, the tree and the man, i.e. in front of them there is a long red fence, which runs all the way from left to right. At the left end, a bike is leaning against the fence. Just to the right of the bike is a yellow mailbox. On top of the mailbox, a cat is sleeping. Below the fence, i.e. in front of and along the fence, a road leads from the left side to the right side. On the road, to the right of the mailbox and the bike, a black-haired girl is bouncing a ball. To the right of the girl, a boy in a red cap is sitting and watching her. To the far right along the road, a lady in a big red hat is walking with some books under her arm. Just to the left of her, on the road, a bird is eating a worm."

Procedure

Participants were told that the experiment concerned pupil dilation in relation to mental workload. It was explained that we would be filming their eyes, but nothing was said about us recording their eye movements. They were asked to keep their eyes wide open so that we could film their pupils, and to look directly ahead so that our equipment could accurately measure their pupil dilation. The eye tracker was calibrated using a five-point calibration procedure with validation. (This is the default setting in Experiment Center 2.4). Participants' eye movements were recorded during both the perception and imagery phase under all three conditions.

In the *control* condition, a picture was shown for thirty seconds. Then the screen went blank, and participants were asked to describe the picture in their own words. They were told explicitly to keep their eyes wide open and to look directly ahead so that the equipment could record their pupil dilation. Figure 1 shows the schematics of the control condition.

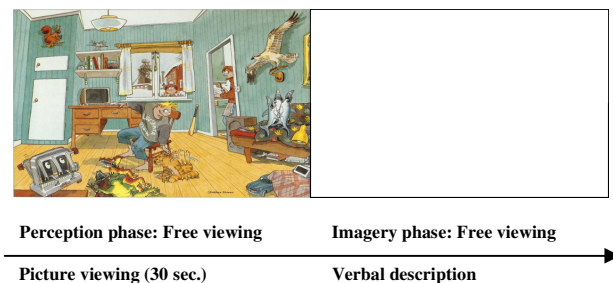

Figure 1: Control condition

In the *fixed-picture* condition, participants were instructed to maintain fixation on a cross in the center of the screen until

it disappeared. The cross was first shown for five seconds, after which a picture appeared behind it for an additional thirty seconds. Then the screen went blank, and participants were asked to describe the picture in their own words. They were told explicitly to keep their eyes wide open and to look directly ahead so that the equipment could record their pupil dilation. Figure 2 shows the schematics of the fixed-picture condition.

Figure 2: Fixed-picture condition

In the *fixed-verbal* condition, participants were likewise instructed to maintain fixation on a cross in the center of the screen until it disappeared. The cross appeared in an otherwise blank screen while a pre-recorded scene description was played from speakers in front of the participants for 1:38 minutes. Then the cross disappeared. Participants were asked to retell the scene. They were told that they could retell it in their own words and did not have to follow the same order. Participants were told explicitly to keep their eyes wide open and to look directly ahead so that the equipment could record their pupil dilation. Figure 3 shows the schematics of the fixed-verbal condition.

Figure 3: Fixed-verbal condition

Afterwards, to assess whether any of the participants had seen through the nature of the experiment, we asked what they thought the true objective of the experiment was.

Analysis

If Laeng and Teodorescu's (2002) conclusion – that eye movements during imagery functionally reenact those of perception – is supported then participants' eye movements should remain centrally fixated during the imagery phase for the fixed-picture condition and the fixed-verbal condition:

i.e., their eye movements should have similar spatial dispersion as during the perception phase and therefore not correspond to directions and positions from the imagined scene. To test this, we chose to analyze eye movements in two regards. First, the overall spatial dispersion of the eye movements was considered. However, spatial dispersion does not give any information about how eye movements correspond to directions and positions in a mental image. Also, it is common that participants "shrink" their mental image and only look at a limited part of the screen during imagery (Gbadamosi & Zangemeister, 2001; Johansson et al., 2006). Therefore, as a second step, a method combining eye movement data and verbal data (cf., Holsanova, 2008) was used.

To analyze the overall spatial dispersion of the eye-tracking data, a modified version of the *coverage measure* proposed by Wooding (2002) was calculated for each phase (perception/mental imagery) and condition. An "attention map" was created by centering a Gaussian function ($\sigma = 0.1W$, $W = 1680$ pixels) at each fixation point and then superimposing all the other functions. The volume under the attention map, after being normalized to unit height, was then used to estimate the spatial dispersion of the eye-tracking data. Within-subject ANOVAs were done to analyze the spatial dispersion between the perception and imagery phases in each condition, as well as between conditions for the imagery phase.

To analyze whether eye movements corresponded to directions and positions from the verbal descriptions and retellings, the method developed and described in Johansson et al. (2006) were used. Since it is possible that participants can make use of either the whole screen or only a part of it in imagining the scene, one cannot simply take physical coordinates on the computer screen as one's areas of interest. Instead, this method uses the relative position of an eye movement compared to each participant's individual gaze pattern over the entire description or retelling. Eye movements are then scored as correct or incorrect according to either *global correspondence* or *local correspondence* coding. The spatial criteria for an eye movement to be considered correct in global correspondence coding is defined as when an eye movement shifts from one object to another it must finish in a position that is spatially correct relative to the participant's gaze pattern over the entire description or retelling. The spatial criteria for local correspondence is defined as when an eye movement shifts from one object to another during the description or the retelling it must move in the correct direction (up, down, left or right). The minimum threshold for the saccadic amplitude to be considered an actual movement from one object to another was set at 35 pixels (10 mm on the screen). In addition to these spatial criteria, we used the temporal criteria from Johansson et al. (2006), where an eye movement from one position to another must appear within five seconds before or after an object is mentioned.

The key difference between global and local correspondence is that global correspondence requires

fixations to take place at the categorically correct *spatial position* relative to the whole gaze pattern, whereas local correspondence only requires that the eyes move in the correct *direction* between two consecutively mentioned objects. Eye movements are considered incorrect when neither the local correspondence nor the global correspondence criteria are met: e.g., when the eyes move with amplitudes below the 35-pixel threshold or in the wrong direction.

As a consequence of applying these spatial criteria a binomial distribution in the data is obtained: the spatial relations are either correct or incorrect. The possibility that a participant would move his or her eyes to the correct position by chance was then defined. For global correspondence coding, both the direction and the distance of the movement must be correct. Many movements are possible. In this study a conservative estimate was chosen, whereby the eyes could move in at least four directions (up, down, left, and right) to at least two locations (full and half distance). In addition to these eight possibilities, the eye might stand still (or move with an amplitude below the 35-pixel threshold). For global correspondence, the probability that the eyes moved to the correct position at the correct time by chance is thus definitely less than one in nine (11%). For local correspondence coding, which requires only correct direction, the corresponding probability is one in five (20%). The data could then be analyzed using a Wilcoxon signed-rank test for significance between the total number of correct eye movements and the expected number of correct movements made by chance.

Finally, to compare the proportion of correct eye movements in global and local correspondence coding between the three conditions a within-subjects ANOVA was used.

Results and discussion

None of the participants saw through to the true objective of the experiment and data from all participants could be included in the results.

The comparison of spatial dispersion between the perception and imagery phases revealed a significantly larger spatial dispersion in the imagery phase under the fixed-picture condition ($F(1,19) = 29.429$, $p < 0.001$) and the fixed-verbal condition ($F(1,19) = 32.934$, $p < 0.001$). The results for the control condition were the opposite: i.e., spatial dispersion was significantly larger in the perception phase ($F(1,19) = 114.553$, $p < 0.001$). The comparison of spatial dispersion in the imagery phase between conditions revealed a significant main effect ($F(2,38) = 8.175$, $p = 0.002$). Bonferroni *post-hoc* tests revealed that spatial dispersion was significantly larger for the control condition than for either the fixed-picture condition ($p = 0.01$) or the fixed-verbal condition ($p = 0.02$). No significant difference was found between the fixed-picture and the fixed-verbal condition.

The average proportion for all participants of correct eye movements by local and global correspondence coding

under each condition is presented in Table 1. Consistent with the results from Johansson et al. (2006) the control condition generated a high proportion of correct eye movements, both by local and global correspondence. However, also the central gaze conditions generated a high degree of correct eye movements in the local correspondence coding as well as a certain degree of correct eye movements in the global correspondence coding. Except for the eye movements in global correspondence coding in the fixed-picture-condition the results were significantly above chance ($p < 0.001$).

The comparison of correct eye movements by global and local correspondence coding in the imagery phase between the three conditions revealed a significant main effect for global correspondence coding ($F(2,38) = 5.544$, $p = 0.008$) but not for local correspondence coding. Bonferroni *post-hoc* tests revealed that there were significantly more correct eye movements (for global correspondence coding) under the control condition than under the fixed-picture condition ($p = 0.03$). No significant difference was found between the other conditions.

Table 1: Percentages of objects with correct eye movements in the imagery phase for all three conditions by both local and global correspondence coding.

	Control	Fixed-Picture	Fixed-Verbal
Global	55.8 %	26.5 %	34.5 %
Local	81.6 %	73.6 %	60.0 %

These results reveal that spatial dispersion of the eye movements was significantly larger in the imagery phase than in the perception phase under the two central gaze conditions, and that there was a significant degree of correct eye movements under the two central gaze conditions; especially for local correspondence coding. However, the results also showed that spatial dispersion was smaller in the imagery phase under the two central gaze conditions than under the control condition.

Figures 4-6 show scanpaths in both the perception and imagery phase for one and the same participant. Figure 4 shows that in the control condition this participant used a lot of the computer screen during imagery and her eye movements had a large spatial dispersion. Positions and directions for the eye movements corresponded to a high degree with described elements of the picture. Figure 5 shows that in the fixed-picture condition this participant had a large number of fixations in the center of the screen during the mental phase but also executed eye movements away from the center, resulting in a larger spatial dispersion than during the perception phase, and eye movements that spatially corresponded to what was described. For example, the eye movements to the far left were executed when the flowers to the far left of the picture were described. It is clear that during the perception phase, the participant looked at the central cross the entire time and never shifted to the flowers. Figure 6 shows that in the fixed-verbal condition

this participant executed a lot of eye movements across a large extent of the screen during the imagery phase, resulting in a larger spatial dispersion than during the perception phase, and eye movements that spatially corresponded to the described scene. For example, the eye movements to the left in this figure were executed when the house, the bike and the mailbox were mentioned, and the eye movements to the far right were executed when the second tree and the lady on the road were mentioned.

Figure 4: Control condition
(left: perception phase, right: imagery phase)

Figure 5: Fixed-picture condition
(left: perception phase, right: imagery phase)

Figure 6: Fixed-verbal condition
(left: perception phase, right: imagery phase)

General discussion

The results show that despite maintaining central fixation during visual perception of either a complex picture or a verbal scene description, eye movements spread out and to a high degree correspond to spatial positions and directions during mental imagery of the picture or scene. These results contradict Laeng and Teodorescu' (2002) conclusion that eye movements during visual imagery reenact those of perception of the same scene. Nevertheless, it was also revealed that eye movements were less spread out during imagery under the two central gaze conditions than under the control condition and the proportion of correct eye movements was by global correspondence coding significantly lower (and not significantly above chance) for the fixed-picture condition than for the control condition. Therefore, it seems that central gazing in the perception

phase to some degree did affect eye movements during imagery. We do, however, propose that this is an effect of the limitation of not being able to move the eyes during perception rather than a support for Laeng and Teodorescu' (2002) functional view. For example, under the fixed-picture condition most of the picture was only seen peripherally and participants were not able to describe as many objects (mean: 4.1) as in the control condition (mean: 7.6) and the description focused to a high degree on picture elements that were in focus during perception (the tree and the bird's nest). For the fixed-verbal condition we propose a similar explanation. Since the participants could not move their eyes when they listened to the scene description it was harder for them to form a mental image of the scene and less objects and spatial relations among them were remembered when the scene was recalled.

If eye movements during imagery are not reenactments of perception would this mean that they do not have a functional and necessary role for the construction of mental images? There has been a vibrant debate recently whether 'looking at nothing' can facilitate memory retrieval of visual scenes and what role internal depictive image representations have in this process (Ferreira, Apel, & Henderson, 2008; Richardson, Altmann, Spivey, & Hoover, 2009). Nevertheless, in this debate, eye movements to regions of a blank screen are interpreted in relation to a previous perception phase: i.e., again eye movements during mental imagery were seen as reenactments of perception. We propose that this is the wrong approach. Johansson et al. (2006) showed that participants who listened to a scene description while looking at a blank screen spontaneously performed eye movements that closely corresponded to spatial positions and directions from their visualizations of the scene. In this case, there was no previous perception phase that the eye movements could be reenacting. Another big problem for the 'reenactment approach' is that eye movements during imagery are idiosyncratic. For example, participants frequently "shrink" their mental image, and only look at a limited part of the screen when visualizing a previously seen picture that covered the entire screen (Gbadamosi & Zangemeister, 2001; Johansson et al., 2006). The results from the current study together with these previous findings strongly show that the phenomenon of eye movements during mental imagery is more complex than a mere reenactment of a perceptual phase. Therefore, to conclude that eye movements are necessary and functionally connected with the construction of a mental image is too strong of an assumption. A better approach might be to see them as a support that can relieve working memory load during imagery. If this is right, they become more likely to appear when a difficult imagery task is performed. This could explain why the results in this paper differ from those of Laeng and Teodorescu (2002). It is a much harder task to visualize and verbally describe a complex picture or scene description than to 'build an image' of the much simpler stimuli used in their study. Another possible interpretation comes from various versions of simulation theory (e.g.

Hesslow, 2002; Thomas, 1999), where eye movements during imagery do not have a direct and necessary link to eye movements from a perception phase. For example, the perceptual activity theory (Thomas, 1999) states that imagery is the reenactment of a perceptual behavior that would be appropriate for exploring the imagined scene as if it were actually present. Eye movements would therefore be likely to appear independently of how they were executed in perception.

Nevertheless, to explain the complex interplay between eye movements and mental imagery fully, further studies need to be performed: e.g., to investigate whether memory retrieval is enhanced by eye movements to blank areas of a screen and how individual differences in spatial cognition and working memory capacity are related to these movements.

Summary

This study showed that despite maintaining central fixation, either while looking at a complex picture or listening to a scene description, participants' eye movements spread out and did correspond to directions and positions during mental imagery of the picture or the scene. Laeng and Teodorescu's (2002) conclusion that eye movements during imagery reenact those of perception was therefore not supported.

Abstract

The paper describes a general two-step procedure for the numerical translation of linguistic terms using parametric fuzzy potential membership functions. In an empirical study 121 participants estimated numerical values that correspond to 13 verbal probability expressions. Among the estimates are the most typical numerical equivalent and the minimal and maximal values that just correspond to the given linguistic terms. These values serve as foundation for the proposed fuzzy approach. Positions and shapes of the resulting membership functions suggest that the verbal probability expressions are not distributed equidistantly along the probability scale and vary considerably in symmetry, vagueness and overlap. The role of vagueness for further investigations in reasoning and decision making is discussed and relations to knowledge representation and working memory are highlighted.

Keywords: verbal probability expressions; vagueness; fuzzy potential membership functions; knowledge representation; diagnostic reasoning; working memory

Introduction

Since the 1960s up to the present time researchers of different scientific areas have sustained an interest in studying the relationship between verbal and numerical probability expressions (Lichtenstein & Newman, 1967; Teigen & Brun, 2003; Smits & Hoorens, 2005). Among these are cognitive psychologists that inquire about the influence of uncertainty expressions on basic cognitive processes such as reasoning and decision making (Windschitl & Wells, 1996) as well as engineers, computer scientists and others that focus on the characterization (Zadeh, 1978, 2002) or on the treatment of uncertainty in applications such as medical decision support systems (Boegl, Adlassnig, Hayashi, Rothenfluh & Leitich, 2004). This broad interdisciplinary interest may be motivated by the essential role language plays in our daily life. Verbal probability terms, such as *probably* or *thinkable* are very widely used to express uncertainty about the occurrence of future events or about the degree of belief in hypotheses. For example, a typical statement that illustrates the use of linguistic terms in the conversation of stock market traders could be: "It is *very unlikely* that there will be a significant increase in the price of oil in the next month vice future."

Several studies consistently show that people prefer words over numbers to express uncertainty (e.g. Wallsten, Budescu, Zwick & Kemp, 1993). This preference may be explained by the possibility of saying something about two different kinds of subjective uncertainty by using only one word. First, the stochastic uncertainty about the occurrence of an event (e.g. the probability of an increase of the oil price) and second, the vagueness of the event (e.g. what is meant by "a significant increase").

The understanding of these two kinds of uncertainty, their relations to each other and the way in which they influence human reasoning and decision making is crucial for any application that aims to support decision makers for example in medicine, business, risk management, marketing or politics. In our view, in order to contribute to the understanding of uncertainty, it is essential to first uncover the underlying relationship between word meaning and mathematical concepts such as subjective probability or fuzzy membership. Therefore, we propose a general two-step procedure for the numerical translation of verbal probability expressions based on (1) empirical estimates modelled by (2) fuzzy membership functions (Zadeh, 1965, Bocklisch & Bitterlich, 1994).

The paper is structured as follows: first, we compare verbal and numerical probability expressions and discuss existing translation approaches. Second, we present our proposal that goes beyond other methodical issues and the results of an empirical investigation. Thereafter, the results are discussed and conclusions (e.g. for the construction of verbal probability scales for questionnaires) are highlighted. Further, potentialities of the fuzzy pattern classification method for reasoning and decision processes are pointed out.

Verbal and Numerical Probabilities

There is broad agreement concerning the different features of verbal and numerical expressions (see Teigen & Brun, 2003 for an overview). Numerical probabilities are commonly described as precise, unambiguous and especially useful for calculations. Additionally, the quality of numerical expressions can be evaluated and compared to predictions of normative models such as Bayes nets. Currently many researchers in the area of cognitive

psychology utilize subjective probabilities for the modelling of human reasoning (e.g. Bayes nets in inductive learning and reasoning (Tenenbaum, Griffiths & Kemp, 2006)). This approach is very fruitful and the obtained results contribute highly to the understanding of psychological processes but, at the same time, it focuses only on the probability dimension of uncertainty. Generally, vagueness is another facet of people's subjective uncertainty and should not be neglected. The effects of vagueness, such as exemplarily described by Kuhn and Budescu (1996) for hazard risk decisions, have received much less research attention in psychology. Although it is investigated more in engineering and other domains, where the practical significance is clearly observable from its prevalence in real-world decisions, vagueness is also crucial for psychological approaches. Zadeh (1965) proposed the fuzzy framework for the handling of vagueness and pointed out that probability theory and fuzzy approaches are complementary rather than competitive (Zadeh, 1995). Hence, it is possible to combine probability and fuzzy accounts and the advantages of bridging the gaps have been discussed recently (Singpurwalla & Booker, 2004).

In contrast to numerical probabilities, probability words are vague, with ambiguous meaning. They cannot be easily used for calculations and their meaning is often only clarified by means of a context (such as domain, speakers' prior knowledge and experience, reference point or prior probabilities and base rates of events). Nevertheless, most people in most everyday situations use words rather than numbers when describing their own uncertainty. Words are perceived as more natural, easier to understand and communicate and they are useful in situations when uncertainty can not at all be verbalized exactly. Numerical and verbal expressions are closely associated and refer to the underlying concept of probability and there is evidence that people can use numbers and words interchangeably (Jaffe-Katz, Budescu & Wallsten, 1989). But, at the same time, words and numbers do not mean exactly the same thing.

Furthermore, it can be assumed from various experiments that the use of numbers versus words affects human reasoning processes under certain circumstances. Windschitl and Wells (1996) show that numeric measures of uncertainty tend to sway people toward rule-based, deliberate thinking, whereas verbal expressions tend to elicit more associative and intuitive reasoning. These findings are of particular importance for reasoning situations that create conflicts between logical reasoning and intuitive beliefs (e.g. the belief-bias effect (Evans, 2003)).

In belief updating processes, such as customers product evaluation, there is evidence for the influence of information format (verbal vs. numerical) on order effects. Shen and Hue (2007) report that numerical information lead to order effects whereas verbal expressions do not. It can be assumed that the utilization of numerical vs. verbal expression formats result in different cognitive processes that in turn have different consequences for decisions.

Translating Words Into Numbers

In order to investigate the impact of verbal versus numerical probability expressions on order effects, decision making and the communication of uncertainty methods have to be developed for the "translation" of verbal into numerical expressions. There are already a number of translation studies that utilized different estimation and translation procedures. Among these are empirical approaches using direct estimation techniques for instance on a scale from 0 to 100 (Beyth-Marom, 1982) or pair comparison methods (Wallsten, Budescu, Rapoport, Zwick & Forsyth, 1986) as well as expert consultations for example to create knowledge bases for decision support systems (Boegl et al., 2004). A summary and discussion of different estimation approaches, that map verbal probabilities onto a numerical probability scale, is provided by Teigen and Brun (2003).

Recurrent findings in the studies using empirical estimations are that the mean estimates of the verbal probability expressions are reasonably similar supporting the idea that words are translatable. At the same time, there is a large variability between individuals indicating inconsistency in word understanding which may lead to communication problems. Although there are different views on whether verbal probability expressions are quantifiable or not (Teigen & Brun, 2003), we agree with Budescu et al. (2003). They propose to treat probability words as fuzzy sets and use fuzzy membership functions (MFs) over the probability scale to represent their vague meanings. They elicited judgments of membership by using a multiple stimuli estimation method in which probability values (0, 0.1, ..., 0.9, 1) are presented simultaneously with a verbal probability expression. Their results show, that the peak value and skew of the MF describing a probability expression depends on the words meaning. Therefore, they conclude that properties of the MF can predict for example the directionality (positive vs. negative verbal expressions, such as probable vs. improbable) of probability words.

Objective of the Paper

This paper has the goal to present a general two-step procedure for the numerical translation of linguistic terms. It is composed of (1) a direct empirical estimation method that yields numerical data participants assigned to presented words and (2) a fuzzy approach for the analysis of the data resulting in parametric membership functions (MFs) of the potential type (Bocklisch & Bitterlich, 1994). We outline this method for verbal probability expressions (e.g. *possible*) but the proposed procedure can also be applied for other linguistic terms such as expressions of frequency (e.g. *occasionally*), strength (e.g. *strong*) or others and is therefore of potential interest for many research areas and applications. Furthermore, our method goes beyond existing approaches for two reasons: first, the presented direct estimation method is frugal, efficient and easy to use to yield data from human decision makers. Therefore, it is suitable for research purposes and especially for applications where expert knowledge is crucial but also rare

or expensive. Second, the proposed parametric MFs of the potential type bring along advantages compared to other MFs (Zadeh, 1965; Budescu et al., 2003). For instance, they are able to account for asymmetric probability terms and are defined continuously over the numerical probability scale. Hence, linguistic terms can be modelled very realistically. In addition, the MFs can be implemented directly in applications (e.g. in fuzzy decision support systems) and the fuzzy pattern classification approach has potentials for psychological research (see Future Prospects at the end of this paper).

In contrast to Boegl et al. (2004) we do not expect that the MFs of the probability words are distributed equidistantly along the numerical probability scale and just like Budescu et al. (2003) we predict the functions to be asymmetric in shape.

Two-Step Translation Procedure

In this section we present the details of the two-step translation procedure for the numerical translation of verbal probability expressions. At first, the estimation technique and the method we used in the empirical study is outlined. Thereafter, the fuzzy analysis and the MFs are specified.

Empirical Investigation

Participants. 121 participants (19 males) took part in the study mainly for exchange of credits. The majority were undergraduate students of the Universities of Chemnitz, Göttingen and Zurich with an average age of 23 years ($SD=4.6$).

Materials and Procedure. Participants read a short contextual story from the area of medical decision making and were requested to take over the perspective of a physician. Then they assigned three numerical values to each of 13 exemplars of probability words (see translated words in Table 1, the original material was presented in German language) that were chosen from previous studies (e.g. Budescu et al., 2003). Among the three numerical values that had to be estimated were: (1) the one that represents the given probability word best and the (2) minimal and (3) maximal values that just correspond. The estimations can be interpreted according to the semantic meaning of the words: the first value characterizes the most typical numerical equivalent for the word, whereas the other values indicate the lower and upper border of the verbal probability expression. Participants were instructed to give their estimates in the frequency format (e.g. “In how many of 100 cases a certain diagnosis is correct if it is for instance *improbable*?”). This frequency format of estimation was proved to be better than for instance the estimation of percentages (Gigerenzer & Hoffrage, 1998). Participants used a PDF online questionnaire to provide their estimates.

Fuzzy Analysis

Fuzzy Membership Functions. Membership functions are truth value functions. The membership value (μ) represents the value of truth that an object belongs to a specific class

(e.g. that the numerical probability value 0.25 belongs to the word *doubtful*). For the analysis of the empirical data provided by the 121 participants a parametric membership function of the potential type (Bocklisch & Bitterlich, 1994; Hempel & Bocklisch, 2009) was used.

This function (see Figure 1) is based on a set of eight parameters: r marks the position of the mean value, a is representing the maximum value of the membership function. Regarding a class structure, a expresses the “weight” of the class in the given structure (we use a fixed $a=1$ in this investigation). The parameters b_l and b_r assign left and right-sided membership values at the borders of the function. Hence, they represent the border memberships whereas c_l and c_r characterize the left and right-sided expansions of the class and therefore mark the range of the class (in a crisp sense). The parameters d_l and d_r specify the continuous decline of the membership function starting from the class centre, being denoted as representative of a class. They determine the shape of the function and hence the fuzziness of the class.

Figure 1: Parameters of the membership function (for $r=0$)

A continuous range of membership functions, varying from a high degree of fuzziness to crisp, is available. This function type allows considering asymmetry in fuzzy classes by individual parameters for the left and right hand branches of the function. As we expect the MFs for the probability expressions to be asymmetric, this feature is especially important for the present study.

Results

In this paragraph we present the results of the statistical and fuzzy analysis of the present study. The descriptive statistics were calculated with the help of SPSS software. For the fuzzy analysis and the modelling of the MFs a software package (Fuzzy Toolbox, 2008) was used.

Descriptive Statistics

Table 1 shows the descriptive statistics for the empirical estimates of the most typical values that correspond to the

presented words. The minimal and maximal estimates, that indicate the borders of the semantic meaning of the linguistic terms, were necessary for modelling the MFs.

Results show that the probability words are distributed all over the numerical probability scale with varying distances. The standard deviation and kurtosis show a systematic pattern: probability words near to the borders of the numerical probability scale (e.g. *impossible* and *certain*) have small standard deviations but high values of kurtosis. And probability words in the middle (e.g. *thinkable* and *possible*) offer a larger spread but smaller kurtosis values. Also systematic differences exist for the skew indicating that probability expressions with means smaller than $P=0.5$ are skewed to the right whereas words with means higher than $P=0.5$ are asymmetric to the left. These findings are consistent with the results reported by Budescu et al. (2003).

Table 1. *Descriptive statistics for the estimates (most typical values)*

probability words	Mean	SD	Skew	Kurtosis
Impossible	1.44	3.01	3.25	13.39
very improbable	5.53	5.48	1.71	2.72
quite improbable	9.99	7.94	1.42	2.2
Improbable	11.68	9.03	1.43	1.82
hardly probable	17.01	11.05	1.15	1.02
sparsely probable	18.57	12.19	1.12	.89
Doubtful	21.34	13.61	.72	.32
Thinkable	49.33	20.24	.35	.1
Possible	51.49	21.6	.54	.53
Probable	67.68	12.49	-.01	-.85
quite probable	75.07	12.89	-1.01	1.02
very probable	83.95	9.08	-1.02	1.2
Certain	96.28	6.45	-2.87	9.99

Fuzzy Analysis

Figure 2 shows the MFs for the 13 verbal probability expressions. The representative values (r) indicating the highest memberships are identical to the reported means in Table 1.

Obviously, the functions differ considerably in shape, symmetry, overlap and vagueness. Functions at the borders (e.g. *impossible*) are narrower than those in the middle (e.g. *thinkable*) which is consistent with the observed standard deviations and kurtosis values. Most functions are asymmetric and are not distributed equidistantly along the probability scale. From the functions' positions, three clusters arise, that may be described by (1) *low* (MFs 1-7), (2) *medium* (MFs 8 and 9) and (3) *high* (MFs 10 - 13) probability ranges. The 13 MFs overlap in large parts and especially when they belong to the same cluster.

To test whether the probability expressions are distinct or not, participants' estimates were reclassified. Table 2 shows the results of the reclassification.

Figure 2: Membership functions of the 13 verbal probability expressions

The second column of the table presents percentages of the corresponding estimation data that was reclassified correctly. According to these results, some of the probability words are unambiguous and the reclassification was very successful (e.g. *certain*; 93.5% reclassified correctly). Others are inconclusive and almost no estimation data point that was used to describe the MF was reclassified correctly (e.g. *improbable*; 2.5 % classified correctly). Instead, the data was classified as belonging to the neighboring functions.

Table 2. *Percentages correct reclassification*

probability words	Scale (13)	Scale (5)
impossible	80.0	95.0
very improbable	33.1	
quite improbable	24.8	
improbable	2.5	
hardly probable	15.1	
sparsely probable	2.5	
doubtful	42.4	77.1
thinkable	41.2	61.3
possible	6.6	
probable	44.2	72.5
quite probable	33.9	
very probable	18.4	
certain	93.5	93.5

For a verbal probability scale that could be employed in psychological research or application, a scale with 13 probability words would not be useful because the words are too indifferent according to their meanings. But if a few words with small overlaps are selected, it is possible to create a scale that differentiates very well (see reclassification rate computed by the Fuzzy Toolbox Software in column three of Table 2). Figure 3 shows an example scale with five probability words described by their MFs.

Figure 3: Membership functions of 5 selected verbal probability expressions

Discussion

This paper aims to present a two-step procedure for the numerical translation of linguistic terms that goes beyond existing approaches. First of all, the estimation of three numerical values for each linguistic term (the most typical, minimal and maximal corresponding values) is very frugal and data can be gained very efficiently, whereas most alternative procedures are more costly (Budescu et al., 2003). The resulting estimation data can be analyzed using the proposed parametric MFs of the potential type. Results show, that the functions are able to model the data in a very efficient way, creating averaged membership functions that describe the linguistic terms continuously over the numerical probability scale. Because of the eight parameters, the functions take into account asymmetry, which was indeed found in the empirical data. Parametric MFs with fewer parameters would model the data without considering asymmetry and would therefore be less accurate and suitable for the reported data. Another advantage of the proposed function type is that the parameters can be interpreted in terms of content on a semantic meta level and illustrate the vague meaning of probability words very realistically.

Large overlaps of the functions (see Figure 2) indicate that the words are very similar in their meanings. Despite the imprecision of natural language, the MFs allow identifying words that are more distinct in their meaning than others. Just as Dhami and Wallsten (2005) we also found five probability expressions (see Figure 3) that are sufficiently distinct. This is especially useful for the creation of verbal probability scales for purposes of research and application that should include unambiguous words when possible.

Finally, the presented translation procedure serves as foundation for future investigations concerning the influence of contexts on word understanding. This influence can then be quantified by changes in the parameters defining the MFs. As these parameters can be semantically interpreted the influence of context on the interpretation of the expressions can be investigated in detailed way. As Wallsten and Budescu (1990) claimed, it is a promising instrument to uncover the various communication roles that probability phrases serve. For instance, it is likely that some of the ambiguous probability words are clarified by the

context in which they are used and therefore will become less vague which can be observed in the MFs.

Future Prospects

Finally, we will present a short outlook that highlights the potentials of the fuzzy approach for further psychological research in the area of diagnostic reasoning and decision making.

An advantage of the proposed MFs and the underlying fuzzy pattern classification method (Bocklisch & Bitterlich, 1994) is that the functions serve for the representation and combination of various kinds of vague knowledge (e.g. fuzzy degrees of symptom intensity such as “high fever” or “low blood pressure”) in a multidimensional way. For example, a physician considering the likelihood that a patient has a certain disease presumably takes into account the intensity of two (or more) present symptoms in combination prior to stating the diagnosis. Figure 4 exemplifies the content of a possible mental model in a simplified manner: three fuzzy classes (diseases A, B and C) resulting out of the multivariate combination of two features (intensities of the symptoms 1 and 2) that are described by fuzzy potential membership functions.

Furthermore, it is possible to integrate both vague and crisp information (such as precise predictions of probabilistic models) in this framework.

Figure 4: Representation of medical knowledge using fuzzy pattern classification method

The distance of the classes as well as their overlap can be interpreted in terms of similarity (disease classes A and B are near to each other and therefore cause similar symptom intensities, whereas disease C is apart and less similar to the other diseases). Furthermore, shapes and positions of the classes provide information about the discriminability of items in working memory which in turn affects reasoning performance. According to Oberauer, Süß, Wilhelm and Wittman (2003), the coordination function of working memory (WM) allows the integration of information (such as symptoms in a diagnostic reasoning process). Therefore,

WM provides simultaneous access to independently varying elements (such as symptoms and diseases) by placing them in a common coordinate system. The coordinate system has limited capacity to hold information and keep them separated from each other. Hence, it is likely that the precision or vagueness of the information elements (as it is described by the MFs) is an important variable influencing diagnostic reasoning processes and decision making performance. Moreover, it seems possible to predict to which extent relevant and irrelevant diagnostic hypotheses will interfere during the reasoning process (Dougherty & Sprenger, 2006) from the fuzzy knowledge representation. For example, it is plausible to assume that irrelevant diagnostic hypotheses that show a strong overlap with the relevant ones interfere more than irrelevant hypotheses that show less overlap. And the overlap can be quantified with this fuzzy approach. This is currently the object of further investigation.

Abstract

Some researchers argue that categorization in early development is knowledge-based rather than perceptually based. This approach requires young children to be able to attend to unobservable properties instead of perceptual features, which are usually more salient. However, potential immaturity of selective attention makes this possibility questionable. Current study tested both young children and adults with a match-to-sample task in which perceptual features were in conflict with the matching rule. Both behavioral and eye tracking data were collected. Eye-tracking results suggested that young children (3- and 4-year-olds) could not inhibit attention to the perceptual features, although behaviorally, 4-year-olds could. These findings are discussed with respect to theoretical accounts of category learning in early development.

Keywords: Cognitive Development, Categorization, Attention, Psychology, Human Experimentation.

Introduction

The ability to learn categories is a critical component of human cognition and this ability is present early in development (e.g., see Eimas & Quinn, 1994; Madole & Oakes, 1999, for reviews). However the mechanisms underlying category learning remain highly contested. Some researchers argue that early categories are perceptually-based, whereas others argue that even early in development, unobservable conceptual properties (such as animacy) play an important role in infants and young children's category learning and category use (see Rakison & Poulin-Dubois, 2001; Sloutsky, in press, for reviews). According to the latter view, early categorization (some have argued that as early as at 7 months of age) is based on features that are not given directly in the input. However, to be able to do so, infants and young children have to be able to selectively attend to

these unobservable properties. This problem is particularly evident when salient perceptual features are in conflict with less salient, often unobservable, "conceptual" features. For example Gelman & Markman (1986) presented 4-year-olds with an inductive inference task. The task was structured as a match to sample triad, such that one of the items belonged to the same kind as the target (but was dissimilar) and another looked similarly (but belonged to a different kind). The authors argued that the unobservable conceptual feature (i.e., taxonomic kind) would override the salient observable features (e.g., appearance similarity). In this case, in addition to the ability to attend selectively to less salient input, young children should also have the ability to inhibit more salient (yet irrelevant) choice option. Given the critical immaturities in the executive function early in development (see Rueda, Fan, McCandliss, Halparin, Gruber, Lercari, & Posner, 2004, Davidson et al., 2006, for reviews), such selectivity seems questionable.

Current research addresses this issue by presenting participants with a simple match-to-sample task and examining their eye movement in the course of the task. This task is substantially simpler than the match-to-sample task used by Gelman and Markman (1986). First, in the current task, participants were explicitly told which aspect of the stimuli they should focus on. And second, instead of pitting appearance versus unobservable properties, we pitted more salient features against less salient ones. Our reasoning was as follows. If participants focus on unobservable information in a more difficult induction task, they should have no difficulty focusing on less salient information in this highly simplified task.

The task includes a target and two test items. There are three within-subjects conditions. In the Supportive condition, the test item that shares the matching rule with the target is also similar to the target. In the Neutral condition, both items are equally similar to the target, with one test item sharing the matching rule. And finally, in the Conflict condition, one test item shares the matching rule, whereas the other one looks similar to the target. Therefore, the latter condition required participants to reject a salient appearance-based item in favor of less salient rule-based item. In sum, the task requires the ability to attend selectively that is critical for many category learning and inductive inference tasks. Given that the task is exceedingly simple, participants' failure in the conflict condition might be particularly informative. If they cannot resolve the conflict in this simple task, it is reasonable to ask: how could they resolve a conflict in more difficult and demanding categorization and induction tasks?

Experiment 1

Method

Participants Sixteen adults (6 women and 10 men, $M = 20.1$ years, $SD = 2.7$ years) participated in this experiment. Adults were undergraduate students from The Ohio State University participating in the experiment for course credit. The experiment used a within subject design and each subjects took all the three conditions in the experiment: Supportive, Neutral, and Conflict conditions. All the participants were tested in a quiet room on campus.

Stimuli consisted of triads of artificial creatures, which were irrelevant components of the task. Each triad also included three rows of circles (referred to as cookies that creatures eat). Examples of stimulus triads are presented in Figures 1-3. These cookies were the critical features that participants were instructed to focus on in the current matching task. To make the irrelevant features perceptually more salient, creatures were bigger and colorful, while the critical features were smaller and shared the same color. The only difference for the critical features was different patterns on the cookies. Two had wave lines on them while the remaining one had diagonal lines. The irrelevant features were drawn from two categories. One category consisted of objects with hands and feet, and the other consisted of bug-like objects with wings and tails. In each triad, the bottom object was the target item, and the two top ones were test items. Half of target and test items were selected from one category and half were selected from the other category. The top two sets of cookies were always different with only one matching the target set. At the same time, irrelevant items varied across the conditions. In the Supportive condition, the “matching distracter” (i.e., the one that had the same

kind of cookies as the target) came from the same category as the target. So the one that looked more similar to the target item also shared the matching rule with the target item. Therefore, the perceptually irrelevant information was consistent with and supportive of the critical features. In the Conflict condition, the “matching distracter” came from the opposite category than the target distracter. So the perceptual information was in conflict with the matching rule. Finally, in the Neutral condition, both test distracters and the target distracter came from the same category. As a result, the matching rule was neither supported, nor in conflict. The right and left sides of the stimuli were counterbalanced.

Figure 1: An example of the stimuli in the supportive condition

Figure 2: An example in the conflict condition

Figure 3: An example in the neutral condition

The locations of the cookies and the creatures were fixed for each trial. The distracters were subtended at visual angles equaling to 6.2° horizontally and 5.2° vertically. The cookies were subtended at visual angles equaling to 4.2° horizontally and 1.6° vertically. The distance between the creatures and the cookies were 2.6° vertically.

Procedure Eprime 2.0 was used for controlling the experiment and Tobii T60 with the sampling rate of 60 Hz was used for collecting eye tracking data.

Before the task, the eye tracker was calibrated to each participant. Participants were told that in this matching task they should choose one of the objects on the top to match the object at the bottom by matching the cookies. They were also instructed to make the choice as quickly as possible. If it was the left creature that matched, they should press “1”, and press “4” if it was the right one. They were given the following instructions: *This is a matching game. The game is to decide which one on the top goes with the one at the bottom. To win the game, you need to choose the one likes the same as cookies as the one as the bottom.*

Prior to testing, participants had three warm-up trials at first, one for each condition. Feedback was provided for the three warm-up trials. During the test phase, participants were given 30 trials, with 10 Supportive, 10 Neutral, and 10 Conflict trials. The trials were mixed and pseudo-randomly assigned into 3 blocks, with 10 trials in each block. The order of the three blocks and the order of the trials within each blocks were randomized. Each trial was preceded by a fixation point at the center of the screen. The duration of the fixation varied between 300 ms to 800 ms. No feedback was provided during the test phase.

Eye tracking Dependent Variables A stream of eye fixations corresponding to their x-y locations on the screen were collected by the eye tracking software for

each subject. Six areas of interest (AOIs) for fixations were defined: three circular areas encompassing the creatures and three rectangular areas encompassing the cookies displayed on the screen. All fixations outside the AOIs were discarded.

Results and Discussion

Behavioral Data The average of accuracy across the three conditions was 97% ($SE = 2.1\%$) and exceeded chance level, one-sample t compared to 50%, $t(15) = 22.94$, $p = .01$. No difference was found between different conditions, $F(2, 30) = .92$, $p = .41$.

Eye Tracking Data The primary analyses focused on the proportion of the eye fixation on the critical features, which were the kinds of cookies in this study. The proportion was calculated by total fixations on the triads of cookies divided by the sum of fixations on the triads of cookies and the fixations on the triads of creatures. The absence of a preference would result in comparable looking across the areas of interest. Before 200 ms, all the eye fixations were at the center of the screen which indicated that participants did focus on the fixation stimulus and did not exhibit eye movements during that period. The time window for eye tracking analysis was two standard deviations above the mean reaction time ($M = 1013.8$ ms, $SD = 480.7$). Therefore, the time window for eye tracking analyses was between 200 ms and 2000ms. The proportions of looking at the critical feature in the Conflict condition across time are presented in Figure 5. The overall proportion of looking at the critical features, i.e., the cookies, was 84.4% ($SE = 5\%$). No difference was found across the three conditions, $F(2, 30) = 765$, $p = .474$. Perhaps not surprisingly, these findings indicate that adults had little difficulty focusing on the critical features and ignoring more salient distracters. As a result, participants exhibited near ceiling accuracy in all three conditions. The importance of these data is that they represent a necessary point of comparison for children’s data. Experiment 2 focused on performance of 3- and 4-year-old children.

Experiment 2

Method

Participants Young children were recruited from the suburbs of Columbus, Ohio. There are 15 4 year olds (9 girls and 6 boys, $M = 50.5$ months, $SD = 2.5$ months) and 15 3 year olds (8 girls and 7 boys $M = 41.8$ months, $SD = 3.4$ months). All participants were tested in a lab on campus.

Procedure The procedure for young children was almost identical to that for adults, except for the following differences. First, a female experimenter presented the task to the participants, controlled the pace of the experiment, and pressed the key based on children's verbal response during the experiment. And second, the instructions "Choose the one that likes the same kind of cookies as the one at the bottom" were repeated before each trial.

Results and Discussion

Behavioral Data Accuracy data are presented in figure 4. For 3-year-olds, difference was found in accuracy across the three conditions, $F(2, 28) = 6.81, p < .01$. Specifically, accuracy in the conflict condition did not exceed chance, one-sample t compared to 50%, $t(14) = 1.56, p = .14$, two-tailed. However, the accuracy was above chance in the neutral and supportive condition, $t_s(14) > 5.78, p_s < .01$. For 4-year-olds, accuracy for all the three conditions exceeded chance, one-sample t compared to 50%, $t_s(14) > 3.67, p_s < .01$, one-tailed. Difference was also found across the three conditions, $F(2, 28) = 3.7, p = .037$. In particular, participants were less accurate in the conflict condition than the other two conditions.

Figure 4 Behavioral data of different age groups
Note: * -- Above chance, $p < .05$.

Eye Tracking Data The time stream between 1000ms and 3000ms was used for analysis. Before 1000ms, eye fixations did not reliably move from the center of the screen to the areas of interest. Data were analyzing by averaging across trials and individuals. The proportions of looking at the critical feature in the Conflict condition by sampling rate (16 ms) and age are presented in Figure 6. Main effect of age was found in proportion of looking at the critical feature, $F(1, 238) = 408.219, p < .01$. 4 year olds showed more fixations on the critical features than 3 year olds. Difference between conditions was found, $F(2, 476) = 109.4, p < .01$. There was an age by condition interaction, $F(2, 476) = 14.94, p < .01$, with larger age difference in looking at the critical feature found in Conflict condition. Therefore, 4-year-olds were not only more accurate in the conflict condition, but also were

more likely to look at the critical feature in the Conflict condition. At the same time, the proportion of looking at critical features by 3- and 4-year-olds was consistently below 50%.

Individual patterns of responses were also analyzed. We were particularly interested whether individuals who were more likely to look at the critical features in the Conflict condition also exhibited greater accuracy. For 3-year-olds, a significant correlation was observed between the accuracy and the overall proportion of looking at the critical features in the Conflict condition ($r = .574, p = .03$). This indicated that accurate participants were more likely to pay attention to the critical features. However, there was no significant correlation in 4-year-olds, $r = .29, p = .29$. This is probably because there was very little variability in the accuracy of 4-year-olds.

To further examine the connection between looking and response accuracy, we split the children into two groups according to their accuracy in the Conflict condition. Those with accuracy above .5 were assigned to the high accuracy group, and those with accuracy below or equal to .5 were assigned to the low accuracy group. Difference in overall proportion of looking was found in conflict condition between these two groups. Those high accuracy children were more likely to focus on the critical features ($M = 36.1\%$, $SE = 5\%$) than those low accuracy children ($M = 16.5\%$, $SE = 6\%$), $t(28) = 2.26, p = .016$, one-tailed.

Further analysis was carried out for examining the online learning during the task. If there was any learning or strategy optimization happening during the task, we should expect the difference in looking across trials. The participants should show more looking to the critical features during the later part of the task than during the earlier part. To test this, data was divided into the earlier 5 and later 5 trials of each condition. Comparison between these two half of the task were made for each condition and each age group. However, no difference was found, $t(14) < .05, p > .16$, one-tailed. Therefore, in the absence of feedback given to participants, there was little evidence of on-line learning to allocate attention to critical features.

Figure 5: Adults' eye tracking data in Conflict condition

Figure 6: Childrens' eye tracking data in Conflict condition

General Discussion

The results point to several important findings. First, under comparable experimental conditions, adult participants and 4-year-olds were less likely to be distracted by the appearance of the stimuli, which were the irrelevant features in this study. When the critical features conflicted with the irrelevant features, their behavioral performance was still above chance, although performance of 4-year-olds (but not of adults) decreased in the Conflict condition. However 3-year-olds could not ignore the irrelevant features and their performance was at chance in the Conflict condition.

Second, performance in the Conflict condition was associated with the proportion of looking to the critical feature. This proportion in adults was greater than in 4-year-olds, and in 4-year-olds greater than in 3-year-olds. In addition in 3-year-olds, correlation was found between the proportion of looking to the critical features and the accuracy on the task in the Conflict condition. Moreover, when children were divided into the groups by their performance in conflict condition, difference was observed in their looking pattern. Thus, the proportion of looking to the target in the Conflict condition was a predictor of performance on the task in this condition.

Third, for 4 year olds, the pattern of their behavior data looked more like adults data, while their pattern of eye tracking data was closer than that of 3 year olds. During

the task, most adults' fixations were focusing on the critical features, while children spent more looking on the irrelevant features. Proportions of looking at the critical features in 4-year-olds were above of those in 3-year-olds, but were remarkably lower than that of adults and never excelled that of looking at the irrelevant features. This indicated that even though 4-year-olds exhibited high accuracy in the Conflict condition, they could not inhibit looking at the irrelevant features. Unlike adults, 4-year-olds' performance was not optimized and their choice between critical features and irrelevant features was not as efficient as adults. This suggested that children at this age were more likely to be attracted to the salient perceptual features instead of the critical but less salient one. Therefore, it is likely that if task demands were increased, 4-year-olds' performance in the Conflict condition would decrease as well.

Fourth, there was no evidence for the learning during the task. Participants did not look more to the critical features later in the task. This indicated that participants used the same strategy throughout the task and the trend that young children could not inhibit looking at more salient perceptual features was robust.

These findings indicate that young children have difficulty attending to less salient but critical task features, while ignoring more salient, but irrelevant features. Even in the very simple task used in the current research with warm up trials and instructions repeated on every trial, 3-year-olds failed in the Conflict condition, whereas 4-year-olds exhibited significant performance decrease. These findings present interesting challenges to the knowledge-based assumption that young children (and even infants) are capable of learning and using categories by spontaneously focusing on unobservable features, while ignoring salient observable features.

At the same, the study also raises a number of important questions for future research. One of them is how the low proportion of looking to critical features explained the high accuracy for 4-year-olds and whether the pattern will change for more difficult tasks. We have preliminary evidence addressing this issue. In an ongoing study, young children were presented with a more challenging induction task. While the stimuli and the procedure are the same as in the current task, participants are asked a more difficult questions. They are informed about an unobservable property of the creature at the bottom and asked which at the top had the same property. For instance, on one trial, experimenter pointed to the creature at bottom, told children that "this one has thick blood", and asked them "Which one on the top do you think also has thick blood". The instructions that those like the same kind of cookies go together

in the matching task were changed into that those like the same kind of cookies have the same thing inside. Similar to the current task, this rule of induction was also repeated every time before each trial. Compared to the matching task, the induction task was more challenging to young children as there was more information they needed to keep track during the task. As a result, the working memory demand was higher and so was the executive function demand. Considering the results of the matching task presented here (i.e., 4-year-olds spent most of the time looking at the irrelevant features), we expected that accuracy of 4-year-olds will drop in the Conflict condition. The results support this prediction: 4-year-olds exhibited low accuracy in the Conflict condition, and it did not exceed accuracy of 3-year-olds in the current study.

Another issue that has to be addressed in future research is related to the online strategy learning and whether children could move from a less efficient learning strategy to a more efficient one during the task. For instance, whether the time pressure and the feedback will help children pay less attention to the irrelevant features.

Finally, an investigation of whether training on selective attention would accelerate children's category learning in general would provide some insight into the development of this ability and also the interaction between the development of executive function and generalization ability.

In summary, many studies have examined how young children learn new categories. The current study provided evidence indicating that young children have difficulty inhibiting attention to irrelevant information. This evidence provides challenges to the knowledge-base approach assuming the ability of infants and young children to focus on less salient aspects of the input, while ignoring more salient.

Acknowledgments

Abstract

Eye-movements represent a great interest in studying the specificity of the reading difficulties that individuals with developmental dyslexia have. In the present study dyslexic children were pair-matched with control children in a sentence reading task. The children read sentences in Bulgarian – a Cyrillic alphabet language with regular orthography. Target nouns with controlled frequency and length were embedded in the sentences. Eye movements revealed highly significant group differences in the gaze time and the total fixation times, word frequency and word length effects as well as interaction for both frequency and length with the group factor. These results, especially the frequency effect found in the dyslexic children, are discussed in the context of previous studies.

Keywords: development dyslexia; eye movements; reading.

Introduction

Developmental dyslexia is described as a condition found in children as young as 6-7 years that impairs their reading skills, while their IQ, reasoning and communication abilities are intact. Still, there is large variability in both the symptoms that dyslexic children demonstrate and in the experimental findings that give support to several theories explaining the underlying causes for dyslexia (see Vellutino, Fletcher, Snowling & Scanlon, 2004 for a review).

Usually, dyslexic children are given non-verbal, phonological or single word reading tasks, which aim to distinguish between different theories. While the rationale behind these experiments is very sound, classical reading experiments are also of great interest. For many years eye movements during reading provide insight into psycholinguistic research. During reading, dyslexic readers exhibit more and longer fixations and a higher percentage of regressions than normal readers. It is still a matter of debate, whether these divergent eye movement patterns of dyslexic readers reflect an underlying problem in word processing or whether they are – as the proponents of the oculomotor deficit hypothesis claim (e.g. Pavlidis, 1981) – associated with deficient visual performance that is causal for dyslexia.

It is a well-documented (and undisputed fact) that eye movements of dyslexic readers differ from those of normal

readers. During reading, dyslexic readers exhibit more and longer fixations, shorter saccades and a higher percentage of regressions than normal readers (for review, see Rayner, 1998).

Hutzler, Kronbichler, Jacobs and Wimmer (2006) used a string processing task that imposes the same requirements as reading to visual perception (letter identification) and oculomotor control (moving the eyes in the same pattern as during reading). The task is different from reading as it does not require linguistic or language processing of the visual information beyond letter identification. In the study above the authors found no differences between the eye-movements of dyslexic and normal readers and concluded that differences in eye-movements during reading are not the cause for the impaired performance.

Hyona & Olson (1995) also tested the hypothesis that the specificity of eye-movements of dyslexic readers is the cause for their reading difficulties. They found word length and word frequency effects on eye-movement characteristics of dyslexic readers. The conclusion they made was that the eye-movement patterns of dyslexic readers are affected by the properties of the linguistic material encountered during reading and therefore eye-movement patterns of dyslexic readers are reflection of the difficulties these readers have during linguistic processing (and not vice versa).

Still, there are few studies of text- or sentence-level reading with dyslexic children. An eye-movement study on reading German text passage found word length effects for both dyslexic and normal readers as well as interaction between the groups (Hutzler & Wimmer, 2004). The words taken from the text passage, however, could not be controlled for possibly confounding factors like predictability and frequency. In a similar task of reading short text passages in Italian, De Luca, Di Pace, Judica, Spinelli and Zoccolotti (1999) found once again strong length effects but much smaller frequency main effect that was marginally significant and did not interact with the group factor. Finally, Hyona & Olson (1995) compared a group of dyslexic children with younger ones and found highly significant word frequency and word length effects

for both groups in a somewhat similar task – reading aloud of English texts. Although there was no main effect of the group factor, an interaction between length and group was still observed (but only in the subject means).

These experiments show an interesting pattern of results. Dyslexic children seem to show strong length effects and weaker frequency effects in text reading but the differences between normal readers and the dyslexic ones resembles the difference between experienced and average readers or in the children case – of younger, less trained in reading children (Olson, Connors, & Rack, 1991). School practices show that children diagnosed with Dyslexia tend to resent reading and as a result of their reading difficulties, they are less exposed to written text than normal children. Whatever the underlying reason for the various symptoms may be, it is clear that reading practice plays some important role in the later reading behavior of dyslexic children and adults. Indeed most theories predict the length effects which can be explained by difficulties in grapheme-phoneme decoding, oculomotor control, attention. The word frequency effect, however, is closely related to reading experience. It could be argued, that for languages with irregular orthography the grapheme-phoneme decoding could be more problematic for less frequent words than for languages with regular orthography – an explanation suggested by De Luca et al. (1999) for their results that showed much stronger length effects than frequency effects for Italian dyslexic readers when compared to the Hyona & Olson study (1995) on English readers (English is a language with irregular orthography, while Italian – with regular).

Clearly, a further investigation of word frequency and word length effect in reading is necessary in order to explore these inconclusive results.

Experiment

This experiment aims to study word length and word frequency effects in Bulgarian language (a Cyrillic language with regular orthography). Target nouns were embedded in sentences that were controlled for the preceding context (neutral) among other possibly confounding factors, thus providing much more reliable results than words selected from text passages.

Stimuli and design

Before conducting the study there was a preparatory phase. As a first step, we collected a large corpus of children texts in Bulgarian. The corpus contains children books, fairy tales, etc. representative for the age groups studied. It consists of 931 320 words in total, among them 58 605 unique.

From this corpus we selected *short* (5 letters) and *long* (8 letters) concrete nouns (animals, objects, flowers, etc.) that were either *high-* or *low-frequency*. To calculate word frequencies we first computed the raw frequency (number of occurrences per million words) and then we performed a logarithmic transformation. After this we chose 16 short words (5 letters) and 16 long words (8 letters) that have

similar low frequency. We also chose 16 short words (5 letters) and 16 long words (8 letters) that have similar high frequency. Summary of the frequencies of the words chosen is presented in Table 1.

Table 1: Summary of the words used in the study.

Frequency was assessed as normalized number of occurrences in a 1 million words corpus of texts that are usually read by children (fairy tales, novels, etc.).

		Frequency per million (ln)		
		min	Max	average
5-letter words	low frequency	0	2.26	1.27
	high frequency	3.29	4.6	3.85
8-letter words	low frequency	0	2.01	1.32
	high frequency	2.96	5.97	3.9

In this way, we were able to vary both word length and frequency in a 2x2 design with factors: word length (short vs. long words) and word frequency (high vs. low frequency).

Each of the 64 target words were embedded in a sentence with neutral preceding context. The target word was never the first word in the sentence. The sentences were with content appropriate for children. Example sentences are as follows (the target words are in bold):

- 5-letters, high-frequency: ‘Подробна **карта** на океаните е нужна на всеки пират’. (A detailed **map** of the oceans is a necessity for every pirate).
- 5-letters, low-frequency: ‘Добрият **бобър** живееше край омагьосаната река’. (The good **beaver** lived near the enchanted river).
- 8-letters, high-frequency: ‘Хитрото **чудовище** пресрещаше пътниците и им задаваше гатанки’. (The clever **monster** stopped passengers and gave them riddles).
- 8-letters, low-frequency: ‘Червеният **карамфил** беше във високата ваза на земята’. (The red **carnation** was in the tall vase on the ground).

The sentences were counterbalance in two lists, so that each participant saw 32 sentences (8 sentences from each condition).

Procedure and apparatus

Sentences appeared one by one on a screen and were read silently. The task of the children was to read each sentence and to understand it. After reading the sentence, the participant had to press the space bar on a standard computer keyboard. The sentence stayed on the screen until the space bar was pressed and then it disappeared. In order to assure careful reading, control questions appeared after

some of the sentences (the questions were related to the content of the sentence). The questions required a ‘yes’ or ‘no’ answer. After reading the question, the participant had to press one of two keys on the keyboard marked with labels ‘YES’ and ‘NO’. There was a fixation cross between the sentences and the participants were instructed to look at it when it appeared.

Each participant had to read 32 sentences, which were presented in a pseudo-randomized order. In the beginning there were 8 practice trials. Data from the practice trials were not included in the analysis. The practice trials were intended to provide an opportunity for the participants to get used to the task.

Eye-movement data were recorded with a Tobii 1750 remote eye-tracker and ClearView 2.7.1 software. The eye-tracker looks like a computer screen with in-built cameras and sensors. That allowed for comfortable and completely unobtrusive recording of eye-movements. Each participant was seated at a distance of approximately 55 cm from the screen. The sentences were presented in black letters on white background. The sentences were presented in Tahoma font (a sans-serif typeface). The size of the letters was chosen to space 3 letters per degree of visual angle. The screen was an integrated 17” TFT monitor set to its native resolution (1280 x 1024).

The equipment recorded gaze coordinates on the screen every 20 ms. ClearView algorithms were used to compute fixation duration and location from these raw data (the fixation analysis filter was set to 40 pixels fixation radius and 100ms minimal fixation duration). ClearView was also used to control stimulus presentation and to collect participants’ answers.

Participants

Seven dyslexic children and seven children with normal reading skills were matched (in pairs) on age and nonverbal IQ. Full matching data are presented in Table 2. Children with attention disorders were excluded from the sample. All participants had normal or corrected to normal vision.

Data analysis and results

Participants performed well on the control questions – all reported participants had above 80% correct answers (see Table 2 for individual scores).

One of the items (8-letters, high-frequency word) was excluded from the analyses due to typo in the stimulus material.

First-pass durations (gaze duration) and total times were selected as dependent measures that reflect well both word frequency and length effects in reading (Rayner, 1998). **First-pass duration** is calculated as the sum of all fixation durations beginning with the first fixation in a region (the target word) until the reader’s gaze leaves the region, left or right. **Total time** is calculated as the sum of all fixation durations in a region (the target word), regardless of their order.

The eye-movement data were analyzed using two separate analyses of variance (ANOVA): using subjects (F1) and items (F2) as cases.

Table 2: Participants in the study. Each dyslexic child is matched with the child in the row below. The column IQ represents the raw score on a non-verbal Raven test with 36 questions (a point is granted per correct answer). The column “Correct Answers” gives the percentage of correct answers for the comprehension questions during the reading task.

Group	Age (months)	Gender	IQ (raw score)	Correct Answers (%)
Dyslexia	103	Male	29	95
Norm	106	Female	33	100
Dyslexia	120	Male	33	90
Norm	120	Male	32	95
Dyslexia	123	Female	32	100
Norm	125	Female	35	100
Dyslexia	128	Male	32	100
Norm	128	Male	32	100
Dyslexia	130	Male	33	90
Norm	131	Male	35	100
Dyslexia	136	Female	34	95
Norm	142	Female	30	85
Dyslexia	141	Female	20	80
Norm	144	Female	27	90

First-pass duration

First-pass durations (Table 3) were analyzed as a function of word length, word frequency, and group (dyslexic or normal readers).

Comparison between dyslexia group and control group

The subjects analysis (repeated-measures ANOVA) on first-pass duration was performed with two within-subjects factors: word length (short and long) and word frequency (low and high), and group (dyslexic or normal readers) as a between-subject factor. The item analysis on first-pass duration was performed with word length and word frequency as between-item factors, and group as within-item factor.

The main effect of group (dyslexic vs. normal readers) on first-pass duration is significant: $F(1, 12) = 20.28$, $p \leq 0.001$; $F(1, 59) = 150.9$, $p < 0.001$. In general, dyslexic readers showed much longer first-pass durations (means were 2044 ms for the dyslexic readers vs. 467 ms for the normal readers).

Table 3: Mean first-pass duration (in ms) as a function of word length and word frequency in dyslexia and control groups.

	Word length	Word frequency		M
		high	low	
Dyslexia group	short	1418	2068	1743
	long	2072	2620	2346
	M	1745	2344	2044
Control group	short	405	421	413
	long	441	600	520
	M	423	511	467

The main effect of word length (short vs. long) on the first-pass duration was significant in the items analysis ($F(1, 59) = 6.02, p < 0.05$) and marginally significant in the subjects analysis ($F(1, 12) = 4.44, p = 0.057$). Longer (8-letters) words lead to longer first-pass durations compared to the short (5-letter) words. Length by group interaction did not reach statistical significance ($F(1, 12) = 2.16, p = 0.17$; $F(1, 59) = 2.65, p = 0.11$). Long words (8-letters) received longer first-pass durations both in the dyslexia and in the control group (see Figure 1).

Figure 1: Average first-pass duration (in ms) as a function of word length in dyslexia and control groups. Error bars represent standard error of the mean.

The main effect of word frequency (high vs. low) on first-pass duration was significant in the subjects analysis and in the items analysis: $F(1, 12) = 10.1, p < 0.01$; $F(1, 59) = 8, p < 0.01$. Low-frequency words lead to longer first-pass durations compared with the high-frequency words. Frequency by group interaction was also statistically significant in both subjects and item analysis: $F(1, 12) = 5.6, p < 0.05$; $F(1, 59) = 5.86, p < 0.05$ (see Figure 2).

Additional tests on simple effects in items analysis reveal that word frequency effect is significant in dyslexia group ($p < 0.05$) and not significant in the control group ($p = 0.13$). The interaction reflects the fact that low frequency words (compared to high-frequency words) lead to greater increase in first-pass duration only in the dyslexia group.

Figure 2: Average first-pass duration (in ms) as a function of word frequency in dyslexia and control groups. Error bars represent standard error of the mean.

Summary of the results for first-pass duration The comparison between dyslexia group and control group demonstrates that *dyslexic children have much longer first-pass duration* in general. Their first-pass durations are approximately 4-5 times longer than for the control group. There was also main effect of word frequency. However, the frequency by group interaction and the additional analysis revealed that the increase in first-pass duration for low-frequency words is present only for the dyslexic group. Main effect of word length on first-pass duration is also found: long words receive longer first-pass durations both in the dyslexia and in the control groups.

Dyslexic children show longer first-pass durations for the long words compared to the short words (word length effect) and for low-frequency words compared to high-frequency words (word frequency effect). So, it seems that eye-movements of dyslexic children are affected by such lexical factors as word length and word frequency.

First-pass durations for dyslexic readers seem to be affected to a greater extend by word-frequency, unlike in some of the previous studies.

Total time

Total times (see Table 4 for means) were analyzed as a function of word length, word frequency, and group (dyslexic or normal readers).

Table 4. Mean total time duration (in ms) as a function of word length and word frequency in dyslexia and control groups.

	Word length	Word frequency		
		High	low	M
Dyslexia group	short	1928	2783	2355
	long	3063	3671	2346
	M	2495	3227	2861
Control group	short	545	556	551
	long	620	747	683
	M	583	652	617

Comparison between dyslexia group and control group

The subjects ANOVA on total time was performed with two within-subjects factors: word length (short and long) and word frequency (low and high), and group (dyslexic or normal readers) as a between-subject factor. The item analysis on total time was performed with word length and word frequency as between-item factors, and group as within-item factor.

The main effect of group (dyslexic vs. normal readers) is significant in the subjects and in the items analysis: $F(1, 12) = 28.4$, $p < 0.001$; $F(1, 59) = 154.3$, $p < 0.001$. In general dyslexic readers showed longer total time gaze durations compared to the normal readers (means are 2861 ms for the dyslexic readers vs. 617 ms for the normal readers).

The main effect of length on total time was significant in both subjects analysis and items analysis ($F(1, 12) = 5.52$, $p < 0.05$; $F(1, 59) = 6.66$, $p < 0.05$). Longer words (8-letters) led to longer total time gaze durations compared to the shorter (5-letters) words. Length by group interaction did not reach statistical significance in both analyses ($F(1, 12) = 3.25$, $p = 0.096$; $F(1, 59) = 3.31$, $p = 0.074$). Additional tests on simple effects reveal that word length effect is significant in dyslexia group ($p < 0.05$) and in the control group ($p < 0.01$). Reading for long words had longer total time durations both in the dyslexia and in the control group (see Figure 3).

The main effect of frequency was significant in both analyses: $F(1, 12) = 6.47$, $p < 0.05$; $F(1, 59) = 6.68$, $p < 0.05$. Low-frequency words led to longer total time durations compared with the high-frequency words. Frequency by group interaction was statistically significant in the items analysis ($F(2, 59) = 5.71$, $p < 0.05$) and marginally significant in the subjects analysis ($F(1, 12) = 4.44$, $p = 0.057$). The interaction between word frequency and group is presented in Figure 4. Additional tests on simple effects revealed that word frequency effect is significant in the dyslexia group ($p < 0.05$) and not

significant in the control group ($p = 0.43$). The interaction reflects the fact that low frequency words lead to greater increase in total time duration only in the dyslexia group.

Figure 3: Average total time duration (in ms) as a function of word length in dyslexia and control groups. Error bars represent standard error of the mean.

Figure 4: Mean total time (in ms) as a function of word frequency in dyslexia and control groups. Error bars represent standard error of the mean.

Summary of the results for total time The comparison between dyslexia and control groups showed that dyslexic children had generally longer total time for viewing the target words than the controls. There was main effect of frequency. However, the frequency by group interaction and the additional analysis revealed that the increase in total time for low-frequency words is present only for the

dyslexic group. Long words receive longer total time durations both in the dyslexia and in the control groups.

The dyslexic children show word length and word frequency effects in eye-movements.

General Discussion

The overall gaze duration and total time for the target words were much longer than the reported by Hutzler & Wimmer (2004) and Hyona & Olson (1995). This could be explained by the age of the dyslexic children – in this study they were between second and fourth grade, while in the above-mentioned studies, the dyslexic children were about 7th grade (about 14 years old). As many dyslexic children tend to develop different strategies with age which help them overcome their reading problems, thus we reason that studying eye-movements of younger dyslexic children give us the possibility to study the specificity of their reading difficulties without the confounding effect of such strategies.

Another possible explanation for the results lies in the silent reading for comprehension task. The children were highly motivated to reply accurately, which can be seen by the very high number of correct answers (see Table 2). We argue that this task is more natural than reading aloud, which sometimes can be done without any comprehension.

Using sentences with embedded target words allowed better controlling for confounding factors and successfully varying word length and word frequency as independent factors.

The main effect of word length replicated most of the previous findings. The interaction between length and group (well-established in previous research) failed to reach significance probably due to the small number of participants. Word frequency, however, showed somewhat different pattern than former studies. Word frequency effects were very weak for Italian dyslexic readers (De Luca et al. 1999) and did not interact with the group factor in neither De Luca et al. (1999), nor Hyona & Olson (1995). This discrepancy once again can be explained by both the age of the participants and the task – the later, however, seems more probable, since frequency effects reflect not only lexical access but also some comprehension and integration processes that take important part in reading for comprehension unlike reading aloud for example. These results contradict previous findings that claim there is no frequency effects in dyslexic children in regular orthography, or that these effects are much weaker than the length effects. The explanation that is suggested is that the frequency effects stem from the irregular orthography. Our data show that this is not the case and that frequency effects are well manifested in the dyslexic population even in a language with regular orthography.

Conclusion

The results from the current study show that young dyslexic children have extremely slow, but otherwise normal reading patterns that are governed not only by word length but also

by frequency – an effect that usually marks good reading skills. The interaction between frequency and group implies that there is some higher-level processing impairment that inhibits the recognition of rare words or that the children simply do not have the same vocabulary range as the controls.

Acknowledgments

We would like to thank all participants in the current study. We also like to thank 151st School, Sofia, for their support during the study in granting us access to participants in the control group. And finally, we would like to thank Veronika Penkova, Kalina Seksenova, Stanislava Borisova, and Yoana Vergilova for their help in data collection.

Abstract

We show how *heuristic-driven theory projection* (HDTP, a method based on higher-order anti-unification) can be used to model analogical reasoning in mathematics. More precisely, HDTP provides the framework for a model of the inductive analogy-making process involved in establishing the fundamental concepts of arithmetic. This process is a crucial component for being able to generalise from the concrete experiences that humans have due to their embodied and embedded nature. Such generalisations are a cornerstone of the ability to create an abstract domain like arithmetic. In addition to generalisations, HDTP can also transfer concepts from one domain into another, which is, for example, needed to introduce the concept ZERO into arithmetic. The approach presented here is closely related to the theories of *Information Flow* and *Institutions*. The latter in particular provides a compelling way to integrate *concept blending* into the HDTP approach.

Keywords: mathematical cognition; mathematical reasoning; analogy; anti-unification; concept blending

Mathematical reasoning as a cognitive process

Although mathematics is usually presented in terms of axioms, concise proofs, theorems and so on, the actual cognitive process of mathematical reasoning is very different. For example, when a mathematician changes a definition this affects the proofs that use it, but such changes are not discussed in mathematical papers. Additionally, mathematics, at least partly, does not consist of discovering eternal, Platonic ideals but in creating mathematical concepts. For example, Lakatos's (1976) account of the history of Euler's conjecture illuminates how the concept POLYHEDRON can differ and how its definition depends on the current circumstances and needs of the mathematician. Put differently, if the Platonic ideal POLYHEDRON does exist, it is not clear how it can be identified by mathematical means – what cognitive processes mathematicians can use to find the correct definition. Thus, mathematical concepts are not necessarily the same as the ideals.

Lakoff and Núñez (2000) describe how our embodied, situated experience is the basis on which abstract mathematical concepts are developed by a process of metaphorical abstraction and transfer. In chapter 3, they describe how basic arithmetic is created from four everyday experiences, which are the source domains of the metaphors. In this way, arithmetic is grounded in situated cognition. To motivate that these four domains in particular are source domains, Lakoff and Núñez analyse linguistic expressions used in the target domain, arithmetic, which they trace back to these four domains. For example, we use the terms *add* and *take away* in arithmetic. Lakoff and Núñez argue that these terms were originally used for

talking about collections of objects, such as physically placing an object into a container, e.g. *adding an onion to the soup*, or physically removing a substance or an object from a container, e.g. *take a book out of the box*.

Analogical reasoning is a central component of the process transforming knowledge of this kind into mathematical concepts. For present purposes we assume that metaphor and analogy are essentially the same cognitive process (Gentner, Bowdle, Wolff, & Boronat, 2001), and we have demonstrated how structure mapping (Gentner, 1983; Gentner & Markman, 1997) – a basic method to compute analogical relations – can account for the overall cognitive process (Guhe, Pease, & Smaill, 2009).

In this paper, we describe a formal cognitive model of this process. This has a twofold motivation: firstly, we want to specify the cognitive processes that mathematicians use, to better understand how mathematical discovery works; secondly, we want to use the model to improve automated theorem provers by incorporating cognitive mechanisms. In Guhe, Smaill, and Pease (2009a, 2009b) we presented formal representations of the four grounding metaphors (the 4Gs) and suggested how *Information Flow* theory (Barwise & Seligman, 1997) may be used to model the analogies involved. The 4Gs are: (1) arithmetic is object collection, (2) arithmetic is object construction, (3) measuring stick and (4) arithmetic is motion along a path.

Here, we present a proof-of-concept of how performing anti-unification (Plotkin, 1970) on such representations can account for aspects of the analogical reasoning involved in the 4Gs. This inductive kind of reasoning provides us with a procedural version of the otherwise static *Information Flow* models and enables us to computationally determine the relationships between the domains (classifications in the case of *Information Flow*). More precisely, we will use *Heuristic-Driven Theory Projection* (HDTP; Schwering, Krumnack, Kühnberger, & Gust, 2009), a general framework for making analogies. HDTP provides us with the means to generalise over two of Lakoff and Núñez's domains to establish a basis for arithmetic as well as the means to generalise over one of the domains as source domain and arithmetic as the target domain to add concepts to arithmetic that are only present in one of the grounding domains. We will also outline how this conception of mathematical reasoning is linked to Goguen's (2006) notion of *concept blending* (which is based on notions by Gärdenfors, 2000 and Fauconnier & Turner, 2002), a further cognitive process for creating mathematical concepts.

Metaphors for arithmetic

Arithmetic is object collection

The arithmetic is object collection metaphor (Table 1) is based on the notion that the repeated manipulation of (small, countable, physical) collections of objects lets us notice certain regularities. For example, we can determine which one of two collections is bigger by aligning the objects in the two collections one-to-one, and the collection that has at least one unpaired object left over is the bigger collection. (Smaller and equal are, of course, determined correspondingly.) This corresponds to the (abstract) arithmetic notion GREATER.

By comparing collections of objects in this way we can also group such collections into groups of collections of equal size, i.e. where after the aligning procedure no object is left unpaired. Each of these groups corresponds to a number in arithmetic.

There are two things to note about this basic metaphor. Firstly, it does not produce a concept of ZERO, because the empty collection is a collection that does not exist physically. (Even calling one object a *collection with one object* is an abstraction of the term *collection*.) Lakoff and Núñez (2000, p. 64) propose that an *entity-creating metaphor* is required to create a concept that is not part of the basic metaphor (like ZERO). This corresponds well with the fact that, historically, ZERO was a rather late invention. Secondly, the subtraction operation requires that a smaller collection be taken from a bigger one, because physically, negative objects do not exist.¹

Table 1: Arithmetic is object collection metaphor (Lakoff & Núñez, 2000, p. 55)

object collection	arithmetic
collections of objects of the same size	numbers
size of collection	number
bigger	greater
smaller	less
smallest collection	the unit (one)
putting collections together	addition
taking a smaller collection from a larger collection	subtraction

Arithmetic is object construction

The arithmetic is object construction metaphor (Table 2) runs along the same lines, except that it is not based on collections of objects, but on objects that are constructed from smaller objects. In this way, fractions are added to arithmetic, although they are not part of the basic metaphor. Consider, for example, an object that is constructed out of seven smaller objects. If now a smaller object that consists of three of the seven overall objects is removed from the original object, the two resulting objects have a size of $\frac{3}{7}$ and $\frac{4}{7}$ of the original.

¹One is reminded of the old joke: If on one floor 5 people leave an elevator containing 3 people, 2 people have to enter the elevator on the next floor in order for it to be empty.

Table 2: Arithmetic is object construction metaphor (Lakoff & Núñez, 2000, pp. 65–66)

object construction	arithmetic
objects	numbers
smallest whole object	the unit (one)
size of object	size of number
bigger	greater
smaller	less
constructed object	result of arith. operation
whole object	a whole number
putting objects together to form larger objects	addition
taking smaller objects from larger objects to form other objects	subtraction

Arithmetic is motion along a path

The *motion along a path* metaphor (Table 3) adds concepts to arithmetic that we experience by moving along straight paths. Numbers are point locations on paths. Addition and subtraction correspond to a movements from point one point on the path to another point on the path. An important new concept that is added to arithmetic by this metaphor is ZERO, which is based on the concept of a path's origin and which provides a direction for the movements along paths, namely towards the origin or away from it.

Table 3: Arithmetic is motion along a path metaphor (Lakoff & Núñez, 2000, p. 72)

motion along a path	arithmetic
acts of moving along the path	arith. operations
a point location on the path	result of an operation; number
origin; beginning of the path	zero
unit location, a point location distinct from the origin	one
further from the origin than	greater
closer to the origin than	less
moving away from the origin a distance	addition
moving toward the origin a distance	subtraction

Heuristic-Driven Theory Projection

Overview

This section provides a short overview of the basic ideas of heuristic-driven theory projection (HDTTP), a formal framework to model analogical mapping and reasoning. A more detailed description can be found in Schwering et al. (2009).

HDTTP establishes analogies between two domains, the source and the target, by detecting common structures. In the mapping phase, source and target are compared for structural commonalities and a generalised description is created, which

subsumes the matching parts of both domains. In the transfer phase, unmatched knowledge in one domain can be mapped to the other to establish new hypotheses.

HDTP is a formal framework that computes analogical relations and inferences for domains represented in first-order logic. Both, source and target domain, are given by axiomatisations, i.e. finite sets of first-order formulae. The basic idea is to associate pairs of formulae from the domains in a systematic way. HDTP uses anti-unification (Plotkin, 1970) to identify common patterns in formulae. In anti-unification, two formulae are compared and the least general generalisation that subsumes both formulae is identified.

Figure 1 provides some examples of anti-unification of terms. Terms are generalised to an anti-instance where different constants or function symbols are replaced by a variable. In (i), first-order anti-unification is sufficient. However, the terms in (ii) differ in the function symbols, i.e. first-order anti-unification fails to detect structural commonalities. Here, higher-order anti-unification generalises function symbols to a variable and retains the structural commonality. It is even possible to generalise terms in which common parts are embedded structurally in a different way, as shown in (iii).² Substitutions accompanying the generalised terms are created, which can be used to reconstruct the original terms.

Figure 1: Anti-unification of terms

HDTP extends this classical anti-unification of terms to formulae and logical theories by iteratively picking pairs of formulae to be generalised from the domains. This process is driven by heuristics. Coherent mappings are preferred, i.e. mappings in which substitutions can be reused. The generalised theory together with its substitutions specifies the analogical relation between source and target. Additional information about the source domain, i.e. formulae with no correspondence in the target domain, can be transferred by replacing symbols using the established substitutions.

Modelling the arithmetical metaphors

HDTP provides two different ways in which Lakoff and Núñez's (2000) grounded domains (Object Collection, Object Construction etc.) can be related to the abstract domain of Arithmetic. Following Lakoff and Núñez, the grounded domains constitute the source, while Arithmetic is the target domain. To establish an analogical relation between Object Collection and Arithmetic, HDTP can construct a generalisation of these

²HDTP uses a restricted form of higher-order substitutions, that allows to expand terms by introducing arguments and nested structures as described in Krumnack, Schwering, Gust, and Kühnberger (2007).

domains:

In this model, both domains are already given. The analogy explains abstract concepts like numbers by linking them to familiar entities from the grounded domains. Thus, the generalisation provides a description of the commonalities of the grounded and the abstract domains.

However, from the cognitive perspective, Arithmetic does not initially exist – it has to be created by an act of abstraction as well. This idea can be modelled by analogically relating two grounded domains, e.g. Object Collection and Object Construction. Arithmetic then emerges as a generalisation of these domains.

In our view, a combination of both approaches is needed to model the cognitive bootstrapping process. By generalising over two grounded domains, an abstract domain is established, which serves as a 'proto-domain' of Arithmetic, i.e. a domain that already contains some arithmetical concepts. This is then refined subsequently, by relating it analogically to other grounded domains, removing peculiarities of the two original domains and/or adding new concepts by analogical transfer.

It should be noted that in pursuing this approach the results may vary depending on which grounded domains are chosen for generalisation and on the order in which other grounded domains are added for refinement. This is due to the heuristics that HDTP applies when building up the generalisation. The more similar the grounded domains are, the richer the generalisation will be, while dissimilar domains give coarser results. Nevertheless, we expect that this effect can be compensated by further mapping the initial generalisation to other domains. A detailed examination of this will be a focus of our future work.

Formalisation of domains

We demonstrate the feasibility of the outlined approach by applying it to simple formalisations of Lakoff and Núñez's

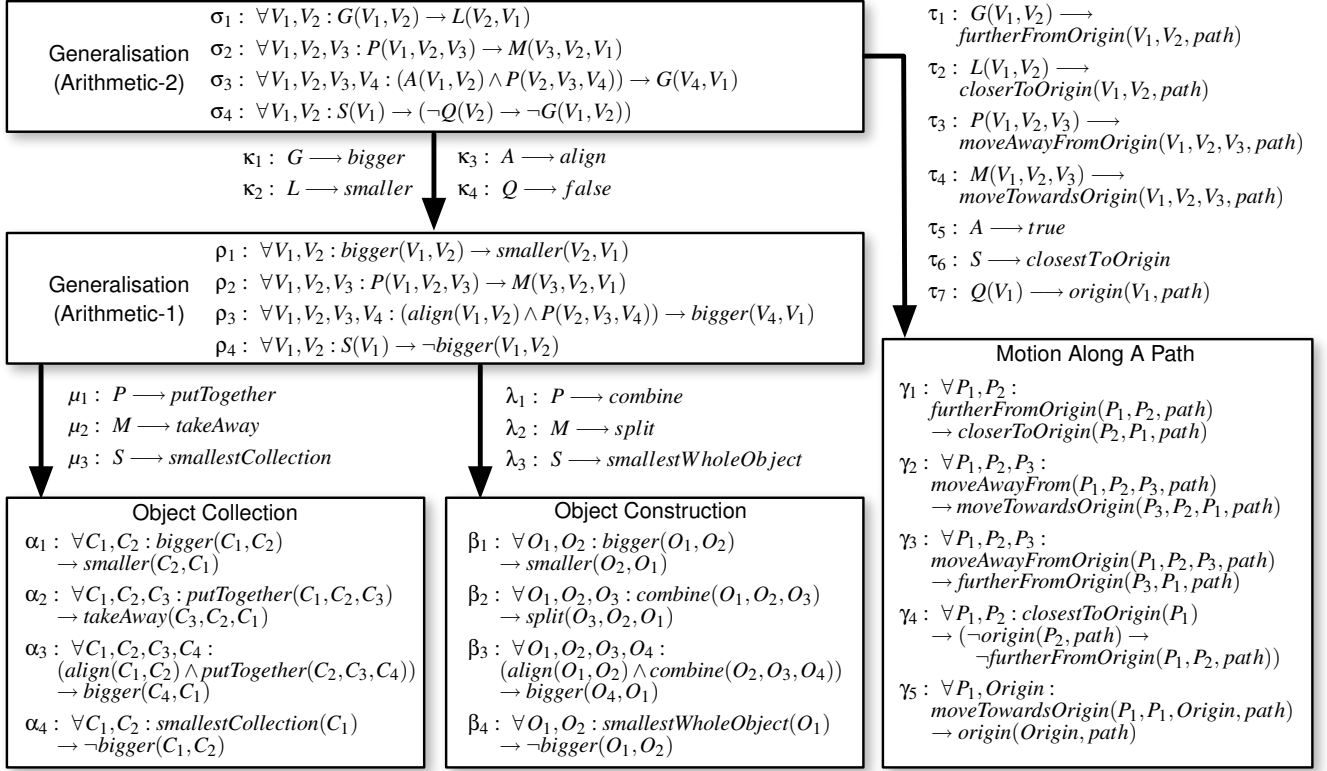

Figure 2: Developing Arithmetic from Object Collection, Object Construction and Motion Along a Path

grounding metaphors. The original descriptions of the domains are only given informally, but we tried to stay as closely to original as possible. One possible axiomatisation in HDTP of the Object Collection domain is given in Table 4. Such a formalisation specifies the vocabulary that is used in the form of *sorts*, *entities* and *predicates* and then provides *facts* and *laws* to describe the structure of the domain. For example, axiom α_3 states that if two collections C_1 and C_2 can be aligned, i.e. all their objects can be paired up, and C_4 is created by putting C_2 and C_3 together, then C_4 will be bigger than C_1 . Note that further formulae need to be added to get a complete axiomatisation, but such formulae can easily be introduced into the system as long as some elementary consistency constraints are satisfied. While adding more formulae to this formalisation might strengthen the support for a specific alignment, it does not necessarily introduce new mappings of concepts to other domains. An example for this is α_6 , which states the transitivity of *bigger*. This formula embeds *bigger* further in the structure of the domain but does not introduce new concepts. *putTogether*, *takeAway*, *bigger* and *smaller* are considered core concepts of the Object Collection domain. In what follows, we will restrict our axiomatisations to such simple versions in which just the cores of the domains are represented and connected to each other. Furthermore, we will omit technical details as well as the specification of sorts and signatures for a more concise presentation.

Generalising two domains

We tested various alternative formalisations, which all resulted in HDTP being able to establish appropriate analogies. Here we present axiomatisations of the grounded domains that are compact and consistent and that import integral parts of the domains. Furthermore, we demonstrate how the transfer of knowledge from one domain to another one works, because this is a hallmark of ‘interesting’ analogies.

In a first step, we generalise the domains of Object Collection and Object Construction. (We only use the basic version of the Object Construction domain here, which largely resembles Object Collection. This version is not sufficient to introduce the concept of fractions.) The axiomatisation of the two domains can be found in the two boxes in the bottom left of figure 2. The grounded domains are restricted to the operations that in arithmetic correspond to *greater*, *less*, *addition* and *subtraction*. The axioms α_i and β_i (for $i \in \{1, \dots, 4\}$) correspond to each other and are generalised in the obvious way by introducing individual variables and variables for operations. For example, the predicate *putTogether* of the Object Collection domain is identified with *combine* of Object Construction and generalised to a variable P . The substitutions μ_1 and λ_1 can be used to reconstruct the original expressions. Note that aligning corresponding clauses in formalisations is only done for the convenience of the reader; HDTP does not rely on such an ordering to find the best possible analogical mapping.

Refining the generalisation

The formulae computed above by generalising Object Collection and Object Construction serve as a first formalisation of elementary arithmetic (labelled Arithmetic-1 in figure 2). The variables introduced by anti-unification are regarded as entities and predicates of this new domain. Because the grounded domains chosen were very similar, and in particular because the grounded domains neither have the concept EMPTY COLLECTION nor EMPTY CONSTRUCTION, the system computes only a subtheory of arithmetic that lacks a neutral element with respect to the operation P (representing ADDITION). A second step of creating analogical mappings is needed to transfer the concept ZERO from a differently structured domain into our Arithmetic-1. This is achieved by the second generalisation between the formalisation of Motion Along a Path and Arithmetic-1 resulting in Arithmetic-2 depicted in figure 2.

The formalisation we chose for Motion Along a Path is different from the other domains in that the predicates take an extra argument, *path*, to indicate the path along which the motion occurs. As a consequence, higher-order anti-unification is applied which leads to the slightly more complex substitutions τ_1 to τ_7 and κ_1 to κ_4 . As before, these substitutions can be used to reconstruct the source and target domains from the generalisation. A further point to note is that γ_4 contains an additional condition in comparison to ρ_4 . This mismatch is handled by introducing a generalised predicate Q , which is mapped to *false* by κ_4 and therefore can be neglected in Arithmetic-1. However, this dummy predicate is used as a hint

for refinement. It indicates that an elaborated version of ρ_4 might be used to describe Arithmetic-1, namely

$$\rho'_4 : \forall V_1, V_2 : S(V_1) \rightarrow (\neg Q(V_2) \rightarrow \neg bigger(V_1, V_2))$$

which mainly states that if V_1 is the smallest number, then either V_2 is ZERO or V_1 is not bigger than V_2 . This new predicate Q can also be used for the transfer of additional formulae, e.g. γ_5 can be introduced into Arithmetic-1 resulting in

$$\rho_5 : \forall V_1, O : M(V_1, V_1, O) \rightarrow Q(O)$$

basically saying V_1 minus V_1 equals ZERO. Thereby, the basic ideas on ZERO are incorporated into Arithmetic-1 by refinement and transfer from the Motion Along a Path domain.

Goguen's notion of concept blending

Another important means to create new mathematical concepts is *concept blending*, in particular in the form presented by Goguen (2006). His figure 3, reproduced below, gives an overview. Each node in this graph corresponds to a *conceptual space* in the sense of Gärdenfors (2000), which, roughly speaking, is a subset of the system's knowledge.

The arrows preserve the inferential structure from space to space, and the diagram commutes. Goguen does not discuss examples from arithmetic, but how from the concepts HOUSE and BOAT the concepts HOUSEBOAT and BOATHOUSE are created by concept blending. The G space contains generic elements, such as PERSON or OBJECT; the I spaces represent more specific conceptual spaces, in his example I_1 represents that a HOUSE is on LAND and that a PERSON LIVES in it and I_2 that a PASSENGER RIDES in a BOAT and that the BOAT is on WATER. Concept blending takes these conceptual spaces and maps them into another space (the B space) in a way that, for example, that the BOAT is mapped onto the PERSON LIVING in a HOUSE, resulting in the concept of a house in which the boat 'lives' – a BOATHOUSE.

The arrows preserve the inferential structure from space to space, and the diagram commutes. Goguen does not discuss examples from arithmetic, but how from the concepts HOUSE and BOAT the concepts HOUSEBOAT and BOATHOUSE are created by concept blending. The G space contains generic elements, such as PERSON or OBJECT; the I spaces represent more specific conceptual spaces, in his example I_1 represents that a HOUSE is on LAND and that a PERSON LIVES in it and I_2 that a PASSENGER RIDES in a BOAT and that the BOAT is on WATER. Concept blending takes these conceptual spaces and maps them into another space (the B space) in a way that, for example, that the BOAT is mapped onto the PERSON LIVING in a HOUSE, resulting in the concept of a house in which the boat 'lives' – a BOATHOUSE.

Fauconnier and Turner (2002, pp. 242–245) discuss blends in arithmetic. Their presentation can be formulated in the form suggested by Goguen (they are a major influence on Goguen's conception in the first place), thus giving an extension to the work described in this paper. For example, Lakoff and Núñez's extended version of the motion along a path metaphor supports an analogue of the rational numbers. Taking this as I_2 and object collection as I_1 , a generalisation G can be found as above, which ignores the division operation of I_2 . Forming the blend B then allows the extra operation to be incorporated into a conceptualisation which respects the generalisation. The blend can be seen as an updated view of I_1 :

Once we have the blend, and reify it, we can adopt the view that the previous conception of number was 'miss-

ing' several numbers that were 'there' but not yet 'discovered'. (Fauconnier & Turner, 2002, p. 244)

Conclusions and future work

We examined to which extent the cognitive processes underlying mathematical thinking can be made formally precise and algorithmically operationalised. For this purpose we took the mathematical metaphors of Lakoff and Núñez (2000) and used the analogy engine HDTP to compute generalisations from the basic source domains of arithmetic based on higher-order anti-unification.

For this, we used formalisations similar to the ones in our earlier approaches using Information Flow theory and created a first generalisation that contained the fundamental concepts of arithmetic. We extended the first generalisation produced by HDTP by incorporating a transfer of concepts, which added new concepts to the 'growing' domain of arithmetic (in our case the idea of a neutral element). Thus, anti-unification cannot only serve to find abstractions of two source domains but also to transfer concepts.

We also briefly described, how Goguen's concept blending is a direct extension of the HDTP approach. A paper detailing the role of concept blending for arithmetic and a treatment within the HDTP framework is currently submitted.

The demonstrated generalisation examples are still quite simple. Enriching the domains to get more interesting transfer candidates is therefore the next step. This notion of 'interestingness' is central to a comprehensive treatment of mathematical discovery, because there is an unlimited number of possible theorems and theories, but only a fraction of these are deemed interesting and useful enough for mathematicians to consider. For automated theorem provers, this is a hard problem; one on which we expect the heuristic nature of the HDTP engine will shed more light.

The grounded domains as we used them here are already generalisations of concrete situations, e.g. for the object collection domain the person/system must already have abstracted over concrete instances of the acts of putting collections together and realised that this is a general law holding in this domain. HDTP should be suited to create these abstractions as well. A more pressing and fundamental case seems to be, however, to create an abstract, generalised number concept that extends beyond the subitising range, i.e. those cardinalities (ranging from one to three or four) for which humans don't need to count but immediately perceive the number of objects and which seem to be innate.

Some other directions in which to extend our work are: (1) How are the results influenced by the order of generalisation? (2) How can the object construction domain be extended such that fractions (rational numbers) can be introduced into the domain of arithmetic? (This is Lakoff and Núñez's fraction extension of the basic metaphor.) (3) How can our approach be extended to include Lakoff and Núñez's *linking metaphors*, which are used for creating more abstract mathematical concepts.

Abstract

Gaze and head orientation are considered to be the most important non-verbal cues people use to help manage the flow of conversation. However, if there are more than two participants, gaze and head orientation become problematic. People can only look at a single participant at a time. When speakers concurrently engage with more than one participant, they often make use of both head and hand orientation. We show two contrasts with existing findings. Firstly, people do not automatically look where the speaker is looking. Secondly, we demonstrate that hand movements are more important for the interaction than head movements. Specifically, changes in speaker hand orientation prompt quicker and more frequent responses from recipients than changes in head orientation.

Keywords: Dialogue; Non-verbal interaction; Multi-party; Gesture; Gaze; Simultaneous engagement;

Introduction

Consider the following situation: Ann, Bob and Claire are discussing a film that Bob and Claire went to see the previous night. Ann asks “Was it good”? Claire responds by saying “I really enjoyed it” while Bob simultaneously pantomimes a yawn. More than one person’s responses are potentially relevant to the interpretation of the answer. Moreover, the orientation of each participant to those responses is also relevant. For example, it matters whether Bob is looking at Ann or Claire as he pantomimes a yawn and it also matters whether Claire is aware that he is looking at her when he yawns.

Putting puzzles about mutual-knowledge to one side, this example highlights the intuition that in multi-party interactions participants often face the challenge of simultaneously monitoring the responses of several people to each contribution (see Goodwin (1979)). People can also design their contributions in ways that directly convey how different participants stand in different relationships to what is said. In a variation of the example above, Claire might look at Ann and say “I really enjoyed it but Bob was bored” while simultaneously pointing toward Bob as she says his name (see Healey and Battersby (2009), for documented examples of this kind).

In the literature on non-verbal communication, a significant body of evidence has accumulated that shows gestures have managerial functions within dialogue (see Bavelas,

Coates, and Johnson (2002) and Jokinen and Vanhasalo (2009)). However, eye gaze and, by association, head-orientation are normally singled out as the most important cues to the current orientation of participants in interaction (see, for example, Argyle (1975)). Kendon (1990) uses the term ‘Face Address System’ to make the claim that speakers use their gaze to identify the intended recipient of their utterance and Streeck (1993) observed that it is the speaker’s gaze that addressees follow, potentially to the speaker’s gesture. Langton, Watt, and Bruce (2000) reflect upon the claims about gaze and although they agree on its importance, suggest that gaze cues should be considered along with cues from the head orientation and hands.

Gullberg (2003) provides a quantitative estimate of the relative importance of a speaker’s face and hands by measuring the eye-gaze patterns of addressees. Her live condition consisted of two people one of which had watched a cartoon. This person then retold the cartoon in narrative form to an addressee who had been configured with eye tracking equipment. The gaze patterns of this addressee were recorded. Only 7% of the speaker’s gestures were fixated by the addressee. 96% of the time the addressee looked at the speaker’s face; only 0.5% of the time was spent on their gestures with the remaining time spent looking at other objects in the room. Whilst this data points to a marked difference in the relative importance of the head and the hands, the interactional situation is different to open multi-party conversation.

Coordinating Multi-Party Interactions

Although eye gaze is an effective cue to focus of attention in dyadic (two-person) interactions it has more limited value in multi-party interactions. We can only look at one person at a time and we can only monitor the gaze of one person at a time. As Loomis, Kelly, Pusch, Bailenson, and Beall (2008) have shown, direction of eye gaze is difficult to estimate in the physical arrangements typical of conversation. In small group conversations people are only able to judge another’s eye gaze direction with a maximum 4° retinal eccentricity whereas other people’s head orientation can be judged effectively up to a 90° retinal eccentricity. This leads to the pre-

diction that, in multi-party conversations, auxiliary cues such as head and hand orientation should therefore be much more important to the conduct of the interaction.

Healey and Battersby (2009) describe how in three-way task-oriented dialogues speakers frequently use combinations of head and hand orientation to enable simultaneous engagement with two other participants. These moments of simultaneous engagement occurred on average once every 25 seconds. However, it is unclear what the consequences of the events are for the other participants in the interaction. Specifically, do these head and hand movements have any demonstrable impact on the responses of the other participants?

This paper addresses the question of whether changes in a speaker's orientation reliably prompt changes in the behaviour of the other participants. It also compares the relative impact of head and hand movements on other participants.

Method

Materials

All data was gathered in the Augmented Human Interaction (AHI) lab at Queen Mary. This lab houses a Vicon optical motion capture system consisting of an array of 12 infra-red cameras which track reflective markers attached to the clothing of participants. Each participant wears an upper body motion capture suit and a baseball cap with reflective markers attached. The motion capture system records the precise 3D coordinates of each marker at a rate of 60 frames per second (see Battersby, Lavelle, Healey, and McCabe (2008) for more details). Video cameras are placed above and to either side of the participants and are time synchronised with the motion capture system. Audio is recorded on the video cameras. Motion capture data from each interaction is time synchronised with the video data. A custom piece of software reads the motion capture data and integrates it with hand-annotation data from ELAN.

Participants

Participants were recruited from undergraduate and masters courses at Queen Mary and either received pay or modules credits and pay for their time. 33 participants (19 female and 14 male) aged between 18 and 30 took part. Each group consisted of three people meaning that the data presented are from 11 triads.

Task Description

Six tuition tasks were developed that consisted of a description of either a short Java program or a description of a system of Government. They were designed to involve an abstract hierarchy with no direct visual analogue. All material was text based with no graphical descriptions.

Procedure

Each group completed three rounds, based on either three Java or three Government tasks. On the first round one member of the triad is randomly assigned to a 'learner' role and the other two participants are assigned 'instructor' roles. These roles are then rotated on subsequent rounds so that each participant is as a learner once and an instructor twice. The instructors are asked to collaborate to teach the learner the structure described in the task description. The learner is removed from the group to another room whilst the instructors are given the descriptions of the task for next round. Once the instructors signal that they understand the task, the descriptions are returned to the experimenter and the learner rejoins the group. All three participants are seated on pre-positioned stools in the AHI lab (see Fig. 1).

Figure 1: Three participants wearing upper body motion capture suits.

There was no time limit on the tuition stage and no restrictions on the interaction other than they were not allowed to use pens or paper. The participants notified the experimenter when they finished each round of tuition. To motivate the participants to adequately teach and learn the material a post completion test (comprising of a drag and drop arrangement of the classes for the computer program, or some multiple choice questions for the government material) was given after each round. Tasks were systematically rotated across groups and the order of the printed sheets of paper was randomised before each round.

Hand Coding of Target Events

All interactions were recorded on video, with cameras above and either side of the group, using synchronised video recording. ELAN was used to hand code these videos. The recordings were coded for all instances of simultaneous engagement in which a speaker who is making a gesture visibly changes the orientation of their hands or head with respect to the other participants. For example, by turning their hand from one participant to another or changing their head orientation. These changes were coded as:

- **Head Moves:** Here the head orientation changes but the gesture remains stationary
- **Hand Moves:** Here the gesture orientation changes, but the head orientation remains stationary
- **Both Move:** Here both the gesture and the head orientation shift

Motion Data Analysis

Taking the hand coded target events for the speaker as the starting point, the motion capture data was used to provide quantitative measures of recipients' responses to target events.

Assigning Recipient Role The motion data was used to provide an operational definition of recipient role. Recipients are either primary or secondary recipients. This role is judged by the head orientation of the speaker. We project a vector from the middle of the forehead for each speaker. The orientation of this vector is compared to a centre line between the two recipients. The primary recipient is defined as the recipient who is on the same side of the centre line as the speaker's current head orientation (see Figure 2).

Figure 2: Defining primary and secondary recipients

Indexing Head Orientation Responses It is impossible to be sure exactly which head movements correspond to changes of orientation by the recipients. Instead, we set a criterion for counting movements as changes of orientation based on a vector projected from each recipient's head as it was for the speaker. A change in orientation is thus defined as a shift of head orientation that crosses the centre line between the speaker and the other recipient (see Figure 3).

Indexing Nod Responses A second index of responses, 'nods', was also generated from the motion capture data. As for changes in head orientation it is impossible to be sure when a head movement really constitutes a nod or is simply a shift in position or unintentional motion of some kind. As for

Figure 3: Indexing head orientation responses

changes in head orientation we set a criterion level of movement of a single frontal head marker in the vertical axis (see Figure 4 for some sample movement). Only movement with a frequency of between 2Hz and 8Hz is used. This removes some of the effects of gross body sways (below 2Hz) and very minor body shakes or fluctuations in data from the cameras (above 8Hz). Movements with an amplitude greater than 5cm are removed as these could likely be a result of shifts in position. The resulting signal, which is smoothed using a window size equivalent to 0.5 seconds, is used to represent periods of head movement that approximate nodding.

Figure 4: Raw head movement motion capture data. An area of potential nodding is circled.

In order to analyse frequency of responses to each simultaneous engagement event by the speaker we create a 5 second window after the event and score, for each recipient, whether a head re-orientation and whether a head nod occurs in that window. In order to provide a measure of response latency we record the first change of head orientation or nod that occurs after the target event and before another target event occurs.

Baseline Response Rates In order to interpret the measures of responses to the target events, it is important to know what the baseline likelihood of a recipient nodding or changing orientation is. To provide this a control comparison sample was created by randomly selecting points where someone was speaking but not producing a target event. Recipient

responses after these control points were then analysed in exactly the same way as for the target events.

Results

The total time for all the dialogues was 2 hours and 54 minutes, each task took on average 5 minutes and 16 seconds. A total of 287 target, simultaneous engagement events involving a change in orientation of the speaker were identified.

Inter-rater Agreement

In order to check the reliability of the hand coding of event types by the 1st author, a random sample of 25 events taken from experimental and control data was independently coded for event type by a second coder. The inter-rater reliability was good with Kappa = 0.78, ($p < 0.001$). The number of each type of target event is shown in Table 1.

Table 1: Number of Changes in Speaker Orientation

Event Class	Count
Head Moves	170
Both Move	86
Hand Moves	31

Recipient Responses

In analysing responses to changes of speaker orientation we distinguish the task role of the recipients (learner or instructor) and their recipient status at the time of the event (primary or secondary). In addition we code whether each recipient is oriented toward the speaker or the other recipient at the time the simultaneous engagement event, i.e. the change in speaker orientation, begins. These judgements are made using the motion capture data.

Recipient Orientation

As Table 2 shows, at the point when the speaker initiates a change of orientation, the primary recipient is more likely to be looking at the speaker than the secondary recipient. The secondary recipient, by contrast, is equally likely to be looking at the other participants ($\chi^2 = 16.9$, $p < 0.001$).

Table 2: Initial Head Orientations

Recipient Role	Oriented To Speaker	Oriented To Other
Primary Recipient	68.0%	32.0%
Secondary Recipient	50.2%	49.8%

Response Frequency

In contrast to recipient orientation (and our preliminary findings (Healey & Battersby, 2009)), there was no difference between the response rates of the primary and secondary recipients. Both were equally likely to respond.

Combining the responses of the two recipients together we can compare the overall frequency of response to a target coordination event with the baseline response rate. For changes in head orientation the recipients' baseline response rate is 41.3% and their response rate to target events is 48.6%; a small but reliable difference ($\chi^2 = 5.75$, $p < 0.05$).

Table 3 illustrates the differences in response rate for each type of event.

Table 3: Response rates by type of event, measured by recipient reorientations

Event Class	Response Rate	Baseline Response Rate	Sig
Head Moves	43.1%	41.3%	Not Significant
Both Move	56.2%	41.3%	$\chi^2 = 10.26$, $p < 0.01$
Hand Moves	63.0%	41.3%	$\chi^2 = 8.14$, $p < 0.01$

For target events in which only the head changes orientation there is no significant increase in response rate (measured by a shift in recipient head orientation) relative to the baseline rate. However, for targets events that involve changes to both gesture and head orientation we see a significant difference of 14.9% between the baseline and the target event. Where only the gesture changes orientation there is a 21.7% increase in response rate.

A slightly different pattern is evident in the head nodding response measure. Combining target events, recipients respond 72.4% of the time compared to a background response rate of 66.0% ($\chi^2 = 5.08$, $p < 0.05$). The breakdown by type is shown in Table 4.

Table 4: Response rates by type of event, measured by recipient nodding

Event Class	Response Rate	Baseline Response Rate	Sig
Head Moves	70.0%	66.0%	Not Significant
Both Move	73.6%	66.0%	Not Significant
Hand Moves	87.0%	66.0%	$\chi^2 = 8.51$, $p < 0.01$

In order to provide a direct comparison of the recipient's relative sensitivity to changes in the speaker's head and hand orientation responses to 'Head Moves' events and 'Hand Moves' events can be compared. This shows a significant difference between the groups using the values for both head

re-orientations and head nods as a measure of response shown above ($\chi^2 = 6.43, p < 0.02$ and $\chi^2 = 5.75, p < 0.02$ respectively).

Response Latency

The time elapsed between a target event until the first response (nod or change of head orientation) for each recipient was analysed in a Mixed Model linear analysis with Recipients and Task as random factors and ‘Condition’ (Target Event vs. Baseline) and Task Role (Learner vs Instructor) as within subjects factors. This showed a reliable main effect of Condition ($F_{(1,1089)} = 14.88, p = 0.00$) but no main effect of Task Role ($F_{(1,1088)} = 1.29, p = 0.25$) and no Task Role \times Condition interaction ($F_{(1,1078)} = 0.39, p = 0.53$).

As Table 5 shows, recipients’ responses to target events were approximately 1 second faster than the baseline responses.

Table 5: Marginal Means for Recipient Response Times

Condition	Marginal Mean	Standard Error
Target Event	2.4 seconds	0.37
Baseline Event	3.4 seconds	0.35

Discussion

The results show two important contrasts with existing findings on non-verbal cues and the co-ordination of interaction. First, in the dialogues reported here people do not automatically look where the speaker is looking. In fact, in the cases where the speaker only changes their head orientation there is no reliable shift in recipient’s head-orientation. The second key finding is that changes of hand orientation are significantly more likely to invoke a response from the recipients than changes in head orientation; the opposite of what would be predicted on the basis of previous work.

The results also show that recipients are demonstrably responsive to the target events, but with a pattern of responses that is different to that typically described in the literature. This provides support for the claim that they are distinctive and significant interactional events. Although it is difficult to generalise beyond the particular task we have used, it seems likely that these moments of simultaneous engagement are a response to the demands of co-ordinating a conversation with multiple participants. As Healey and Battersby (2009) note, they are also distinguished by relying on physical co-presence in mutually shared space as a specific resource for interaction. For example, they cannot be deployed in point-to-point video communication.

Our analysis suggests that recipient role (primary or secondary) can manifest itself non-verbally. Whilst hand movements are more marked than head movements in initiating recipient responses, we see differing patterns of recipient head

orientation through the dialogue. The primary recipient is more likely to be looking at the speaker than they are to be looking at the secondary recipient before a simultaneous engagement event occurs. Secondary recipients do not share this pattern though, and are equally likely to be looking at either party. It is interesting that this distinction between roles is not found when measuring responses, perhaps suggesting that the target events unify the recipients’ behaviour.

The clear difference between our data and that of previous findings is the introduction of the third person. It would be intuitive, and logical, to understand the conflicting results with the statement that multi-party dialogue is simply different to dyadic dialogue. Whilst this is true, there is also the possibility that multi-party dialogue only allows us to see fully the underlying process that is present in *all* dialogue; dyadic interaction simply masks them.

Conclusion

We examined a corpus of multi-party dialogues comprising of video and motion capture data. Moments where the speaker simultaneously engaged both recipients were coded for. These events were broken down by changes in the speaker’s orientation of their head, their gesture or both and the significance of these changes for the recipients was examined. These changes in speaker orientation were shown to hold interactional significance. In contrast to existing findings in the literature, movements of the hands elicited a higher and faster response rate than movements of the head.

Tracking Lexical and Syntactic Alignment in Conversation

Abstract

As much empirical work attests, people have a reliable tendency to match their conversational partner's body movements, speech style, and patterns of language use – amongst other things. A specific version of this tendency, *Structural priming*, which occurs when prior exposure to a particular linguistic structure facilitates one's subsequent processing of the same structure, has gained widespread acceptance. Pickering and Garrod (2004) propose that *cross-person structural priming* is a basic mechanism of conversational coordination – part of an automatic, resource-free *alignment* mechanism that is the basis for all successful human interaction. We present evidence to the contrary from two analyses of a corpus of ordinary conversation. The first suggests that the level of structural (syntactic) matching is no different from chance, and the second that the observed statistical correlation between prime form and target form may be entirely associated with repetition of lexical form.

Keywords: structural priming; alignment

Introduction

The apparent tendency for speakers to repeat their own or others syntactic or structural choices in conversation – a phenomenon referred to as *structural* or *syntactic* alignment – has been a subject of particular scrutiny (see Pickering and Ferreira (2008) for an overview).

The evidence for such alignment in dialogue comes from two main sources: experimental studies of task-oriented dialogue (e.g. (Branigan, Pickering, & Cleland, 2000)), and corpus studies that track frequency of use of these same constructions in language use outside of the laboratory setting (e.g. (Gries, 2005)).

In the basic experimental set-up of Branigan and colleagues, there are two participants, one of whom is a confederate of the experimenter. The participants describe picture cards to each other, the critical items of which require the use of ditransitive verbs in their descriptions. In English, there are two syntactic structures which can be used; one a double object structure (“The thief giving the nurse the banana”), and the other using a preposition (“The thief giving the banana **to** the nurse”). The confederate uses a scripted description of the ditransitive prime sentences, thus manipulating which type naive subjects are exposed to. Participants are more likely to use the type of structure that they have just used or been exposed to. This has been found to hold across comprehension and production (Branigan, Pickering, Stewart, & McLean, 2000; Bock, Dell, Chang, & Onishi, 2007), from main clauses to rel-

ative clauses (Branigan, Pickering, McLean, & Stewart, 2006) and even across languages in bilingual speakers (Hartsuiker, Pickering, & Veltkamp, 2004). Different factors found to increase the *strength* of syntactic alignment include the distance between the prime and the target, participant role (Branigan, Pickering, McLean, & Cleland, 2007) and, importantly for the interactive alignment model (see below), reuse of the same or semantically related lexical items (Branigan, Pickering, & Cleland, 2000).

In a corpus study using the International Corpus of English (ICE-GB), Gries (2005) looked at the same syntactic alternation. His data show that there is a tendency to reuse the form of a ditransitive verb most recently encountered (double object or prepositional), in line with the experimental results. Similar results have been found to hold with different constructions such as particle placement of phrasal verbs (Gries, 2005), future markers (“will” versus “going to”) and comparatives (“cleverer” versus “more clever than”) (Szmrecsanyi, 2005).

Pickering and Garrod (2004) argue, in their *Interactive Alignment* model, that alignment is the basis for successful communication; “successful dialogue occurs when interlocutors construct similar situation models to each other” (Pickering & Garrod, 2006, p206). In order to do this, interlocutors *align* on situation models; however, as this alignment is not usually negotiated explicitly, it is hypothesised to arise automatically from local alignment, via resource-free *priming* mechanisms.¹ Alignment at local levels, including lexical (repetition of words) and the syntactic alignment discussed above, “percolates”, leading to alignment at other levels.

From priming to alignment?

There are three problems with using these studies to support the claim that cross-speaker structural priming is ubiquitous in conversation. First, automatic priming predicts an increase in matching of *all* structures across turns, but this claim has not been directly tested. For practical reasons, experimental studies have focussed on situations in which specific syntactic alternatives can be used to describe the same situation. Similarly, corpus studies have tended to track the frequency of use of spe-

¹Note that the observed effects are alignment effects; priming mechanisms are their hypothesised cause, leading to two distinct questions – does such alignment occur; and if it does, is it caused by priming?

cific constructions across participants and time, rather than addressing whether or not people tend to match one-another in general (e.g. Gries (2005)). One exception is Reitter, Moore, and Keller (2006), who examined general syntactic similarity, but results were unclear. Reitter et al. (2006), used two corpora, one task-specific (Map Task) and one more general (Switchboard), and saw a large difference: while *same*-person priming was found in both datasets, *cross*-person priming was found only in the task-specific dialogues.²

The second problem is that the data used in these studies is not adequately representative of ordinary dialogue. As Pickering and Garrod (2004, p187) say:

The interactive alignment model was primarily developed to account for tightly coupled processing of the sort that occurs in face-to-face spontaneous dyadic conversation between equals with short contributions. We propose that in such conversation, interlocutors are most likely to respond to each other's contributions in a way that is least affected by anything apart from the need to align.

However, in the experiments, the confederate is scripted, and the naive participants were told that if they didn't understand they "could say "Please repeat," but nothing else" (Branigan et al., 2007, p175). And while corpora can provide more spontaneous data, Gries (2005)'s corpus is biased towards written and spoken *monologue*, and a significant proportion of the dialogues it samples involve specialised institutional settings, e.g. legal cross-examinations and broadcast interviews.

The third problem is that these studies have not used a control condition. As a result the chance level of structural matching is unknown and effects such as conversational genre cannot be discounted (cf. Tannen (2007)).

In order to address two of these issues,³ we conducted an experiment which tested the degree of match of dative alternation structures in a corpus of naturally occurring dialogue data. We compared this measure to control conditions for the same genuine conversational data manipulated to create 'dialogues' from turns actually occurring in different conversations (see below).

Experiment 1

Method

The corpus used here is the Diachronic Corpus of Present-Day Spoken English (DCPSE). This consists of 885,436 words together with a full set of parse trees that have been hand-checked by linguists. It includes

²In fact, the opposite appeared to hold in the general corpus – participants seemed to *avoid* repeating each others' syntactic structure.

³The first issue we address in additional work; see e.g. Healey, Howes, and Purver (2010); Healey, Purver, and Howes (2010).

several distinct genres of dialogue. We consider the two-person portions of the three largest samples: Face-to-Face Formal (90,000 words), Face-to-Face Informal (403,000 words) and Telephone Conversations (47,000 words). This gives us 127 dialogues with an average of 45.24 turns per person (per dialogue), which ought to provide us with the data most likely to exhibit alignment phenomena (see above).

Creating control dialogues In order to discount the potential biasing effect of conversational structure (e.g. recurrent patterns of turn-taking, topic shifts, openings and closings) on syntactic similarity, a control condition that captures how similar two people's conversational turns would be by chance is needed. For each 'real' dialogue in each genre in the corpus, we therefore create two types of 'fake' control dialogue. For the first, the *random-speaker* control, one speaker's turns are kept and interleaved with the turns of another speaker from a different dialogue (matching dialogues by genre, matching by length as closely as possible, and discarding any 'unmatched' turns). This 'fake' dialogue thus maintains turn order for each speaker; but consists of the turns of two speakers who did not, in fact, interact. For the second 'fake' dialogue, the *random-sentence* control, a new dialogue of the same length is created by randomly choosing sentences, each time allowing a new choice of dialogue and speaker (but always matching dialogue genre). This 'fake' dialogue thus maintains neither turn order nor speaker identity (see table 1 for comparisons).

Table 1: Real and control dialogues comparison

GENUINE DIALOGUE:

A: Are you going to go to all of the phonology lectures
 B: I think I ought to do that
 A: Yes. I think you had. Yeah
 B: I mean I don't know how much I'll take in
 A: I think I'll go to most of them. But I won't go to all of pragmatics the day before

RANDOM-SPEAKER CONTROL DIALOGUE:

A: Are you going to go to all of the phonology lectures
 C: Well uh ask one of the stallholders down Chapel Street. They'll all know
 A: Yes. I think you had. Yeah
 C: Uhm I was down there the other day and I got some excellent salmon
 A: I think I'll go to most of them. But I won't go to all of pragmatics the day before

RANDOM-SENTENCE CONTROL DIALOGUE:

A: Are you going to go to all of the phonology lectures
 D: Uhm one of the few. Oh George was impossible
 E: Just normal water
 F: Yes. What do they call it
 G: Oh dear. It does not bode very well

Creating these control dialogues allows us to compare the syntactic similarity observed in the real data with the similarity that would be observed by chance. By choosing a suitable similarity metric, we can express the

average similarity observed between turns or between speakers; and examine the difference between the real and control corpora. Choosing a general syntactic similarity metric (which takes all observed structural rules into account) would allow us to compare with Reitter et al. (2006); see e.g. Healey, Purver, and Howes (2010). In this paper, we only consider the specific ditransitive alternation discussed above, allowing comparison with Branigan, Pickering, and Cleland (2000) and Gries (2005).

Metric and predictions Considering only a single syntactic phenomenon gives us essentially a binary metric: a target sentence scores 1 if it reuses the form of the most recent prime sentence, and 0 otherwise. More concretely, each sentence is given a score of 1 only if:

1. it uses one possible form of the phenomenon in question: a double-object or prepositional-object construction; and
2. the most recent prior sentence in the same dialogue which exhibits the same phenomenon also uses the same form.

and 0 otherwise. Summing sentence scores and normalising by the number of sentences gives us the score for each individual in a dialogue. These scores can then be compared between the real and control corpora.

We test three key predictions:

1. Priming: Sentences in real conversations should display reliably more turn-by-turn structural matching than would occur by chance.
2. Person: Structural matching should be observed both between sentences produced by the same participant, and between those produced by different participants.
3. Genre: Relatively restricted registers should promote a higher level of cross-speaker structural matching than less restrictive registers.

Results

Two different analyses were carried out: the first compares real levels of matching against the control dialogues as outlined above, and the second compares the level of (real) same-person matching against (real) other-person matching.

In order to test predictions on Priming (1) and Genre (3) the average turn-by-turn syntactic similarity scores for each dialogue participant⁴ in each Genre were analysed in a mixed analysis of variance with Dialogue Type (Real \times Control) as a within subjects factor and Genre (Face-to-Face Formal \times Face-to-Face Informal \times Telephone Conversations) as a between subjects factor.

⁴Shown as N in tables 2 and 3. As we were only looking at 2-person dialogues this equates to 127 dialogues overall.

For overall similarity (this measure includes both same-person and other-person matching), the analysis showed no reliable difference between the Real and Control (i.e. ‘fake’) dialogues (random-sentence control: $F_{(1,251)} = 1.067, p = 0.30$, random-speaker control: $F_{(1,251)} = 0.11, p = 0.92$),⁵ no significant main effect of Genre (random-sentence control: $F_{(2,251)} = 1.279, p = 0.28$, random-speaker control: $F_{(2,251)} = 1.881, p = 0.16$) and no interaction between Dialogue Type and Genre (random-sentence control: $F_{(2,251)} = 0.213, p = 0.81$, random-speaker control: $F_{(2,251)} = 0.809, p = 0.45$). The absolute levels of syntactic matching of the dative alternation were not reliably different from chance (see Table 2). There were also no significant results when comparing only cross-person similarity with its control condition.

Comparing same-person versus cross-person similarity using a mixed analysis of variance with Speaker (Same \times Other) as a within subjects factor and Genre as a between subjects factor showed a reliable difference between the Same and Other person ($F_{(1,251)} = 4.124, p = 0.043$), no significant main effect of Genre ($F_{(2,251)} = 1.058, p = 0.35$) and no interaction between Dialogue Type and Genre ($F_{(2,251)} = 0.499, p = 0.61$) (see Table 3). This means that there is reliably more matching to one’s own prior utterances than to another person’s.

Discussion

These results seem to show that, at least for the dative alternation construction, in contrast to hypothesis (1), sentences in the DCPSE do not show reliably more structural matching than would occur by chance. In regards to (2), the overall level of same-person matching was higher than that of other-person matching (in line with experimental findings that production-production priming is higher than comprehension-production). However due to the control conditions used, it is not possible to ascertain whether the same person matching on its own is reliably higher than chance (though recall that both other person matching and overall levels of matching were not). As for hypothesis (3), although it appears from tables 2 and 3 that there is greater matching in the more restricted registers as predicted, pairwise comparisons did not show any significant effects. This could be due to the relatively small values, and limited number of cases, and further work is necessary to see if this is a genuine effect.

As the observed power values were in some cases as low as 0.2, we cannot reject the null hypothesis outright. Power calculations suggest that we require four times more data in order to be able to do so, and to this end we are currently conducting analyses on the

⁵For completeness we report exact probabilities but throughout adopt a criterion probability level of < 0.05 for accepting or rejecting the null hypothesis.

Table 2: Mean Dative Alternation Similarities

Dialogue Type	N	Real Similarity	(s.d.)	Random- Sentence	(s.d.)	Random- Speaker	(s.d.)
Face-to-Face Formal	60	0.017	(0.016)	0.013	(0.016)	0.018	(0.019)
Face-to-Face Informal	94	0.013	(0.015)	0.012	(0.014)	0.014	(0.016)
Telephone Conversation	100	0.012	(0.025)	0.012	(0.018)	0.011	(0.022)
Overall Mean	254	0.014	(0.019)	0.012	(0.016)	0.014	(0.019)

Table 3: Mean Dative Alternation Similarities

Dialogue Type	N	Same Person	(s.d.)	Other Person	(s.d.)
Face-to-Face Formal	60	0.010	(0.014)	0.007	(0.010)
Face-to-Face Informal	94	0.008	(0.012)	0.005	(0.007)
Telephone Conversation	100	0.007	(0.012)	0.006	(0.019)
Overall Mean	254	0.008	(0.012)	0.006	(0.014)

British National Corpus (BNC), which includes 2884 2-person conversations (Healey, Purver, & Howes, 2010). Another alternative to increase power would be to treat each occurrence of either form of the dative alternation as a separate datapoint, as Gries (2005) did, rather than taking an overall value per person per conversation. Experiment 2 reports such an approach.

Experiment 2

These results suggest that there is little or no priming above chance for the dative alternation in ordinary dyadic conversation. *Prima facie*, this is inconsistent with the evidence from Branigan, Pickering, and Cleland’s experiments and also Gries’ corpus study on the same constructions.

Other than the power issues discussed above, these differences could be due to differences in the data used. Whilst our natural conversational data is obviously different from the task specific experimental data, it is also different to the corpus data used by Gries, in one important respect. Although the DCPSE corpus overlaps with the ICE-GB corpus used by Gries, the data in the DCPSE is all spoken, while the ICE-GB contains a mixture of written and spoken data.⁶ Additionally, our experiment 1 used only dyadic (two-person) dialogues, as this makes creation of the control corpora more straightforward.⁷

Method

A further study was therefore carried out, following Gries’ methodology but using the DCPSE, to attempt to replicate his positive results. We once again restricted the analysis to the three largest genres, but this time

⁶Note, however, that (Gries, 2005) did not find any significant effect of MEDIUM.

⁷Although one might expect that priming would be stronger in the canonical two-person case – see (Pickering & Garrod, 2004).

Table 4: Comparison of corpus data used

	Spoken	Written	Total prime/ target pairs
Gries (2005)	600,000	400,000	3003
This paper	540,000	N/A	1438

included all conversations in those genres (i.e. we did not restrict this to dyadic conversation as in experiment 1, but still discounted e.g. broadcast interviews, legal cross-examinations and spontaneous commentaries, which would also have been included in Gries’ data; see table 4). Following Gries, prime-target pairs in the DCPSE were coded for the variables shown in table 5, using the DCPSE’s ICECUP tool to detect particular forms based on fuzzy tree fragments (Nelson, Wallis, & Aarts, 2002).

Results

The general result, as for Gries, is the significant effect between C_{PRIME} and C_{TARGET} ($\chi^2_{(1)} = 10.573, p = 0.001$), as shown in table 6. We observe priming for both the ditransitive and prepositional dative forms: observed target frequencies of each are greater than expected frequencies when following a prime of the same form, and lower than expected when following a prime of the other form.

The variables in table 5 were entered into a General Linear Model (GLM) analysis with C_{TARGET} as the dependent variable and C_{PRIME}, V_{FORMID}, V_{LEMMAID}, S_{PSEAKERID} as independent variables and D_{ISTANCE} as a covariate. Like Gries (2005), we found a main effect of C_{PRIME} ($F_{(1,1425)} = 76.364, p = 0.000$) as expected given the general result above, and indicating that the form of the prime strongly predicts the constructional choice of the target, and an interaction effect of C_{PRIME}

Table 5: Variables

Variable	Description
CPRIME	the form of the prime (ditransitive v prepositional dative)
CTARGET	the form of the target (ditransitive v prepositional dative)
CID	yes if CPRIME and CTARGET are the same form, no otherwise
DISTANCE	the number of parsing units between prime and target
VFORMID	yes if the verb and its form were identical in prime and target, no otherwise
VLEMMAID	yes if the verb lemma was identical in prime and target, no otherwise
SPEAKERID	yes if the speaker of prime and target was the same person, no otherwise

\times VLEMMAID, ($F_{(1,1425)} = 28.969, p = 0.000$) indicating that when the verb lemma is identical across prime and target, the effect of priming is stronger. We did not find an effect of CPRIME \times SPEAKERID, as Gries did, however, this could be due to the different corpora used, as written material would inevitably only include cases where the producer of prime and target are the same (note also that the effect he found was a marginal one).

Following Gries, a second analysis using CID as a dependent variable was carried out. There was a significant main effect of CPRIME ($F_{(1,1425)} = 4.935, p = 0.026$), the direction of which suggests that there is more likely to be an identical target following a ditransitive prime than a prime in the form of the prepositional dative. There was also a significant main effect of VLEMMAID ($F_{(1,1425)} = 27.255, p = 0.000$), such that the target is more likely to have the same form as the prime if the verb lemma used is the same. Like Gries, we did not find an effect of distance when it was entered into the model linearly, but when transformed to a logarithmic scale, it had a significant effect on CID ($F_{(1,1425)} = 4.540, p = 0.033$). Adding GENRE to the model did not reveal any additional effects to those outlined above.

Table 6: Observed v expected frequencies

CPRIME:	CTARGET: Ditrans	CTARGET: Prep	Total
Ditrans	527 (497.1)	319 (348.9)	846
Prep	318 (347.9)	274 (244.1)	592
Total	845	593	1438

These results suggest that whilst there are genuine alignment effects being observed, due to the large effect

of VLEMMAID we cannot rule out the possibility that they are lexically specified, or collocational, rather than specifically syntactic or structural. To test this possibility, two post-hoc analyses were carried out. When the prime-target pairs which have an identical lemma are removed from the analysis, there is no longer any effect of CPRIME on CTARGET ($F_{(1,1211)} = 0.563, p = 0.45$), and there are also no other significant effects. See also table 7 ($\chi^2_{(1)} = 0.454, p = 0.50$). Conversely, looking just at those with an identical lemma we get a large effect of CPRIME on CTARGET ($F_{(1,1211)} = 171.358, p = 0.000$), as is obvious from table 8 ($\chi^2_{(1)} = 105.6, p = 0.000$). Note that these findings do not, in fact, contradict Gries (2005), as his major finding was that individual verbs differ in their sensitivity to priming effects, a finding that is supported by the evidence that the variation in our data can be accounted for by those cases in which the lemma is identical between prime and target.

Table 7: Observed v expected frequencies of prime-target pairs where LEMMAID = no

CPRIME:	CTARGET: Ditrans	CTARGET: Prep	Total
Ditrans	370 (375.8)	304 (298.2)	674
Prep	308 (302.2)	234 (239.8)	542
Total	678	538	1216

Table 8: Observed v expected frequencies of prime-target pairs where LEMMAID = yes

CPRIME:	CTARGET: Ditrans	CTARGET: Prep	Total
Ditrans	157 (129.4)	15 (42.6)	172
Prep	10 (37.6)	40 (12.4)	50
Total	167	55	222

Conclusions

The results show that, in ordinary dyadic conversation, there is no unequivocal evidence of syntactic priming effects for the specific constructions that have been the focus of previous experimental and corpus work. The results presented here show that individual people do tend to repeat the same structure. However, they are no more likely to converge on the same version of each structure with their conversational partners than would be expected by chance. In addition, the overall likelihood of a match in syntactic structure across turns appears to be accounted for by the repetition of specific words.

Our results seem to be inconsistent with previous findings, however, as already noted, there may be several reasons for this disparity. Firstly, laboratory based experiments on dialogue are always subject to concerns about

ecological validity and it's possible that the restricted, task-oriented, exchanges used in previous studies do not generalise well to the more open-ended dialogue samples in the corpus data. Note though, that the present results do replicate the strong effects of lexical choice on syntactic similarity reported by Branigan, Pickering, and Cleland (2000). Another point of contrast between the current study and previous work are the specific characteristics of the corpus we use. Our data only includes exchanges in ordinary dialogue (and is further restricted in experiment 1 to dyadic exchanges). We specifically exclude spoken monologue, institutionally specialised contexts such as tutorials and broadcast interviews and one-sided interactional activities such as story-telling. Note however, that in doing so we focus on just those cases where Pickering and Garrod (2004) predict that priming should be strongest.

Our data are also compatible with studies on *lexical alignment* – reuse of previously encountered *words*. Despite well documented experimental evidence of lexical alignment (Brennan & Clark, 1996), there are also questions as to how this scales up to genuine conversation – a study of relative lexical overlap in conditions allowing or prohibiting verbal feedback (Hadelich, Branigan, Pickering, & Crocker, 2004) found that in the conditions which were more akin to genuine dialogue (where verbal feedback was permitted), there was less relative lexical overlap.

Additionally, our experiment 2 is in fact an extension of Gries' (2005) work, and completely compatible with it, though it does suggest a shift of focus. While a statistical correlation between prime form and target form is observable, this may be almost entirely associated with repetition of lexical form, rather than reuse of syntactic structure *per se*.

While there is insufficient data in the DCPSE corpus to definitively prove that structural priming effects are absent in ordinary conversation, these results indicate that the strength and ubiquity of structural priming (see e.g. Pickering and Ferreira (2008)) may have been overstated.

Abstract

All human languages have restrictions on sound sequences, called *phonotactic constraints*. Knowledge of phonotactic constraints is typically tested using pseudoword rating tasks, e.g., an English speaker might be asked to rate acceptability or wordlikeness of the phonotactically illegal /bnɪk/ and the phonotactically legal /bɪk/. We introduce a new method of testing knowledge of phonotactic constraints. Instead of asking subjects to rate pseudowords, we ask them to assign pseudowords to pictures of novel objects. The set of available pseudowords is larger than the set of pictures and includes both legal and illegal pseudowords. We find legal pseudowords to be less likely to be left unassigned to pictures than illegal pseudowords. Thus, the listeners show knowledge of the phonotactics of English. We suggest that the present method has important advantages over rating tasks: it is a more direct measurement of the influence of phonotactics on the lexicon, and it allows the experimenter to detect influences of sound symbolism and lexical analogy and separate them from the influence of phonotactics.

Keywords: phonology; phonotactics; sound symbolism; analogy; acceptability

Introduction

The grammars of all languages contain restrictions on possible sound sequences, called *phonotactic constraints*. For instance, despite /bnɪk/ and /bɪk/ not being actual English words, /bɪk/ obeys the phonotactic constraints of English but /bnɪk/ does not because there are no word-initial stop+nasal sequences in English. Native English speakers would also rate /bnɪk/ as being less acceptable than /bɪk/, showing that they have knowledge of the phonotactic constraints of their language (Chomsky & Halle 1965).

The phonotactic constraints are thought to place restrictions on the way the lexicon of the language can develop in the future, such that newly coined or adopted words are likely to also obey the phonotactics of the language. If a word does not obey the phonotactics of a language into which it is borrowed, it often changes to fit the phonotactics. One way this change can happen is through misperception (Ohala 1981). Berent et al. (2007), Dupoux et al. (1999), and Pitt (1998) have documented that phonotactically illegal sequences are often perceived as similar legal sequences, e.g., English listeners often perceive

natural productions of /bnɪk/ by speakers of Russian, for whom the /bn/ cluster is phonotactically legal, as having a vowel between /b/ and /n/. Thus a word like /bnɪk/ is likely to be misperceived by English speakers as /bənɪk/ and borrowed into English as /bənɪk/.

An additional, and much more controversial, way in which phonotactic constraints can influence the development of a language is by militating against the adoption or retention of phonotactically illegal words. Thus, phonotactically illegal words may be less likely to be borrowed and retained in the language than phonotactically legal words. An intriguing piece of evidence for this influence of phonotactics is provided by Berg (1998:230-233) who examines the probability of Old English words surviving into Modern English depending on the phonotactics of the initial cluster in Modern English. He finds that 803/968 (83%) words containing a phonotactically legal cluster (/kr/, or /sn/) have survived, compared to 555/774 (72%) for words containing now illegal clusters (/kn/, /gn/, and /wr/, $\chi^2(1)=31.1$, $p<.001$). He argues that “a word may pass out of the system because of phonological problems” (Berg 1998:231), suggesting that phonotactic constraints may not only force illegal words to change but also force illegal words out. A plausible mechanism for this effect is suggested by Martin (2007), who provides simulation data from neural networks showing that, as long as sublexical-to-lexical feedback is assumed, words that are phonotactically suboptimal are less likely to be selected for production than more well-formed competitors.

Knowledge of phonotactics is typically tested using rating tasks (for recent representative examples, see Bailey & Hahn 2001, Coleman & Pierrehumbert 1997, Frisch et al. 2000, in press, Shademan 2005, Treiman et al. 2000), involving a metalinguistic judgment of ‘acceptability’, ‘grammaticality’, ‘goodness’, ‘wordlikeness’ etc. However, judgment tasks offer at best an indirect way to gauge the hypothesized effect of phonotactics on lexical selection. One goal of the present paper is to develop a more direct method for examining the potential influence of knowledge

of phonotactics on lexical choice experimentally (Berg 1998, Martin 2007).

Phonotactic constraints are not the only influence on lexical selection. Two other potential factors are sound symbolism (e.g., Sapir 1929, Ultan 1978 vs. Diffloth 1994) and lexical analogy (e.g., Bailey & Hahn 2001, Shademan 2005). A word containing a consonant cluster that is never observed in English may nonetheless be selected (and receive high ratings in a judgment task) if it is sufficiently phonologically similar to an existing English word. In addition, words that contain sounds that iconically represent some aspects of their referents may be especially likely to enter the lexicon. In the present study, we focus on size symbolism, where high vowels like [i] symbolize small creatures while low vowels like [a] symbolize large ones (Sapir 1929, Ultan 1978).

Methods

40 native English speakers were recruited from the Psychology/Linguistics human subjects pool and participated for course credit. All reported being native English speakers. Each subject was presented with a Microsoft Powerpoint file containing instruction slides followed by experimental slides.

The instructions asked the subject to imagine oneself in the distant future, arriving on an unknown planet (called Terra Enigmatica) and discovering the remains of an Earth colony that was established by speakers of both English and Wilkipaengo (the language name was invented, so as to avoid the influence of knowledge regarding non-English phonotactics). The rest of the story, shown in (3), explained the importance of matching names to creatures and stressed that the lists ‘inadvertently’ included non-English names that should not be assigned to creatures.

- (3) It appears that the colony was established by speakers of both English and Wilkipaengo. Before disappearing, the colonists recorded an archive of messages.

Listening to the English, you notice some unfamiliar words. The words appear to be names for creatures common to Terra Enigmatica. According to the recordings, some creatures are benign while others are extremely dangerous and may be responsible for wiping out the entire colony!

Now you need to match the creatures you’ve encountered to the names given to them by the English-speaking colonists.

You are not interested in the Wilkipaengo names that seem to have somehow crept into your lists.

The backstory was designed to avoid the speakers treating the nonsense words as loanwords from another language,

since languages often have more tolerance of phonotactic violations in borrowings than in the native vocabulary (e.g., McCauley 1968, Pierrehumbert 2006, Schutze 2005). We also wanted to avoid asking speakers to ‘name’ the creatures believing that such an instruction would unleash the subjects’ creativity and perhaps lead them to choose the strangest-sounding words to match the strangeness of the novel creatures (although see Martin 2007 for corpus data showing that even names of characters of role-playing games produced (largely) by English speakers tend to obey the phonotactics of English). Thus, the backstory is designed to suggest to the speakers that the words to be assigned to creatures should be ordinary English words that speakers of English would be using in speech. In Schutze’s (2005) terms, we are after the “dictionary scenario” where the word is assumed to be unknown to the subject but to be a regular English word that could be found in a big enough dictionary of the right variety of the language. An important goal for future work is to determine the extent to which subjects’ behavior in the task is influenced by instructions.

The experimental slides, which followed the instruction slides, are exemplified by Figure 1.

Figure 1: An experimental slide containing draggable and playable sound files and creature animations.

When a subject came to an experimental slide, s/he clicked on ‘Play animations’, which played all creature animations simultaneously. The animations were made using Electronic Arts’ Spore™ and featured movement and animal sounds. After playing the animations, the subject would double click on the sound files of pseudowords on the left and drag the desired sound files onto the creatures they name using the computer mouse. This procedure avoids presenting subjects with orthography (see Clopper & Pisoni 2007 for a related free classification paradigm for acoustic stimuli). The subjects could listen to the sound files as much as they wanted to and could also replay creature animations if desired. They were instructed to make sure that they listened to all the words on a slide before proceeding to the next one.

There were six experimental slides, each containing six animated creatures and twelve sound files of pseudowords. Six of the pseudowords on each slide began with a consonant cluster that is phonotactically illegal in English

while six began with either a single consonant or a legal consonant cluster. Consonant cluster legality was fully crossed with vowel identity such that half of the words with legal clusters contained one vowel, and half another vowel. The vowels contained in words differed across slides, with two slides featuring [i] and [a], two featuring [u] and [æ], and two featuring [ou] and [eɪ]. The order in which vowel pairs were presented was counterbalanced: half the subjects were exposed to each of the slide sequences in (4).

(4) $i/a \rightarrow u/\text{æ} \rightarrow eɪ/ou \rightarrow u/\text{æ} \rightarrow i/a \rightarrow eɪ/ou$
 $eɪ/ou \rightarrow u/\text{æ} \rightarrow i/a \rightarrow eɪ/ou \rightarrow u/\text{æ} \rightarrow i/a$

There were two matched sets of pseudowords such that for each phonotactically illegal pseudoword there was a legal pseudoword that differed from the illegal counterpart only in the onset. All pseudowords had a (C)CVC structure. The legal and illegal counterparts were never presented to the same subject. Rather, they appeared in the same positions on the same slides but for different subjects. This was done to avoid presenting minimal pairs differing only in the (legality of) the onset and thus perhaps drawing abnormal degree of attention to phonotactics. Half of the subjects assigned to each vowel sequence order received each pseudoword set. The mappings between legal and illegal clusters are shown in (5) with numbers of word pairs exemplifying a mapping in parentheses.

(5) bd/bl (9), bn/bl (3), bn/br (1), bw/kw (1), bz/sp (3), bz/sk (1), bz/bl (1), dg/dw (3), dg/dr (5), fn/fl (3), fn/fr (1), gd/gl (3), gd/gr (3), kp/kw (6), ks/sk (3), lb/bl (4), lb/w (3), sr/fl (1), nd/dr (1), nd/pl (1), pn/pl (2), pt/pr (2), pw/pl (2), sr/sw (3), sr/tr (3), tk/tw (2), tn/tw (2)

Results and Discussion

The effect of phonotactic legality is shown in Figure 2. Phonotactically legal words were significantly more likely to be assigned to creatures than the corresponding phonotactically illegal words (by items, $t(71)=8.05$, $p<1/10^{11}$; by subjects, $t(39)=5.57$, $p<1/10^5$).

The legal/illegal pairs in which the illegal pseudoword was (unexpectedly) used less often than the legal one are drVC/dgVC ($n=4$), dwæf/dgæf, fneɪk/freɪk, kwum/kpum, and twɪs/tnɪs.

Figure 2: The effect of phonotactic legality on a word's frequency of being assigned to any creature (maximum possible difference = 20; pairs with no difference in popularity between legal and illegal words ($n=4$) not shown).

It is important to distinguish between underuse of legal clusters, which could then be argued to have been perceived as illegal by the subjects, and overuse of illegal clusters. Figures 3 and 4 show that in the present case we are dealing primarily with underuse of the legal clusters [dr] and [Cw] (all words beginning with these clusters are shown as darkened blocks in Figure 3) rather than overuse of the corresponding illegal words.

Figure 3: The distribution of popularities of legal words with the legal words beginning with /dr/ or /Cw/ shown darkened

Figure 4: The distribution of popularities of illegal words. Darkened blocks represent illegal words that are minimal pairs for the legal words in Figure 3 (differing in onset cluster)

The underuse of /dr/ onsets may be due to the speaker's strong affrication of /d/ in these clusters, possibly resulting in the cluster being perceived as the phonotactically illegal cluster /dʒr/ by listeners who produce less affrication of /d/ in /dr/ (cf. Ohala 1981). The lack of preference for Cw over illegal clusters may be due to the legal clusters having a very low type frequency in English, which makes these clusters, though legal, marginal (for effects of type frequency on acceptability ratings, see Bailey & Hahn 2001, Coleman & Pierrehumbert 1997, Frisch et al. 2000, in press, Treiman et al. 2000).

Finally, the strong preference for /fneik/ over /freik/ (the former is used by 8 more subjects than the latter and is the most popular illegal word in the present study: the clear outlier in Figure 4) is likely to be an effect of lexical analogy to the word 'snake'. To assess possible effects of lexical analogy and sound symbolism, we tested whether some words might be preferentially paired with certain creatures by cross-tabulating sound files and the creatures they are paired with and looking for cells with values that are significantly higher than expected under the null hypothesis. We tested three different null hypotheses: 1) subjects are randomly pairing words with creatures within a slide (which produces a 1/12 change of assigning a word to a creature), 2) subjects randomly pair phonotactically legal words with creatures within a slide, and 3) for each slide, subjects choose a set of words to assign to creatures, and then randomly match the words within the set with creatures on the slide. With any of the three null hypotheses, there were three words that were paired with particular pictures more often than would be expected if the null hypothesis were true. The words were /fneik/, /blun/, and /blut/ (assigned to their preferred creatures 43%, 42%, and 37% of the time they were assigned to *any* creatures; $p=.0005$, $p=.0003$, $p=.0006$ respectively according to the binomial test with null hypothesis 3; the Bonferroni-adjusted critical p value is $.05/72=.0007$). The preferred creature-word

pairings are shown in Figure 5. The likely explanation for these preferred assignments is lexical analogy to the words 'snake' [sneik], 'bloom' [blum], and 'blue' [blu] respectively: the creatures in question are the only snake-like, bloom-like, and blue creatures on their slides.

Figure 5: Non-random word-creature pairings.

Schutze (2005) objects that the "dictionary scenario" (exemplified by our backstory) is inappropriate for use in nonce probe tests of grammatical knowledge because of being particularly subject to effects of lexical analogy. The present findings confirm the presence of lexical analogy effects in the scenario. However, we do not believe this invalidates the use of the "dictionary scenario" in the present paradigm even if one believes in grammar as a cognitive module that is separate from the lexicon (Schutze 2005). Unlike in rating tasks, lexical analogy effects can be detected (and factored out) in the present task by searching for non-random picture-word co-occurrences. In order to examine possible differences between rating tasks and word-picture matching, we have conducted a wordlikeness rating task where "1" meant "not at all like English words" and "5" meant "very much like typical English words". The same pseudowords were used but no pictures were presented. We observed that [fneik] received the highest ratings out of all phonotactically illegal pseudowords. Given the results of the picture-matching task, we would argue that this result is due to lexical analogy to the word /sneik/. We would not have been able to infer this based on the rating data alone, leaving the effect unexplained.

The use of pictures in the present experiment may discourage the use of phonological analogy to existing words that are phonologically similar to the experimental pseudowords but not semantically similar to any of the pictures of the slide, e.g., the pseudoword /glog/ could be

rated highly wordlike on analogy with /grog/ or /log/ but the existence of /grog/ and /log/ might not lead the subjects to assign /glog/ to a creature because /grog/ and /log/ are not names for animals (or features of animals). This hypothesis remains to be tested.

Both rating tasks and the present paradigm are limited by the fact that phonotactically illegal sound sequences are often misperceived as phonetically similar legal sequences (Berent et al. 2007, Dupoux et al. 1999, Pitt 1998). Furthermore, as Berent et al. (2007) show, phonotactically illegal sequences are not equal in how likely they are to be misperceived. In particular, typologically marked onsets with falling sonority like /lg/ are more likely to be misperceived by English speakers than onsets with flat sonority like /bd/, which are less likely to be misperceived than clusters with rising sonority like [bn] or [pw]. While we might have expected that English listeners would judge words beginning with /lg/ to be particularly unnatural and would be unlikely to assign them to objects, the finding that such clusters are most likely to be misperceived as legal sound sequences (e.g., /læg/) throws a wrench into this expectation. Thus, it is a priori unclear whether illegal clusters strongly violating sonority sequencing should be assigned to creatures more often or less often than illegal clusters that do not violate sonority sequencing (as much).

The breakdown of onsets by sonority is shown in Figure 6. Assuming that [s] is extrasyllabic, the optimality of the sonority sequence in the onset rises from left to right.

Figure 6: Frequency of being assigned to any creature as a function of sonority (C="obstruent"). This figure does not include /dr/ clusters.

There is a statistically significant difference between C{z;s;n} and C{l;r} ($W=349$, $p=.00001$). However, there is only a trend for {n;C}C clusters to be used less than C{z;s;n} clusters ($W=137$, $p=.034$, which would not reach $p_{critical}$ with the Bonferroni correction), and /lb/ clusters are assigned to creatures numerically more often than clusters that should be more acceptable according to sonority

sequencing. The effect of sonority on acceptability of illegal clusters is thus ambiguous and requires perception data for interpretation.

In future work, it appears important to supplement data from picture-word matching with data on how the stimuli are perceived by the same subjects. We expect that subjects who often misperceive an illegal cluster as a related legal sequence should be more likely to assign words containing the cluster to pictures of novel objects. Nonetheless, the presence of the effect of phonotactic legality in the present data as well as in rating studies of phonotactics (Bailey & Hahn 2001, Coleman & Pierrehumbert 1997, Frisch et al. 2000, in press, Treiman et al. 2000) shows that the perceptual mechanism of repairing phonotactically illegal sequences does not succeed in repairing the sequence 100% of the time, leaving room for speakers to choose between borrowing or retaining phonotactically legal and illegal pseudowords, thus repairing phonotactic violations on the lexical level (Berg 1998). The imperfection of perceptual repair is what allows rating studies as well as the present method to assess knowledge of phonotactics.

Following the completion of all experimental slides, we asked subjects to review all creature animations and rate the creatures' size and cuteness. Subjective and objective (height, width, area, thickness) measures of the size of a creature, the height of F0 in the creatures' vocalizations, and ratings of creature cuteness did not correlate with the presence or absence of any segments or segment features in the words subjects assigned to the creature (all $p>.1$). Thus, size sound symbolism did not seem to play an important role in this experiment. We hypothesized that this may be due to the presence of many dimensions other than size in the visual stimuli. Figure 7 presents the results of an ongoing follow-up study. Thus far 7 subjects have been asked to name ten (5 big, 5 small) monochromatic 2-dimensional creature pictures using 20 words (half phonotactically illegal, half containing [i] or [u], half containing [a] or [au]). As Figure 7 shows, words with high vowels tended to be assigned to small creatures while words with low vowels tended to be assigned to large creatures ($\chi^2(1)=8.21$, $p=.004$). Thus, size sound symbolism effects may be observed in the present task when size is a salient dimension of variation for the presented objects.

Figure 7: An effect of size sound symbolism with simpler creatures.

Conclusion

Asking subjects to match a set of pseudowords with a smaller set of novel objects provides a new way to assess the subjects' knowledge of phonotactics. This method provides important advantages over the traditional method of assessing knowledge of phonotactics (acceptability or wordlikeness ratings). First, the proposed method is a much more direct way of assessing the influence of phonotactics on lexical selection (found to operate in historical data by Berg 1998 and Martin 2007). Second, the method facilitates separating out and investigating the effects of lexical analogy and may restrict the occurrence of lexical analogy to words that are semantically related to the pictures, although analogies based on such words may be more likely in the present task than in rating. The method may also be profitably used to examine the effect of sound symbolism and how it competes with phonotactics.

This task does share some shortcomings with rating tasks. First, it requires somewhat accurate perception of illegal clusters. Given the evidence that phonotactically illegal sequences are often misperceived as similar legal sequences (e.g., Berent et al. 2007, Dupoux et al. 1999, Pitt 1998), the present task should ideally be followed by an assessment of the same subjects' perception of the stimuli. This might be accomplished using discrimination, transcription or identification tasks, or testing for the presence/absence of identity priming between the similar-sounding legal and illegal sound sequences (Berent et al. 2007, Dupoux et al. 1999, Pitt 1998). Second, the present instructions still require subjects to explicitly judge whether or not the presented words could be words of English. Future work should investigate the importance of this instruction.

Finally, the principal disadvantage of the present task compared to rating is that subjects perform the task much more slowly than a comparable rating task (the subjects in the word-picture matching version of the present task took on average 15 minutes to go through the 72 words, while a rating task using the same words took only 3 minutes). A possible way to reduce the time demands is to present fewer words and pictures per slide, thus simplifying the decision. The principal potential disadvantage of such a move is a reduction in the possibilities for detecting effects of lexical analogy due to an even more restricted set of referents to be assigned to the words.

Abstract

Using interactive computer-based methods of instruction, this research examined the contribution of whole (3D) anatomical knowledge to learning sectional anatomy. Participants either learned sectional anatomy alone or learned whole anatomy prior to learning sectional anatomy. Sectional anatomy was explored either with perceptually continuous navigation or discretely, as in the use of an anatomical atlas. Learning occurred over repeated cycles of study, test, and feedback, and continued to a high performance criterion. After learning, transfer of knowledge to interpreting biomedical images and long-term retention were tested. Whole anatomy was learned quickly and transferred well to the learning of sectional anatomy: initial accuracy was higher, learning of sectional anatomy was completed more rapidly, and there was less error over the entire course of learning. Knowledge of whole anatomy benefited the long-term retention of sectional anatomy at 2-3 weeks. Learners demonstrated high levels of transfer to the interpretation of biomedical images.

Keywords: learning; transfer; computer; anatomy.

Introduction

In medicine and many areas of science, anatomy education serves as a vital foundation for high level knowledge and skill. Unfortunately, anatomy is challenging to learn. Large volumes of material must be learned in relatively short periods of time. Anatomical structures often have irregular and indistinct shapes. They have little variation in color and texture, and they are related to each other in complex three-dimensional arrangements. Moreover, a comprehensive education in anatomy extends to include a thorough knowledge of sectional anatomy, which is necessary for diagnostic imaging, microscopy, and dissection.

Sectional anatomy is particularly challenging to learn. A spatial transformation occurs when a two-dimensional section is taken from a three-dimensional object. The two and three-dimensional structures may look very different from each other. In addition, multiple mappings are possible between these representations of anatomy. One-to-many mappings occur because anatomy can be sectioned at different depths and orientations, resulting in significant variation in the presentation of structures across a series of sections. Many-to-one mappings occur because differently shaped structures can appear similar in a sectional image.

The challenges in learning sectional anatomy might be reduced by facilitating cognitive organization of the mass of information in the sections (consider Bower, Clark, Lesgold,

& Winzenz, 1969). Given that anatomical sections are derived from whole anatomy, helping students develop a thorough understanding of the shapes and relationships of whole structures prior to learning sectional anatomy would seem an ideal way to help students organize the information in the sections. The benefit of organization for learning and memory has been established for verbal materials, but it is not clear what effect organization has in domains where spatial reasoning is required.

Knowledge of whole anatomy may also serve as a mental model that supports reasoning about sectional anatomy. Reasoning has been found to play a large role in the successful interpretation of histological sections viewed under the microscope (e.g., Pani, Chariker, & Fell, 2005).

A second approach to helping students organize information in sectional anatomy may be in the presentation of sectional anatomy itself. Serial presentation of the sections would be expected at a minimum, but additional support may be found by providing smooth, seamless navigation through the sections. Work in *anorthoscopic perception* and *kinetic completion* suggests that with this approach, learners may see the series of sections as a unified whole. On the other hand, continuous presentation of sectional anatomy can be considered a form of animation, and there has been mixed success in using animation in instruction (e.g., Hegarty, 2005; Tversky, Morrison, & Betrancourt, 2002).

In the current study, we explored both approaches to organizing sectional anatomy. Half of the participants learned whole anatomy before learning sectional anatomy (*transfer* groups), while the other half learned only sectional anatomy (*sections alone* groups). Within each of these groups, half of the participants learned sectional anatomy using a continuous presentation, and half learned with a discrete presentation -- analogous to turning the pages of an anatomical atlas.

Participants learned neuroanatomy in interactive computer-based environments. This approach holds potential for helping learners build rich mental representations of anatomy. For example, a computer-based model of 3D anatomy can be rotated to allow exploration of anatomy from any angle. It can be virtually dissected, restored to its original state, and then dissected again.

The instructional programs were designed to promote efficient learning through a method that we call *adaptive exploration*. With graphical models and exploratory tools

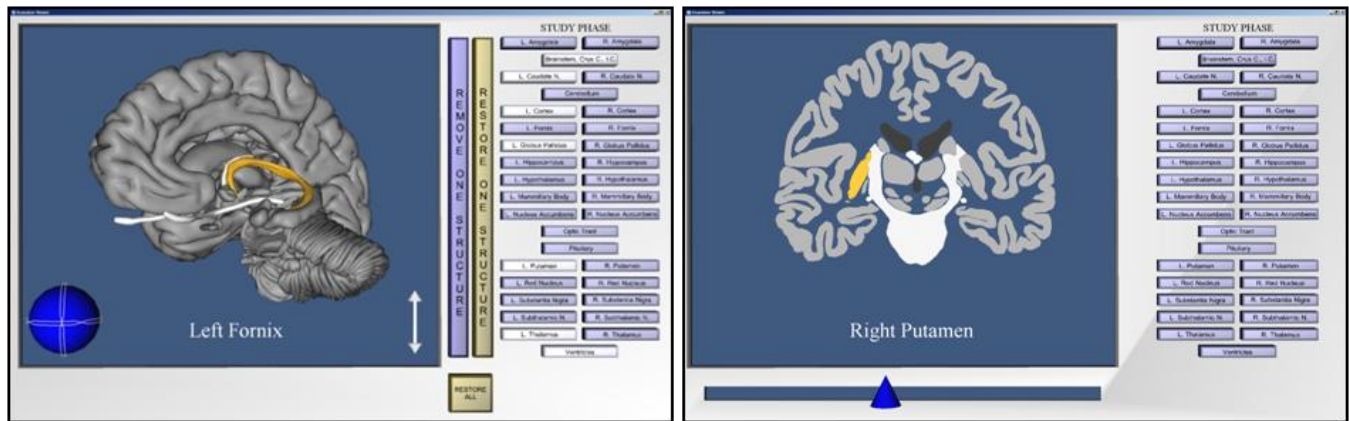

Figure 1: Screenshots of the anatomical model and the interface in the study phase of the whole anatomy learning program (left) and the sectional anatomy learning program (right).

available, learning was measured over multiple trials of study, test, and feedback until a high performance criterion was reached. In testing and feedback, participants learned the nature of the test to be mastered and were continually updated on progress in learning. This information allowed learners to adaptively adjust exploration of anatomy during study. Additionally, this approach to learning conforms to what appears to be best practices in regard to optimizing long-term retention through repeated testing (e.g., Karpicke & Roediger, 2008).

All participants learned 19 neuroanatomical structures across three standard views of anatomy: coronal, sagittal, and axial. After learning was completed, we measured the degree to which participants could transfer anatomical knowledge to interpreting biomedical images. Retention of anatomical knowledge was measured 2-3 weeks after learning was completed.

Method

Participants

Seventy-two undergraduate students at the University of Louisville were recruited for the study through advertisements placed around campus. All were at least 18 years of age. Only those respondents who reported minimal knowledge of neuroanatomy were enrolled. Participants were paid \$8.00 per hour for their participation.

Each participant was administered the Space Relations subtest of the Differential Aptitude Tests, a test of spatial ability, prior to beginning the study (DAT-SR; Bennett, Seashore, & Wesman, 1989). The mean and the distribution of scores were balanced across the four learning groups.

Materials

A three-dimensional (3D) computer graphical model of the human brain was created for this research (see Figure 1). Digital images of neuroanatomical cryosections in the Visible Human project (Vers. 2.0) of the National Library of Medicine were used as source material for the model (Ratui, Hillen, Glaser, & Jenkins, 2003). The brain model is

composed of 19 structures, including the cerebral cortex, ventricles, cerebellum, brainstem, amygdala, caudate nucleus, fornix, globus pallidus, hypothalamus, hippocampus, mammillary bodies, nucleus accumbens, optic tract, pituitary, putamen, red nucleus, substantia nigra, subthalamic nucleus, and thalamus. The structures were colored in dark gray (ventricles), medium gray, and white to approximate the basic appearance of light and dark structures in typical biomedical images of the brain.

Three relatively dense sets of serial sections were created from the brain model. There were 60 coronal sections, 50 sagittal sections, and 46 axial sections. All sections were taken at equal intervals.

MRI images were used to test transfer of knowledge. The images were made available from the SPL-PNL Brain Atlas (Kikinis et al., 1996). The images are typical gray scale T1 images of structures in the head and neck. The images were slightly brightened and contrast enhanced and presented at a screen resolution of 895 x 895 pixels. Visible Human images also were used to test transfer. These images were from the Visible Human 2.0 dataset. The images were high resolution color images of structures in the head and neck.

Computer programs for learning neuroanatomy were created using the C++ programming language and the Open Inventor library for interactive graphics. There was a common format for all of the learning programs. The differences between the programs were modifications related to the type of anatomy presented and the different presentations of sectional anatomy.

In all of the learning programs, a participant completed two learning trials -- one block of trials -- before a single run of the program terminated. Participants were presented with the same form and view of anatomy (e.g., sectional anatomy, coronal view) throughout the two trials in a block.

Each learning trial was composed of three phases: study, test, and feedback. Throughout each phase, tools were available that functioned specifically for either whole or sectional anatomy. In the study phase, participants had three minutes to freely explore the brain. On selecting a structure, its name appeared on the screen. In the test phase, the

participant's task was to identify the anatomical structures in the model. Testing was self-paced. In the feedback phase, the participant saw the same orientation of the brain, and used the same tools and procedures, as in the study phase. In addition, structures were color coded to provide participants with information about their performance on the test.

In the study and feedback phases for whole anatomy learning, a rotation tool allowed participants to smoothly rotate the model 360 degrees forward and backward or right and left. A zoom tool allowed participants to move the model closer or further from view. Buttons were available that allowed participants to remove or restore structures.

In the test phase of a trial, model rotation was constrained to a total range of 90 degrees of motion -- 45 degrees in any direction from the initial viewpoint. This ensured that a participant's performance on the test was specific to the viewpoint being learned in that trial.

Two programs were created for learning sectional anatomy, one for the continuous and one for the discrete form of navigation. In the study phase of a trial, both programs presented a set of anatomical sections in serial order in a single viewing plane. There was a slider at the bottom of the screen, and the two learning programs differed in the way the slider functioned. In the continuous program, moving the slider resulted in continuous movement back and forth through the series of sections. A section of the brain was always visible, and the transition between sections comprised a type of animation. In addition, a highlighted structure remained highlighted in each section in which it appeared.

In the discrete presentation program, movement between sections was perceptually discontinuous. When participants moved the slider, the brain became invisible. The number of the corresponding section in the series appeared prominently at the bottom of the viewing area. On stopping at a numbered section, a 0.75 second delay occurred before the appropriate section of the brain appeared. When participants moved to a new section, highlighting was removed.

The test phase of a learning trial was the same in the two programs. Participants were given a series of test sections, presented one at a time. In each section, one or more structures were indicated with a red arrow, and the participant's task was to correctly label those structures. Although all 19 structures were tested in each trial, the section of a structure that was tested varied across trials.

During the feedback phase of the trial, participants used the slider to find each of the test sections in the series. A message reading "Test Section" appeared prominently on the screen when a test section was accessed by the slider. The tested structures in each test section were identified with the same red arrows that appeared in the test.

Three computer programs were created to test transfer of knowledge to the interpretation of biomedical images. In the first test, Uncued Recognition, participants were presented with a set of 9 images, one at a time, and asked to identify all of the structures they thought they recognized in each image. Participants identified structures by indicating the

location of a structure with the mouse (leaving a red dot on the image) and then selecting the name of the structure from a list on the interface. The images alternated through coronal, sagittal, and axial views, in that order.

The remaining two test programs provided cues to the presence of structures in the images. In the Submit Structure test, the name of a single structure was presented at the bottom of each image, and participants selected the appropriate structure in the image. In the Submit Name test, a single structure was designated by a red arrow in each image, and participants selected its name from a list on the interface. Each test was comprised of three subtests, one for each view of anatomy.

A sectional anatomy test and a whole anatomy test were created for testing long-term retention. For participants who had only seen sectional anatomy, the test of whole anatomy was a test of transfer rather than retention. These tests were the same as tests given during learning and were created for all three views of anatomy.

Apparatus

Participants sat individually at computer workstations with large high resolution LCD screens (24 inch, 1200 x 1952 pixels). Participants were tested alone in small quiet rooms with the doors closed.

Design and Procedure

The core experimental design was a 2 X 2 between-groups factorial: anatomy course (transfer vs. sections alone) by sectional anatomy presentation (continuous vs. discrete).

Prior to beginning any of the learning or testing programs in the study, participants were trained on all aspects of the task using instructional software developed for this purpose.

During the learning portion of the study, performance in identifying 19 neuroanatomical structures was measured over multiple blocks of trials. Percent correct was calculated for each trial, and mean percent correct was calculated for each block of two trials. Participants continued learning anatomy until they reached a minimum of 89.5 percent accuracy (17 of 19 structures) in each of three consecutive learning blocks—all three views of anatomy. Across blocks of learning trials and throughout testing, the order in which view was presented was standardized at coronal, followed by sagittal, and then axial.

Immediately after learning was completed, participants were given the three tests of transfer to biomedical images in the order Uncued Recognition, Submit Structure, and Submit Name. For each test, participants were tested with each image type (MRI and Visible Human) in all three views of anatomy. The two image types were counterbalanced across participants.

Two to three weeks after learning was completed, participants were given the test of long-term retention for sectional anatomy followed by the test of long-term retention/transfer for whole anatomy. Tests were given for all three views of anatomy.

Results

Learning

Learning Trajectories Multilevel modeling was used for statistical analysis of performance in learning (Raudenbush & Bryk, 2002). Binomial models were appropriate for these data. Variables tested for inclusion in the multilevel model included learning block, anatomy course (AC), sectional anatomy presentation (SAP), and spatial ability (DAT-SR). Spatial ability was a significant factor in each of the models of learning but will not be discussed in this paper. Details of model parameters are available from the authors.

To establish the relative efficiency of learning whole anatomy and sectional anatomy, the transfer group's performance in whole anatomy was compared to the sections alone group's performance in sectional anatomy. Participants learning whole anatomy had substantially higher performance in the first block of trials and learned at a faster rate than participants learning sectional anatomy (see Figure 2). Mean percent correct identification in block one was 54 percent for whole anatomy and 36 percent for sectional anatomy, $t(69) = 5.780$, $p < .001$. Both groups improved in performance over successive blocks, $t(68) = 15.746$, $p < .001$; however, the increase in performance was much greater for participants learning whole anatomy: AC, $t(68) = 7.359$, $p < .001$.

There were no effects on the efficiency of learning sectional anatomy due to the type of sectional anatomy presentation in any of the analyses of learning. This variable was not retained in the multilevel models and will not be discussed further in the presentation of results on learning.

In a second analysis, transfer of learning from whole to sectional anatomy was measured by comparing performance

in sectional anatomy for the transfer and sections alone groups. Participants in the transfer groups performed significantly better in the first block of sectional anatomy learning than participants in the sections alone groups (see Figure 2). Mean percent correct identification was 73 percent in the transfer groups and 36 percent in the sections alone groups, $t(69) = 13.522$, $p < .001$. Although both groups improved over time, the transfer groups continued their learning at a slower rate than the sections alone groups: AC, $t(70) = -3.321$, $p = .002$.

In a third analysis, differences between conditions were further explored by comparing performance in sectional anatomy for the transfer and sections alone groups after relating performance to the total time spent learning neuroanatomy. For the transfer groups, learning blocks were numbered to reflect the time participants spent learning both whole and sectional anatomy. Nearly two thirds of the participants in the Transfer groups (21 of 36) completed whole anatomy learning in 4 blocks and transferred to sectional anatomy in block 5. Therefore, performance in sectional anatomy learning was compared beginning at block 5. Modeled performance in Block 5 was 71 percent for the Transfer groups and 81 percent for the Sections alone groups, AC, $t(69) = -3.030$, $p = .004$. The 10 percent difference is equivalent to 2 of the 19 structures on the test.

Learning Time to Achieve Criterion Performance In each learning trial, time was constrained to 3 minutes for study and 3 minutes for feedback. Therefore, we considered the number of blocks required to reach the performance criterion as one measure of learning efficiency. An ANCOVA was performed to compare the number of blocks of trials required to complete learning for whole and

Figure 2: A comparison of performance in whole anatomy and sectional anatomy (left) and a comparison of performance in sectional anatomy beginning at block 1 (right).

Figure 3: Sectional anatomy retention.

sectional anatomy. Spatial ability was correlated with the number of blocks required ($r = -.236$, $p = .046$) and was entered as a covariate, $F(1,67) = 7.785$, $p = .007$. Participants learned whole anatomy in significantly fewer blocks ($M = 5.2$) than participants learned sectional anatomy ($M = 10.7$), $F(1, 67) = 57.555$, $p < .001$.

A second ANCOVA compared the transfer and the sections alone groups on the number of trial blocks required to reach criterion in sectional anatomy learning. Again, spatial ability was correlated with the number of blocks to reach criterion ($r = -.298$, $p = .011$) and was included as a covariate, $F(1,67) = 7.678$, $p = .007$. Participants in the transfer groups completed sectional anatomy in 2.5 fewer blocks ($M = 8.2$) than participants in the sections alone groups ($M = 10.7$), $F(1, 67) = 7.282$, $p = .009$.

A third ANCOVA was performed to look for differences between the groups in the number of blocks of trials necessary to complete all learning in neuroanatomy. Spatial ability was correlated with the number of blocks to reach criterion ($r = -.344$, $p = .003$) and was included as a covariate, $F(1,67) = 10.129$, $p = .002$. Participants in the transfer groups completed whole anatomy and sectional anatomy in 2.7 more blocks than participants in the sections alone groups completed sectional anatomy (transfer, $M = 13.4$; sections alone, $M = 10.7$), $F(1, 67) = 6.021$, $p = .017$.

Total Error in Learning Neuroanatomy Over the entire course of learning, participants in the transfer groups made fewer errors ($M = 77$) in learning neuroanatomy than participants in the sections alone groups ($M = 100$), $F(1, 67) = 3.870$, $p = .053$. This occurred even though the transfer groups were required to complete two presentations of anatomy and took 2.7 more blocks to do so. Spatial ability was a significant covariate in the analysis of total error, $F(1, 67) = 13.995$, $p < .001$.

Testing

Long-Term Retention and Transfer MANCOVA was used to analyze retention of sectional anatomy and retention/transfer of whole anatomy. DAT-SR was included as a covariate.

Retention of sectional anatomy remained high two to three weeks after learning, with several participants reaching 100% accuracy in the first test (see Figure 3). There was an interaction of AC with view, Wilks' Lambda (Λ) = .898, $F(2, 63) = 3.570$, $p = .034$. The transfer groups were more accurate than the sections alone groups for retention of the sagittal view of sectional anatomy (transfer $M = 87.8$, sections alone $M = 83.1$), $t(57) = -2.675$, $p = .03$ (Bonferroni). No differences between the groups occurred for retention of the coronal and axial views.

In the analysis of retention/transfer for whole anatomy, participants in the transfer groups were more accurate than participants in the sections alone groups in identifying whole anatomy, $F(1, 64) = 15.306$, $p < .001$. Participants in the transfer groups tested at 97% mean accuracy in identifying whole brain structures. Although participants in the sections alone groups had never seen whole anatomy, they reached an overall mean accuracy of 89.5%. This meets the numerical criterion used for successful learning. Given this high rate of transfer, it is important to consider that there was a relatively substantial effort required to achieve this performance. All tests in this experiment were self-paced. In an analysis of test duration, participants in the sections alone groups took substantially more time than the transfer groups to complete the three tests for whole anatomy ($M = 14.5$ minutes vs. 8.8 minutes, a difference of nearly 6 minutes), $F(1, 61) = 54.331$, $p < .001$. This

Figure 4: Transfer to MRI and Visible Human images for the discrete and the continuous sectional anatomy presentation groups.

suggests that participants who had received sectional learning alone were not recalling a representation of whole anatomy but were inferring it.

Transfer to Biomedical Images In scoring Uncued Recognition and Submit Structure, correct answers were decided ahead of time, and images were created with the structure boundaries drawn on them. During scoring, the experimenters were blind to the participants' identities and experimental conditions. MANOVA was used to analyze performance on each test.

Transfer performance was quite high, particularly for the two cued tests (Submit Structure and Submit Name; see Figure 4). Within each test, performance varied widely among individuals, with some participants performing extremely well. In Submit Structure and Submit Name, the best performing participants were above 90% accuracy.

There were no differences in transfer due to learning group. Performance was higher for Visible Human than for MRI images in all three tests: Uncued Recognition, $VH M = 47\%$, $MRI M = 40\%$, $\Lambda = .440$, $F(1, 65) = 82.659$, $p < .001$; Submit Structure, $VH M = 72\%$, $MRI M = 58\%$, $\Lambda = .704$, $F(1, 64) = 26.913$, $p < .001$; Submit Name, $VH M = 80\%$, $MRI M = 64\%$, $\Lambda = .378$, $F(1, 64) = 105.282$, $p < .001$.

In two of the three transfer tests, Uncued Recognition and Submit Name, there was a main effect of sectional anatomy presentation: Uncued Recognition (continuous $M = 41.7$, discrete $M = 44.9$), $F(1, 65) = 3.962$, $p = .051$; Submit Name (continuous $M = 70.1$, discrete $M = 73.4$), $F(1, 64) = 4.835$, $p = .032$. Participants who learned with a discrete presentation were more accurate in identifying structures than participants who learned with a continuous presentation.

Discussion

Knowledge of whole anatomy served as an effective basis for learning sectional anatomy. Whole anatomy was learned quickly—in half of the time of sectional anatomy. Knowledge of whole anatomy transferred well to learning sectional anatomy. Accuracy in block 1 of sectional anatomy was twice as high for the transfer groups, and learning of sectional anatomy was completed more quickly. There was less error over the entire course of learning for participants learning both representations of anatomy.

Knowledge of whole anatomy benefited long term retention of sectional anatomy. Because the participants who learned whole anatomy required *fewer* trials with sectional anatomy, this advantage for retention is inconsistent with the well-known test effect. In the test effect, a *greater* number of tests of knowledge during learning leads to an advantage for long-term retention. However, tests administered during learning and at retention are identical to each other. For the present research, such a test effect would show better long-term retention for the *sections alone* groups.

On the other hand, the groups that learned both whole and sectional anatomy did require more total trials to learn.

Thus, the improvement in long-term retention is potentially due to a type of test effect, one that we have not seen described elsewhere. In this case, additional testing of whole anatomy is contributing to the long-term retention of sectional anatomy, a further instance of transfer of learning.

The transfer of knowledge to the interpretation of biomedical images served as a gold-standard test of the present methods of computer-based learning of neuroanatomy. The high levels of transfer obtained, along with the high levels of long-term retention, strongly encourage the use of these methods in neuroanatomy instruction.

Abstract

We present a sketch of a computational account of the relationship between certain aspects of introspection with aspects of third-person ascription of mental states (mindreading). The theory we propose is developed in large part as a reaction to what we perceive to be a lack of precision in the literature and a lack of experimental techniques to properly inform the debate on the relationship between 1st and 3rd-person ascription. We first discuss the set of phenomenology associated with self-ascriptions and other-ascriptions before briefly mentioning patterns of deficits associated with each. We sketch the very beginnings of a theory of mindreading in both the 1st and 3rd person within a computational cognitive architecture having mental simulation as one of its core operations. The theory we develop provides computationally-grounded explanations that are compatible with both clinical data and the phenomenology of 1st-person attribution.

Keywords: Mental Simulation; Cognitive Architecture; Metacognition; Mindreading; Philosophy of Mind.

Introspection and Mindreading

The ability to predict and explain behavior, both self- and other-generated, is a defining feature of human intelligence and a crucial phenomenon to be accounted for at the process-level; especially for those of us interested in computational theories of cognitive architecture. One of the major constituents of this ability takes the form of being able to ascribe mental states in service of behavior prediction and/or explanation. We will refer to mental state ascription more colloquially as “mindreading.” Typically, mindreading is mentioned as being related to predicting and explaining the behavior of others, but what of our ability to report on our own mental lives? This ability is generally termed introspection, and one important scientific task will be to clarify its relationship (or lack thereof) to mindreading.

After presenting some of the generally agreed-upon phenomenological features of introspection, we briefly summarize the theoretical options for the mindreading-introspection relationship and some of their immediate entailments. Finally, we present our own account of their relationship in terms of a computational cognitive architecture capable of both 1st and 3rd-person ascription via mental simulation.

Introspection: Phenomenology

Characterizing the nature of introspection has been one of the most active areas of epistemology and the philosophy of psychology. This being the case, many distinctions have been made in the process, as definitions of what it is to introspect become ever-more specialized. While some of these distinctions have arisen from a priori philosophical analysis, the advent of novel experimental procedures and the further development of neuroscience have added a substantial amount of data on introspection that is providing constraints on what our theories of self-ascription look like.

Even with its many distinctions, there seem to be a few phenomenological features that all parties agree to be related to, if not constitutive of introspection (Schwitzgebel 2010). While there is a minority who believe that either we have no mental states like beliefs to introspect or that self-attributions are only unconscious, automatic processes of self-interpretation (Carruthers 2009); the majority of others agree that humans have a window on their mental lives. Most philosophical work in the area has been dedicated to clarifying the role, function, and features of introspection.

Following the discussion in (Schwitzgebel 2010), what mostly seems to be agreed upon is that:

1. Introspection is about the mental/internal, and thus not about the non-mental/external.
2. Introspective judgments are accompanied by a strong sense of certainty, even stronger than judgments about other forms of sense data.
3. Introspective judgments are relatively direct in the sense that they occur directly without needing to be inferred from other supporting data, supporting a distinction between detecting versus reasoning about one’s mental states.
4. Introspection occurs in the “specious present,” comprised of a very short time period just before and just after the introspective act.
5. While effortful and non-automatic, introspective judgments about one’s own mental life seem easier to produce and less prone to subjective feelings of uncertainty than judgments about the mental lives of others.

Whatever sort of theory we intend to develop ought to at least coarsely capture these features and preferably provide

explanations for them in terms of computational mechanism.

Psychological and Clinical Data

In the case of mindreading, it's been long established that those on the autism spectrum have deficits associated with mindreading; especially in regard to appreciating the false beliefs of others when trying to predict or explain their behavior (Baron-Cohen 1995). The same subjects have trouble engaging in spontaneous pretence, both self-directed and with other children. Of course, a small percentage of those on the autism spectrum are high-functioning enough to pass typical tests of false belief understanding, and more advanced tests that probe second-order false belief understanding. Results as to performance of autistic subjects on introspective tasks have been somewhat mixed. Some data suggest that autistics are capable of self-report and robustly utilize self-ascriptions of beliefs, intentions, desires and the like (Nichols & Stich 2003) to describe how they feel at randomly cued intervals. On a more contrarian note, the number of subjects in these experiments are small (N less than 5) and consisted of extremely high-functioning patients, blunting some of the force of such a charitable interpretation. Other experimental results with autistic populations suggest serious deficits with introspective judgments as well as mindreading.

Those diagnosed with schizophrenia provide a second set of clinical data on both mindreading and introspection. Recently, large scale studies conducted by (Sprong 2007, Corcoran 2001) have suggested deficits in mindreading across different categories of schizophrenia. Schizophrenia has long been thought of as a characteristic deficit in introspection and self-monitoring, with delusions resulting from an inability to properly identify stimuli as being generated internally by the operations of the mind (e.g. inner speech, volitional imagery) or externally by other sources (Frith & Done 1988).

A third set of individuals consists of those with severe brain damage or those who have for some reason, required a commissurotomy, or severing of the main bundle of neural fibers connecting the right and left hemispheres of the brain. It has been reported that this subject pool demonstrates that the left hemisphere of the brain generates unconscious, automatic self-interpretations of the form we mentioned earlier (Gazzaniga 1967). Finally we have numerous psychological studies purporting to show healthy subjects having only the most tenuous grip on their inner lives. Perhaps most famous are the early studies of Nisbett and Wilson demonstrating subjects' lack of insight into the processes whereby they arrive at a decision (Nisbett & Wilson 1977). In this case, the subject falls prey to a particular form of automatically induced bias, but is asked for an explanation for why they chose as they did. It's unclear to us and apparently to Nisbett and Wilson as attested in their later writings (Wilson, 2002) that these results challenge the notion of introspection as traditionally conceived.

Prior Work

As we've mentioned, introspection and mindreading have been perennial topics in the philosophy of mind, and have now become important areas of study for psychologists and neuroscientists. While it isn't feasible to even topically review the prior work in the area, two sets of items are worth mention. The first of these concerns the lack of consensus on how to perform experiments to test claims about introspection, and subsequently how to interpret the results. Many of the studies performed have subject pools with $N < 5$, and rely on hermeneutical analyses of written reports by these subjects to draw conclusions (Hurlburt & Heavey 2006). The second claim, which relates in a way to the first, is that while purporting to explain the variety of phenomena we've mentioned so far, contemporary theories of introspection (Carruthers 2009, Nichols & Stich 2003) provide little more than box-and-arrow diagrams and verbal argumentation to support their favored position. Much of the verbal argumentation is aimed toward giving a convincing interpretation for the so-called data on introspection, which itself seems to defy consistent analysis, even by co-authors (Hurlburt & Schwitzgebel 2007)! Many of these theories endorse one form or another of the so-called theory-theory, simulation theory, or modular theory of mindreading. While space doesn't allow for detailed descriptions of the commitments made by each of the preceding options, we think it to be generally the case that each provides a set of constraints as to how computations underlying both introspection and mindreading might be made. In very broad strokes, theory-theory is committed to the existence of a body of theoretical knowledge about how beliefs, desires and other mental states stand in causal relation to one another to enable the prediction and explanation of behavior. Various strains of theory-theory have been proposed to underwrite both mindreading and introspection (Gopnik 1993). One way that theory-theory can be applied is inside a cognitive module, which is somewhat isolated from central cognition, and houses specific representational and processing resources dedicated solely to mindreading and introspection. Modules are generally thought to implement specific computational constraints on the variety and complexity of information allowed in and out of them, but different theorists have different takes on what these constraints are (Carruthers 2009, Leslie & Thaiss 1992). Finally, simulation theorists propose that we use our own mental states and inferential resources to construct mental simulations of ourselves-as-the-target, where the target is an agent whose behavior is to be predicted or explained (Goldman 2006). Current theorists have used these frameworks to define their particular notions of mindreading and introspection. Along with interpretation of clinical and other data, constraints generated by theory-theory and its' alternatives have led researchers to draw conclusions about whether or not these two abilities are served by different or identical computational mechanisms.

Imprecision

What seems so curious to us is why these theorists choose to commit to any of the frameworks we just mentioned in the last section. In essence, both simulation theory and modular theories of mindreading were developed as reactions to what are perceived implausibilities associated with theory-theory. For example, questions remain about what the contents of such a theory would be and how inference is performed efficiently using them. Classical questions from the artificial intelligence perspective regarding computation over such theories in dynamic environments (e.g. the frame problem, the relevance problem and their cousins) have never been addressed by the leading proponents of theory-theory. In addition theory-theory seems to commit to theories about the mental states of others, but also theories about how mental states are manipulated by inference procedures. Having detailed theories of the inferential tendencies of others seems to be a bit of an intellectual stretch for many. Similar questions about the structure and constraints that modules impose plague supporters of modular ideas about mindreading and introspection. The imprecision we describe poses not only a problem for a theory-laden interpretation process, but also for off-line simulation theorists (Goldman 2006) and some simulation-theory hybrids (Nichols & Stich 2003). In these cases, the mindreader selects a number of “pretend” beliefs, desires, and other relevant mental states and inserts them into their own practical decision-making system, taking the result “off-line;” meaning, any actions inferred in light of these pretend states are not actually sent to the motor system for execution as they would normally be for non-pretend inputs. While at least one of us (PB) is sympathetic to simulation, it isn’t clear on any account of simulation how the pretend inputs are selected for simulation in the first place. All of these concerns serve to illustrate a more general point about theories of mindreading. In general, those who propose conceptual models for mindreading do so with an eye to philosophical issues or to empirical data without regard to how computations performed by these models might take place.

We feel that computational implementation provides at least a coarse guide to how feasible one option might be over another. Most computational models have been of the false belief task (Wimmer & Perner 1983). Examples from (Goodman et al. 2006), (Bello et al. 2007) and (Berthiaume 2008) almost completely cover the space, which is somewhat disappointing, given the many hundreds of false belief studies and associated variants that have been conducted since Wimmer and Perner’s original experiment. While space doesn’t allow for a detailed discussion, we now turn toward sketching an implementation of mindreading and introspection in a computational cognitive architecture that captures some of the general phenomenology and is sensitive to the constraints imposed by psychological and clinical studies.

Cognitive Architecture

Descriptions of the Polyscheme cognitive architecture in which we have conducted our modeling efforts can be found in (Cassimatis et al. 2009). A detailed account of the architecture and how coordination is achieved between its various elements can be found therein. For the sake of exposition, we only describe architectural features that are central to our account of the mindreading-introspection relationship.

Cognitive Architecture: Specification

Polyscheme is comprised of a number of *processing elements* (PE’s) that communicate with one another via a *focus of attention* (FoA). Each PE maintains its own proprietary memory, data structures, algorithms for elaborating propositions, and internal knowledge representation that maps onto propositional form. Every PE is wrapped in an interface that allows two-way communication with the FoA through a propositional language. Choices of what PE’s to include in the architectural specification are made through appeal to evolutionary, cognitive developmental, neuroscientific, and computational constraints. The PE’s that serve our purposes in explaining mindreading are represented in figure 1 and include rule matching, categorization, gaze detection, difference detection, identity hypothesis generation/evaluation, temporal and spatial reasoners, and a perceptual buffer.

Strings of the form $P(x_0, \dots, x_n, t, w)$ are called *propositions*. Simply stated, P is a relation (i.e. *Loves*, *Hates*, *Color*, *MotherOf*) over the set of objects x_i during the temporal interval t in a world w , which bears a truth value. We designate “E” as the temporal interval containing all other temporal intervals. A proposition’s truth-value is a tuple $\langle F, A \rangle$ consisting of the positive evidence for (F) and negative evidence against (A) the proposition and a scalar valence. Evidence takes on one of the following values: F, $A \in \{C, L, l, m, n\}$ representing *certainly*, *very likely*, *likely*, *maybe*, and *unknown*.

Cognitive Architecture: Mindreading

Propositions in Polyscheme have truth-values in mentally simulated worlds. Polyscheme’s “beliefs” that are derived from perceptual data or via inference exist as propositions that are true in “R” or the real world; however the architecture is also capable of entertaining counterfactual, past, future-hypothetical, and other forms of simulated worlds. Polyscheme’s “beliefs” about the real world are propositions with “R” in the final argument slot. What we’re really interested in is how Polyscheme is able to identify and reason about the beliefs of other agents, including reflection on its own beliefs. In past work, we have shown how 3rd-person ascription is reducible to a substrate of domain-general representational primitives and processing elements including mental simulation of counterfactual worlds, reasoning about identity, categories, and by applying conditional rules (Bello et al. 2007). While

this surely sounds like quite a lot of mechanism, all of these abilities seem to be roughly in place by two years of age in typical human children, and none of them implies any commitment to innate modules or core theories. We do take mental simulation to be a critical operation for the ascription

that mismatches between self and other-related propositions are detected as exceptions in simulated worlds C where $\text{Same}(\text{self}, \text{other}, E, C)$ is true. An immediate concern is how such a rule fails to immediately generate a contradiction, since $\text{Holds}(\text{?P}, \text{self}, \text{?t}, \text{?w})$ is true, and $\neg \text{Holds}(\text{?P}, \text{self}, \text{?t}, \text{?w})$

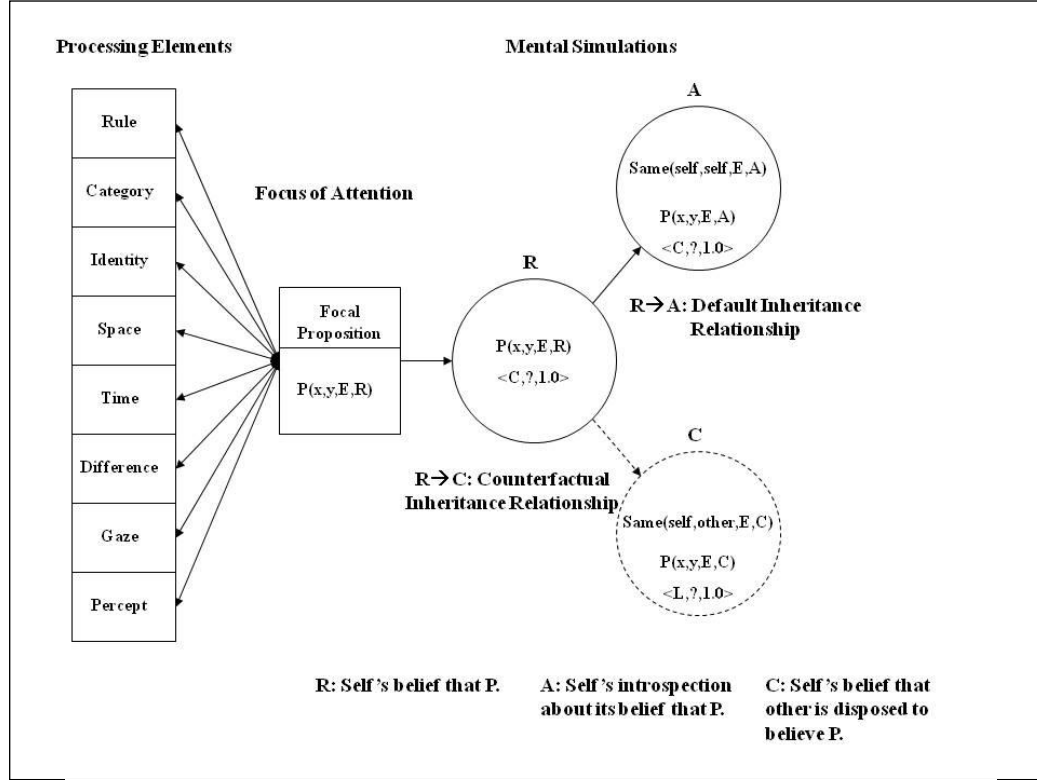

Figure 1: Polyscheme

of beliefs, which according to our theory proceeds in the following way:

1. Categorize other entity as an agent using category PE.
2. Construct counterfactual world C where $\text{Same}(\text{self}, \text{other}, E, C)$ is true.
3. Detect differences between self and other using identity PE
4. Apply an override for each difference detected using conditional rule PE, forcing self-related propositions to resemble other-related propositions.
5. Proceed with inference and predict behavior appropriately.

The conditional rule PE implements a general-purpose rule that roughly looks like the following:

$\text{Holds}(\text{?P}, \text{self}, \text{?t}, \text{?w}) \wedge \neg \text{Holds}(\text{?P}, \text{other}, \text{?t}, \text{?w}) \wedge \text{Same}(\text{self}, \text{other}, E, \text{?w}) \rightarrow \neg \text{Holds}(\text{?P}, \text{self}, \text{?t}, \text{?w})$

Actual implementation of this rule is somewhat more complex, but incidental to our discussion. It suffices to say

$\text{?w})$ is inferred as a consequent. Recall that propositions in Polyscheme have truth-values that are more differentiated than bivalent true or false. Also recall that Polyscheme's beliefs are propositions indexed to "R," the real world. Worlds in Polyscheme are related to one another via a process of *inheritance*. Inheritance relates a child world to a parent world, and operates in the following way: if during the course of inference, Polyscheme is asked to focus on a proposition P in a child world, it will check to see if P has a truth value in that world. If it doesn't, Polyscheme will look at the child's parent world to see if P has a truth value there. If it does, the truth value for P in the child world will be assigned the same value it has in the parent world. The inheritance procedure is visually depicted in figure 1 above. The inheritance procedure captures the idea that if we are to imagine a world in which some proposition like "pegasus exists" is true, other unrelated things we know about, such as "New York is north of DC" are vacuously true in our imagined world by virtue of the fact that they inherit truth values for these propositions from "R," the real world.

The rule we've given that performs an override looks like it might generate a contradiction. Polyscheme's world-simulation PE detects that $\text{Same}(\text{self}, \text{other}, E, C)$ is a counterfactual claim, and when inheriting truth-values from

the parent world “R” for propositions in the counterfactual child-world C, they inherit into C as only being very likely true or very likely false, rather than the certainly true or certainly false values they would be assigned if the counterfactual status of Same(self, other, E, C) was never detected. Since Holds(?P, self, ?t, C), etc. would inherit into C with less-than-certain truth values, Polyscheme can continue to infer in C without running into the danger of contradiction.

Inheritance, Overrides and Mindreading

How do inheritance and overrides in simulation relate to one another, and to both mindreading and introspection? We will differentiate between introspection of currently-held beliefs and 3rd-person ascription by appealing to different inheritance relationships with “R” that define them. Specifically, we are interested in the difference between *alternate* worlds and *counterfactual* worlds. We qualify what we mean by alternate world in the following fashion: an alternate world is such that no proposition in it is the truth-functional negation of a proposition in its parent world. For purposes of our discussion, “R” will always be the parent world of whatever simulations we are considering, whether they are alternate worlds or counterfactual worlds. This is in contrast to counterfactual worlds, which we’ve already explained, and which contain propositions that are truth-functional negations of propositions in their parent worlds. The difference between these two modes of simulation is illustrated in figure 1. When introspecting on currently-held beliefs, Polyscheme entertains an alternate world in which it is the same as itself. It does so by inheriting from its parent world “R” using an inheritance relationship called *I_{aw}*. We call this the “default” inheritance relationship since it perfectly preserves truth-values for propositions between parent and children worlds. In contrast, the counterfactual inheritance relationship, called *I_{cw}*, weakens the truth values for propositions inherited from a parent world R into a child world C, allowing counterfactual reasoning to proceed without immediately inferring a contradiction.

When introspecting, an alternate world A is considered in which Same(self, self, E, A) is true. According to the definition of strict identity, there are no differences between self and self, and thus nothing to override in such a world. However, when simulating oneself in the past or in the future, we might simulate a counterfactual world where Same(self, self_at_now-2, E, C) or a world where Same(self, self_at_now+10, E, C), and so on. Since these past or future versions of oneself might be importantly different from the standpoint of mental states, we note differences between these versions of ourselves and our current self, perform appropriate overrides, and make subsequent predictions or develop explanations. In this way, some sorts of introspective judgments work exactly the same way as 3rd-person ascription of mental states, while not committing us to the idea that introspection and

mindreading are somehow identical and served by exactly the same set of cognitive operations (Carruthers 2009).

Accounting for the Data

Our theory satisfies a number of the conditions discussed in our introduction. Firstly, it should be clear that since we are simulating a world where we are ourselves, introspection about current mental states is clearly not aimed at perceptual features or external objects. The objects under consideration are propositions inherited from Polyscheme’s set of beliefs. This satisfies #1, the *mentality condition*. Since we differentiate simulating alternate worlds in which currently-held mental states are considered, versus counterfactual worlds in which either simulate ourselves as another agent entirely, or simulate ourselves in the past or future, there is a temporal constraint put on what we consider to be introspection proper. Simulation of past and future-selves certainly would count as self-knowledge, but there are acknowledged differences between self-knowledge broadly speaking, and introspection proper. This satisfies #3, or the *temporal locality condition*. Inheritance is not an inferential operation in the sense of having an associated logical operator with an associated semantics. Inheritance floats and attenuates the truth values of propositions from parent worlds to their children when required. In this way, truth of a proposition in a simulated world is arrived at non-inferentially, satisfying #3, the *directness condition*. Introspective judgments made in alternate worlds do not require any overrides relative to their counterparts arrived at counterfactually. If we associate some degree of effort or cognitive cost to performing an override of any sort, judgments about currently held beliefs will be guaranteed to seem at least as easy and likely much easier than judgments made about the mental lives of others, or of ourselves in the distant past or future. This satisfies the #5, the *ease condition*. Finally, properties of the two different inheritance relationships produce propositions in child worlds with different truth values. Inheriting from R into an alternate world produces propositions in the alternate world that have exactly the same truth value that they do in R. This contrasts to the relationship between propositions in R, and how they inherit into counterfactual worlds with slightly weakened truth values. This suggests that introspectively considered propositions are more certain than their non-introspective counterparts, satisfying #2, the *certainty condition*.

As for the clinical and psychological data, it’s difficult to speculate on how any existing model correctly accounts for disorders of mindreading and introspection. But speaking purely speculatively, some of the psychological data on confabulation (e.g. the Nisbett and Wilson results) can be attributed to the mechanisms in Polyscheme which produced its base set of beliefs in R. Since there is no requirement to have introspective access to the workings of these mechanisms, Polyscheme would merely take any propositional content generated by these mechanisms, and ascribe them to itself in an alternate world. In this way,

Polyscheme has introspective access to the propositional content, without necessarily having access to the means by which it is acquired. In the case of autism, much has been said about cognitive deficits associated with autistic patients. Some of these deficits include the inability to follow and understand the targets of other agents gaze, thus eliminating a major source of evidence for understanding what other people currently believe. Other deficits have been hypothesized to include an inability to separate self versus other-centric representations, marked deficits in engaging in pretence and other forms of counterfactual simulation, and general lack of global coherence in cortical processing, all of which are critical elements of our story about mindreading and introspection. Similar deficits in schizophrenic subjects might be addressed by lesioning or confusing our inheritance and world-simulation mechanisms, which detect whether or not we're mindreading self or other-related targets. Of course, these are wild speculations, and we haven't produced any implementation. We only mention them to provide a prima facie story about how much deficits might be reproduced in a computational cognitive architecture.

Summary

We have given the rudiments of an account of the relationship between mindreading and introspection in an existing computational cognitive architecture using a single simulative mechanism, but having separate conditions of operation for each. We discussed our model's capacity to capture some of the defining features of introspection that have yet to be accounted for by competing models, providing a new way to generate and test hypotheses regarding the relationship between mindreading and introspection. While space hasn't permitted the inclusion of detailed computational models and associated model traces, these can be found for an example of 3rd-person ascription (the false belief task) and 1st-person ascription (the smarties task) on the first author's website: <http://www.pbello.com/mindreading.html> produced in a deprecated version of Polyscheme.

Abstract

The mental model theory of reasoning postulates that individuals establish the consistency of a set of assertions by constructing a mental model in which all the assertions hold. Mental models represent what is true but not what is false, and this principle of ‘truth’ predicts that certain assertions should yield systematic errors. We report an experiment in which participants evaluated the consistency of assertions based on quantifiers and sentential connectives, e.g., *All of the artists are barbers or else all of the barbers are artists; Some of the artists are not barbers*. The results showed that participants judged consistent assertions to be inconsistent, and vice versa, much more often for the predicted assertions than for control problems, which should be unaffected by the failure to represent what is false. These results provide a litmus test for mental models, because no current alternative theories of reasoning predict them.

Keywords: deductive reasoning; mental models; consistency; illusions.

Introduction

Are humans inherently rational? Without any training, they are able to make valid deductions. Consider the following problem:

Carol invested in capital securities or else she invested in municipal bonds.

She did not invest in municipal bonds.

Therefore, she invested in capital securities.

You do not need to know anything about securities or bonds to tell that the inference is valid. The ability to make valid inferences is a cornerstone of rationality, and as such, many theories argue that humans make use of formal rules akin to those in logic (Braine & O’Brien, 1998; Rips, 1994). According to those theories, humans make mistakes because they misapply the rules. Likewise, theories based on a probabilistic calculus believe that humans are rational, and that cognitive scientists use the wrong criteria to assess rationality, because everyday reasoning is probabilistic (Oaksford & Chater, 1998, 2007). Our own alternative theory is that human reasoning is based on *mental models*, or iconic representations of possibilities (Johnson-Laird, 2006; Johnson-Laird & Byrne, 1991). Mental models represent what is true and not what is false, and this

constraint can lead to inaccurate models of assertions. Thus, human reasoning is fallible in practice, and individuals should succumb to systematic errors in judgment and inference. These errors are at present a unique prediction of the model theory, and so they serve as a litmus test for mental models. In the present paper we examine fallacious judgments of consistency for assertions combining quantifiers such as ‘all’ and connectives such as ‘or else’.

Mental models and illusions

A foundational assumption of the model theory is the *principle of truth*: the mental models of a set of assertions represent only those possibilities consistent with the truth of assertions. The principle applies to assertions as a whole as well as to clauses within them. For example, an exclusive disjunction *A or else not B* yields the following mental models, where each horizontal line represents a model of a possibility, and ‘ \neg ’ is used to denote negation:

$$\begin{array}{l} A \\ \neg B \end{array}$$

The models do not represent what is false according to the disjunction, such as the case in which *A* is false and *B* is true. And, for those possibilities that make the exclusive disjunction true, such as the case in which *A* is true, the falsity of the corresponding possibility, in this case the negation of $\neg B$, hence *B*, is not represented in the models. This means that a *literal* (a proposition such as $\neg B$ that contains no sentential connective) is represented in a model only if it is true in a possibility. Thus, the first of the models above represents the possibility that *A* is true, but it does not represent the fact that the literal $\neg B$ is false in the possibility. Mental models do not represent what is false, whether it is an affirmative or negative literal, but in certain cases, such as when an inferential task is easy, individuals can construct *fully explicit models*. They represent both what is true and what is false in each possibility and therefore yield the correct representation of the assertion. The fully explicit models of *A or else not B* are as follows:

$$\begin{array}{ll} A & B \\ \neg A & \neg B \end{array}$$

where the affirmative *B* in the first model represents the falsity of the negation, $\neg B$, and the negative $\neg A$ in the

second model represents the falsity of affirmative, *A*. As these models show, the disjunction is equivalent to the biconditional: *A if and only if B*. However, very few people grasp the equivalence, because it is evident only to those who envisage what is false and construct fully explicit models.

The principle of truth may seem like a useful compromise to reduce the load on working memory, but it has an unexpected consequence: it predicts *illusions*, i.e., judgments and inferences that are compelling but erroneous (Johnson-Laird & Savary, 1999). Illusions can occur when individuals assess conclusions, make inferences, or evaluate the consistency of a set of assertions. For example, consider this problem:

There is a pin and/or a bolt on the table, or else a bolt and a nail on the table.

There is a bolt and a nail on the table.

Is it possible that both assertions could be true at the same time?

Reasoners in one study overwhelmingly responded ‘yes’ (Johnson-Laird, Legrenzi, Girotto, & Legrenzi, 2000), but the response is a fallacy predicted by the principle of truth. It is a fallacy because ‘or else’ in the first premise is an exclusive disjunction, i.e., if one clause of the disjunction is true, the other must be false. Hence, the truth of the second premise, *there is a bolt and a nail on the table*, implies that both clauses in the first premise are true. And that contravenes the meaning of ‘or else’, which means that the two assertions cannot be true at the same time. However, reasoners do not grasp this inconsistency and instead incorrectly judge the two assertions to be consistent.

Previous studies have corroborated the existence of illusory *deductions* from disjunctive and biconditional premises (Johnson-Laird & Savary, 1999). They have also corroborated them in singly quantified premises (Yang & Johnson-Laird, 2000). But, no study has examined the interaction between connectives and quantifiers. Our aim was accordingly to test whether illusions also occurred in a new domain: the evaluation of the *consistency* of assertions that depend on both quantifiers and connectives (as in Problem 1 below).

Illusions with quantified assertions

Our experiment examined two sorts of assertions that should yield illusions: exclusive disjunctions of quantified assertions, such as *All the A are B or else some of the B are A*, and biconditionals of quantified assertions, such as *All of the A are B if and only if All of the B are A*. Half of the problems used in the study were those that the principle of truth predicts should yield illusory judgments of consistency, and the other half were those that the principle of truth predicts should yield correct responses. Here is an example of an illusory problem based on an exclusive disjunction:

1. Illusion (disjunction)

All of the artists are barbers or else some of the barbers are artists.

All of the barbers are artists.

Is it possible for both statements to be true at the same time?

The disjunction yields two mental models that represent the two clauses (*All of the artists are barbers* and *Some of the barbers are artists*). Each model contains a set of individuals, where each line represents an individual and denotes the individual’s properties. We lay out the two models as follows:

1.		2.
[artist]	barber	barber artist
[artist]	barber	barber artist
		barber

These models represent each set by a small but arbitrary number of individuals (two or three in the present models), and the square brackets denote that a set has been represented exhaustively (cf. the notion of ‘distribution’ in logic). One consequence of these exhaustively represented properties is that they cannot be added to new individuals in the model (see, e.g., Johnson-Laird, 2006). So, you cannot add instances of artists that are not barbers to the first model.

Consider the first mental model, which represents the first clause of the disjunction, *All of the artists are barbers*. The second assertion in the problem, *All of the barbers are artists*, is true in this model. The model theory predicts that individuals judge a set of assertions to be consistent if all the assertions hold in at least one mental model. Hence, people should judge that the two assertions are consistent. However, this judgment is flawed. The principle of truth predicts that the mental models represent the truth of each clause in an exclusive disjunction, but not the concurrent falsity of the other clause. Suppose that the first clause in the disjunction, *All of the artists are barbers*, is true. Hence, the second clause must be false, i.e., none of the barbers is an artist. This case is inconsistent with the first clause of the disjunction, and so it is impossible. Now suppose that the second clause of the disjunction is true, i.e., some of the barbers are artists. In this case, it must be false that all of the artists are barbers, i.e., at least some of them are not barbers. So, we have the conjunction of at least some of the barbers are artists and at least some of the artists are not barbers. There is accordingly just one fully explicit model of the disjunction:

artist	barber
artist	barber
	barber
artist	¬barber

The second assertion in the problem, *all the barbers are artists*, is accordingly inconsistent with this model, and the

correct evaluation of the two assertions is that they are inconsistent.

The same compound assertion used in (1) yields a control problem, as in (1’):

1’. Control (disjunction)

All of the artists are barbers or else some of the barbers are artists.
None of the barbers is an artist.
Is it possible for both statements to be true at the same time?

The second assertion, *none of the barbers is an artist*, is inconsistent with the mental models above, and so the theory predicts that individuals should respond that the two assertions are inconsistent. In this case, they will be correct, because the second assertion is also inconsistent with the fully explicit model above.

An example of an illusory problem based on a biconditional assertion is:

2. Illusion (biconditional)

All of the artists are barbers if and only if all of the barbers are artists.
None of the artists is a barber.
Is it possible for both statements to be true at the same time?

Biconditional assertions are true whenever both of its clauses are true or else when they are both false. In the case of a biconditional, the principle of truth predicts that a mental model of a biconditional will represent the possibility in which both clauses are true, but not the possibility in which both clauses are false. Hence, the biconditional assertion yields the following mental model in which the two sets of individuals are co-extensive:

[artist]	[barber]
[artist]	[barber]

According to the principle of truth, individuals should respond that the second assertion, *None of the artists is a barber*, is inconsistent with the first assertion, because the second assertion does not hold in the mental model above of the biconditional assertion. Mental models fail to represent the possibility in which both clauses of the biconditional are false, i.e., at least some of the artists are not barbers and at least some of the barbers are not artists. The fully explicit models would include both the model above and represent such a possibility, e.g.:

¬artist	[barber]
[artist]	¬barber

This model *is* consistent with the second assertion in the problem, and so the correct response is that the two assertions are consistent.

The same compound assertion can also yield a control problem:

2’. Control (biconditional)

All of the artists are barbers if and only if all of the barbers are artists.
Some of the artists are barbers.
Is it possible for both statements to be true at the same time?

The second assertion is consistent with the mental model, which is a correct possibility, and so individuals should respond correctly that the two assertions are consistent.

Method

Participants and procedure. 28 participants were recruited through an online platform hosted by Amazon.com. None of the participants had received any training in logic. Participants were told to take as much time as they needed to answer the questions and were asked to answer as accurately as possible.

Design and materials. Participants acted as their own controls and evaluated 18 sets of assertions (see Appendix), and each set contained one compound quantified assertion (e.g., *All the artists are beekeepers if and only if some of the beekeepers are not artists*) and one simple assertion. There were four sorts of problem: illusions of consistency (C/I), where ‘C’ denotes the predicted response of consistent, and ‘I’ denotes the correct response of inconsistent, their controls (I/I), illusions of inconsistency (I/C), and their controls (C/C). 12 of the problems were based on disjunctions, and 6 of them were based on biconditionals, for which it is impossible to have illusions of inconsistency. For each set of assertions, participants pressed one of two buttons on the screen (labeled ‘yes’ and ‘no’) to respond to the question ‘Is it possible for both statements to be true at the same time?’ The contents of the assertions concerned occupations (e.g., artists, beekeepers, and chemists). Each participant received the problems in a different random order. The corresponding mental models and fully explicit models are given in the Appendix.

Results

Table 1 provides the overall percentages of correct responses for the six sorts of problem. The data strongly support the predictions of the model theory.

Table 1: The percentages of correct responses for illusory and control problems in the different conditions

	Illusions	Controls
Disjunctions		
Consistent problems	36%	85%
Inconsistent problems	7%	75%
Biconditionals		
Consistent problems	43%	80%

Overall, the illusions (29% correct) were reliably harder than the control problems (80% correct; Wilcoxon test, $z = 4.49$, $p < 0.0001$), and 24 out of the 28 participants did worse on illusions than controls (Binomial test, $p < .00001$). There was no reliable difference in performance between disjunctive and biconditional consistent problems (Wilcoxon test, $z = 0.12$, $p > 0.9$). And participants succumbed to illusory inferences in both disjunctive and biconditional assertions. As the Table shows, however, a reliable interaction occurred: the illusions of consistency were more compelling than the illusions of inconsistency (Wilcoxon test, $z = 3.24$, $p < 0.002$). The control problems demonstrated that participants interpreted the sentential connectives correctly. The illusions of inconsistency likewise rule out the possibility that individuals had alternative interpretations of the connectives.

One might be tempted to argue that the results could be explained if individuals interpreted the exclusive disjunctions as inclusive ones. Yet this cannot be the case, because inclusive disjunctions merely add possibilities, and so they do not change the consistency of the assertions in the problems. We conclude that illusions of consistency in quantified assertions are a robust phenomenon.

General Discussion

Our results show that robust illusions of consistency, and of inconsistency, occur with compound assertions that consist of quantified clauses. Participants were more likely to succumb to illusions of consistency – they judged that assertions were consistent when in fact they were inconsistent. One contributory factor may have been that individuals need to show that no model exists in which the assertions hold in order to establish inconsistency. In contrast, to establish consistency, they only need to construct one model in which the assertions hold. That is, inconsistency calls for a more exhaustive search than consistency.

In general, illusions serve as a litmus test for mental models, because no other current alternative theory can predict or explain the results. The results of the present study support the principle of truth. They also show that judgments of inconsistency are more difficult than judgments of consistency (Johnson-Laird, Girotto, & Legrenzi, 2004). Theories based on formal rules of inference (Braine & O'Brien, 1998; Rips, 1994) cannot account for the illusions, because these theories rely on valid rules of inference. If such theories incorporated invalid rules to explain illusions, they would predict many inferences that individuals never make. Invalid inference rules are a recipe for irrationality, and could render theories of deduction unstable. Moreover, performance can be enhanced when reasoners are given remedial instructions (Khemlani & Johnson-Laird, 2009; Yang & Johnson-Laird, 2000).

Theories based on the probability calculus cannot readily account for performance in the task of evaluating

consistency either. Chater and Oaksford (1999, 2007) assign probabilistic meanings to quantified clauses. For instance, *All the A are B* is interpreted as meaning $p(B|A) = 1$, and *Some of the A are not B* means that $p(B|A) < 1$. But, how does one assess consistency? If it is simply a matter of consistent conditional probabilities, then a problem based on these assertions:

All of the A are B or else all the B are A.

Some of the A are not B.

should be judged as consistent, because both assertions can have a probability > 0 . But, the model theory predicts that these assertions should be evaluated (erroneously) as inconsistent, and indeed 61% of our participants corroborated this prediction. At the very least, the probabilistic theory needs to add some additional machinery to cope with inconsistency. A conditional probability of the form:

$p(B \& C \& D | A)$

has the value of zero in case the conjunction of B, C, and D, is inconsistent, even if the individual conditional probabilities $p(B | A)$, $p(C | A)$, $p(D | A)$ all have non-zero values.

In sum, reasoners in our study made systematic errors in reasoning about the consistency of disjunctions and biconditionals of singly quantified assertions. They tended to err on problems that called for them to take into account possibilities that rendered the assertions false, and thus corroborated the model theory's principle of truth.

Can similarity-based models of induction handle negative evidence?

Abstract

Even if we don't like it, we often face counterexamples to the inferences we have made or would like to make. With the exception of the SimProb model (Blok, Medin & Osherson, 2007), models of inductions to date have predominantly focused on the relevance of positive evidence to the inference process. Here we provide data from single and double premise arguments in a category-based property induction task using positive and negative evidence. A simple similarity model, the Similarity-Coverage model (Osherson et al., 1990) and the SimProb model are tested on negative and mixed evidence arguments.

Keywords: Induction; Negative evidence; Similarity

The relevance of negative evidence

Ever since Hume, induction has been an area of immense research efforts in philosophy (e.g., Goodman, 1955; Hempel, 1966; Lipton, 2004), psychology (e.g., Blok, Medin, & Osherson, 2007; Heit, 2000; Osherson et al., 1990; Rehder, 2009; Rips, 1975; Sloman, 1993) and cognitive science (e.g., Kemp & Tenenbaum, 2009) in general. Among the prominent questions studied have been: What is the logical basis for induction? What role does prior (semantic) knowledge play in inductive reasoning? Why are some kinds of fact more easily projectable than others? And how should we model inductive inference? Despite these extensive efforts little is known on the influence of negative evidence in induction.

Negative evidence, however, is ubiquitous in everyday reasoning. In some circumstance, evidence may go against our established views. Your favorite restaurant serves you a bad meal, your friend, that is always late, shows up on time and your oh so reliable car won't start. In other instances, you might be making a new inference with both positive and negative evidence present. You check out a new restaurant and receive a great starter and desert but a burned steak and overcooked vegetables. Negative evidence in category-based property induction is defined here as evidence from an instance of the conclusion category that does not possess the to-be-projected property. In other words the evidence constitutes a clear counterexample of something possessing the to-be-projected property. The questions we would like to address here are: How does negative evidence affect our generalizations? What determines the relevance of negative evidence? How do we combine evidence to reach a conclusion?

In research on induction involving positive evidence, Rips (1975) found that the similarity of the evidence to the conclusion influences its relevance. People are more willing to generalize the attribution of a property from a robin to a sparrow than from an eagle to a sparrow because robins and sparrows are more similar. Models of induction involving positive evidence have tried to capture this intuition. The similarity coverage model for instance uses the maximum similarity between premises and conclusion as one component to their model (Osherson et al., 1990). Similarly Sloman's (1993) feature model uses the overall match in the number of features between the premises and the conclusion as a determinant of argument strength. The SimProb model (Blok, Medin, & Osherson, 2007) turns similarity between premises and conclusion into probabilities and uses those to determine argument strength.

The question we are addressing here is whether similarity also determines the relevance of negative evidence. If similarity functions in the same way for positive and negative evidence in determining whether a piece of evidence is considered to be relevant to the conclusion, then existing models of induction based on similarity should be able to handle arguments involving negative evidence. To our knowledge, the SimProb model (Blok, Medin, & Osherson, 2007) is the only model explicitly designed to handle negative evidence. Other models require some adaptation to handle the intuition that the belief in a proposition should decrease with the encounter of negative evidence.

A second question of importance when modeling induction is how to combine the evidence. One approach might be to simply add to argument strength for positive evidence and subtract for negative evidence. Alternatively as the SimCov (Osherson et al., 1990) and the SimProb model (Blok, Medin, & Osherson, 2007) suggest, one could assign the greatest importance to one premise by virtue of its similarity to the conclusion for instance and adjust the resulting argument strength in accordance with the remaining evidence. Furthermore the manner in which the second premise exerts its influence can be implemented in different ways. The SimProb model suggests a weighting by similarity to the first premise. The SimCov model uses the relative positions of the premise categories in a conceptual similarity representation to determine the influence of additional premises. These are only a few examples of the various possibilities to combine data, but they highlight the complexity of the issue.

The aim here is to test whether similarity based models of induction are able to handle negative evidence in a category-based property induction task. We present data from an induction task involving single and double premise arguments with positive and negative evidence and fit three models. In the next section we'll describe in more detail the three models used.

Similarity-based models of induction

We evaluated three models, each relying essentially on similarity to predict the strength of an argument. The models differ in how information is combined in arguments with two or more premises and in the implementation of negative evidence premises. The first model is a simple similarity based model (Sim). The second model is the similarity-coverage model (SimCov) as proposed by Osherson et al. (1990). In the present study, we adapted the model to account for negative evidence. The third model is the similarity-probability model (SimProb; Blok, Medin, & Osherson, 2007).

The Sim model

In this model the strength of the argument is directly related to the similarity of the conclusion category and the premise category (or categories). Formally, the argument strength S_c of an argument with conclusion c and a set of premises then is:

$$S_c = \sum_{p=1}^n e_p \text{sim}_{cp}$$

where sim_{cp} is the similarity between the conclusion category and the category of premise p and e_p indicates whether the premise is positive or negative (respectively $e_p=1$ or $e_p=-1$). Note that in this expression similarities are combined in a very straightforward manner, summing them (or subtracting, depending on whether it's a positive or a negative premise) across the number of premises.

The SimCov model

In the SimCov model, the strength of an argument depends on two components. A similarity component captures the similarity between premise and conclusion categories, and thus the relevance of the premise. The coverage component captures the idea of how much of the nearest superordinate category containing both premise and conclusion categories is covered by the premise(s). We modified the model to account for negative evidence by making the similarity of a premise and a conclusion category negative when the premise is negative.

Formally, the argument strength according to the SimCov model is a weighted sum of the similarity and the coverage component:

$$S_c = \alpha \times \text{similarity}_c + (1 - \alpha) \times \text{coverage}_p$$

where α is a free parameter determining the relative weight of each component. The similarity component represents the similarity between premise and conclusion category. In case of multiple premises, the similarity component is equal to the premise category that is most similar to the conclusion category. As in the previous model, when the most similar premise category is in a negative premise, the similarity is negative.

The coverage component is calculated as follows:

$$\text{coverage}_p = \frac{1}{N} \sum_{i=1}^N \max(\text{sim}_{p_1i}, \text{sim}_{p_2i}, \dots, \text{sim}_{p_ni})$$

where i is an element of a relevant comparison set and N is the size of that set. The comparison set consists of known members of the nearest superordinate category containing both premise and conclusion categories. The coverage term implements the diversity principle (Carey, 1985). In a double positive premise argument, the more diverse the two premise categories are, the larger the coverage term will be – the more the nearest superordinate category is “covered” by the premise categories. Again, when the most similar premise category is in a negative premise, the similarity is negative in the expression.

The SimProb model

In the simprob model, inductive reasoning is considered as a conditional probability judgment. Given a certain prior belief about something, the evidence considered will update this prior belief. Formally, the belief update elicited by the premise a is given by:

$$P(c|a) = P(c)^\alpha$$

with

$$\alpha = \left(\frac{1 - \text{sim}_{ca}}{1 + \text{sim}_{ca}} \right)^{1-P(a)}$$

When there are two premises, the most relevant premise a (the premise that would influence the prior belief the most) is combined with the lesser relevant premise in the following way:

$$P(c|a, b) = P(c|a) + \left[\frac{(1 - P(c|a)) \times (1 - \text{sim}_{ab})}{(P(c|b) - P(c))} \right]$$

There are elegant symmetrical expressions to implement negative evidence (see Blok et al., 2007, for details). The basic idea is that the probability of a negative premise is 1 minus the probability of the same but positive premise, and that similarity between two premises will raise the posterior probability of the conclusion instead of decreasing it.

The SimProb model makes use of prior beliefs regarding the premises and conclusion. In the present study, we use blank properties. Following Blok et al., (2007) in their handling of blank properties, we use a uniform and low prior probability (fixed at .2) for all premises and conclusions.

An obvious parallel between the three models is that they all rely heavily on similarity to account for argument strength. There are differences however, in how similarity is used and – for arguments with multiple premises – how premise information is combined. The Sim model simply adds and subtracts similarities in the multiple premise case. SimCov picks the most relevant premise based on similarity and discards the similarity of the other premise. SimProb picks the most relevant premise, updates the conclusion probability and then modifies the resulting probability according to the less dominant premises.

Present research

The primary goal of this study was to see whether models that use similarity as a determinant of relevance of the evidence are able to handle negative evidence. To that end, we first established what influence negative evidence has on argument strength. We then tested a simple similarity model (the Sim Model), that only takes similarity into account, the SimCov model (Osherson et al., 1990) that also considers the coverage of the conclusion category and the SimProb model (Blok, Medin, & Osherson, 2007), that was specifically designed to be able to handle negative evidence.

The models are evaluated on data from a standard category-based property induction task using properties that participants are likely to have very little knowledge about. The properties are projected from either one or two exemplars to another exemplar of the same category. Participants are asked to judge how likely the conclusion is given the premises, for instance, how likely is it that magpies have a syrinx given that parakeets have a syrinx? The models are tested on four kinds of arguments:

Single Positive:

Parakeets have a syrinx.

Magpies have a syrinx.

Single Negative:

Parakeets **do not** have a syrinx.

Magpies have a syrinx.

Double Positive:

Parakeets have a syrinx.

Penguins have a syrinx.

Magpies have a syrinx.

Mixed Positive & Negative:

Parakeets have a syrinx.

Penguins **do not** have a syrinx.

Magpies have a syrinx.

Note that in the mixed arguments, the negative premise was always the premise presented second.

Method

Participants 76 students from the University of Leuven, Belgium, participated in the study. Participants received course credits in return for participation.

Design Two groups of participants rated the inductive strength of 40 target and 14 filler arguments. Filler items were arguments that were clearly true or false. One group evaluated 20 single positive arguments and 20 mixed positive and negative premise arguments. Fillers for this group consisted of single and double positive arguments. The other group evaluated 20 single negative premise and 20 double positive premises arguments with fillers being single positive and mixed positive and negative premises. The exemplars and properties used were identical for the two groups matching the characteristics across positive and negative arguments.

Materials To create arguments, we selected exemplars from four animal categories (i.e., *birds*, *fish*, *insects* & *mammals*) from the Leuven Concept Norms (DeDeyne, et al., 2008). For each category, the norms contain exemplars generated by participants as well as pair-wise similarity ratings between them. The norms also contain typicality ratings for each exemplar. Exemplars of the two premises and the conclusion were matched for typicality across the single and double premise arguments. The to-be-projected properties were biologically plausible blank properties. For each animal category we selected five kinds of characteristics (i.e., anatomical, behavioral, developmental, metabolic, necessity) that people were likely to have little knowledge about (e.g., Robins require amylase for their digestion). The task was administered in form of a questionnaire. The first page contained a description of the task with the instruction and an example argument. This was followed by 54 arguments starting with 3 warm-up fillers. The remaining 11 fillers were evenly distributed across the items. One random order of items and its reverse was used.

Procedure The induction task was presented as part of a battery of test. Students participated in a large group and took no longer than 10 minutes to complete the task.

Results

Preliminary Analysis Five participants were excluded from the analysis due to a lack of variance in their responses. In a subsequent reliability analysis, the two groups showed high consistency in their responding (Cronbach's alpha of .88 and .95). The data were averaged across participants and subsequent analyses were carried out on the items.

Manipulation Check Each of the 40 target items appeared once with positive and once with negative evidence. Of these, 20 items were single premise and 20 were double premise arguments. Figure 1 shows the average argument strength across those four conditions.

Figure 1: Argument strength for all four types of argument. Error bars are 95% CI.

Arguments containing negative evidence (darker bars) were rated lower in argument strength than those with positive evidence. For positive and negative evidence, arguments having two premises increased argument strength. Note though that in the mixed positive-negative premise arguments the increase in argument strength is due to the addition of a positive rather than negative premise.

The data were submitted to a 2×2 mixed factorial analysis of variance with type of evidence (contains negative evidence vs. does not contain negative evidence) as repeated measure and type of argument (single vs. double premise arguments) as between subjects factor. Although the data suggested that adding a positive premise has a greater effect if the first premise is positive as opposed to negative, the interaction between argument type and evidence type was not significant ($F(1, 38) = 3.2, p = .08$). Both main effects of type of evidence ($F(1, 38) = 27.8, p < .001$) and type of argument were significant ($F(1, 38) = 38.3, p = .001$). Single negative premise arguments were rated weaker than single positive premise arguments ($t(19) = 2.2, p < .05$). Similarly mixed positive-negative premise arguments were judged less strong than those with two positive premises ($t(19) = 5.9, p < .05$). Adding a positive premise to either a positive ($t(38) = 5.2, p < .05$) or a negative premise ($t(38) = 2.1, p = .05$) increased argument strength.

The data confirmed the intuition that negative evidence should have an adverse effect on argument strength. Arguments involving negative evidence were rated lower than those with positive evidence. For positive evidence, we

also found a monotonicity effect (Nisbett, et al., 1983); more premises led to stronger arguments.

Modeling preliminaries In order to evaluate the model fits, we use the correlation between the averaged observed and predicted argument strength within each condition. To derive predicted values from the models, we extracted pairwise similarity ratings between items from the Leuven Concept Norms (De Deyne, et al., 2008). Although the SimProb model provides predicted values in terms of conditional probabilities the other two models do not and we therefore do not make any claims about the scales of the predicted values and will not discuss differences between the models in those terms.

In terms of model parameters, the Sim model does not contain any free parameters. The SimCov model uses the alpha parameter to determine the relative influence of its two components (i.e., the similarity component and the coverage component). Figure 2 presents model fits (i.e., correlations between predicted and observed) across the whole range of the alpha parameter. In all four conditions a reduction in the alpha parameter led to a reduction in fit indicating that the coverage term did not play a role. Consequently we fixed the alpha parameter at 1.

Figure 2: Model fits plotted against the complete range of the alpha parameter of the SimCov model in each condition.

The SimProb model requires prior probability judgments for the properties as input parameter to the model. Nevertheless, Blok et al. (2007) suggest that the SimProb model can handle arguments containing blank properties. They recommend using uniform and low prior probabilities, as this will ensure that the similarity component of their model will do most of the work. We therefore opted for uniform priors across premises and conclusion of .2.

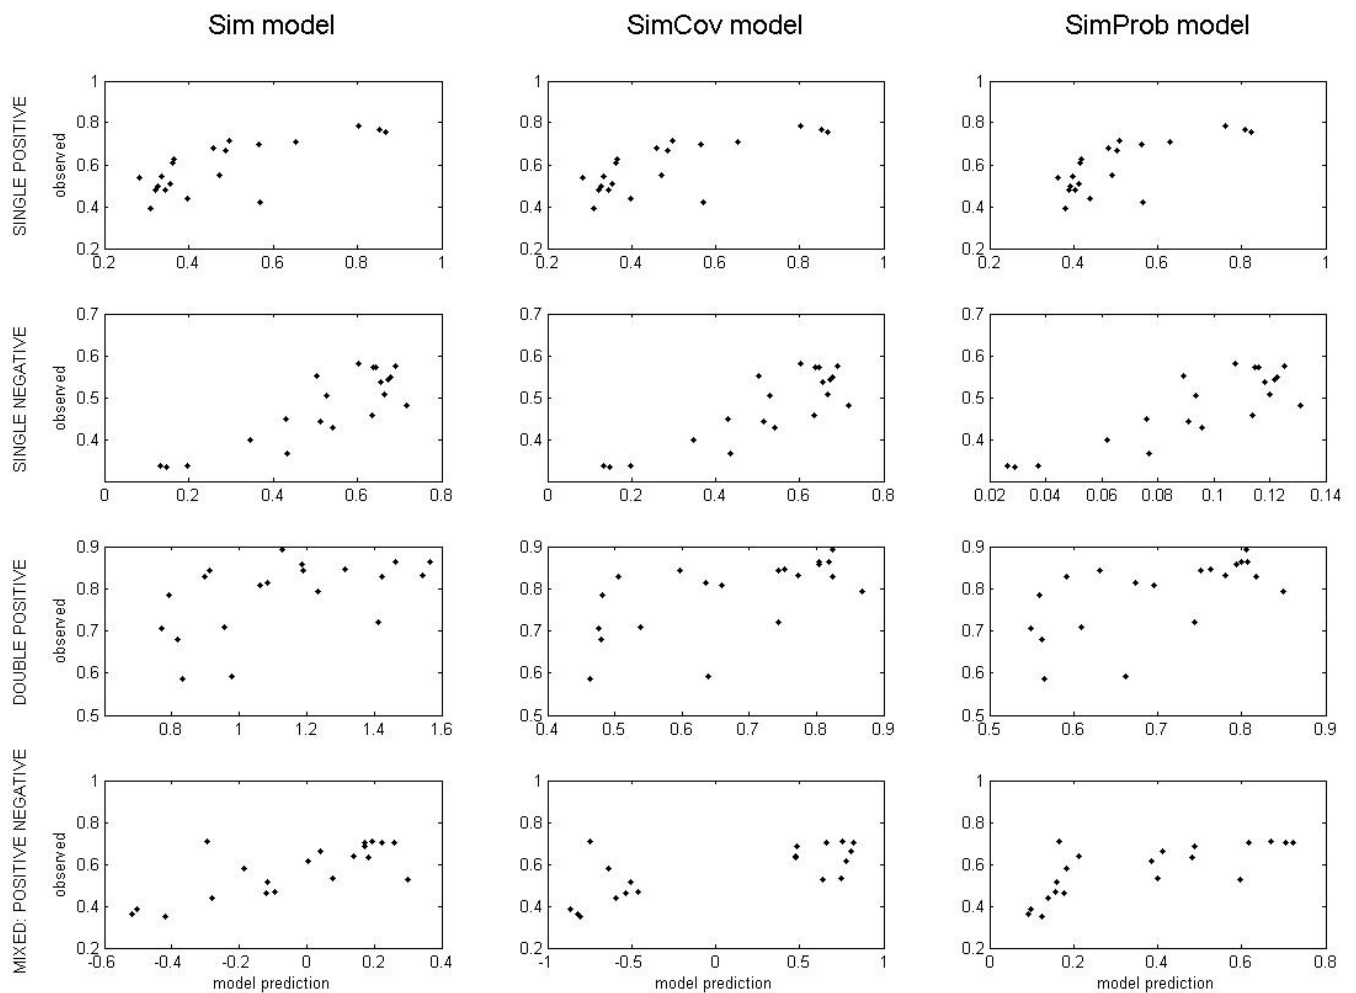

Figure 3: Scatter plots of observed against predicted values for each model across single positive, single negative, double positive and mixed positive-negative arguments.

Modeling results Figure 3 shows the scatter plots of the predicted versus observed values for each of the three models (columns) across the four types of argument (rows). All correlation coefficients were significant at $p < .05$ with $n = 20$. For single positive premises arguments (top row), the three models showed virtually identical results with a good fit of $r = .74$ for all three models. Looking at single premise arguments with negative evidence (2nd row), the models were equally capable at predicting participants' responses and even showed a better fit ($r = .85$). There was no difference in model predictions or fit across the three models. Thus for single premise arguments the three models can equally well account for argument strength involving positive and negative evidence.

The third row shows that for double positive premise arguments the three models differed in their predictions. The Sim model showed a somewhat weaker fit ($r = .53$) than the

SimCov ($r = .61$) or the SimProb ($r = .62$) models. Applying a t-test to the Fisher's Z transformed correlation coefficients however showed that the difference was not significant ($t(17) = .56, n.s.$). Overall the fit of the models for double positive premise arguments was not as good as for single premise arguments.

Testing the fit for mixed positive and negative premise arguments (4th row) we find no difference between the models in terms of the correlation coefficient (Sim: $r = .75$; SimCov: $r = .73$; SimProb: $r = .73$). However the scatterplot shows that the SimCov model, unlike the other two, predicts two separate clouds of data points across the range of observed values. The human data clearly showed a continuous distribution across the whole range of possible values without two separate clouds. The difference in overall mean of each cloud in the predicted data seems to drive the correlation. This is due to the max function in the

similarity component choosing the premise (positive or negative) that has the greater similarity and dropping the influence of the other premise. In contrast the Sim model and the SimProb model take both premises into account.

General Discussion

In making an inference, we have to determine whether a piece of information is relevant or not. For evidence in favor of our inference, theories of induction (Blok, Medin, & Osherson, 2007; Osherson, et al., 1990; Rips, 1975; Sloman, 1993) have suggested that the relevance is determined by the similarity between the evidence and the conclusion. In everyday reasoning, however, we often face at least some evidence that is not in line with our favored conclusion. Here we have tested whether models that use similarity to determine relevance are able to handle arguments involving negative evidence.

The model fits showed that for single premise arguments all three models were able to account for the data from both positive and negative premise arguments equally well. This indicates that the relevance of negative evidence can also be modeled using similarity. For double premise arguments all three models did a decent job with positive evidence. However, for mixed positive-negative premise arguments only the Sim and the SimProb model were able to account for the data. Although showing a good fit in terms of the correlation coefficient, the SimCov model showed a pattern of predicted values not reflected in human data. Taken together, two factors can account for the behavior of the SimCov model. First, with our data the coverage component of the SimCov model did not contribute to the prediction of argument strength. One reason for this might be that the generalizations in our arguments were to other exemplars rather than the category itself. Second, the similarity component only takes into consideration the most similar premise disregarding the other. If this happens to be the negative one, predicted values are low. Conversely if the max function selects the positive premise predicted values are high. Without an influence of the coverage terms two clusters of predicted values emerge.

The results from the double premise arguments again support the fact that similarity can be used to determine the relevance of negative just as well as positive evidence. However the results highlight that with several pieces of evidence it becomes important to consider how to model the combination of both positive and negative evidence. Differences in how the models combine the evidence make them better or worse candidates in modeling negative evidence with multiple premises. Disregarding one piece of evidence over another clearly does not resemble participants responses. However similarly a simple additive model like the Sim model becomes less realistic in the case of multiple premises of the same kind, evident in our double positive condition.

The aim of the present study was not to provide a new model of induction but to test whether similarity-based models of induction can handle arguments involving

negative evidence. We have shown that similarity can indeed be used to model relevance of negative evidence. In addition, our data highlight the importance of taking all evidence into account. Models of induction that try to account for the influence of negative evidence will need have a specific mechanism to combine positive and negative evidence.

Abstract

In two studies the effectiveness of dynamic and multiple static visualizations was investigated for a highly perceptual learning task, namely locomotion pattern classification. In Study 1a, seventy-five students viewed either dynamic, static-sequential, or static-simultaneous visualizations. For tasks with intermediate difficulty dynamic visualizations led to better recognition of the locomotion patterns than static-sequential visualizations, but not than static-simultaneous visualizations. To test whether the presentation of the static-simultaneous visualizations in rows or their permanent visibility was accountable for this effect, three additional static-simultaneous conditions were investigated in Study 1b. Seventy-five students viewed the static-simultaneous visualizations either presented in columns, in matrices, or in circles. The dynamic condition outperformed all three additionally investigated static-simultaneous conditions in the intermediate tasks. Accordingly, for learning how to classify locomotion patterns dynamic visualizations are better suited than most static presentation formats. Nevertheless, presenting static-simultaneous visualizations appropriately can achieve equal results at least for tasks with intermediate difficulty.

Keywords: learning; dynamic visualizations; multiple static visualizations; spatial ability

Learning with Visualizations

Dynamic visualizations have not always been found to lead to better learning than static visualizations (Tversky, Bauer-Morrison, & Bétrancourt, 2002). Bétrancourt and Tversky (2000) have suggested that dynamic visualizations should be superior only for specific tasks. In particular, they will aid learning if understanding the content explicitly requires understanding of its dynamic aspects like trajectory or continuity of changes. These dynamic aspects can be conveyed directly through a dynamic visualization. Thus, in many studies in which dynamic visualizations failed to be beneficial, a direct depiction of the contents' dynamic aspects may not have been necessary (e.g., Byrne, Catrambone, & Stasko, 1999). On the other hand, tasks that require a profound understanding of continuous changes often benefit from dynamic visualizations (e.g., hand manipulation tasks, Ayres et al., 2009; Wong et al., 2009).

Similarly, the current study focuses on a task that explicitly requires identifying the continuity of the depicted dynamics and involves a strong perceptual component, namely recognizing biological locomotion patterns of fish as a basis of species classification. To accomplish this task, it is important that learners correctly perceive the underlying kinematics, for instance, to decide whether a fin moves in a wave-like or a paddle-like manner. The continuity of these dynamics can be shown explicitly only in dynamic visualizations. However, one can argue that multiple static visualizations may also foster the understanding of continuity, but that this is likely to depend on how they are presented. In particular, to foster the understanding of continuity static pictures have to be presented in a way that they facilitate mental animation (e.g., Paas, Van Gerven, & Wouters, 2007). Mental animation is the process of inferring movements from static pictures based on knowledge about relevant components and their causal relations to other components (Hegarty, 1992). We assume that both, temporal as well as spatial aspects of presenting static pictures affect how well they support mental animation.

Temporal Aspects of Presenting Static Pictures

The main difference concerning temporal aspects of presenting multiple static pictures is their sequentiality. They can be depicted either sequentially or simultaneously. In a sequential presentation one picture is shown after another at the same position, whereby later pictures replace former ones. In a simultaneous presentation all pictures are shown next to each other on a single screen. The temporal alignment of visual elements is easier in a sequential presentation because elements that are identical across the pictures are depicted at identical spatial positions (unless they change their position over time). However, to make comparisons between relevant objects the information of earlier pictures has to be memorized until later pictures are shown (Paas et al., 2007). Hence, integrating information across the pictures may be challenging for learners. In contrast, in a simultaneous presentation the depicted information remains visible on the screen and therefore comparisons among discrete steps are enabled. Moreover, in

static-simultaneous visualizations learners can regulate the pacing of their cognitive processing by deciding when to look at a picture and for how long. This all suggests that a simultaneous presentation of static pictures may be better suited to foster mental animation than a sequential one.

This assumption was confirmed by Boucheix and Schneider (2009), who found that static-simultaneous visualizations were as good for understanding a mechanical system as dynamic ones and that they outperformed static-sequential ones. This was especially true for learners with low spatial ability (but see Kim et al., 2007). For the locomotion pattern classification task used in the current study, we found a very similar result pattern, namely that dynamic visualizations outperformed static-sequential ones, whereas static-simultaneous visualizations reached the same performance as dynamic ones (Imhof, Scheiter, Gerjets, 2009). These findings suggest that dynamic visualizations may not be the only solution to convey knowledge about dynamic changes. The first part of the current study (Study 1a) focused on replicating the findings of Imhof et al. (2009) with more standardized visualizations and a broader range of classification tasks at different levels of difficulty.

Spatial Aspects of Presenting Static Pictures

When using static-simultaneous visualizations the question arises of how to arrange the static pictures on the screen to facilitate mental animation. In the study by Imhof et al. (2009) as well as in Study 1a the static pictures were represented in two rows of five pictures each. A row representation requires comparisons between different pictures to be made from left to right or vice versa. This should be advantageous for several reasons: Firstly, it corresponds to the reading order for texts (in Western cultures) and is also common for other static-simultaneous visualizations (e.g., comics). Secondly, eye tracking research has shown that irrespective of the depicted stimulus horizontal eye movements are more likely to occur than vertical ones (Tatler & Vincent, 2008). Finally, arranging multiple visualizations of an object that is moving from left to right in a row corresponds to the moving direction of this object. Taken together, a row presentation should facilitate mental animation, because it better corresponds to the nature of the depicted movement as well as to our typical viewing behavior. This may be why it is also the common presentation format for static-simultaneous visualizations used in former studies (Boucheix & Schneider, 2009; Imhof et al., 2009; Kim et al., 2007). However, it is unclear whether the static-simultaneous presentation formats used so far yield similar performance as dynamic visualizations, because the pictures remain visible all the time or because their spatial arrangement facilitates mental animation. Hence, in Study 1b we compared dynamic visualizations to three additional variants of static-simultaneous ones, namely to column, matrix, and circle presentations (Figure 1).

When depicting pictures in columns comparisons have to be made from upper to lower positioned pictures or vice versa. This spatial layout may yield the advantage that at

least for pictures presented in a landscape format the distance between to-be-compared elements in two pictures is smaller. Hence, shorter saccades are required. Moreover, for the current task the elements that need to be compared to each other to determine their relative position (i.e., the fins) and thus to infer the locomotion pattern from it are vertically aligned. Hence, only few visual search processes are needed. On the other hand, this arrangement corresponds neither to the reading order nor to the objects' moving direction. In Study 1b we additionally implemented a matrices presentation of the pictures, where horizontal as well as vertical processing was needed. Finally, the circle presentation took into account that the depicted locomotion patterns are cyclic (i.e., reiterating) so that the last picture of one movement cycle automatically leads to the beginning of a new cycle without forcing the learner to skip back to the beginning of the row or column.

The question of how different spatial layouts of static-simultaneous visualizations influence their effectiveness compared to dynamic visualizations was investigated in Study 1b. If dynamic visualizations were superior to these static-simultaneous variants, this would indicate that the row presentation format used earlier is advantageous because of its specific spatial layout and not just because the pictures are permanently visible, which is also true for the other static-simultaneous variants.

The Role of Spatial Ability

In line with prior research we considered learners' spatial ability as a possible moderator of the effectiveness of dynamic and static visualizations during learning (e.g., Boucheix & Schneider, 2009; Hays, 1996). Hegarty (1992) proposed that learners' spatial ability plays a role for the process of mental animation. Moreover, Hegarty and Sims (1994) showed that high spatial ability learners outperformed low spatial ability learners in mechanical mental animation tasks. Furthermore, Hays (1996) showed that low spatial ability learners particularly benefited from learning with dynamic visualizations compared to static ones or no visualizations suggesting that these learners have fewer abilities to mentally animate the dynamics based on static pictures (Hegarty & Waller, 2005). Whereas low spatial ability learners suffer from "poor" instructions, high spatial ability may compensate for such instructions (cf. ability-as-compensator hypothesis, Mayer & Sims, 1994; see also Boucheix & Schneider, 2009). Accordingly, for the current study benefits in favour of dynamic visualizations (and potentially, static-simultaneous-rows visualizations) should be more pronounced for low rather than for high spatial ability learners.

Hypotheses

For *Study 1a*, in which we addressed the temporal aspects of static visualization formats, we assumed that dynamic visualizations would be superior to static-sequential visualizations, but not to static-simultaneous visualizations presented in rows, thereby replicating findings from earlier

studies with a broader range of recognition tasks and more standardized visualizations (see below). In *Study 1b* we tried to further disentangle temporal and spatial aspects of presenting multiple static pictures by testing whether dynamic visualizations would be superior to other static-simultaneous presentation formats. We assumed that dynamic visualizations would show stronger advantages in this case, thereby suggesting that the benefits of static-simultaneous visualizations presented in rows are not just due to temporal aspects but also due to their spatial layout.

For both studies, we assumed that higher spatial ability would be associated with better learning outcomes than lower spatial ability. Moreover, we proposed that learners with lower spatial ability would benefit stronger from learning with dynamic visualizations compared to static visualizations than those with higher spatial ability.

Study 1a

Method

Participants and Design. We randomly assigned 75 university students (average age: 24.48 years, $SD = 4.34$; 53 female) to one of three visualization conditions: dynamic vs. static-sequential vs. static-simultaneous-rows.

Figure 1: The four to-be-learned locomotion patterns (relevant movements indicated by arrows).

Materials. Participants were asked to learn how to classify fish according to their locomotion patterns based on visualizations that illustrated four different locomotion patterns. These locomotion patterns differed in terms of the used body parts that generate propulsion (i.e., the body itself or several fins) and also in the manner of how these body parts are moving (i.e. wave-like or paddle-like; cf. Figure 1). One of the major challenges in identifying these locomotion patterns is that fish may deploy a variety of other movements in addition, for instance, for navigation. These navigational movements used by a fish displaying a specific propulsion locomotion pattern can easily be confused with movements used for propulsion in another locomotion pattern.

We varied the *presentation format* of the visualizations as independent variable. Dynamic representations were compared to nine either sequentially or simultaneously (in rows) presented static visualizations.

We developed highly realistic 3D-models of fish performing the four to-be-learned locomotion patterns based on which 2D-animations were rendered that were standardized in terms of the perspective, the background and the position of the fish. These animations were used as dynamic learning materials. The static pictures were

extracted from these animations by an expert and represented the key states in the movement cycles.

In the *dynamic condition* the movement cycles of the locomotion patterns were presented in loops in the animations (72 s per locomotion pattern). In the *static-sequential condition* the nine static pictures were presented twice successively for 4 s each. In the *static-simultaneous-rows condition* the same pictures were presented in parallel for 72 s. They were arranged in two rows corresponding to the two phases of the locomotion patterns (cf. Figure 2, upper left part). To facilitate the transition from the first to the second row, the fifth picture was depicted twice, once as the last picture of the upper row and once as the first picture of the lower row. The pictures' size was half of the size of the dynamic and the static-sequential conditions. There was no need for the subjects to scroll the page.

During learning the participants saw visualizations for each of the four to-be-learned locomotion patterns in a predefined order. The presentation was system-controlled and accompanied by narration. The narration explained the locomotion pattern in terms of typical fish using this locomotion pattern, body parts involved, kind of movements executed (undulation versus oscillation), parameters of the movements (e.g., amplitude), and maximum velocity.

Figure 2: Static-simultaneous presentation formats.

Measures. Learners' spatial abilities were assessed with two different tests, namely the mental rotation test (MRT, Vandenberg & Kuse, 1978), and a short version of the paper folding test (PFT, Ekstrom et al., 1976). Both spatial ability measures were used in the analyses as continuous factors.

To assess learning outcomes a locomotion pattern recognition test consisting of pictorial multiple-choice items was administered. Underwater videos of real fish performing one of the four locomotion patterns were used as test stimuli. The number of test items was constrained by a number of aspects (e.g., resolution, visibility of the fish from a certain perspective, clear depiction of the respective locomotion patterns). For each of the four locomotion patterns seven videos were identified. To choose for each item the kind of locomotion pattern that was depicted, learners had to identify the body parts relevant for

propulsion and their way of moving. Possible answers were the correct terms of the four locomotion patterns and the additional answer “I don’t know” (see Figure 3). Each item was awarded one point for the correct answer (max. 28 points). The recognition test items were categorized by two independent domain experts into items with low, intermediate, and high task difficulty. Their decisions were based on the visibility of the relevant parts used for propulsion as well as on the absence or presence of miscellaneous movements of the fish’s body parts that could have been mistaken as being relevant for propulsion (e.g., movements only necessary for navigational purposes). Videos that showed the pattern relevant for propulsion continuously and contained no other movements were assigned a low task difficulty (8 items). Videos that showed the pattern relevant for propulsion continuously, but contained movements similar to another locomotion pattern were assigned an intermediate task difficulty (11 items). Videos that either showed the pattern relevant for propulsion continuously, but contained additional movements similar to at least two other locomotion patterns or videos that did not show the relevant propulsion pattern continuously or that did show it in a non-salient manner (whereby all of these videos contained movements similar to at least one other locomotion pattern) were assigned a high task difficulty (9 items). Five cases of disagreement between the two experts were resolved by negotiation.

Figure 3: Screenshot of a recognition test example item.

Procedure. After completing paper-based the MRT, PFT, and a demographic questionnaire, participants read an introduction, which was followed by the computer-based learning phase. Finally, learners worked on the computer-based pictorial recognition test.

Results

Performance in the three recognition subtests was analyzed by a MANCOVA with presentation format (dynamic vs. static-sequential vs. static-simultaneous-rows), the MRT, and the PFT as independent variables (Table 1).

There was an overall effect for presentation format ($F = 2.28$, $p = .04$) and for the PFT ($F = 3.62$, $p = .02$), but no other main effect or interactions. There was an effect for presentation format only for recognition tasks with an intermediate difficulty ($F = 4.00$, $p = .02$). Dynamic visualizations were superior to static-sequential visualizations, but not to static-simultaneous-rows

visualizations. Higher performance in the PFT was associated with better recognition for tasks with low ($F = 7.52$, $p < .01$) and intermediate difficulty ($F = 9.18$, $p < .01$).

Table 1: Adjusted means (and standard errors) for recognition performance (in % correct) as a function of presentation format and task difficulty (Study 1a).

Task Difficulty	Presentation Format		
	dynamic (n = 25)	static-sequential (n = 25)	static-simultaneous-rows (n = 25)
low	92.65 (3.90)	84.58 (3.88)	86.43 (3.93)
intermediate	87.83 (4.33)	71.85 (4.30)	74.30 (4.36)
high	71.80 (4.57)	72.67 (4.55)	74.36 (4.61)

Discussion of Study 1a

The results confirmed that dynamic visualizations are better suited to convey knowledge about the continuity of locomotion patterns compared to static-sequential visualizations, but not to static-simultaneous visualizations presented in rows – at least for recognition tasks with an intermediate difficulty level. These findings hence replicate those of a former study, where digital underwater videos as well as black-and-white animated line drawings were used as dynamic visualizations (Imhof et al., 2009). Hence, the results obtained by Imhof et al. were not an artefact of either low visibility of important kinematical aspects in the underwater videos or their potentially oversimplified representation in the animated line drawings, because the visualizations in the current study were of high quality in terms of the visibility and fidelity of important features.

In sum, the results suggest that dynamic visualizations as well as static-simultaneous-rows presentations allow for the construction of an adequate mental representation of kinematics; however, it is yet not clear whether the relative good performance of the latter condition is due to its temporal (permanent visibility) or its spatial aspects (rows), which is why Study 1b was conducted.

Study 1b

Method

Participants and Design. We randomly assigned 75 university students (average age: 23.35 years, $SD = 3.71$, 57 female) to three static-simultaneous conditions, namely a static-simultaneous-columns, a static-simultaneous-matrices, and a static-simultaneous-circles condition, to compare their performance to that of students in the dynamic visualization condition of Study 1a.

Materials. The learning domain, the measures as well as the procedure were identical to Study 1a. In the *static-simultaneous-columns condition* the single pictures were

arranged in two columns corresponding to the two phases of the locomotion patterns (cf. Figure 2, upper right part). To facilitate the transition between the left and the right column the fifth picture was depicted twice, once as the last picture of the left column and once as the first picture of the right column. In the *static-simultaneous-matrices condition* the nine pictures were presented in 3x3 matrices, ordered primarily from left to right and secondarily from top to bottom (cf. Figure 2, lower left part). Contrary to the static-simultaneous-rows and the static-simultaneous-columns condition no pictures were depicted twice. In the *static-simultaneous-circles condition* the single pictures were presented in a clockwise arrangement with the first picture at the 12 o'clock position (cf. Figure 2, lower right part). In this condition the ninth picture was not presented, because it depicted the same state in the locomotion pattern as the first picture. The pictures in all conditions had the same size as those in the static-simultaneous-rows condition in Study 1a.

Results

Performance in the three recognition subtests was analyzed by a MANCOVA with presentation format (static-simultaneous-columns vs. static-simultaneous-matrices vs. static-simultaneous-circles vs. dynamic), the MRT, and the PFT as independent variables (Table 2).

There was an overall effect for presentation format ($F = 2.64, p = .01$), for the MRT ($F = 4.93, p < .01$) and for the PFT ($F = 2.82, p = .04$), but no interactions. There was an effect for presentation format for recognition tasks with low ($F = 4.01, p = .01$) and intermediate difficulty ($F = 6.41, p = .001$). Dynamic visualizations led to better recognition for tasks with low difficulty compared to the static-simultaneous-matrices visualizations as well as for tasks with intermediate difficulty compared to all three static-simultaneous conditions. Moreover, higher performance in the MRT was associated with better recognition performance for tasks with low ($F = 4.55, p = .04$) and intermediate difficulty ($F = 14.59, p < .001$). Furthermore, higher performance in the PFT was associated with better recognition for tasks with low difficulty ($F = 4.63, p = .03$).

Discussion of Study 1b

None of the additionally tested spatial layouts of the static-simultaneous visualizations achieved the same recognition performance as the dynamic visualizations for tasks with an intermediate level of difficulty. For recognition tasks with a low level of difficulty we found dynamic visualizations to be superior to static-simultaneous visualizations presented as matrices, showing that this presentation format bears the fewest of all advantages for the task at hand.

The possible advantage of a circular presentation that it adequately represents the cyclic nature of the locomotion patterns might have been cancelled out by the fact that with this presentation format the orientation of the pictures interfered with the swimming direction of the fish. That is, for pictures presented in-between the 3 o'clock and the 9 o'clock position, the next picture is depicted to the left of its

previous picture, whereas the swimming direction of the fish still indicates a movement from left to right. Moreover, contrary to the assumption that the spatial contiguity in a column supports the visual alignment of to-be-compared elements and hence might facilitate mental animation, this condition was not any better than the dynamic condition.

In sum, the results suggest that dynamic visualizations are superior to different static-simultaneous presentation formats as long as the spatial layout of the static pictures does not support mental animation processes in a way that corresponds to our reading/viewing behavior and that is in line with the moving direction of the depicted object.

Table 2: Adjusted means (and standard errors) for recognition performance (in % correct) as a function of presentation format and task difficulty (Study 1b).

Task	Presentation Format			dynamic (n = 25)
	static-simultaneous columns (n = 25)	static-simultaneous matrices (n = 25)	static-simultaneous circles (n = 25)	
Difficulty				
low	83.85 (4.13)	72.40 (4.47)	79.21 (4.07)	92.78 (4.36)
intermediate	70.26 (4.20)	63.65 (4.55)	66.90 (4.14)	88.36 (4.43)
high	66.69 (4.76)	62.58 (5.16)	61.52 (4.70)	71.77 (5.02)

General Discussion

The superiority of dynamic visualizations over most static presentation formats for learning tasks that explicitly require the identification of the continuity of movements and involve a strong perceptual component was supported in Studies 1a and 1b. However, consistent with prior findings (Boucheix & Schneider, 2009; Imhof et al., 2009) a static-simultaneous presentation of multiple pictures in rows led to the same performance as the dynamic visualizations. Accordingly, for this specific case where the moving direction of the depicted object and the spatial layout of the pictures correspond to each other, learners seem to be well able to mentally animate the sequence of pictures and hence to infer the kinematics from it (Hegarty, 1992). However, this result pattern holds true only for tasks of intermediate difficulty. The fact that we did not find the same results for tasks of low difficulty can be explained in terms of a ceiling effect. The items are maybe so clearly identifiable that learners from all experimental conditions (except for the matrices condition in Study 1b) achieved very good results. According to the expert opinions there were always at least two concurring patterns visible in items with high task difficulty. Which one of these is used for propulsion cannot be answered only on the basis of perceptual input. Rather conceptual knowledge acquired from the spoken explanations, which were identical in all experimental conditions, had to be used to answer these items. Additional design techniques like cueing (De Koning et al., 2009) or enriching static displays (Münzer, Seufert, & Brünken,

2009) could further enhance the effectiveness of static-simultaneous presentation formats.

Astonishingly, there was no moderating effect of spatial ability concerning the effectiveness of different presentation formats of visualizations. Therefore, the assumed ability-as-compensator hypothesis could not be confirmed. In further studies this issue should be addressed in more detail, because there is an ongoing discussion about the separate components that make up the construct spatial ability (for an overview see Hegarty & Waller, 2005). Especially, the dynamic spatial ability component might be a relevant dimension for mental animation in dynamic tasks (D'Oliveira, 2004; Hunt et al., 1988). Hence, it might be that the tests used here may not have addressed those spatial ability components that might be most relevant to mental animation, even though they are commonly used in visualization research. Despite of these doubts concerning the validity of the measures used, we were nevertheless able to show that irrespective of visualization format higher spatial ability was associated with better learning outcomes than lower spatial ability for tasks with low and intermediate difficulty, thereby replicating the findings of Hegarty and Sims (1994). Hence, we can at least conclude that spatial abilities are relevant to the task at hand. Nevertheless, further studies need to address the question of how mental animation from static-simultaneous visualizations supports learning.

Acknowledgments

The study is part of a research project on the "resource-adaptive design of visualizations for supporting the comprehension of complex dynamics in the Natural Sciences" funded by the Leibniz-Gemeinschaft.

Working Memory Constraints on Multiple Center-Embedding

Fred Karlsson (fgk@ling.helsinki.fi)

Department of Modern Languages, PO Box 24
FI-00014 University of Helsinki, Finland

Abstract

Gibson's (1998) theory on the locality of syntactic dependencies claims that multiply center-embedded clauses are unacceptable if they contain a parse-state with at least two long unresolved predicted categories in addition to the top-level verb. 'Long unresolved' means a syntactic prediction spanning at least three intervening new discourse referents. This claim was based on experimental analysis of invented examples. Karlsson (2007b) provided corpus data demonstrating that, contrary to widely accepted views in linguistics and cognitive science, there are well-defined constraints on how many (maximally three) and what types of multiple center-embeddings occur in spoken and written discourse in natural languages. Gibson's theory of the processing of multiple center-embeddings will be evaluated in the light of Karlsson's empirical data. The corpus data do not support the idea of a discrete limit on working memory capacity, because almost one third of the extant examples of multiple center-embedding are more complex than Gibson's acceptability limit stipulates. Spoken language processing complexity is clearly below Gibson's limit, written language is capable of transgressing it.

Keywords: center-embedding; clausal embedding; cognitive explanation; complexity; embedding; multiple center-embedding; recursion; syntactic complexity.

Definition of Center-Embedding
