Explanations of PC effects have been advanced from several theoretical perspectives. Some emphasize the lexical and phonemic content of the context in determining the identification of the target sound (Elman & McClelland, 1988; Samuel & Pitt, 2003). Gestural theorists, who assume that listeners parse the acoustics in terms of its articulatory sources, argue that listeners attribute the acoustic properties of a target sound to the coarticulatory context rather than to the target (Fowler, 1996, 2006). Auditorists attribute context-induced shifts in category boundaries to general auditory processes such as frequency contrast or spectral contrast (Diehl & Kluender, 1989; Kingston, 1992; Kingston & Diehl, 1995; Lotto & Kluender, 1998). Such auditory explanations are unavailable for compensation effects such as vowel-dependent pitch height compensation (Fowler, 2006; Lotto & Holt, 2006). Motivated by such cases, Lotto & Holt (2006) suggest that the spectral contrast explanation be supplemented with a "general learning" mechanism for category formation from correlations between stimulus parameters.

The generality of PC effects is accentuated by evidence for contextual compensation with speech and non-speech sounds in human and non-humans (Holt, Lotto, & Kluender, 2000; Lotto, 2004). For example, when /da/–/ga/ syllables are preceded by tone glides matching in frequency to the third formant (F_3) transition of /al/ or /ar/, listeners' syllable identi-

fication responses shifted in the same direction as when targets were preceded by real speech (/al/ or /ar/). The same effect was observed even when steady-state tones at the offset frequency of /al/ or /ar/ F_3 were used (Lotto & Kluender, 1998; cf. Viswanathan, Fowler, & Magnuson, 2009). Lotto, Kluender, & Holt (1997) conditioned four Japanese quails to exemplars of /da/ and /ga/ syllables. Two birds were trained to peck a key when presented with good /da/ exemplars and to not peck when presented with good /ga/ stimuli while two other quails were trained in the reverse condition (/ga/ positive, /da/ negative). After reaching a preset criterion of 10:1 ratio of pecks to positive versus negative stimuli, birds were presented with novel ambiguous CVs preceded by either /al/ or /ar/. All birds displayed a significant shift in peck rates across the change in preceding liquid. The /da/-positive birds pecked substantially more for CVs preceded by /ar/, while /ga/-positive birds pecked more for CVs preceded by /al/. Crucially, both the task and the results were essentially the same as in Mann (1980)'s experiment with human subjects. There is thus strong support for a language-independent, auditory mechanism of compensation.

In this paper, we develop a computational model of PC effects using rational analysis of speech perception and production. Rational analysis (RA; Anderson, 1990; Marr, 1982;) attempts to explain aspects of cognition as adaptive responses to the environment; its central claim is that much of people's behavior when performing some cognitive tasks can be understood as optimal, according to some criterion. RA represents a different type of explanation from existing theories of PC: instead of explaining the behavioral locus (e.g. gestural processing, lexical knowledge, general auditory processes) of PC effects, the model presented here gives an account of *why* PC effects occur, as a consequence of listeners optimally solving the problem of categorization given context-induced variation.

RA accounts have been developed for visual word recognition (Norris, 2006), spoken-word recognition (Norris & McQueen, 2008), perceptual magnet effects (Feldman & Griffiths, 2007; Feldman et al., 2009), and other cognitive domains, such as vision (Marr, 1982; Yuille & Kersten, 2006) and manual movement (Trommershäuser, Gepshtein, Maloney, Landy, & Banks, 2005). Our analysis of PC effects grows out of the rational model of perceptual magnet effects of Feldman et al. (2007, 2009). While "optimal" can be understood in Bayesian (e.g. Tenenbaum & Griffiths, 2001) or maximum likelihood (e.g. Fried & Holyoak, 1984) terms, following Feldman et al. and other recent rational accounts of speech perception (Clayards, Tanenhaus, Aslin, & Jacobs, 2008; Norris & McQueen, 2008), we use Bayesian inference here.

Model

Our rational model for PC effects assumes a simple scenario where an idealized optimal listener has to categorize some signal as one of two phonetic categories; this is analogous to

the task listeners perform in the two-alternative forced choice (2AFC) paradigm commonly used in PC experiments. The model formalism is adapted from that used by Feldman et al. (2009). We differ in allowing model parameters to change with context, and focus on different aspects of the model's predictions.¹

The modeled listener hears signal S in context k , and must decide whether it belongs to category c_1 or c_2 . Listeners in this model assume S is normally distributed around a target pronunciation T , itself normally distributed around a category mean, and categorize based on the likelihood that S is an instance of the speaker producing an example from c_i in context k , with target T . Formally,

$$T | c_i, k \sim N(\mu_{c_i, k}, \sigma_c), \quad S | T, c_i \sim N(T, \sigma_s)$$

where $\mu_{c_i, k}$ is the mean of category i mean in context k , σ_c^2 is the variance in T around the category mean, and σ_s^2 is the variance in S around T . We assume for simplicity that σ_c and σ_s are the same for categories 1 and 2. Although we assume that T is the variable shifting by context, if it is instead assumed that S shifts by context in a similar way, all results turn out the same.² It thus does not matter under this analysis whether contextual variation is in the target pronunciation, T , or the acoustic signal itself, S .

The probability S comes from category c_1 can be calculated with Bayes' rule:

$$P(c_1 | S, k) = \frac{P(c_1 | k)P(S | c_1, k)}{P(c_2 | k)P(S | c_2, k) + P(c_1 | k)P(S | c_1, k)} \quad (1)$$

$P(c_i | k)$ is the probability of category i occurring in context k , i.e. in the lexicon as a whole. The $P(S | c_i, k)$ are calculated by integrating over all possible T , giving a logistic function:

$$P(c_1 | S, k) = \left(1 + \frac{f_2}{f_1} e^{b - Sg} \right)^{-1} \quad (2)$$

where

$$b = \frac{1}{2} \frac{\mu_{c_1, k}^2 - \mu_{c_2, k}^2}{\sigma_s^2 + \sigma_c^2}, \quad g = \frac{\mu_{c_1, k} - \mu_{c_2, k}}{\sigma_s^2 + \sigma_c^2}$$

and $f_i = P(c_i | k)$ is the frequency of category i in context k .

Studies of PC generally focus on locating the *crossover point*, where S is maximally ambiguous between categories, i.e. S' (see Fig. 1) such that $P(c_1 | S', k) = P(c_2 | S', k) = 0.5$. Solving from (2) gives

$$S' = \frac{\mu_{c_1, k} + \mu_{c_2, k}}{2} + \frac{\sigma_s^2 + \sigma_c^2}{\mu_{c_1, k} - \mu_{c_2, k}} \ln\left(\frac{f_2}{f_1}\right) \quad (3)$$

¹Space constraints prevent us from giving detailed derivations below; these are given by (Feldman et al., 2009).

²Specifically, if we assume compensation is in S , of the form

$$T | c_i, k \sim N(\mu_{c_i}, \sigma_c), \quad S | T, c_i, k \sim N(T + \Delta_{i, k}, \sigma_s).$$

That is, the distribution of T varies by category, but is not affected by context. Given T , the distribution of S has a mean offset from T by an amount $\Delta_{i, k}$, which depends on the context.

Figure 1: Schematic of a modeled identification curve. μ_1, μ_2 are category means, S' is the crossover point, and Δ_1, Δ_2 are miscategorization probabilities.

Perceptual compensation is thus captured in this model in terms of a shift in the crossover point as a function of the context. Note that if it is assumed that $f_1 = f_2$, S' is simply halfway between the category means, while if category frequencies are not equal ($f_1 \neq f_2$), S' is shifted.

The shape of the identification curve also changes as system parameters are changed. Two important properties of the curve, schematized in Fig. 1, are the slope at the crossover point and the misclassification probabilities at the category means.

The identification curve's slope at the crossover point is a rough measure of the “degree of uncertainty” (Clayards et al., 2008) of the category boundary:

$$\text{slope at } S' = \left. \frac{dP(c_1|S, k)}{dS} \right|_{S=S'} = \frac{\mu_{c_1, k} - \mu_{c_2, k}}{4(\sigma_c^2 + \sigma_e^2)}$$

The shallower the slope, the greater the uncertainty. The slope is steeper when the difference in category means is larger relative to category variances. Unlike the crossover point's location, the slope does not change depending on whether $f_1 = f_2$.

Categorization uncertainty can also be quantified as the *misclassification probabilities* Δ_1 and Δ_2 , defined as the probability a signal S produced at the mean of category i — a “perfect” exemplar from c_i — is misclassified. We find

$$\Delta_1 = \left(1 + \frac{f_1}{f_2} e^{\frac{(\mu_1 - \mu_2)^2}{2V}}\right)^{-1} \quad \Delta_2 = \left(1 + \frac{f_2}{f_1} e^{\frac{(\mu_1 - \mu_2)^2}{2V}}\right)^{-1}$$

where $V = \sigma_c^2 + \sigma_e^2$. The misclassification probabilities decrease as the ratio of the difference in category means to the variance increases. When $f_1 > f_2$, Δ_1 decreases and Δ_2 increases (and vice versa for $f_1 < f_2$).

To illustrate the adequacy of the proposed model and its treatment of perceptual compensation, the next section re-

ports the results of a simulation study of PC for anticipatory vowel-to-vowel coarticulation in English.

A Simulation Study

A modified replication study of Beddor et al. (2002)'s seminal perception and production study of vowel-to-vowel coarticulation in English was conducted. The perceptual results serve as the observed PC responses. These were compared to responses predicted by the rational model, using parameter values obtained from two production studies.

Observed perceptual responses

Eighteen native English speakers at the University of Chicago participated in a perception experiment, consisting of a training phase followed by a test phase. The training phase was intended to expose subjects to speech in which each of $V_1 = /a/$ and $V_1 = /e/$ was equally likely to occur in the context of following $V_2 = /a/$ or $V_2 = /i/$, corresponding to $f_1 = f_2$ in our model. The test phase asked listeners to classify an ambiguous vowel V_1 as $/a/$ or $/e/$, in the context of $V_2 = /a/$ or $/i/$.

In the training phase, listeners heard CV_1CV_2 tokens ($C = /p/, /t/, \text{ or } /k/, V = /e/ \text{ or } /a/, V_2 = /a/ \text{ or } /i/$). Tokens were constructed by splicing together CV syllables produced in isolation by an adult male speaker of English. A total of thirty-six tokens were constructed ($= 3C \times 2V_1 \times 3C \times 2V_2$). Each CV_1CV_2 token was heard ten times, for a total of 360 tokens, presented in random order. To encourage attention to the training stimuli, listeners performed a phoneme monitoring task where they were asked to identify whether or not each token contained a medial $/t/$.

In the test phase, listeners performed a 2AFC categorization task on V_1 in bV_1bV_2 context, with V_1 varying in F_1 - F_3 along an 9-step $/a-e/$ continuum, and $V_2 = /a/$ or $/i/$. The nine-step continuum was generated using Akustyk (Plichta & Preston, 2004), an add-on program for vowel analysis in Praat (Boersma & Weenink, 2001), by interpolating the formant values between two syllables ($/ba/$ and $/be/$) produced in isolation.³ The test tokens were then created by splicing together each individual continuum syllable with either a $/bi/$ or a $/ba/$ syllable, also produced in isolation. The same speaker produced the speech stimuli used in both the training and test phases. Each subject heard each test stimulus ten times, for a total of 180 tokens, presented in random order. Subjects were paid a nominal fee to participate in the studies.

Fig. 2 shows empirical curves of the proportion of $V_1 = /a/$ responses in $V_2 = /a/$ and $V_2 = /i/$ contexts, as a function of position on the V_1 continuum. Error bars correspond to 95% confidence intervals over individual-subject proportions.

The V_1 categorization responses ($1 = /a/$) were modeled using a mixed-effects logistic regression (Baayen, 2008; Jaeger,

³The F_1 values of the nine steps along the $/a-e/$ continuum were 713Hz, 682Hz, 635Hz, 606Hz, 592Hz, 563Hz, 522Hz, 500Hz, and 483 Hz. Values for the higher formants were adjusted as well to create a more natural-sounding continuum. For simplicity, we focus on the coarticulatory effect on F_1 since the context vowels only vary in height and not in backness.

2008) with VOWEL CONTEXT (/a/ or /i/) and CONTINUUM (1–9) as fixed effects, and random effects of SUBJECT and BLOCK (test token number) on the intercept. As a measure of model quality, Nagelkerke’s pseudo- R^2 was 0.64, relative to a model with only the intercept. There were significant effects of CONTINUUM and VOWEL CONTEXT ($p < 0.001$), as well as their interaction ($p < 0.05$). The effect of VOWEL CONTEXT was an increase in $V_1=/a/$ responses for $V_2=/i/$ compared to $V_2=/a/$, in agreement with the results of Beddor et al. (2002): native English listeners appear to perceptually compensate for the coarticulatory effects of a following vowel.

Model-predicted perceptual responses

To predict expected identification curves using Eqn. 2, we need the category means of /a/ and /e/ (V_1) in the context of following /a/ or /i/ (V_2), and category variances for V_1 in $V_2=/a/$ and $V_2=/i/$ contexts.⁴ (Recall that we are assuming equal variances of $V_1=/a/$ and $V_1=/i/$, given the following context.) Eqn. 2 also includes the relative probability (f_1/f_2) of $V_1=/a/$ and $V_1=/i/$ in each V_2 context. We assume that $f_1/f_2 = 1$ following the training phase.

The category mean and variance parameters were estimated from two production studies. Category means were based on 40 productions of the form bV_1bV_2 (10 for each combination of $V_1 \in \{a, e\}$ and $V_2 \in \{a, i\}$) by the speaker whose speech was the basis of the training and test tokens. Category variances were calculated from productions of initial stressed /adV₁CV₂/ sequences ($V_1 \& V_2 = /a/, /e/,$ or $/i/$ and $C = /p/$ or $/b/$), each repeated ten times in random order, by four male, phonetically-trained native English speakers. No subjects who participated in the perception experiment participated in the production studies as well.

We thus assumed that during the experiment, subjects adjusted their expectation of category means to match the speaker they were hearing, but that their category *variances* reflected variation across speakers.⁵

For all production data, formant values were measured at the midpoint of the target V_1 . Means and variances were calculated over Bark-transformed F_1 values for V_1 . Variances for V_1 when $V_2=/a/$ were taken to be the mean of the variances for /aCa/ stimuli and for /eCa/ stimuli. Variances for V_1 when $V_2=/i/$ were calculated similarly. The resulting model parameters are listed in Table 1.

The predicted identification curves for $V_2=/a/$ and $V_2=/i/$ contexts are given in Fig. 2. For comparison with the experimental results, Step 1 was taken to be the mean of μ_{c_2} (where c_2 is “ $V_1=/e/$ ”) in $V_2=/a/$ and $V_2=/i/$ contexts, and Step 9 was

Table 1: Model parameters obtained from the production study, where c_1 is “ $V_1=/a/$ ”, c_2 is “ $V_1=/e/$.” B=Bark.

V_2	μ_{c_1}	μ_{c_2}	$\sigma_C^2 + \sigma_S^2$
/a/	6.69 B	4.67 B	0.568 B ²
/i/	6.76 B	4.26 B	0.619 B ²

taken to be the mean of μ_{c_1} (where c_1 is “ $V_1=/a/$ ”) in $V_2=/a/$ and $V_2=/i/$ contexts.

Qualitatively, the fit between the experimental and model-predicted curves in Fig. 2 is very good, without fitting any free model parameters to the production data. Both experimental and model curves show a rightward shift for $V_2=/a/$ context, and the predicted slope at the crossover point for both pairs of curves are approximately the same.⁶ However, the quality of the fit depends on how rational model parameters are derived from the production study, and should be interpreted with caution. For example, category variances ($\sigma_C^2 + \sigma_S^2$) would be smaller if based on tokens from a single speaker rather than several speakers, making the slope of the rational model curves steeper.

Figure 2: Dashed lines: Proportion of /a/ responses for $V_2=/a/$ (right curve) and $V_2=/i/$ (left curve) contexts, across all subjects. Error bars are 95% confidence intervals, based on individual-subject proportions. Solid lines: Predicted identification curves, based on production data. Dotted line: Crossover point (rate=0.5).

Discussion

We have illustrated a rational model of perceptual compensation effects and shown that, given a simple probabilistic model for the observed values of an acoustic-phonetic cue

⁴Nearey & Hogan (1986) propose two models for deriving identification curves from production data. Their ‘NAPP’ model is similar to the present model, but is not derived from an RA viewpoint. We also map production data to model parameters differently.

⁵Another interpretation of these category variances, suggested by a reviewer, is that subjects assume the tokens have category variances typical of a single speaker, but also account for some “noise” in perception, beyond the variance observed in the production data of an individual speaker.

⁶The correlation between the two sets of curves is very high ($r = 0.987$, $p < 0.001$), indicating good qualitative agreement.

(here, F_1 values) associated with a speech sound, it is possible to understand perceptual compensation as an idealized rational listener arriving at an optimal solution based on evidence from prior experience. In this model, by choosing the most probable categorization response given the context, based on their knowledge of the probability distribution of the relevant cue in that context, listeners appear to ‘undo’ the effect of coarticulation. Different contexts are associated with different cue distributions, and hence difference categorization responses.

Rational models provide a very general expression of the computational problem being solved when performing some cognitive task, and are largely orthogonal to proposed mechanisms by which the task is performed. Our model proposes an abstract explanation for why PC occurs, but is compatible with a role for different proposed mechanisms for PC effects via “prior knowledge” encoded in the cue distributions and category frequencies. The model assumes that listeners have different cue distributions for different contexts, but does not specify the source of the distributions; it could be that knowledge about gestures or general auditory capabilities generate or underly the distributions. The category frequencies could reflect knowledge of lexical or phonotactic probabilities, as pointed out by Feldman et al. (2009).

The model is able to accommodate two types of PC effects — language-dependent and domain-general — usually emphasized in opposing accounts of PC. That PC effects are language-dependent is expected because many coarticulatory effects are language-specific. Since language-specific coarticulatory effects are reflected in acoustic-phonetic cues, listeners’ categorization responses should mirror the (language-specific) probability distributions of the relevant cues. The model is general in that it is not restricted to linguistically-relevant acoustic cues. As long as a non-linguistic acoustic cue has a probability distribution, the idealized rational listener (human or non-human) would seem to compensate in the same way as she would if the acoustic cue were linguistic.

Our model predicts that compensation effects could be ameliorated or even reversed via adjustments to the model parameters. In general, an observed PC effect corresponds to different values of S' (the crossover point) in different contexts, say k_1 and k_2 . The second term of (3) predicts that S' in k_1 and S' in k_2 depend on the relative frequencies of c_1 and c_2 in these contexts. Thus, if f_2/f_1 differs significantly by context, the context-dependent PC effect can be exaggerated, diminished, canceled, or even reversed. Failure to compensate could therefore occur for sudden change in f_2/f_1 for k_1 but not k_2 . Since this proposed effect depends on the second term of (3), compensation could also be undone by changes in variances ($\sigma_C^2 + \sigma_S^2$) or category mean differences ($\mu_{c_1,k} - \mu_{c_2,k}$) for k_1 versus k_2 . We are currently running experiments to test the predicted effects of category frequency on compensation.

This understanding of PC failure has serious implications for current theories of sound change. Many researchers,

most notably Ohala (1993), argue that articulatory and perceptual factors shape phonological systems through listener misperception-induced sound changes, and that the synchronic typology of sound patterns is a consequence of the phonologization of such phonetic “precursors” (Barnes, 2006; Blevins, 2004; Blevins & Garrett, 1998, 2004; Kavitskaya, 2001; Yu, 2004). That is, sound change occurs when listeners mistake as representative of the speaker’s target pronunciation the effects of the speakers’ production system, the listeners’ own perceptual system, or ambient distortion of the acoustic stream. However, this account assumes that errors in perception (i.e. failure to compensate for contextual variation) lead to adjustments in perceptual and production norms. The fact that perceptual compensation is observed so robustly in speech raises questions about the feasibility of this type of model of sound change. Earlier work has assumed that failure to compensate for contextually-induced variation occurs when listeners do not detect the conditioning context. Our model suggests that the relative magnitude of compensation can be mediated by properties of the language’s lexicon (e.g. the relative frequencies of phones) as well as speakers’ prior experience with the language (e.g. pronunciation variation). That is, given certain lexical or contextual conditions, a change in compensatory response may take place even when the conditioning contextual information is accurately perceived.

Conclusion

The model proposed here allows the incorporation of both speech-specific and general auditory factors. It proposes that perceptual compensation effects emerge as a consequence of an optimal response to the problem of categorization in the presence of context-induced variation. To be sure, the present model is simplistic, and only a first step toward modeling compensatory phenomena in general. Future work will develop more general models, e.g. with unequal category variances and multiple (>2) categories, and explore their effects on predicted categorization behavior. Nonetheless, the present model contributes to the growing number of studies that attempt to understand speech perception from a rationalist point of view (Clayards et al., 2008; Feldman & Griffiths, 2007; Feldman et al., 2009; Norris & McQueen, 2008).

Acknowledgments We thank Matt Goldrick and James Kirby for comments on an earlier version of this paper, Max Bane for statistics discussion, and Ed King for setting up the experiment. Part of this work was presented at the 2009 Linguistic Society of America meeting. MS is supported by a Department of Education GAANN fellowship.

Abstract

Although previous research has established that multiple top-down factors guide the identification of sounds during speech processing, the ultimate range of interaction across levels of linguistic structure is still unknown. In a set of experiments, we investigate whether interactive effects emerge between the two most disparate domains: pragmatic inference and acoustic speech perception. We use contexts that trigger pragmatic expectations regarding upcoming coreference (expectations for either *he* or *she*), and, in those contexts, we test listeners' identification of phonetic category boundaries (using words on the /hi~/i/ continuum). The results indicate that pragmatic inference can indeed alter listeners' identification of phonetic categories.

Keywords: Phonetics, pragmatics, categorical perception, pronoun interpretation, implicit causality

Introduction

There is a growing body of evidence suggesting that language processing requires the integration of multiple sources of linguistic knowledge across multiple levels of linguistic structure. These relevant knowledge sources range from low-level features of the acoustic signal, through lexical and morpho-syntactic properties of words and phrases, up to higher-level semantic and pragmatic inferences about the speaker's intended message (e.g., Ganong 1980 and Pitt 1995 for lexical effects on phoneme perception; Spivey & Tanenhaus 1998 for lexical effects in syntactic processing; and van Berkum, Brown, & Hagoort 1999 for pragmatic effects in syntactic processing, among many others). Occupying the far ends of this spectrum are phonetics and pragmatics. Therefore, we submit that identifying contexts in which comprehenders bring together cues from these two very distinct domains would provide a strong demonstration of the maximum extent of this interactivity.

Our experiments test for interactive effects at the pragmatic-phonetic interface in contexts in which listeners' comprehension of an acoustically ambiguous word might reflect pragmatic biases of the discourse context. To do this, we use words whose interpretation is inherently discourse dependent—namely, personal pronouns. Based on existing pragmatics work on pronoun interpretation, we use contexts in which listeners have been shown to anticipate subsequent reference to a particular referent. We then capitalize on the fact that the English third person pronouns *he* and *she*

constitute minimal pairs in order to construct acoustically ambiguous words that vary along a *h~sh* continuum. The results we find attest to the extent of interactive effects that any successful language processing model must capture. The results also contribute to the well-established literature on phoneme identification by broadening the set of known factors that can influence processing.

Modeling Pragmatic Interaction

Interactive approaches to processing are characterized by models “in which lexical, structural (syntactic) and interpretive knowledge sources communicate and interact during processing in an optimally efficient and accurate manner” (Marslen-Wilson & Tyler 1980). Existing work has identified top-down pragmatic effects, i.e. interaction, within syntactic processing, but interactive effects between pragmatic and phonetic information sources have not, to our knowledge, been demonstrated before.

Early work demonstrated the effect of pragmatic factors on other levels of sentence processing, showing that appropriate discourse contexts can eliminate syntactic garden paths (Crain & Steedman 1985; Altmann & Steedman 1988). This work established that comprehenders treat material following a definite NP (*The horse in The horse raced past the barn fell*) differently depending on the number of available referents (the number of horses) in the discourse context. These contextual effects have been attributed to a felicity constraint that requires that a definite NP have a unique and identifiable referent—a constraint that encourages comprehenders to interpret post-nominal material (*raced past the barn*) as NP modification rather than a main verb. Referential context has also been shown to yield online effects in syntactic processing (Ni, Crain, & Shankweiler 1996; van Berkum, Brown, & Hagoort 1999; Sedivy 2002). These results lend support to models of incremental processing in which comprehenders have access to pragmatic information before sentence-internal syntactic decisions have been fully resolved. Our work also relies on referential biases, but we push the extent of interactivity further by showing that discourse context can influence the identification of a phonetic category boundary.

Modeling Contextual Effects in Phonetics

Existing work on the factors that influence phoneme identification has established that listeners use more than

just the acoustic signal. The contextual factors that have been shown to have an impact include cues such as lexical status, syntactic category, and semantic congruity. The influence of such contextual factors can be captured both in models that permit top-down contextual information to impact sound perception directly, as in McClelland & Elman's (1986) TRACE model as well as in models in which the perceptual system operates fully independently from other levels of language processing and top-down factors only exert an influence at the point of lexical decision, as in Norris, McQueen, & Cutler's (2000) Merge model. Models like TRACE permit interaction at all levels whereas models like Merge attribute top-down effects to the integration of multiple information sources when a lexical decision is made. We use the term *interactive effects* here to refer to listener responses that reflect biases from information sources at different levels of linguistic structure, but we do not distinguish between the interaction and integration accounts (for discussion of this debate as well as methods for distinguishing the two approaches, see Norris et al. 2000, Magnuson, McMurray, Tanenhaus, & Aslin 2003, and Samuel & Pitt 2003). Our primary goal here is to extend the observed range of top-down effects beyond the previously reported lexical, syntactic, and semantic levels.

Contextual effects based on lexical status were first shown by Ganong (1980) in experiments that established that listeners' phonetic category judgments can be influenced by the lexical status of the stimulus: Ambiguous sounds along the /t~/d/ continuum are more likely to be reported as /t/ when presented as the onset in a *task~dash* continuum and are more likely to be reported as /d/ when presented as part of a *tash~dash* continuum.

Phonetic category judgments are also sensitive to syntactic context: Acoustically ambiguous words along the *to~the* continuum are more likely to be reported as *to* in contexts with a verb, as in *We tried to go*, than in contexts with a noun, as in *We tried the gold* (Isenberg, Walker, & Ryder 1980; see also van Alphen & McQueen 2001).

Furthermore, there is evidence that ambiguous sounds are interpreted differently depending on the semantic congruity of the target word in a particular context: Ambiguous sounds along the *path~bath* continuum are more likely to be reported as /p/ in the context *She likes to jog along the...* and are more likely to be reported as /b/ in the context *She needs hot water for the...* (Miller, Green, & Schermer 1984). Miller et al. report, however, that semantic congruity effects disappear when the task requires listeners to focus only on the target word, rather than on the full sentence frame.

One way of understanding these syntactic and semantic effects is to assume that a particular interpretation of the acoustically ambiguous item is more accessible or more strongly activated given the surrounding lexical items. In other words, lexical items like *go* and *gold* constrain the part of speech of the preceding word. Similarly, contexts that mention *hot* and *water* activate the word *bath*, whereas contexts that mention *jogging* activate *path*. These associations can be said to reflect comprehenders' syntactic

knowledge and their mental models of particular events and event participants. As such, these results point to the dynamic integration of information sources ranging from hierarchical syntactic structures to real-world event knowledge. However, these associations may also be attributed to simple co-occurrence frequencies (see Willits, Sussman, & Amato 2008 for a co-occurrence-based account of data that has previously been taken to support highly interactive models). That is, it is possible that these results do not reflect listeners' understanding or parsing of the context in question, but rather reflect statistical frequencies over adjacent words.

The results presented in this paper go beyond this previous work in several important ways. In our contexts, we simultaneously hold constant both the lexical status of our target items and their syntactic category. Furthermore, our target items can be considered semantically neutral in that they are used across semantic contexts and their relationships to other words in the context do not reduce to co-occurrence frequencies.

Our experiments demonstrate that phoneme identification is sensitive to pragmatic inferences about referents in the discourse context and to domain-general causal reasoning. First, Experiment 1 replicates the Ganong effect of phonetic~lexical interaction for the /h~/j/ continuum. Experiments 2 and 3 use a novel design to test whether listeners' pragmatic expectations can influence phonetic category identification. For the second and third experiments, lexical status is not at issue because all acoustically ambiguous sounds yield legitimate lexical items, allowing us to attribute the effects we observe to interactive effects between pragmatic and phonetic cues.

Experiment 1: Ganong Replication for /hi~/ji/

In order to establish that the /h~/j/ continuum is a valid one for assessing phonetic category perception, we first obtained a measure of the effect of lexical status on acoustic perception by replicating the Ganong effect for /h~/j/. We tested whether listeners would judge the ambiguous onset of a monosyllabic item (e.g., [ɪk/]) as more /j/-like if the English lexicon contains a word with a /j/- onset (e.g., *sheik*) and lacks a corresponding word with a /h/- onset (**heik*, **heek*).

Methods

Participants 35 native English-speaking Northwestern University undergraduates received either \$6 or course credit for their participation in the study. A subset of these participants also completed Experiments 2 and 3. Note that this experiment, labeled here as Experiment 1, was always completed as the last part of the experiment session if the session included multiple tasks.

Materials Six pairs of items were created such that each pair consisted of a word and a non-word. The pairs *sheik*/**heik*, *sheen*/**heen*, and *sheaf*/**heaf* were the /j/-

biasing pairs in which the /j/- onset constituted a word. The pairs *heids/*sheeds*, *heels/*sheels*, and *heave/*sheave* were the /h/-biasing pairs in which the /h/- onset constituted a word. Onsets ranged from /h/ to /j/ along a 20-step acoustic continuum. Unlike the /t~/d/ continuum, which can be generated by varying a single acoustic parameter, namely voice onset time, /h~/j/ is not differentiated by a single simple parameterizable acoustic variable. Therefore, we combined two naturally produced tokens of *he* and *she* at varying intensities (McGuire, 2007; Munson & Coyne, *in press*). The duration of the fricative portion, which may also serve as a cue to differentiate these two items, was the average of the /hi/ and /ji/ tokens. Items were constructed such that each of the 6 pairs appeared with each of the 20 /hi~/ji/ steps. Participants heard all items twice.

Procedure Participants listened to the items through headphones while sitting in a sound-attenuating booth. For each item, they were asked to indicate using a button box whether the onset of the item sounded more *h*-like or more *sh*-like on a 4-point scale.

Results and Discussion

As predicted, listeners were more likely to report hearing an initial /j/ for /j/-biasing items (items on the *sheik~heik*, *sheen~heen*, and *sheaf~heaf* continua; mean score=2.9, where 1 is /h/ and 4 is /j/) than for /hi/-biasing items (items on the *heids~sheeds*, *heels~sheels*, and *heave~sheave* continua; mean score=2.4). There was a main effect of lexical status with the data collapsed across steps ($F(1,33)=192.737$, $p<0.001$). The results are shown in Figure 1 with error bars for standard error of the mean.

Figure 1: Impact of lexical status on perceived phonetic category for /hi~/j/ continuum in Experiment 1

The main effect of lexical status replicates the effect originally observed by Ganong for the /t~/d/ continuum, extending the effect to the /h~/j/ continuum. Because a subset of the participants had already participated in Experiments 2 and 3 during the experiment session, we also compared performance based on prior experiment participation. There was no difference between participants who had only participated in Experiment 1 and those that had participated in multiple experiments ($F<1$).

Experiment 2: Referential Context

In our first examination of whether listeners' pragmatic knowledge and reasoning influences their phonetic category perception, we used contexts in which all contextually relevant referents were of the same gender in order to see if referential context biased listeners' interpretation of a subsequent acoustically ambiguous pronoun. If listeners do not combine pragmatic and phonetic information in determining phonetic category membership, we would expect to see category assignments based only on the acoustic input of the pronoun, regardless of referential context. On the other hand, if listeners can combine pragmatic and phonetic cues and if pragmatic information is available when listeners are making phonetic category decisions as part of the interpretation of words in full-sentence discourse contexts, we would expect to see category assignments that differ by context.

Methods

Participants 26 native English-speaking Northwestern undergraduates participated. All individuals went also participated in Experiments 1 and 3 during the same session.

Materials 40 sentences were constructed consisting of two clauses connected by *because*. The first clause introduced two individuals of the same gender and the second clause contained an acoustically ambiguous pronoun, as in (1-2).

(1) *he*-biasing context:

Luis reproached Joe because ☐ hadn't done the work.

(2) *she*-biasing context:

Joyce helped Sue because ☐ was up against a deadline.

If listeners infer that the discourse context is limited to the two named individuals in the first clause, then the pronoun in the second clause must be linked to an antecedent that is matched for gender. Because the two available referents in the discourse context were of the same gender, the sentences strongly bias the interpretation of the acoustically ambiguous pronouns to *he* in contexts like (1) or *she* in contexts like (2). We normed a total of 20 steps along the /hi~/j/ continuum (using the /hi~/j/ component in isolation, not in sentential contexts) to find steps that were centered around the point of maximum ambiguity for listeners. From those 20, we selected a smaller set of 5 steps for testing in order to increase the number of trials at each

data point without repeating items. Each sentence contained a pronoun consisting of one of the 5 /hi~/ /ji/ steps. We manipulated gender bias within subjects and between items. Participants heard all items once.

Procedure Participants listened to the sentences through headphones while sitting in a sound-attenuating booth. For each item, they were asked to indicate on a button box whether the sentence mentioned *he* or *she*, using a 4-point scale. After each sentence participants were asked a *yes/no* comprehension question based on the sentence's meaning (but not the interpretation of the pronoun) to ensure they were focused on understanding the sentence and not simply focused exclusively on the ambiguous phoneme.

Results and Discussion

Only trials where participants correctly answered the comprehension question were included in the results. As predicted by an interactive account, we found that items with *she*-biasing contexts that contained only female referents yielded higher *she* ratings (mean score=2.3 where 1 is *he* and 4 is *she*) than *he*-biasing contexts that contained only male referents (mean score=1.6). There was a main effect of gender context with the data collapsed across steps ($F(1,26)=37.860, p<0.005$). The results appear in Figure 2.

Figure 2: Impact of referential context on perceived phonetic category in Experiment 2

These results support a model of processing in which pragmatic biases are brought to bear on decisions regarding phonetic category membership, at least to the extent that referential context influences listeners' expectations about which individual will be mentioned next.

One question that can be raised regarding Experiment 2 is whether the experiment actually tests listeners' pragmatic reasoning or whether the results can also be explained by semantic neighborhood or co-occurrence effects. Sentences that contain female names may simply be more likely to contain the word *she*, and sentences that contain male names

may be more likely to contain the word *he*. Given this concern, Experiment 3 uses contexts in which a female name and a male name are both present. Instead of relying on a single-gender referential context, Experiment 3 uses listeners' pragmatic reasoning about event causality in order to shift co-reference biases.

Experiment 3: Causal Reasoning

In order to construct contexts in which domain-general aspects of pragmatic reasoning might influence sound perception, we used sentences containing verbs from the class of so-called implicit causality verbs (Garvey & Caramazza 1974, *inter alia*). These verbs have been shown to guide listeners' coreference expectations by describing events in which one participant (either the subject or object, depending on the verb) is implicated as central to the event's cause and is thus likely to be re-mentioned in a subsequent *because* clause.

Methods

Participants 26 native English-speaking Northwestern University undergraduates participated. All individuals also participated in Experiments 1 & 2 during the same session. This experiment was completed as the first task.

Materials 40 sentences were constructed consisting of two clauses connected by *because*. The first clause introduced two individuals of opposite gender and an implicit causality verb; the second clause contained an acoustically ambiguous pronoun. Items were balanced for implicit-causality bias (subject preference vs. object preference) and the position of the male and female names (subject vs. object), as in (3-6).

- (3) *she*-biasing context, object verb bias
Luis reproached **Heidi** because ☐ was getting grouchy.
- (4) *he*-biasing context, object verb bias
Joyce helped **Steve** because ☐ was working on the same project.
- (5) *she*-biasing context, subject verb bias
Abigail annoyed Bruce because ☐ was in a bad mood.
- (6) *he*-biasing context, subject verb bias
Tyler deceived Sue because ☐ couldn't handle a conversation about adultery.

Each sentence contained one acoustically ambiguous pronoun (taken from the 5 steps on the /hi~/ /ji/ continuum that were normed for the Experiment 2 materials). Participants heard all items once. In order to ensure that any measured effect was due to the pragmatic biases of the IC verbs and not the plausibility of the sentence continuations (e.g. *he/she was getting grouchy*), we normed the sentences and confirmed that both *he* and *she* versions were judged to be significantly more plausible than a set of implausible

passages ($F(1,11)=770.95$, $p<0.001$, with 12 subjects who did not participate in Experiments 1, 2, or 3).

Procedure The procedure was the same as in Experiment 2.

Results and Discussion

Only trials in which the comprehension question was answered correctly were included in the results. As predicted, we found that *she*-biasing contexts yielded higher *she* ratings (mean score=2.5) than *he*-biasing contexts (mean score=2.0). There was a main effect of gender context with the data collapsed across steps and across verb types ($F(1,26)=18.738$, $p<0.001$). The results appear in Figure 3.

Figure 3: Impact of referential context on perceived phonetic category in Experiment 3

These results support a model of language in which listeners' pragmatic reasoning regarding who is likely to be implicated as the cause of an event influences their phonetic category decisions.

General Discussion

As we described in the introduction, a body of accumulating evidence points to the integration of multiple information sources during language processing. The results presented here suggest that the range of interacting cues spans the conceivable range of linguistic information sources and that phonetic information interacts with high-level causal inferencing about events, event participants, and the likelihood of co-reference across clauses in a discourse.

Our results are in keeping with work showing that the larger discourse context can influence language processing at lower levels. Furthermore, our results suggest that current processing models—be they interactive or integrative—which combine multiple cues from multiple linguistic domains must be refined and better articulated to capture the range of interactivity shown here.

Existing models of phoneme identification currently account for contextual effects such as the semantic congruity effect in one of two ways. Highly interactive models permit direct interaction between acoustic cues, the lexicon, and contextual cues (contextual cues broadly construed, e.g. visual cues, speaker information, acoustic context) such that top-down biases can influence the perceptual system itself (Goldinger 1996; Johnson 1997; Luce & Pisoni 1998; McClelland & Elman 1985). On the other hand, integrative models have been proposed that specify the point of lexical decision as the stage at which listeners combine higher-level information sources with lower-level phonetic cues (Norris et al. 2000). Both types of models could in principle be adapted to account for our results, so long as the range of contextual cues is not restricted to lexical or co-occurrence-based input. For interactive models, an important question is whether pragmatic information is integrated directly into the speech perception process, adding an additional set of non-acoustic cues into the lexical decision process, or whether pragmatic context yields an expectation for a particular continuation, which in turn makes the perceptual process more sensitive to certain acoustic cues. For models that rely on post-perceptual integration of information, however, context serves as a check on an encapsulated perception process; for those models, our results show that pragmatic biases can act as relevant constraints, in addition to other biases that are introduced by lexicality, syntax, or semantics. The difference in effect size between Experiments 2 and 3 may point to differences in the timecourse and strength of such biases.

Just as existing models of phoneme identification could in principle be extended to include higher-level top-down biases, another option for modeling our results would be to adapt existing sentence processing models to capture effects at lower levels of processing. Existing constraint-based sentence processing models have up until now primarily targeted syntactic processes not phoneme decisions (MacDonald 1994; Jurafsky 1996; Spivey & Tanenhaus 1998; McRae, Spivey-Knowlton, & Tanenhaus 1998; Levy 2008, among others). These models—crucially their architectures for integrating multiple cues—could be adapted to fit our data by incorporating discourse-based constraints that interact fully with other processing biases, including those generated at the phonetic level. The work described in this paper attests to the importance of a unified approach that models a range of information sources and their influence on each other during processing.

Existing models have thus not fully addressed the question of precisely which linguistic levels show interactive effects and what mechanism would allow phonetic and pragmatic information to be combined. Our results, which present a new type of interaction, help establish the extent of possible interactivity that must be accounted for, though the results also raise questions regarding the exact nature of these interactive effects.

Recent evidence on the neural bases of lexical effects on phonetic perception points towards the interactive approach (Myers & Blumstein, 2008). The contexts used here provide an opportunity to explore whether different processing systems make use of different strategies for incorporating information from different levels. If multiple systems are in operation, it is possible that the levels in closest proximity interact in a more dynamic fashion. By identifying contexts that induce interactive effects at quite disparate linguistic levels, future work can explore whether the timecourse of such effects are attributable to integrative or interactive mechanisms. Future work must address these questions, and the paradigm we have introduced here provides useful contexts for such work precisely because these contexts permit the manipulation of biases that may be active when listeners are interpreting sounds in rich discourse contexts.

Abstract

A central idea in many successful models of category learning—including the Generalized Context Model (GCM)—is that people selectively attend to those dimensions of stimuli that are relevant for dividing them into categories. We use the GCM to re-examine some previously analyzed category learning data, but extend the modeling to allow for individual differences. Our modeling suggests a very different psychological interpretation of the data from the standard account. Rather than concluding that people attend to both dimensions, because they are both relevant to the category structure, we conclude that it is possible there are two groups of people, both of whom attend to only one of the dimensions. We discuss the need to allow for individual differences in models of category learning, and argue for hierarchical mixture models as a way of achieving this flexibility in accounting for people's cognition.

Keywords: Selective attention, Category learning, Generalized Context Model, Individual differences, Hierarchical Bayesian modeling

Introduction

Selective attention is one of the most compelling theoretical ideas in the study of human category learning. The basic idea is that, to learn a category structure, people selectively attend those dimensions of the stimuli that are relevant to distinguishing the categories. Nosofsky's (1984) landmark paper showed that, for stimuli represented in terms of underlying continuous dimensions, selective attention could help explain previously puzzling empirical regularities in the ease with which people learn different category structures (Shepard, Hovland, & Jenkins, 1961).

The Generalized Context Model (GCM: Nosofsky, 1984, 1986) incorporates an attention process that has proven enormously helpful in accounting for human category learning behavior. Kruschke (1992) developed a natural extension of the GCM that was able to learn selective attention weightings on a trial-by-trial basis for dimensional stimuli, and Lee and Navarro (2002) showed that the same approach worked equally well for stimuli represented in terms of discrete features rather than continuous dimensions.

In this paper, we raise the possibility that different people might apply selective attention differently when learning the same category structure. We re-analyze

Figure 1: Condensation category structure “B” from Kruschke (1993).

human performance on a single task conducted by Kruschke (1993), using the GCM, but allowing for individual differences. We find evidence that one group of people attended primarily to one dimension of the stimuli, while a second group of people attended primarily to the other dimension. This finding runs counter to a standard analysis that does not allow for individual differences, and shows a distribution of attention across both dimensions.

Category Learning Data

The data we use in our re-analysis comes from Kruschke (1993), who studied the ability of ALCOVE to account for human learning across four category structures. Each structure involved the same eight stimuli—consisting of line drawings of boxes with different heights, with an interior line in different positions—but divided them into two groups of four stimuli in different ways. The category structure we use is the so-called “Condensation B” structure, which is shown in Figure 1. The eight stimuli are arranged by their heights and positions, and the four above and to the left of the dividing line belong to Category A. The stimuli are numbered 1–8 in the figure, for ease of reference later when we present modeling results.

Kruschke (1993) collected data from a total of 160 participants, with 40 attempting to learn each category structure. The task for each participant was, over eight consecutive blocks within which each stimulus was presented once in a random order, to learn the correct category assignment for each stimulus, based on corrective feedback provided for every trial. With the aim of analyzing human performance using the GCM—which means trial-by-trial learning is not being modeled—the data can be represented by d_{ik} , the number of times the i th stimulus was categorized as belonging to Category A by the k th participant, out of the $t = 8$ trials on which it was presented. In an analysis that does not consider individual differences, the behavioral data can be further summarized as $d_i = \sum_k d_{ik}$, the total number of times all participants classified the i th stimulus into Category A, out of $t = 40 \times 8$ total presentations.

Generalized Context Model Analysis

In this section, we present a standard version of the GCM, show how it can be formulated as a graphical model to enable fully Bayesian statistical inference¹, and present its application to the current data.

The Standard GCM

The GCM assumes that stimuli can be represented by their values along underlying stimulus dimensions, as points in a multidimensional psychological space. For the current data, there are only two dimensions, so the i th stimulus is represented by the point (p_{i1}, p_{i2}) . The first dimension has an attention weight, w with $0 \leq w_d \leq 1$, and the second dimension then has an attention weight $(1 - w)$. These weights act to ‘stretch’ attended dimensions, and ‘shrink’ unattended ones. Formally, the psychological distance between the i th and j th stimuli is $d_{ij}^2 = w(p_{i1} - p_{j1})^2 + (1 - w)(p_{i2} - p_{j2})^2$.

The GCM assumes classification decisions are based on similarity comparisons with the stored exemplars, with similarity determined as a nonlinearly decreasing function of distance in the psychological space. We follow Nosofsky (1986) and model the similarity between the i th and j th stimuli as $s_{ij} = \exp(-c^2 d_{ij}^2)$, where c is a generalization parameter. The GCM also assumes that categories are represented by individual exemplars. This means that, in determining the overall similarity of a presented stimulus i to Category A, every exemplar in that category is considered, so that the overall similarity is $s_{iA} = \sum_{j \in A} s_{ij}$. Final categorization response decisions are based on the Luce Choice rule, as applied to the overall similarities. We assume an unbiased version of the choice rule, so that the probability that the i th stimulus

¹Note that this does *not* mean we are proposing a “Bayesian” or “rational” version of the GCM (cf. Griffiths, Kemp, & Tenenbaum, 2008). We are simply using Bayesian statistics, rather than traditional model-fitting methods and frequentist statistical approaches, to make inferences about GCM parameters from data. That is, we are using Bayesian inference as statisticians do, and as psychologists should do, to relate models to data.

Figure 2: Graphical model implementation of the GCM.

will be classified as belonging to Category A, rather than Category B, is modeled as $r_i = s_{iA} / (s_{iA} + s_{iB})$. The observed decision data themselves are then simply modeled as $d_i \sim \text{Binomial}(r_i, t)$, meaning that each of the t presentations of the i th stimulus has a probability r_i of being categorized as belonging to Category A.

Graphical Modeling Implementation

Our analyses are implemented using the formalism provided by graphical models. A graphical model is a graph with nodes that represents the probabilistic process by which unobserved parameters generate observed data. Details and tutorials aimed at cognitive scientists are provided by Lee (2008) and Shiffrin, Lee, Kim, and Wagenmakers (2008). The practical advantage of graphical models is that sophisticated and relatively general-purpose Markov Chain Monte Carlo (MCMC) algorithms exist that can sample from the full joint posterior distribution of the parameters conditional on the observed data. Our analyses rely on WinBUGS (Spiegelhalter, Thomas, & Best, 2004), which is easy-to-learn software for implementing and analyzing graphical models (see Lee & Wagenmakers, 2010).

A graphical model implementation of the GCM is shown in Figure 2. The known stimulus locations p_{ix} , to-

Figure 3: Joint and marginal posterior distributions over attention w and generalization c parameters of the GCM, when applied to the condensation data.

gether with the attention parameter w generate the pairwise distances d_{ij}^2 . These distances, together with the generalization parameter c generate the pairwise similarities. These similarities, in turn, lead to response probabilities r_i which generate the observed data d_i .

Results

Our results are based on 3 chains of 5,000 samples each, with a burn-in of 1,000 samples, whose convergence was checked using the standard \hat{R} statistic (Brooks & Gelman, 1997).

The key result is shown in Figure 3, which plots the joint posterior distribution of the generalization and attention parameters (as a scatterplot), as well as their marginal distributions (as histograms). The marginal posterior for the attention parameter w —which gives the weight for the position dimension—lies between about 0.55 and 0.7. This result can be interpreted as showing that people give significant attention to both dimensions, although they are probably focusing a little more on the line position than the rectangle height. In condensation tasks, both stimulus dimensions are relevant to determining how stimuli belong to categories, and so the shared attention result makes sense. In other words, the standard application of the GCM produces a psychologically reasonable inference about selective attention, and it is tempting to view this analysis as the end of the story.

Individual Differences Analysis

The standard analysis assumes, however, that all people used exactly the same parameterization of the GCM to guide their category learning. But an examination of the individual learning curves in the current data suggests a large degree of variation between subjects, and raises the possibility that there are psychologically meaningful individual differences.

Types of Individual Differences

Figure 4 gives a schematic picture of four different assumptions about individual differences. Each panel shows a data space, containing the possible outcomes of an experiment. In the No Differences panel, there is a single true point, represented by the circular marker, corresponding to one parameterization of a cognitive process. The gray circles show the variety of behavioral data that might actually be produced in an experiment. The assumption of no individual differences means the goal of inference would be to find the circular marker from the gray points, and corresponds to the standard analysis of the GCM we have presented.

In the Continuous Differences panel there are many true points, again shown by circular markers. Each of these points could correspond to an individual subject's data from an experiment. The individuals are not identical (i.e., there is no longer a single point), but nor are they unrelated (i.e., their points are not spread across the entire data space). This sort of individual differences can be accommodated by hierarchical or multi-level models, in which there is a single hierarchical group distribution over the parameters of the individuals (e.g., Rouder & Lu, 2005).

In the Discrete Differences panel there are two true points, shown by a circular and a square marker. Each of these points could correspond to the data from different individuals, or from different subgroups, each with multiple individuals, in an experiment. The two points correspond to fundamentally different parameterizations of a cognitive process, or even to fundamentally different cognitive processes, and so the overall data is a mixture of two different cognitive processes. Mixture models are typically used to accommodate this sort of individual differences (e.g., Lee & Webb, 2005).

Figure 4: Four different assumptions about individual differences.

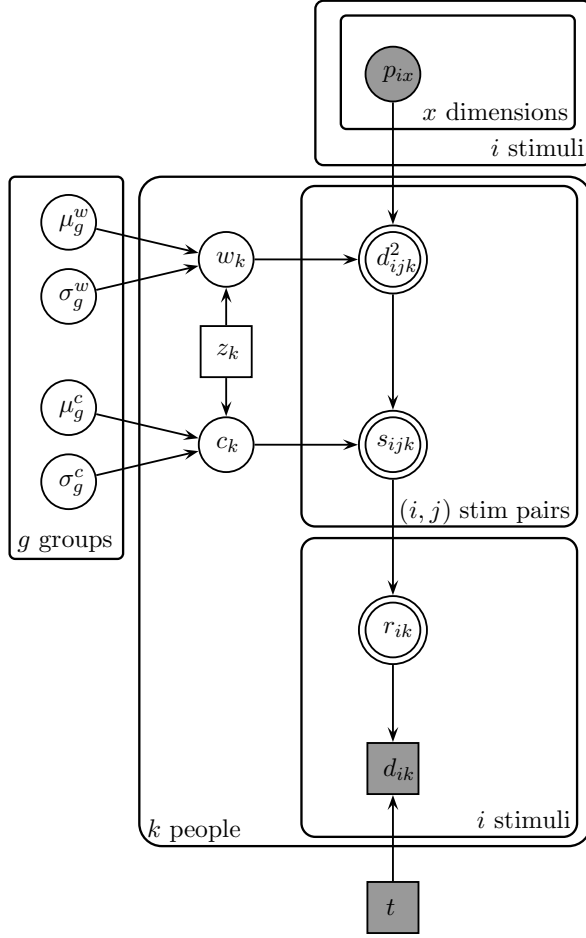

Figure 5: Graphical model for the GCM with individual differences.

The obvious strategy for a more complete account of individual differences is to combine both Continuous and Discrete differences, as in the bottom-right panel on Figure 4. Here, there are two types of true points—indicated by circular and square makers—and constrained individual variation within each type. A combination of both hierarchical and mixture modeling naturally deals with these patterns of differences. The mixture component identifies the fundamentally different cognitive processes, and the hierarchical component captures the variation within each process. We are not aware of cognitive modeling that has adopted this approach, but it seems the most general and natural way to extend the GCM analysis.

Graphical Model Implementation

Figure 5 shows the graphical model that extends the GCM to allow for continuous and discrete individual differences. There is now a plate for the participants, so that the k th participant has attention w_k and generalization c_k parameters. These are drawn hierarchically

from one of a set of Gaussian distributions depending on their group membership z_k . Formally, this means $w_k \sim \text{Gaussian}(\mu_{z_k}^w, \sigma_{z_k}^w)$ and $c_k \sim \text{Gaussian}(\mu_{z_k}^c, \sigma_{z_k}^c)$.

Statistically, this is a hierarchical (or “random-effect”) mixture model. Psychologically, people belong to different qualitative groups, given by z_k , and their attention and generalization parameters are sampled from a continuous Gaussian distribution corresponding to their group.

We put standard vague priors on the group means and standard deviations, and on the latent assignment indicator variables. We then applied this extended GCM model to the current condensation data, assuming there were two groups of participants.

Results

Once again, our results are based on 3 chains of 5,000 samples each, with a burn-in of 1,000 samples, whose convergence was checked. Our key findings are laid out in Figure 6. The top-most bar graph shows the inferred allocation of the 40 participants into the two groups, as measured by the posterior expectation of the z_k variable. There are unambiguous assignments for 36 participants, with 24 belonging to Group 1 and 12 belonging to Group 2. This lack of uncertainty in mixture model latent assignment is usually an indication that there are multiple groups.

The attention and generalization properties of the two groups, in the form of the joint and marginal posterior distributions of μ_g^w and μ_g^c , are shown in the next two panels. Group 1 on the left has an attention weight above 0.8, while Group 2 on the right has an attention weight close to 0. The natural interpretation is that the first group of participants is primarily attending to the position dimension, while the second group is almost exclusively attending to the height dimension.

Below the posterior distribution for the groups, a posterior predictive check of fit to the behavioral data is shown. For each of the 8 stimuli the posterior predictive distribution over the number of times it is classified as belonging to Category A is shown by the squares, with the area of each square being proportional to posterior predictive mass. The single thick line shows the average observed categorization behavior for those participants assigned to the group. The many thin lines show the individual participant behavior for the group. It is clear that Group 1 and Group 2 have participants showing qualitatively different patterns of categorizing the stimuli, and these differences are captured by the posterior predictive distributions.

The bottom-most panels in Figure 6 interpret the different category learning of the groups. The original stimulus space and category structure is shown, with bars showing the average number of times each stimulus was placed in Category A and Category B by members of the group. To understand Group 1, note that stimuli 4 and 5 are the ones least clearly categorized correctly. This is consistent with a focus on the position dimension, which would assign these two stimuli incorrectly. Similarly, for Group 2, stimuli 2 and 7 are categorized very poorly.

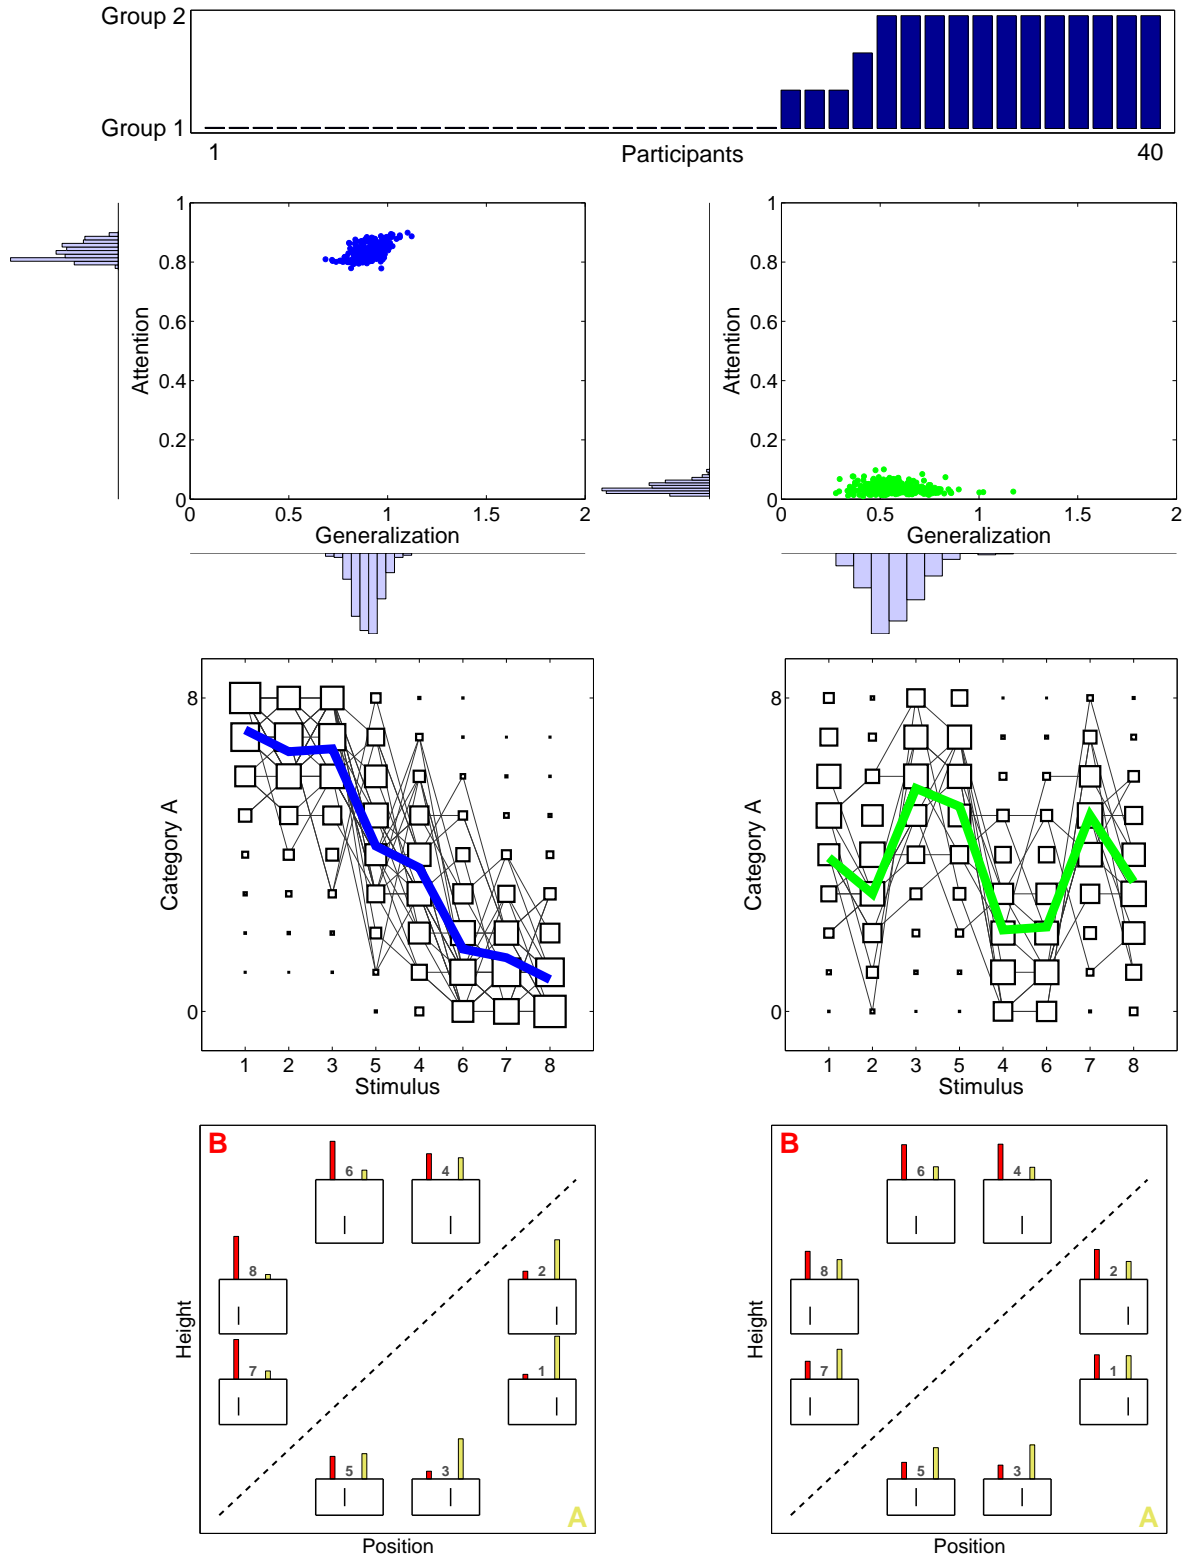

Figure 6: Results from GCM analysis assuming two groups of participants, showing the allocation of participants to groups, posterior and posterior predictive distributions for the groups, and the interpretation of the different groups in terms of the stimuli and category structure itself. See text for details.

This is consistent with a focus on the height dimension.

Finally, we compared a one-group to a two-group model, calculating the Bayes Factor using the Savage-Dickey method described by Wetzels, Grasman, and Wagenmakers (2010). This came out about 2.3 in favor the two-group model, meaning that the data are more than twice as likely to have come from two groups of participants than a single group. While this is far from conclusive evidence, it does suggest that the possibility there are two different groups of participants deserves serious consideration.

Discussion

Our extended analysis of Kruschke's (1993) condensation data, using a GCM with the ability to detect continuous and discrete individual differences, tells an interesting story. It suggests that there are two groups of participants, each of whom focus most of their attention on just one stimulus dimension while learning the category structure. The standard result of attention being distributed roughly evenly across both dimensions seems to be an artefact of failing to consider individual differences in modeling.

We realize that applying the GCM to the condensation data is non-standard, because the GCM is usually applied to category learning experiments with a training and a testing phase, rather than a single category learning sequence. Ideally, our modeling would be applied to transfer data collected after categories were learned to criterion, and it is possible the dynamics of learning provide a partial explanation for the individual differences we observe, although we do not think they can provide a full explanation. We also realize that there are many possible variations of the GCM that could be tried.

Accordingly, we certainly do not claim our single re-analysis automatically undermines the existing large and coherent body of work examining selective attention mechanisms in category learning. Systematic investigation of category learning across many tasks, looking for the presence of discrete and continuous individual differences, is needed to gauge the generality of our current results. We think this would be a worthwhile exercise, given the theoretical influence of selective attention mechanisms in the category learning literature.

We also think our analyses underscore a more general point, which is that it is important to consider and model individual differences in all of cognition. Finally, we think the ease with which very general assumptions about individual differences could be implemented to extend the standard GCM analysis shows the advantage of using Bayesian statistics to relate cognitive models to data.

Categorisation, Deference and Cognitive Style

Nick Braisby (Nick.Braisby@winchester.ac.uk)

Department of Psychology, University of Winchester, Winchester, SO22 4NR, UK

Sharon Hanlon (S.Hanlon@winchester.ac.uk)

Department of Psychology, University of Winchester, Winchester, SO22 4NR, UK

Abstract

Despite the importance of psychological essentialism as an account of categorisation, it is unclear what import findings of individual difference have. The present study is designed to investigate individual differences in relation to deference, a key indicator of essentialist thought. This replicates previous findings of individual differences in deference, and demonstrates a strong association between deference and field dependence (Witkin et al., 1962). In spite of the status of field dependence as a cognitive style, this study finds it has highly localised influences in relation only to categorisations and categorisation-related actions that are partly social in nature. Implications for essentialism are discussed.

Keywords: categorization, deference, essentialism, cognitive style

Introduction

Categorisation research has largely adopted a core methodological assumption of cognitive science that adults are sufficiently alike that it makes sense to talk of a 'typical' cognizer, and to pursue generalisations that disregard individual differences (von Eckardt, 1993). Yet from the earliest days of categorisation research, important individual differences have been found. Moreover, in recent years, studies have uncovered individual differences with regard to psychological essentialism. However, with the exception of research conducted in the middle of the last century, there have been only few studies of the basis for such individual differences, and whether their scope is restricted to or extends beyond categorisation itself. This paper reports a study designed to evaluate individual differences in relation to deference and essentialism in the categorisation of natural kinds.

Psychological essentialism represents an important and popular theoretical account of categorisation. According to psychological essentialism people believe, and act as if, category membership is determined by the possession of an essence (Medin & Ortony, 1989). People are deemed to believe that objects have essences, that essences are causally responsible for other properties such as appearance, and that essences are responsible for category or kind membership.

Findings that have been argued to support psychological essentialism include those of Keil (1986, 1989) and Rips (1989). Rips described a transformation in which a bird-like animal came to appear more like an insect as a consequence of exposure to radiation. Participants judged the animal to

be a bird still, even though they felt it was more similar to an insect. Keil reported the results of similar studies with children. For example, transformations included making a raccoon look and behave like a skunk through being painted and implanted with an odour sac. While younger children tended to categorise this as a skunk, older children considered it still to be a raccoon. Moreover, even younger children are disposed to categorise objects according to presumed essences (Gelman, 2000). Gelman & Wellman (1991) showed that 4 and 5 year old children appear to believe that an apple seed will grow into an apple tree, regardless of the environment in which this happens. Apparently children believe something inside the seed, and not contingent features of the environment, is causally responsible for the properties it later acquires.

Though largely developed to explain natural kind categorisation, the apparent explanatory success of psychological essentialism has led other researchers to seek to apply it in other domains, most notably to artefacts (Bloom, 1996; 1998; though see Malt & Sloman, 2007) and social categories (e.g., Haslam, Rothschild & Ernst, 2000, 2002; Haslam & Whelan, 2008; Rothbart & Taylor, 1992).

Of course, there have been criticisms of essentialism. Malt (1994) showed that categorisation of instances of water is not fully explained by the proportion of H₂O people believe the instances contain. Braisby, Franks & Hampton (1996) showed that categorisation is at odds with predictions suggested by Putnam and Kripke's articulation of essentialism. There has also been discussion of whether essentialism is required to explain the empirical evidence cited in its favour (Ahn et al., 2001; Strevens, 2000).

Deference and Individual Differences

Braisby (2001, 2004) also examined the further implication of essentialism that people should defer in their categorisations to appropriate experts, an implication developed by Putnam (1975) in a thesis he labelled the Division of Linguistic Labour (see also Kripke, 1980). Since, according to essentialism, categorisation is determined by micro-structural (e.g., genetic) properties, then scientists expert in the appropriate domain are likely to have more category-relevant information than lay-people. If lay people are psychological essentialists then they should rationally defer to people with more knowledge of the relevant properties, e.g., expert scientists. However, in a series of studies examining deference for biological and

chemical categories, Braisby found that participants deferred in only approximately one-third of cases for biological categories, and only slightly more than this for chemical categories. Braisby's conclusion was that the data concerning deference did not support essentialism but could be explained by a perspectival or similarity-based account of categorisation.

However, Braisby also found significant individual differences in the propensity to defer. Whereas many participants consistently switched their categorisation judgments to conform to those of experts, still others consistently maintained their categorisation judgments regardless of expert opinion. Therefore, an alternative explanation of these data is that some participants were psychological essentialists, while the judgments of others were similarity-based. Hampton, Estes & Simmons (2007) also found evidence of individual differences in essentialism. In an examination of Rips's (1989) transformation study, they found that some participants steadfastly maintained their categorisation both before and after the transformation. Only a minority of participants fitted the pattern reported by Rips.

An important question to resolve is whether such individual differences reflect deeper differences in the way that people cognize, or whether people flexibly deploy information and beliefs in making categorisation judgment depending on the task and context. Surprisingly, there is relatively little evidence to bear on this question.

There have nevertheless been demonstrations of individual differences relating to categorisation. Lewellen, Goldinger, Pisoni & Greene (1993) found that participants who scored higher on measures of lexical familiarity were more successful in rejecting foils in a semantic categorisation task. There have been a number of individual differences reported in relation to category learning. For example, McKinley and Nosofsky (1995) found individual differences both in the time course of learning, and also in the final categories learned. DeCaro, Thomas & Beilock (2008) also found that working memory influences category learning. Rule-based categories were learned more quickly by participants with a greater working memory capacity, and what they called information-integration categories were learned more quickly by participants with a smaller working memory capacity. Kalénine & Bonthoux (2006) showed that individual differences in 3-4 year olds' preferences for thematic or taxonomic matches affected their choice of superordinate categories – children showing greatest sensitivity to taxonomic relations showing superior performance in categorising living things.

While the above studies show how individual differences in cognitive processes impact categorisation, there is also a body of work which suggests that individual differences in categorisation arise from more global differences in cognitive style.

Lee, Kagan, & Rabson (1963) found that participants who adopted an analytic strategy when pairing visual stimuli (e.g., on the basis of a shared feature) learned analytic

concepts (e.g., objects with a missing leg) more quickly than relational concepts (e.g., objects related to school). Participants who did not adopt this strategy when pairing visual stimuli, however, learned analytic concepts more slowly than relational ones. Interestingly, Lee et al. related their use of the term analytic to 'field dependence' – the phrase earlier coined by Witkin, Dyk, Faterson, Goodenough & Karp (1962). Norenzayan, Smith, Kim & Nisbett (2002) found that a similar distinction – between analytic and holistic processing affected category learning and similarity judgments.

Cognitive Style

According to Witkin, Oltman, Raskin, & Karp (1971), cognitive styles are "the characteristic, self-consistent modes of functioning which individuals show in their perceptual and intellectual activities" (p. 3). One such style, field dependence, is a construct intended to capture an individual's characteristic mode of perception (Witkin, 1975). It was initially tested using the body-adjustment test and the rod-and-frame test to assess perception of the true vertical, in a visual or postural field that may present misleading information. Typically, some people – field-independent – will accurately judge the true vertical regardless of the contents of the visual field, while others – field-dependent – would fail to do so, presumably being misled by the visual field. Witkin et al. (1962) developed other measures of field-dependence. The embedded figures test and group embedded figures test have since become commonly used. The group embedded figures test (see Figure 1) involves asking participants to find a simple geometric figure (e.g., the triangle labeled X at the top) within a more complex visual object (e.g., the geometric shape at the bottom).

Here is a simple form which we have labeled "X":

This simple form, named "X", is hidden within the more complex figure below:

Figure 1. Sample image from the group embedded figures test

Differences in field dependence have been linked to other socio-psychological differences including, for example, identity, awareness of self and locus of control. Developmental research has suggested that children tend to

become more differentiated in their field dependence as they develop. Witkin, Oltman, Raskin & Karp (1971) suggest that field dependence in children is initially relatively fluid, but begins to crystallise around the age of ten and then appears stable during adulthood. Not surprisingly, there has been much interest in the distinction within research on education (Sternberg & Grigoernko, 1997).

Reflecting its possible status as a more global reflection of an individual's cognitive style, field-dependence-independence has sometimes been described as a distinction between global and articulated processing. However, the precise nature of the distinction remains unclear. There have been suggestions that field dependence is closely tied to underlying spatial ability (Sternberg & Grigoernko, 1997). There have also been arguments that field dependence reflects sensitivity to social information. In a complex design, Mausner & Graham (1970) asked pairs of participants to rate the speed of a flickering light, and then do so again when given information about the performance of the other member of their pair. Such reinforcement had no effect on the performance of field-independent participants. However, reinforcement led to a dramatic shift in the performance of field-dependent participants. Most strikingly, field-dependent participants who were told their estimates of speed were incorrect, but that their partner's estimates were correct, shifted uniformly and almost completely toward their partner's judgments.

This finding suggests one explanation for individual differences in relation to deference (and essentialism). Field dependent participants, sensitive to social information, including the views of others, may be more likely to shift their judgments towards those of experts. Field independent participants may be more reluctant to do so. If this is the case, then this relative difference in propensity to defer may give rise to considerable variability in the extent to which people's judgments conform with essentialism.

Experiment

The experiment was therefore designed with a number of aims in mind. First, it was important to replicate the findings of Braisby (2001) concerning individual differences in deference, and so determine whether such differences are robust. Second, and in order to better understand such differences, it was decided to take measures of participants' field dependence. Third, although the focus of the study is categorisation, in order to determine the scope of individual differences, a number of other judgments were also sought from participants. As in Braisby (2001), the experiment examined the extent to which lay-people defer in their categorisation of biological natural kinds to experts, as predicted by essentialism.

Method

Design

The experiment adopted a mixed design with the factor of

Polarity (Yes, No) of expert judgment being within-subject, and Field Dependence (Field dependent, Field independent) being a between-subject factor.

Participants

40 participants volunteered to participate, 20 of whom were undergraduate students from the University of Winchester. 20 participants were drawn from the immediate residential neighbourhood, all of whom were in employment.

Materials

Following Braisby (2001), categories were four natural (living) kinds : apple, potato, salmon, chicken. These were chosen also to be food-stuffs so that they, and the prospect of their genetic modification, would be relatively familiar to the participants. Within these constraints, the kinds were chosen to be as typical as possible of their immediate superordinate categories (i.e., fruit, vegetable, fish, bird).

For each category, two scenarios were developed, one of which contained a positive categorisation judgment from scientific experts (biologists) and one of which contained a negative judgment. All scenarios conformed to the following pattern: "You have just bought a(n) X from a reputable retailer. On examining its packaging closely you find that it has been genetically modified. You also discover that according to most biologists the object you have bought [is/is not], in fact, an X. The object looks, feels, smells and tastes just like a X."

The group embedded figures test is a timed test and comprises a test booklet containing instructions, a practice section, and two test sections. In these two sections, 18 complex geometric shapes are provided and participants must identify in each a given simple shape.

Procedure

Participants were tested individually. Half of the participants were presented with the GEFT first and the categorization scenarios second; the remaining participants received the categorization scenarios and then the GEFT.

When presented with the GEFT, participants were first asked to read through instructions and complete the practice section. They then completed sections 2 and 3 of the GEFT, being given a limit of 5 minutes for each section.

The 8 categorisation scenarios were untimed and presented in one of two orders. Half of the participants were presented with the scenarios in random order, and the remaining participants were presented with the scenarios in the reverse of this order. On reading each scenario, participants were asked to answer six questions, including a categorization question, as follows.

Categorisation: Is the object that you have bought a(n) X?

Superordinate categorisation: Is the object that you have bought a(n) [Superordinate]?

Eat: Would you eat the object you have bought (either as is or prepared)?

Serve: Would you serve the object you have bought at a dinner party for your friends (either as it is or prepared)?

Buy: Would you continue to buy this kind of object?

Eat if served: Would you eat the same kind of object as the one you have bought (either as it is or prepared) if a friend served it to you at a dinner party?

As the categorisation question was the most central to the analysis, and to minimise any interference from other questions, this question was always presented first. Participants were required to answer Yes or No to each question. Lastly, participants were asked to rate how difficult they found making their judgments on a scale of 1-7, 1 being very easy and 7 being very difficult.

Results

Participants responses to the six Questions were recoded to express agreement with the expert judgments, and aggregated across the four categories. A median split was employed to divide participants into Field Dependent and Field Independent groups. The overall mean difficulty rating was 3.64, and this did not differ by Field Dependence.

A two-way ANOVA was conducted for each Question with Polarity (Yes, No) as within-, and Field Dependence (Dependent, Independent) as between-subject factors.

Categorisation

Agreement with biologists' judgments was influenced by Polarity ($F(1,38) = 5.87$, $\eta_p^2 = 0.13$, $p < 0.05$), with participant's agreeing more when biologists' judgments were reported as affirmative (mean = 3.68) than when they were reported as negative (mean = 2.80). There was a significant effect of Field Dependence ($F(1,38) = 22.81$, $\eta_p^2 = 0.34$, $p < 0.0005$), with Field dependents showing much higher levels of agreement (mean = 3.78) than Field independents (mean = 2.71). Polarity and Field Dependence did not interact.

Superordinate categorisation

Agreement with biologists' judgments was strongly influenced by Polarity ($F(1,38) = 47.81$, $\eta_p^2 = 0.56$, $p < 0.0005$), with participant's agreeing the superordinate categorisation when biologists' judgments were reported as affirmative (mean = 3.89) but largely disagreeing when those judgments were negative (mean = 1.73). There was no effect of Field Dependence nor did Polarity and Field Dependence interact.

Eat

There were no effects of Polarity or Field Dependence, nor an interaction between them.

Serve

There were no effects of Polarity nor an interaction with Field Dependence, but there was a main effect of Field Dependence ($F(1,38) = 6.95$, $\eta_p^2 = 0.16$, $p < 0.05$) with Field dependents showing greater agreement with biologists'

judgments (mean = 2.94) than Field independents (mean = 2.32).

Figure 2. Proportions of participants by Deferring Style and Field Dependence

Buy

There were no effects of Polarity or Field Dependence, nor an interaction between them.

Eat if served

There was a significant effect of Polarity ($F(1,38) = 13.86$, $\eta_p^2 = 0.27$, $p < 0.005$), but no interaction with Field Dependence, nor an interaction between them. Regardless of Field Dependence, more participants agreed with the biologists' judgment when this was in the affirmative (mean = 3.13) than in the negative (1.29).

Individual Differences

Lastly, each participant was classified according to their responses to the Categorisation question. Participants who consistently deferred to biologists' judgments in all eight scenarios were classified as Switchers; those who consistently did not switch their categorisations for any category were classified as obdurate; remaining participants were classified as mixed. This factor of Deferring Style was entered with Field Dependence in a log-linear analysis. This revealed a significant interaction between Deferring Style and Field Dependence (Chi-square (2) = 20.52, $p < 0.0005$) as shown in Figure 2.

Discussion

The first key aim of this experiment was to replicate the findings of Braisby (2001) in order to examine whether individual differences in deference are robust. Overall, 53%

of participants consistently deferred to expert judgment, 35% were consistently obdurate, and just 13% showed a mixed pattern (of deferring with some categories and being obdurate with others). Experiment 2 of Braisby (2001) obtained similar proportions: 62%, 31% and 7%, respectively. Thus, these data strongly support the view that the evidence for deference with regard to biological natural kinds is both mixed, and susceptible to substantial individual difference.

The second aim was to investigate the relationship between deference and field dependence. The data confirm that there is such a relationship and it is a strong one, with 34% of the variance in responses to the categorisation question being explained by this dichotomous factor. In this study, substantially more field dependent participants defer to expert judgment (89%) than field independents (23%). Considerably more field independent participants are obdurate when categorising in the light of expert judgment (55%) than field dependents (11%). These striking contrasts not only suggest the effect of field dependence is strong, they suggest reasons for individual differences in essentialism. Field dependents, willing to seek external frames of reference for making their categorisation judgments, appear more susceptible to externally provided information about the presence, role or value of essential properties. Field independents may by contrast tend to rely more on internally generated judgments of category membership which, given the hidden and/or unknown nature of essences, are likely to be based on a more superficial similarity judgment.

Lastly, by including other questions concerning the transformed natural kinds, it is possible to gauge the scope of these individual differences. Were field dependence to impact all measures, for example, it could be argued that it is not intimately related to categorisation, and perhaps that the influence of field dependence masks more subtle and interesting categorisation effects. However, there was no effect of field dependence on three of the five other questions asked. Indeed, only the questions concerning serving food to others, and eating it if it were served by others, showed an influence of field dependence. It is noteworthy that these two questions also involve a social dimension, while the other three questions arguably do not. Far from field dependence showing an over-powering or global impact on these results, it appears as though this factor bears only on those aspects of categorisation and categorisation-related actions that are social in nature. Indeed, when one recalls that Putnam (1975) called his Division of Linguistic Labour a socio-linguistic hypothesis, it seems hardly surprising that the quite particular feature of deference should be influenced by field dependence.

Another interpretation is that field dependence influences how participants understood the scenarios. Elements that are vague, such as the quantifier 'most', or open to different interpretation, such as the reputability of the supplier, may be particularly susceptible to different interpretations that perhaps align with field dependence. Likewise field

dependence may alter whether people judge that genetically modified exemplars continue to be members of their original categories. These are intriguing possibilities, and the current data do not rule them out. However, there are reasons to doubt these could be the whole story. First, though the literature on field dependence is considerable, the authors are not aware of evidence for an influence on language understanding. Second, the data actually suggest these possibilities are unlikely. It would be hard, for instance, to reconcile the claim that field dependent and independent people derive different understandings of the scenarios, with the evidence that, when questioned, only certain highly specific questions show such an influence. In fact, it is only those questions which have an explicitly social element that reveal an effect of field dependence. This pattern is more consistent with field dependence having a highly specific influence, related to the informational demands of the task, rather than a global influence relating to people's understanding.

Some notes of caution are in order however. This initial study, while promising, remains exploratory, and much more needs to be done to confirm the impact of cognitive style on categorisation in general. Though these data are suggestive as to the meaning of individual differences in essentialism, it is unclear whether the same relationship would be found in different domains. Of particular interest would be social domains such as sexual orientation (cf. Haslam, Rothschild & Ernst, 2000; Braisby & Hodges, 2009) where claims for essentialism are already contested.

However, these data are illuminating in that they appear to confirm of an important social dimension to psychological essentialism, and one which can lead people to different categorisations. What is less clear is whether these data might shed light on field dependence itself. While such an aim is beyond the scope of this paper, it seems clear that field dependence is more than a spatial ability. It appears to involve a sensitivity to social information and as such implies less of a gap between cognitive science and the social world than one might at first imagine.

Abstract

Research suggests a developmental shift from forming categories based on perceptual features, to recognizing deeper characteristics and relationships. One process found to highlight deeper properties is comparison between items. The bulk of the research on comparison, however, has been done with familiar items or familiar relationships. An open question remains: under which conditions will comparison help children attend to the deeper properties of novel objects? In two experiments we explore the effect of comparison in a word learning task and its interaction with prior knowledge, language support, and the perceptual features of the compared items. Our results suggest that comparison only highlights deeper similarities when children are given some support to counteract or reduce the influence of surface level features. These results have implications for how to best teach children depending on the amount of prior knowledge that they bring to the task.

Keywords: word learning; comparison; superficial vs. relational similarity

Introduction

The ability to look beyond surface similarities and make deeper connections between items is an important achievement in cognitive development. Although perceptual feature similarities (e.g., shape, material) are often a useful basis for grouping objects together, some categories may be better characterized by more abstract qualities. In analogy-making tasks and in categorization tasks, children seem to shift from attending to surface properties to being able to attend to relational or conceptual similarity at around age 5 (Gentner & Namy, 1999; Loewenstein & Gentner, 2005). The evidence also suggests that even young children who would not spontaneously attend to deeper similarities will do so with enough support. In two studies we examine the circumstances in which comparison is helpful in highlighting deeper similarities for novel categories for which children have no preexisting knowledge, even when the objects share perceptual features as well.

Comparison and deep similarities

A large body of research suggests that comparison is a mechanism that works to highlight deeper features. The evidence suggests that although a child may seem to only

attend to surface, perceptual features when presented with a single item, being presented instead with two or more items to compare has the effect of highlighting deeper, relational features shared by those items. Researchers have found this effect in tasks such as word extension and analogical mapping. In these analogy tasks, children are typically shown a standard card showing three items that share some relational property. For example, Figure 1 shows a target card and two possible matches. The card on the left matches the target in superficial properties (they are three squares), whereas the card on the right matches it in relational similarity (two same-color figures flanking a different-color figure). Research using this sort of task indicates that without extra support, 4-year-olds will attend to properties of the specific items, rather than to the relational structure. However, when allowed to view two examples of the relational structure (say a second card with two white triangles flanking a black triangle) and compare it with the original target, the similarity in relational structure will be highlighted, allowing the child to abstract away from unimportant details such as the shapes of the items (Gentner, Rattermann, Markman, & Kotovsky, 1995).

Figure 1: Example of an analogical mapping task.

A similar effect of comparison has been found in word learning tasks. Gentner and Namy (1999) taught 4-year-olds new names for known objects. For example, they showed children a picture of an apple and informed them that a toy dog had a special name for it: “blicket”. Then children were offered a choice between a picture of a banana and a picture of a balloon and asked which of those would also be called a blicket. Surprisingly, four-year-olds chose the superficially similar balloon, rather than the taxonomic match, the banana, also a fruit. However, when allowed to see more than one standard (e.g., a pear and a bunch of grapes), children chose more taxonomic matches. More recently Gentner, Loewenstein, and Hung (2007) found that four-year-olds were similarly able to use

comparison to learn novel names for specific parts of novel animal and object drawings. The process of comparison is thought to highlight deeper relations between items by promoting structural alignment (Gentner & Namy, 1999). Structural alignment refers to how considering two or more items together can focus attention on common relational structure that would not be readily apparent from only a single item. But how would comparison work if novel objects were used?

Comparison of Novel Objects

A first step in investigating whether comparison of novel objects can help children see beyond surface properties to deep features is to determine what these terms mean in the context of novel stimuli. A definition of surface properties can be transferred fairly straightforwardly from previous comparison research involving familiar items. That is, surface properties consist of perceptual features such as the shape, material, texture, and color of an object. Defining deep characteristics of novel objects is more complicated, for exactly the reason that such objects were chosen for this research: there is no prior knowledge or history associated with them. For example, in some previous work the deep features that are highlighted in comparison are defined as conceptual representations (Gentner & Namy, 2006). However, in other contexts, particularly analogical mapping studies, deep characteristics consist of the higher order relations or structures shared across items (Gentner et al., 1995). Gentner and Rattermann (1991) refer to this deeper level of similarity as analogy, and define it as “similarity in relational structure, independently of the objects in which those relations are embedded” (p. 226). For example, Figure 1 shows a sample analogical mapping involving a structure of two identical darker figures flanking a lighter figure. Understanding this structure at the analogy level means understanding that such a relation can encompass a flanking structure in various dimensions, such as darkness or size, and despite dissimilarities in other features like shape or texture (Gentner et al., 1995).

Drawing from this research on analogy, in the current experiments deep characteristics of novel objects are defined as the structure of the objects. Specifically, we designed the novel objects in these experiments such that the connections and relations between parts of individual objects conform to a generalizable structure. Figure 2 shows an example set of the novel object stimuli created for these experiments. The structure shared by the exemplars and structure choice test item in this set is one of three identical shapes, arranged vertically, and decreasing in size from bottom to top. While there is variation in surface level features, such as shape, color, material, and texture, the underlying structure is maintained. In this way, the novel objects created for the current experiments were carefully manipulated to have certain surface properties and deep features, in particular relational structure.

Exemplars	Test Items	
 <p>Comparison</p>	 <p>Structure Choice</p>	 <p>Superficial Choice</p>
 <p>Non-Comparison</p>		

Figure 2: Sample item set from Experiment 1. Materials used include green foam and orange yarn.

Prior Knowledge Another key issue to consider in relation to the comparison of novel objects is the role of prior knowledge about the items that are compared. Much of the research cited so far supports the hypothesis that the development from categorization based on surface similarities to categorization based on higher order relations is driven by increases in domain knowledge. For example, understanding of higher order analogical relations has been found to develop between the ages of 4 and 8 years, but 4-year-olds can learn to appreciate and correctly use such relations through explicit teaching or over the course of targeted training (Kotovsky & Gentner, 1996). Experiments with novel objects offer a new way to test, and possibly further support, this hypothesis by controlling the amount of domain knowledge that participants have available. As will be shown in the first experiment, our novel object stimuli allowed us to directly explore the question of the role of prior knowledge in comparison. Using novel objects ensured that participants were not familiar with the stimuli, and we also manipulated the labels used (novel vs. known) to further control the amount of prior knowledge brought into the task. The label manipulation relates to the next issue as well.

Language Use Another guiding question of our design of the current experiments has to do with the role of language. Specifically, in the first experiment we explore an intriguing finding on the role of language in analogical mapping. Previous research shows that children as young as three years old can map familiar relational labels, like “top,” “middle,” and “bottom” onto spatial relations between presented items, and use those mappings to make correct relational choices, even in the face of tempting perceptual choices (Loewenstein & Gentner, 2005). We wondered whether the use of familiar structure related labels could have a similar influence on children’s comparison processes with novel objects. Such labels would offer children some support in linking familiar structural representations with the novel objects to be learned; the first experiment tests whether they can effectively use this support to aid task performance.

Perceptual Features Our final guiding question about the role of perceptual features influenced our overall task

design and is the focus of the second experiment. To address this question we drew on research from the word learning literature. Our task has many parallels to the novel noun generalization (NNG) paradigm, in which a child is presented with a novel object that is labeled with a novel name, and is subsequently asked whether he or she would apply that label to various other novel objects that vary from the original in specific dimensions such as shape, size, color, or texture, while matching in other dimensions. Research using the NNG task has provided many interesting findings about the kinds of object properties that children use to guide their learning and labeling of different kinds of items. For example, from a young age children consistently and preferentially use the shape of an object, as opposed to other features like size, color, or material, to guide their labeling and categorization of artifact-like items (Jones, Smith, & Landau, 1991). On the other hand, the material of an item is treated as more important than other features in guiding children's novel noun generalization of non-solid substances (Soja, Carey, & Spelke, 1991). Because the novel objects created for the current experiments are artifact-like, we were concerned that having a shape match between exemplars and test items would strongly influence our results. To avoid the possible confound of a shape match, we minimized the degree of shape matching and manipulated other features known to be less influential in artifact-like object naming, particularly material and color. The second experiment in particular explores how the manipulation of these perceptual features influences comparison.

In two experiments we explored the effect of comparison on preschooler's learning about novel objects. We used previous work on comparison as well as word learning to guide our experimental task design. The current experiments explore the roles of prior knowledge, of language, and of perceptual features in children's comparisons of novel objects. The first experiment explores the role of prior knowledge and language, and the second experiment focuses on the role of perceptual features.

Experiment 1

The first goal of Experiment 1 was to create and test an experimental task that paralleled those used in the comparison literature but that involved only novel objects. To this end, we modeled our task after one designed by Gentner and Namy (1999, Experiment 2) in which children were presented with either one or two standard items (non-comparison and comparison conditions) and then decided which one of two test items best matched the standard, a perceptual choice or a taxonomic choice. The authors used drawings of familiar items, and carefully chose the stimuli such that each standard item was more strongly perceptually similar to the perceptual choice than the taxonomic choice. The design of our stimuli aimed to capture similar relations between the perceptual and

structural characteristics of novel objects. We manipulated the surface level features of material, color, and shape to create exemplar objects that strongly matched the superficial choice test object. We manipulated the relationships between the parts of these objects to create structural similarities between the exemplar objects and the structural choice test object, which was perceptually dissimilar to the exemplars (see Figure 2). In this way we believe our experimental task is an accurate translation of the Gentner and Namy (1999) task from familiar item drawings to novel physical objects.

The other goal of Experiment 1 was to test two of our guiding questions: what is the role of prior knowledge and what is the role of language in novel object comparison? We included two labeling conditions: a novel label condition and a known label condition consisting of structurally related familiar words. The combination of novel objects and novel labels ensured that children in that condition had no prior knowledge of the task items. In the known label condition, we used familiar words that related to structure to see whether children could effectively use language support to make connections to known structural relationships.

If children treat novel objects similarly to how they treat familiar items, then we should see similar results in our novel label condition as those of Gentner and Namy (1999); that is, children will make more perceptual choices when there is non-comparison between exemplars, and will make more structural choices when there is comparison. In other words, comparison of novel objects will function as it does with familiar items, highlighting the deeper relations present between them. On the other hand, because children have no prior knowledge of novel objects given novel labels, comparison might not function in the same way, perhaps instead highlighting surface rather than deep features. Additionally, we expected the use of known labels to be effective in highlighting object structure in both the comparison and non-comparison conditions, and thus act to increase children's structural choices in both comparison conditions.

Method

Participants. Fifty-two 4-year-olds ($M = 4;6$) were assigned to the comparison or non-comparison condition, and to the novel label or known label condition in a 2 x 2 design.

Materials. The stimuli consisted of 16 novel objects created in the lab (8 exemplars and 8 test items). There were four sets of test items consisting of a structure choice and a superficial choice. For each set of test items there were two exemplars (see Figure 2 for a sample set). All exemplars were structural matches with the structure choice for their group, and also matched in material and color with the superficial choice. Due to the extent of surface similarity between the pairs of exemplars, this set is referred to as "high similarity" throughout this paper.

Both of the exemplars were used for the comparison condition, and the exemplar that matched the superficial choice somewhat on shape was used for the non-comparison condition.

Two types of labels were also used in two labeling conditions: novel and known. For the novel labeling condition four pseudoword labels were created, one for each set of objects. For the known labeling condition, four real, structurally related words were selected to go with each set of objects. The words selected were intended to be familiar to four-year-olds; for example, the items in Figure 2 were given the familiar label “stairs.” The other known labels were “see-saw,” “bumps,” and “spiral.”

Procedure. Participants sat at a table across from the experimenter. Participants were randomly assigned to one of four conditions: novel label comparison, novel label non-comparison, known label comparison, and known label non-comparison.

In the comparison conditions, the experimenter showed the participant two exemplar objects and labeled each with either the same novel label or with the same known label. For example, in the novel label comparison condition, the experimenter would say, “This is a tink. This is also a tink. See how they are both tinks?” The participant was able to examine the objects before the experimenter put them out of sight. Then the experimenter brought out two test items on a tray and asked the participant to “Get the tink.” The experimenter then recorded whether the participant chose the structure match or superficial match. The non-comparison condition proceeded in a similar manner but with only one exemplar shown and labeled, for example “This is a tink. See how it is a tink?” In all conditions participants completed four trials with the order of trials counterbalanced across participants. In the novel label conditions the novel nouns used to label the four stimuli sets were also counterbalanced.

Results

The dependent variable was the average number of structure match choices that participants made across all test trials. Average numbers of structure choices were submitted to a 2 (comparison or non-comparison) x 2 (label type: novel or known) between-subjects analysis of variance (ANOVA). There was a main effect of label type such that children made more structure choices when objects in the task were given familiar, relational labels, $F(1, 48) = 12.43, p < .001$. There was also a significant interaction between comparison condition and label type, $F(1, 48) = 4.72, p = 0.03$ (see Figure 3). In the novel label condition, children made fewer structure choices after comparing two exemplars compared to viewing only one exemplar. This relationship was reversed in the known label condition, with more structure choices made in the comparison condition than the non-comparison condition.

Post hoc *t*-tests were conducted to further explore this interaction. Within the novel label condition, structure

choices were marginally lower in the comparison than non-comparison condition, $t(24) = -1.77, p = 0.089$. This difference did not reach significance in the known label condition ($p = 0.17$), however looking across labeling conditions, structure choices following comparison were significantly higher with known compared to novel labels, $t(29) = 4.46, p < .001$.

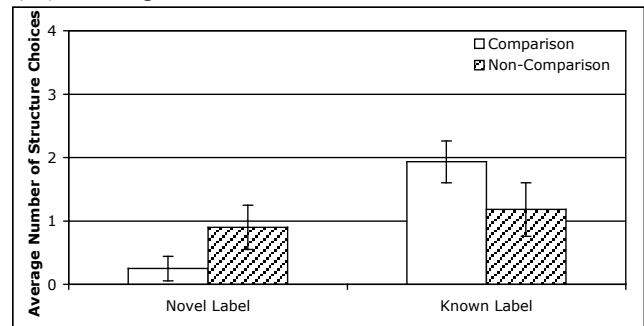

Figure 3: Experiment 1 results; all stimuli were high similarity.

Discussion

Overall the results of Experiment 1 show that the availability of prior knowledge in a task influences how comparison functions. Comparing the novel label condition to the Gentner and Namy (1999) experiment on which it was modeled, we found the opposite pattern of results. Rather than highlighting deeper relations between items, comparison in the novel label condition seemed to very strongly cue children’s attention to the perceptual similarities between novel objects. The results of the novel label condition add support to the hypothesis that the capacity of comparison to highlight deeper features depends on the amount of relevant domain knowledge that participants have. In the novel label condition participants had no prior knowledge of the objects to help them identify the deeper structural similarities, and instead focused on surface level features to guide responses. Overall, the novel label condition of Experiment 1 shows that comparison of objects about which children have no prior knowledge functions differently than comparison of familiar items.

On the other hand, the results of the known label condition show that if there is some conceptual support, such as familiar labels that highlight the structure of objects, comparison seems to work in a way similar to that seen in studies using familiar items. This result is also consistent with previous work showing that young children can use language to guide performance in analogical mapping tasks (Loewenstein & Gentner, 2005). The role of language in this context seems to be to situate the novel objects in terms of familiar representations, allowing for recognition and use of structural properties in the task.

In the next experiment we explore the role of perceptual similarity in novel object comparison.

Experiment 2

The goal of Experiment 2 was to test the role of perceptual features in comparison of novel objects. This experiment also allowed for further exploration of how comparison operates in a context of low prior knowledge, that is, our task involving novel objects with novel labels. The first experiment showed that the process of comparison was only conducive to making structural choices when supported by familiar structure-related labels. In the second experiment we set out to investigate another way in which comparison of novel objects would highlight their deeper shared structure. To this end we used the same general procedure as in the novel label condition of Experiment 1, but varied the perceptual features of the novel objects. In Experiment 2, the stimuli were designed such that there was a lower degree of surface feature similarity between the exemplars in relation to each other as well as in relation to the test items (see Figure 4). With this manipulation, the results of the task using the low surface similarity novel object set can be directly compared to the results of the Experiment 1 novel label condition, which used a high surface similarity object set.

We predicted that the number of structure choice responses would increase overall when the task involved low surface similarity novel objects as compared to the high similarity objects of Experiment 1. Comparison of the high similarity objects seemed to more strongly highlight the perceptual feature overlap than the common structure of the objects. Therefore we reasoned that reducing the degree of that overlap should reduce the amount that comparison highlights surface features, and allow children to see the deeper relational match of the structure choice.

Method

Participants. Twenty-four additional four-year-olds ($M = 4;4$) were recruited for the second experiment, and were randomly assigned to the comparison and non-comparison conditions.

Materials. The stimuli consisted of 16 novel objects created in the lab (8 low similarity exemplars and the 8 test items from Experiment 1). As in the first experiment, there were four sets of test items consisting of a structure choice and a distractor choice, and four corresponding pairs of exemplars. All exemplars were structural matches with the structure choice for their group. For the low similarity exemplars, one object matched the distractor choice somewhat in shape only, and the other object did not match the distractor choice in shape, material, or color. For each pair of exemplars, both objects were used for the comparison condition, and the exemplar that matched the distractor choice somewhat on shape was used for the non-comparison condition.

Procedure. The procedure was the same as that used for the novel label condition of Experiment 1. Participants were randomly assigned to one of two conditions:

comparison or non-comparison. As in the first experiment, each participant completed four trials; trial presentation order as well as the novel nouns used to label the four stimuli sets were counterbalanced.

Exemplars	Test Items	
 Comparison		
 Non-Comparison	Structure Choice	Distractor Choice

Figure 4: Sample item set from Experiment 2. Materials used include yellow cellophane, blue clay, orange yarn, and green foam.

Results

As in Experiment 1 the dependent variable was the average number of structure match choices that participants made across all test trials. Average numbers of structure choices from both Experiment 2 (low similarity) as well as the novel label condition of Experiment 1 (high similarity) were submitted to a 2 (surface similarity: high or low) \times 2 (condition: comparison or non-comparison) ANOVA. There was a main effect of surface similarity such that number of structure match choices was higher when surface similarity was low, $F(1, 46) = 26.36$, $p < 0.001$. There was also a significant interaction between surface similarity and comparison condition, $F(1, 46) = 6.07$, $p = 0.02$ (see Figure 5). As shown in the results of Experiment 1, in the high surface similarity condition (novel label condition of Experiment 1) children made fewer structure choices after comparing two exemplars compared to initially viewing only one exemplar. The interaction here shows that this relationship reversed for the low surface similarity objects used in Experiment 2: children made more structure choices in the comparison condition than the non-comparison condition.

Figure 5: Experiment 2 results; all labels were novel. Note high similarity data is from the novel label condition of Experiment 1.

Post hoc *t*-tests were conducted to further explore this interaction. Participants were able to make significantly more structure match choices in the comparison condition when the exemplars had low surface similarity rather than high surface similarity, $t(30) = 5.51$, $p < 0.001$. Additionally, there was not a significant difference in number of structure choices in the non-comparison condition between high and low surface similarity, $p = 0.28$.

Discussion

The results of Experiment 2 help to shed some light on the role of perceptual feature similarities in comparison processes involving novel objects. In this experiment we varied the extent to which the exemplar objects shared surface feature similarities with the distractor choice test item. As shown in Experiment 1, when the exemplars were highly similar to the superficial choice in several dimensions, specifically material, color, and shape, comparison actually seemed to highlight surface similarities especially strongly. However when children performed the same task but with the low surface similarity exemplar objects of Experiment 2, comparison seemed to better highlight the deeper, structural relations between the exemplars and the structure choice test item. While this increase in number of structure choices in the comparison condition for low similarity as compared to high similarity objects was predicted, what is surprising is the magnitude of the increase. Specifically, administering this task with low surface similarity novel objects increased performance, in terms of number of structure choices, to the same extent as labeling objects with familiar structure related words.

General Discussion

In the current experiments we set out to explore the role of prior knowledge, language, and perceptual features in making comparisons of novel objects. We wondered whether the act of comparison highlights deeper relations rather than surface similarities, as has been found with studies using familiar items. In Experiment 1 we found that, in line with previous research in analogy making, prior knowledge of the items being compared does indeed matter: comparison *hindered* performance when novel objects and novel labels were used, that is, when prior knowledge of items was low. In the first experiment we also found that the use of known, structure-related labels led to increased identification of structural matches between novel objects. This indicates that language plays a role of supporting the integration of prior knowledge with new category information. In Experiment 2 we found that perceptual features also impact the comparison of novel objects. Reducing the degree of surface similarity between exemplar and test objects improved performance to the same extent as using familiar labels. Together these

experiments show that in order for comparison to be beneficial, support has to be provided through links to prior knowledge. In the absence of prior knowledge that can be brought to bear, it is important to ensure that the possibility of mistakenly highlighting surface is minimized by comparing items of low similarity.

These results have implications for educational practices related to teaching new categories and concepts. Linking newly introduced items to familiar concepts, particularly with language, helps children make deeper connections between new items, and perhaps aids them in creating rich representations of new categories. Additionally, introducing new objects by presenting items that are more variable in surface features (i.e., share less surface similarity) further helps children by reducing the tendency to attend only to the superficial, especially when those feature similarities run counter to the deeper relationships.

Abstract

We examined effects of normal aging on category learning, comparing performance and strategy choice on two learning tasks: one where a one-dimensional rule governed category membership and one where a multi-dimensional rule defined category structure. Paradoxically, we demonstrated that older adults can outperform younger adults in some types of complex category learning. In the current task—which required that multiple dimensions be integrated—simpler integration rules enabled more rapid achievement of reasonable levels of performance. As cognitive aging is associated with a reduction in working memory resources, older adults tended to adopt these simpler decision rules more often, facilitating complex category learning. Results provide some unique evidence highlighting potential adaptive benefits of cognitive aging. Implications are discussed.

Keywords: category learning, aging, rule-based, information-integration

Introduction

The learning of new categories is an important task throughout one's life span. While the literature investigating younger adults' category learning skill is vast, less is known about older adults' category learning competencies. In the current investigation, we sought to demonstrate that normal cognitive aging can confer cognitive performance benefits as older adults may favor simpler cognitive strategies known to facilitate learning and decision performance.

Previous research investigating aging and feedback-based category learning often draws the general framework of Ashby and colleagues (e.g. Ashby, Alfonso-Reese, Turken, & Waldron 1998). The framework involves contrasting two different task types that are assumed to be best solved by two distinct learning systems. The most basic difference between the tasks, as typically stated, is whether one or several dimensions of the probe determine category membership. In the so-called *rule-based tasks*, only one dimension of the probe determines category membership and these tasks are believed to rely on an explicit learning system capitalizing on simple verbalizable rules. In *information-integration tasks*, the values of several dimensions determines membership via a complicated combination rule. In these tasks, simple one-dimensional rules will not suffice for error-free performance. Learning in these tasks is thus said to be guided by an implicit learning system

employing integration of dimensions at a “pre-decisional” stage. Moreover, it is suggested that there exists a *rule-bias*—a new learning endeavor will start off with the explicit learning system but compete with, and possibly lose against, the implicit system for determining the response.

The results with regard to older adults' learning in these tasks are mixed. Ashby, Nobel, Filoteo, Waldron and Ell (2003) demonstrated that older adults reached the learning criterion (10 correct consecutive responses, CCR) later than young adults in both a rule-based and an information-integration task. However, they did not investigate the cognitive processes used to guide categorization. Filoteo and Maddox (2004) compared younger and older adults on two versions of an information-integration task—one with a linear and one with a non-linear combination rule. Older adults were impaired compared to young adults on both versions. Via computational modeling the authors provided evidence suggesting that the age-related differences were less marked among individuals using simple one- or two-dimensional rules. In contrast, in a study comparing young and old adults on a probabilistic category learning task (the weather prediction task; Gluck & Bower, 1988) and an information integration task, age-related differences were only found in the probabilistic but not in the information integration task (Price, 2005).

Individual differences in working memory are known to influence cognitive task strategies and decision making performance (Cokely & Kelley, 2009; Cokely, Kelley, & Gilchrist, 2006). Furthermore, considerable evidence has documented declines and metacognitive changes associated with working memory during normal aging (e.g. Baltes, Staudinger, & Lindenberger, 1999; Herzog, Dixon, Hultsch, & MacDonald, 2003). Interestingly, individual differences in working memory have been shown to be a factor on success rates in category learning (DeCaro, Thomas, & Beilock, 2008). DeCaro et al. hypothesized that individuals with high working memory abilities should outperform individuals with low working memory abilities in rule-based tasks. In information-integration tasks it was hypothesized that low-capacity individuals would have a benefit: they may have less capacity to engage the explicit system in extensive hypothesis testing of the complex com-

ination rule. Thus low ability individuals might switch to the implicit system earlier than high-ability individuals and show faster learning. DeCaro et al. showed that high-ability individuals reached the learning criterion faster than low-ability individuals in a rule-based task. In contrast, in an information-integration task, low-ability individuals reached the learning criterion faster—a benefit assumed to stem from an earlier switch to the implicit system. Of note, however, Tharp and Pickering (2009) demonstrated that the learning criterion used by DeCaro et al (i.e. 8 CCR) were insufficient for capturing learning of the information-integration combination rule and thus reaching that criterion is likely not a reliable indicator that implicit learning has taken place. Tharp and Pickering demonstrated that considerably fewer participants in an information-integration task were able to sustain performance long enough to reach the stricter criterion of 16 CCR. Further, the responses from around 40% of the individuals reaching the 8 CCR criterion could be well captured by one-dimensional categorization models, suggesting that it is possible to reach 8 CCR with explicit memory and simple one-dimensional rules. DeCaro, Carlson, Thomas and Beilock (2009) subsequently tested low- vs. high ability individuals again, using the stricter 16 CCR, and the interaction between tasks and abilities disappeared. Moreover, when assessing learning strategies in the two tasks for the two groups DeCaro et al found evidence suggesting that the low-ability individuals primarily used one-dimensional rules.

Might older adults also benefit from the use of simpler processes in the tasks used by DeCaro et al and Tharp and Pickering? Previous research suggests it is unlikely that older adults would be able to proceed in learning the information integration task with the implicit learning system (see also Filoteo & Maddox, 2004). Previous research also suggests that in tasks similar to implicit category learning (i.e., implicit learning of new associations) age-related decline in performance is to be expected (Curran, 1997; Harrington & Haaland, 1992; Howard & Howard, 1997, 2001). Moreover, there is evidence that older adults prefer simpler strategies over complex strategies in various tasks, for example in mental arithmetic (Geary, Frensch & Wiley, 1993), in memory (Dunlosky & Hertzog, 1998, 2000) and decision making (Chen & Sun, 2003; Johnson, 1990; Mata, Schooler & Rieskamp, 2007). Thus, this leaves us with two nested hypotheses for the current study: (1) older adults will not address the information integration task with the implicit system, and (2) advantages demonstrated by older adults in an information-integration task will stem from older adults' use of simple, verbalizable rules, in contrast to a larger portion of younger adults who might attempt futile hypothesis testing with more complex rules.

Experiment

In the following experiment we tested younger adults and older adults on a categorization task. The stimuli consisted of pictorial drawings with four binary cues and the task was to learn to categorize the stimuli into two different categories with guidance by outcome-feedback. The task exactly followed DeCaro et al. (2008).

Method

Participants

Fifty eight participants were tested. Twenty nine of the participants were younger, aged 20-32 ($m = 25.1$, $SD = 3.1$), and the other 29 participants, were older, aged 64-79 ($m = 69.9$, $SD = 3.3$). Participants were recruited from the participant pool of the Max Planck Institute for Human Development, Berlin. All were compensated 10 € for participation.

Procedure

Participants completed a computer-based category learning experiment adapted from DeCaro, Thomas & Beilock (2008). During the experiment, the participant was shown colored geometric figures on a computer screen and asked to place each one into either category "A" or category "B" by pressing buttons on a keyboard. Immediate feedback was given after each trial. After 200 of such trials, the participant was informed that a new set was to begin and the rules had changed, but were not informed by which rule to sort. Participants completed 4 sets of 200 trials. There were two different sets of rule-based tasks and two sets of information integration tasks, rotated across participants in four different orders. In the rule-based tasks one dimension decided category membership (in one set it was symbol color and in the other set symbol shape). There were also two different sets of information-integration tasks. Three of the four dimensions were regarded as relevant (with background color respectively number of embedded symbols being irrelevant). The correct combination rule was given by assigning each binary value of the dimensions with 1 or -1 and then linearly combining those values:

If value (X) + value (Y) + value (Z) > 0 respond A, otherwise B.

In addition, participants completed a battery of cognitive ability measures. These results are not reported as they are beyond the scope the current paper.

Results

As a first step, to statistically investigate the extent to which we replicated DeCaro et al (2008), our initial analyses followed DeCaro et al. First, we log-transformed the number of trials to reach the criterion

of 8 CCR, as the variable was positively skewed. Second, for the set of analyses directly aiming at comparing the results with DeCaro et al (2008) we only included participants who reached the criterion on all four task rules (two rule-based and two information-integration, of 200 trials each), and who were not higher than 2 *SD* above the mean in trials to criterion in each block.

First, we analyzed whether performance on any of the two different rules within each task differed and interacted with age. We performed one repeated measurement ANOVA per task, with rule type as within factor and age as between factor. In the rule-based task one rule was easier to learn than the other ($F(1,41) = 5.17$; $p = .03$) but this did not interact with age ($F(1,41) = .12$; $p = .73$). In the information-integration task rules did not differ in difficulty ($F(1,41) = .001$; $p = .97$) and there was no interaction with age ($F(1,41) = .26$; $p = .62$). Therefore, we averaged data across both rule types within each task.

Second, we investigated whether there was an effect of age on the ability to reach the 8 CCR criterion and if this interacted with task. We performed a repeated measurement ANOVA with task (rule-based vs. information-integration) as within-subjects factor and age as between-subjects factor. Overall, the age groups did not differ on the number of trials they took to reach the criterion ($F(1,41) = .07$; $p = .80$). The criterion was reached faster in the rule-based than the information-integration task ($F(1,41) = 9.96$; $p = .003$). Most importantly, there was a significant interaction between age and performance in the two tasks (Figure 1; $F(1,41) = 4.69$; $p = .04$). While the younger adults' ability to reach the criterion deteriorated significantly in the information-integration compared to the rule-based task ($F(1,15) = 28.05$; $p < 0.001$) the older adults reached it about equally fast across tasks ($F(1,15) = .25$; $p = .62$).

Following Ashby et al. (2003), DeCaro et al.(2008, 2009), and Tharp and Pickering (2009), and to further investigate the learning trajectories in the two tasks we next looked at the number of participants reaching the three different criteria used in those studies (8, 10 and 16 CCR) and the mean number of trials it took to reach the criterion (Table 1 and 2). All subsequent analyses included all participants.

It is evident that in the rule-based task most younger adults reached all three criteria while about 1/3 of the old adults did not reach the strictest criterion (Table 1). In the information-integration task on the other hand (Table 2), fewer older adults reached all criteria, but the number of learners dropped off proportionally in both age-groups as a function of how strict the criterion was. Critically, the older adults required fewer trials to criterion than the younger adults only when considering 8 CCR.

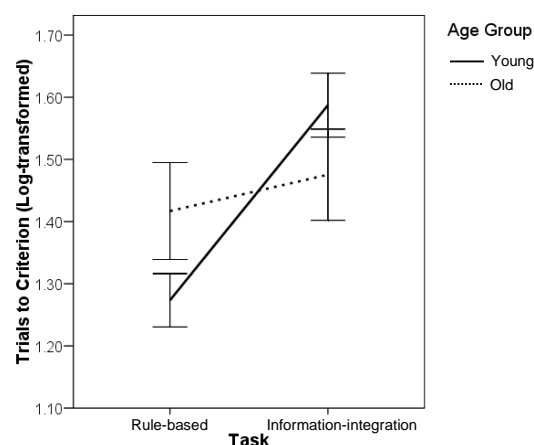

Figure 1. Average trials to reach the 8 CCR criterion as a factor of age group and task. Error bars represent ± 1 SE.

Table 1. Rule-based task: number of learners and mean trials-to-criterion (TTC) as a function of age and criterion

CCR	Number of learners (max 29 per group)		Mean TTC (SD)	
	Young	Old	Young	Old
8	28	22	25.9 (16.1)	45.0 (33.1)
10	28	19	32.0 (19.0)	48.2 (35.2)
16	26	14	44.8 (25.1)	52.7 (30.4)

Table 2. Information-integration task: number of learners and mean trials-to-criterion (TTC) as a function of age and criterion

CCR	Number of learners (max 29 per group)		Mean TTC (SD)	
	Young	Old	Young	Old
8	27	19	53.9 (32.2)	47.5 (31.3)
10	21	15	69.0 (25.1)	77.9 (33.8)
16	4	2	91.0 (21.6)	155.8 (2.48)

To provide a more transparent impression of performance in the two tasks we next examined the proportion of correct responses as a function of task and age (Figure 2). First, performance on the two rule-types of each task did not interact with age, so we averaged the data across rule-types. In a repeated measurement ANOVA there were two main effects

and one interaction. The younger adults performed better overall than the older adults ($F(1,56) = 14.74$; $p < 0.001$), and performance was better in the rule-based than in the information-integration task ($F(1,56) = 124.4$; $p < 0.001$). The interaction suggests that the impact of age on performance was different depending on the task ($F(1,56) = 4.04$; $p = .049$). The difference between the age groups was larger in the rule-based task ($m_{\text{young}} = 91.2\%$ vs. $m_{\text{old}} = 78.8\%$) than in the information-integration task ($m_{\text{young}} = 71.3\%$ vs. $m_{\text{old}} = 65.0\%$).

Figure 2. Proportion correct as a function of task and age-group. Error bars are SE \pm 1.

Next, to investigate whether the observed interaction reflected differences in the use of strategies we performed a rough strategy assessment for the information-integration task. The present task is limited when it comes to allowing reliable estimates of what model explains the data best and we thus refrain from sophisticated quantitative model assessments including parameter estimation. Indeed, several different models, including exemplar-models (e.g. Juslin, Olsson, & Olsson, 2003; Nosofsky & Johansen, 2000) and rule-plus-exception models (Nosofsky, Palmeri, & McKinley, 1994) are likely to give rise to a set of similar responses as one-dimensional and multi-dimensional rules under some values of the parameters. However, for the purpose of the present paper we were primarily interested in whether the age group differed in how many dimensions they utilized. A simplified means of assessing the correspondence between data and predictions from a model is to count the number of trials for which the data and the model gives the same answer (e.g. DeCaro et al., 2009). We defined the same set of 10 different strategies as DeCaro and colleagues (2009), including the correct three-dimensional rule, three different one-dimensional rules, and six different multi-dimensional rules (all of which could potentially be easily verbally described). Because we wanted to investigate what strategy accounted for

participants responses when they had reached the 8 CCR criterion (and not what different strategies were at play early during learning), we used the responses containing the 8 CCR as well as the subsequent 8 x 3 responses and compared them to the different strategies' predictions (in total 32 trials). We reasoned that at that point the response strategy should be more stable than during the beginning of the task when the participants presumably tried out different ways of responding. The model comparison was done separately for each of the two different rule-types of the information-integration task. Next, we looked at which model had the lowest deviation between responses and model predictions for each individual and each rule-type of the information-integration task. We did not count individuals where there was a tie between two or more strategies (separately for the two rule-types of the task). This resulted in a total of 40 valid strategy assessments for the young adults and 30 for the old adults. We contrasted multi-dimensional with one-dimensional strategies and counted the number of times (max 2 per person since there were two versions of the task) where a one-dimensional model or a multi-dimensional model had the lowest deviation. The results (Figure 3) suggest that for younger adults about equally many of the information-integration tasks were best described by a one-dimensional strategy (52.5 %) as by a multi-dimensional strategy (47.5 %). However, for the older adults more were better described by a one-dimensional strategy (76.7 vs 23.3 %).

Discussion

With this study we sought to demonstrate potential adaptive benefits of aging. In a task where category membership was governed by the integration of several dimensions (in the present paradigm denoted an *information-integration task*) younger adults performed better than older adults overall (Figure 2). Importantly, however, older adults were able to produce reasonable levels of performance (i.e. to reach the 8 CCR criterion) somewhat faster than young adults (Figure 1). To investigate one potential mechanism underlying this advantage we did a simplified strategy assessment in the information-integration task. For the younger adults about equally many were best fit by one-dimensional as by multi-dimensional strategies. In contrast, for the older adults the larger proportion were best fit by one-dimensional strategies (Figure 3).

The results are intriguing in that they imply two important facets of age-related effects on the ability to acquire new categories. First, we find no evidence that the older adults engage an implicit learning system when trying to master the information-integration task. Had that been the case we should have observed sustained levels of performance inde-

pendent of the learning criterion. Instead we observed the opposite (Table 2). Further, we ascribe the reasonable levels of performance produced by the older adults in the information-integration task mainly to their adoption of simple, one-dimensional rules. For this particular task, such rules are able to lead to performance well above chance. Thus, while the younger adults presumably tried different versions of multi-dimensional rules, performance might have suffered initially from erroneous responses, while in the meantime the older adults could sustain reasonable performance by not doing that.

Figure 3. The proportion of information-integration tasks (with two different rule types) per age group where responses were best captured by a multi-dimensional (correct) multi-dimensional (incorrect) or a one-dimensional strategy.

The data presented in the current study replicates and extends the performance differences reported by Ashby et al (2003) who used the 10 CCR criterion. Our contribution extends the data presented by Ashby et al (2003) by demonstrating that older adults adopt one-dimensional rules to a larger extent than younger adults. Moreover, on the assumption that older adults represent a population with lower working memory capacities than younger adults we replicate DeCaro et al (2008, 2009), providing converging evidence on the influence of individual differences on the ability to acquire new categories.

Nevertheless, the data does not allow us to claim that younger adults engaged the implicit system in the information integration task. Performance dropped off as a function of learning criterion (Table 2). Further, nothing in the fit of a multi-dimensional strategy per se can tell us whether it was executed by an explicit or an implicit system. Unfortunately, there is some debate regarding whether the present set of stimuli are most suitable for studying the implicit system, as they may not be sufficiently complex (i.e.

they involve binary stimuli dimensions). Rather, it has been suggested that the more complex Gabor patches are better for that purpose (e.g. Maddox, Ashby, & Bohill, 2003).

A number of interesting follow-up studies would help in clarifying some questions. First of all, it would be interesting to replicate the same experiment as reported here with the Gabor patch stimuli in order to investigate whether the ability to learn the tasks as well as the best performing strategies reveals the same pattern as reported here, even though the stimuli are more complex. Furthermore, follow-up experiments specifically designed for reliable quantitative model comparisons could provide a more detailed picture regarding the cognitive processes at play. Such experiments could for example aim at contrasting predictions by one- two- and three-dimensional rules with predictions by exemplar-models and rule-plus-exception models.

Results provide some new and unique data on potential benefits of cognitive aging. A large body of research has converged to reveal the benefits of simple decision strategies - in some cases “*less can be more*” (e.g. Gigerenzer, Todd, & the ABC Research Group, 1999). To the extent that cognitive aging biases older adults toward the use of simpler decision processes, there may be many benefits of cognitive aging that are currently underappreciated.

Authors' Note

We thank Gregor Caregnato and Paula Parpart for assistance in data collection. We thank DeCaro and colleagues for their experiment materials.

Encoding higher-order structure in visual working memory: A probabilistic model

Abstract

When encoding a scene into memory, people store both the overall gist of the scene and detailed information about a few specific objects. Moreover, they use the gist to guide their choice of which specific objects to remember. However, formal models of change detection, like those used to estimate visual working memory capacity, generally assume people represent no higher-order structure about the display and choose which items to encode at random. We present a probabilistic model of change detection that attempts to bridge this gap by formalizing the encoding of both specific items and higher-order information about simple working memory displays. We show that this model successfully predicts change detection performance for individual displays of patterned dots. More generally, we show that it is necessary for the model to encode higher-order structure in order to accurately predict human performance in the change detection task. This work thus confirms and formalizes the role of higher-order structure in visual working memory.

Keywords: change detection; visual short-term memory; working memory; probabilistic model

Introduction

Working memory capacity constrains cognitive abilities in a wide variety of domains (Baddeley, 2000), including general intelligence and reading comprehension (Daneman & Carpenter, 1980). The architecture and limits of the working memory system have therefore been extensively studied, and many models have been developed to help explain the limits on our capacity to hold information actively in mind (e.g., Cowan, 2001; Miyake & Shah, 1999). In the domain of visual working memory, these models have grown particularly sophisticated (Alvarez & Cavanagh, 2004; Bays, Catalao, & Husain, 2009; Cowan, 2001; Luck & Vogel, 1997; Wilken & Ma, 2004; Zhang & Luck, 2008). However, nearly all of these models focus on memory for extremely simple displays of presegmented objects. Furthermore, these models address only average performance across displays and do not make predictions about the difficulty of particular displays.

By contrast to these simple displays, memory for real-world stimuli depends greatly on the background knowledge and principles of perceptual organization our visual system brings to bear on a particular stimulus. For example, when trying to remember real-world scenes, people encode both the gist and detailed information about some specific objects (Hollingworth, 2004). Moreover, they use the gist to guide their choice of which specific objects to remember (Hollingworth & Henderson, 2000), and when later trying to recall the details of the scene, they are influenced by this gist, tending to remember objects that are consistent with the scene but were not in fact present (Lampinen, Copeland, & Neuschatz, 2001). Existing models of the architecture of

working memory do not address any of these hierarchical encoding or perceptual grouping factors. For this reason, they are unsatisfying as explanations of what observers will remember about more complex displays in which objects are not randomly chosen, but instead make up a coherent scene.

In this paper we reformulate change detection as rational probabilistic inference in a generative model (similar in spirit to Huber, Shiffrin, Lyle, and Ruys (2001) and Hemmer and Steyvers (2009b)). Rather than modeling the memory process per se, we model how observers encode a scene, and treat change detection as a probabilistic inference that attempts to invert this encoding model. We show that earlier models of visual working memory capacity are special cases of this framework, and show how our model can be extended to include the encoding of gist or higher-order structure. We thus take the first steps toward formalizing working memory capacity for displays in which the items are not all treated independently.

Visual working memory

One of the most popular ways to examine visual working memory capacity has been with a *change detection* task (Luck & Vogel, 1997). In this task, observers are presented with a small number of different colored squares (2, 4, 8, or 16) and told to remember which color appeared in which location. The squares then disappear for a brief period, and when they reappear they either are all the same colors as before, or contain one square which has changed color. Observers must report whether the display is the same or whether one of the squares changed color.

It is generally found that observers accurately detect changes when there are fewer than 3-4 simple colored squares, and as the number of squares increases above 4 observers accuracy steadily decreases (Luck & Vogel, 1997). In order to quantify this decrease and derive a capacity measure for the contents of visual working memory, change detection tasks have been modeled and formalized (Rouder et al., 2008; Wilken & Ma, 2004). For example, in the standard “slot” model of visual working memory (Cowan, 2001; Luck & Vogel, 1997; Rouder et al., 2008), it is assumed that on a display with N items observers perfectly recall the color of K items and completely forget the other $N-K$ items on the display. Using this model, it is possible to convert change detection performance into an estimate of K , and these capacity estimates, termed Cowan’s K , are widely reported in the literature on visual working memory (Alvarez & Cavanagh, 2004; Brady, Konkle, & Alvarez, 2009; Cowan, 2001; Luck & Vogel, 1997).

Figure 1: Methods of the change detection task modeled and used in Experiments 1 and 2. Observers are first briefly presented with a display, and then after a 1 sec blank are presented with another display where either the items are exactly the same or one item has changed color. They must say whether the two displays are the same or different.

Aside from Cowan’s K, there are other models used to quantify working memory capacity (Bays et al., 2009; Wilken & Ma, 2004; Zhang & Luck, 2008). However, the displays used always consist of simple stimuli like colored dots that are sampled uniformly, limiting any overarching structure or gist. All existing models of change detection thus ignore the presence of higher-order structure and prior knowledge that characterize change detection in real-world scenes (Simons & Rensink, 2005).

A probabilistic model of change detection

We present a probabilistic model of change detection that attempts to bridge the gap between the simple models used to formalize working memory capacity and the complicated phenomena that characterize memory for real-world scenes. Thus, we sought to model change detection in cases where the displays to be remembered were not just random colored dots but also exhibited some higher-order structure. As stimuli we created 5x5 patterns in which each space was filled in by a red or blue circle (or black and white square, see Figure 3). The items could form patterns that were anything from completely random to completely one color or vertical or horizontal lines. Our displays were thus simple relative to real scenes but were complex enough that we expected existing models, which encode dots at random, would fail to predict what people remember about these displays.

Our modeling preceded in two stages, mirroring the two stages of a standard change detection task: view and encode display one, then view display two and decide if a change occurred (See Figure 1).

While the observer is encoding the first display, they have access to the color of all the dots present in the first display. We propose that observers use this information to do two things: first, they infer what “gist” may have given rise

to this display; then, using this gist, they select the subset of the dots least well captured by the gist and encode these items specifically into an item memory. The specific dots to encode are selected based on how unlikely they are under the gist. Those that are the biggest outliers (e.g., least well captured by the gist) are encoded into an item memory that specifically encodes their colors.

After a short viewing, the first display disappears and the observer is left with only what they encoded about it in memory. Then, some time later, a second display appears and the observer must decide, based on what they have encoded in memory, whether this display is exactly the same as the first display. Thus, at the time of the second display (detection), the observer has access to the new display and the information in memory. Using the constraint that at most one item will have changed, it is then possible to use Bayesian inference to put a probability on each possible first display, and, using these probabilities, to calculate the likelihood of that the display changed.

Importantly, when the model encodes no higher-order structure it recovers the standard slot-based model of change detection. However, when the displays do have higher-order regularities or ‘gist’, our model uses this information to both select appropriate individual items to remember and to infer properties of the display that are not specifically encoded.

Encoding

The graphical model representation of the encoding model (shown in Figure 2) specifies how the stimuli are initially encoded into memory. We observe the first image (D^1), and we use this to both infer the higher-order structure that may have generated this image (G) and to choose the specific set of K items to remember from this image (S).

In the model, any given “gist” must specify which displays are probable and which are improbable under that gist. Unfortunately, even in simple displays like ours with only 2 color choices and 25 dots, there are 2^{25} possible displays. This makes creating a set of gists by hand and specifying the likelihood each one gives to each of the 2^{25} displays infeasible. Thus, as a simplifying assumption we chose to define gists using Markov Random Fields, which allow us to specify a probability distribution over all images by simply defining a small number of parameters about how nodes tend to differ from their immediate neighbors; such models have been used extensively in computer vision (Geman & Geman, 1984). We use only two gist parameters, which specify how often dots are the same or different color than their horizontal neighbors (G_h) and how often dots are the same or different color than their vertical neighbors (G_v). Thus, one particular gist ($G_h = 1, G_v = -1$) might specify that horizontal neighbors tend to be alike but vertical neighbors tend to differ (e.g., the display looks like it has horizontal stripes in it). This gist would give high likelihood to displays that have many similar horizontal neighbors and few similar vertical neighbors.

We treat each dot in these change detection displays as a random variable D_i^1 , where the set of possible values of each

Figure 2: The model expressed in graphical model notation for (A) encoding and (B) detection. Filled circles indicate a node is observed (the model has access to it). Unfilled circles indicate the model must infer the value of the node. The arrows are colored based on what kind of process they represent. D1=the first display, D2=the second display, G=the gist S=specific items, C=the presence of a change.

D_i^1 is -1 (color 1) or 1 (color 2). To define the distribution over possible displays given the gist parameters, $P(D|G)$, we assume that the color of each dot is independent of the color of all other dots when conditioned on its immediate horizontal and vertical neighbors.

We thus have two different kind of neighborhood relations (clique potentials) in our model. One two parameters (G_h and G_v) apply only to cliques of horizontal and vertical neighbors in the lattice (N_h and N_v) respectively. Thus, $P(D^1|G)$ is defined as:

$$P(D^1|G) = \frac{\exp(-En(D^1|G))}{Z(G)} \quad (1)$$

$$En(D^1|G) = G_v \sum_{(i,j) \in N_v} \psi(D_i^1, D_j^1) + G_h \sum_{(i,j) \in N_h} \psi(D_i^1, D_j^1)$$

where the partition function:

$$Z(G) = \sum_{D^1} \exp(-E(D^1|G))$$

normalizes the distribution. $\psi(D_i^1, D_j^1)$ is 1 if $D_i^1 = D_j^1$ and -1 otherwise. If $G > 0$ the distribution will favor displays where neighbors tend to be similar colors, and if $G < 0$ the distribution will favor displays where neighbors tend to be different colors.

The "gist" of the display is therefore represented by the parameters G of an MRF defined over the display. Our definition of $p(D^1|G)$ thus defines the probability distribution $p(display|gist)$. To complete the encoding model we also need to define $p(items|display, gist)$ ($p(S|D^1, G)$). To do so, we define a probability distribution that preferentially encodes outlier objects (objects that do not fit well with the gist).

We choose whether to remember each object from the display by looking independently at the conditional probability of that object under the gist, assuming all of its neighbors are fixed $p(D_i^1|G, D_{/i}^1)$. S denotes the set of K specific objects encoded: $S = s_1, \dots, s_k$. To choose S , we rank all possible sets

of objects of size 0, 1, 2, ... to K objects based on how unlikely they are under the encoded gist. Thus, the probability of encoding a set of objects (S) is:

$$p(S|G, D^1) = \prod_{j: s_j \in S} [1 - p(D_j^1|G, D_{/j}^1)] \prod_{j: s_j \notin S} p(D_j^1|G, D_{/j}^1) \quad (2)$$

This defines $p(S|D^1, G)$, which provides the probability of encoding a particular set of specific items in a given display, $p(items|display, gist)$, in our model.

To compute the model predictions we use exact inference. However, due to the computational difficulty of inferring the entire posterior distribution on MRF parameters for a given display (e.g., the difficulty of computing $Z(G)$), and because we do not wish to reduce our gist to a single point estimate, we do not compute either the maximum posterior MRF parameters for a given display or the full posterior on G . Instead, we store the posterior in a grid of values for G in both horizontal and vertical directions ($G_h = -1.5, -1, -.5, 0, .5, 1, 1.5$, $G_v = -1.5, -1, -.5, 0, .5, 1, 1.5$). We compute the likelihood of the display under each of these combinations of G_h and G_v and then choose the items to store (S) by integrating over the different choices of G (we store the full posterior over S). We choose a uniform prior on the gist (e.g., a uniform prior on MRF parameters G).

In summary, to encode a display we first treat the display as an MRF. We then calculate the posterior on possible gists by calculating a posterior on G at various (pre-specified) values of G . We then use this G and the original display to compute a posterior on which set of $\leq K$ items to encode into item memory (S). At the completion of encoding we have both a distribution on gists (G) and a distribution on items to remember (S), and these are the values we maintain in memory for the detection stage.

Detection

At the detection stage, we need to infer the probability of a change to the display. To do so, we attempt to recover the first display using only the information we have in memory and the information available in the second display. Thus, using the probabilistic model, we work backwards through the encoding process, so that, for example, all the possible first displays that don't match the specific items we remembered are ruled out because we would not have encoded a dot as red if it were in fact blue.

More generally, to do this inference we must specify $P(D^1|S)$, $P(D^1|D^2)$, $P(D^1|X)$, $P(S|G, D^1)$. Almost all of these probabilities are calculated by simply inverting the model we use for encoding the display into memory initially with a uniform prior on possible first displays. Thus, $P(D^1|G)$ is given by Equation 1, and $P(S|G, D^1)$ is given by Equation 2.

Those probabilities not specified in the forward model represent aspects of the change detection task. Thus, $P(D^1|S)$ is a uniform distribution over first displays that are consistent

with the items in memory and 0 for displays where one of those items differs. This represents our simplifying assumption (common to standard “slot” models of visual working memory) that items in memory are stored without noise and are never forgotten (it is possible to add noise to these memory representations by making $P(D^1|S)$ a multinomial distribution over possible values of each item, but for simplicity we do not model such noise here). $P(D^1|D^2)$ is uniform distribution over all displays D^1 such that either $D^1 = D^2$ or at most one dot differs between D^1 and D^2 . This represents the simple fact that the task instructions indicate at most one dot will change color.

Together these distributions specify the probability of a particular first display given the information we have about the second display and information we have in memory, $P(D^1|G, S, D^2)$. Given the one-to-one correspondence between first displays and possible changes, we can convert this distribution over first displays to a distribution over possible changes. Our prior on whether or not there is a change is 0.5, such that 50% of the mass is assigned to the “no change” display and the other 50% is split among all possible single changes. Thus:

$$P(C|G, S, D^2) = \frac{0.5P(D^1 = D^2|G, S, D^2)}{0.5P(D^1 = D^2|G, S, D^2) + 0.5\sum P(D^1 \neq D^2|G, S, D^2)}$$

This fully specifies the model of change detection.

Experiment 1 and 2

To examine human memory performance, we collected data using Amazon Mechanical Turk, where we had observers perform a change detection task for each of 24 different displays. We then compared this performance to our model.

The model makes predictions about how hard it is to detect changes in particular displays of colored dots (i.e., some changes will be more difficult to detect than others). In addition, it makes predictions about overall accuracy for a particular set of displays. We can thus examine how well the model fits with human memory performance in two distinct ways: (1) How many particular items (K) the model needs to recall to match human performance overall, and (2) how well the model’s predictions about the difficulty of particular displays correlate with human memory performance.

Method

We sampled a set of 16 displays from the Markov Random Field model we use to define our gist (using Gibbs Sampling). Four of these displays were sampled from each of $G_h = \pm 1$, $G_v = \pm 1$. In addition, we generated 8 displays randomly. In Experiment 1, these 24 displays consisted of red and blue dots. In Experiment 2 they were exactly the same displays, but composed of black and white squares instead.

The displays were presented to 65 participants in Exp. 1 and a separate set of 65 participants in Exp. 2 using Amazon Mechanical Turk. The first display was flashed up for 750 ms (timing was controlled using Javascript), followed by

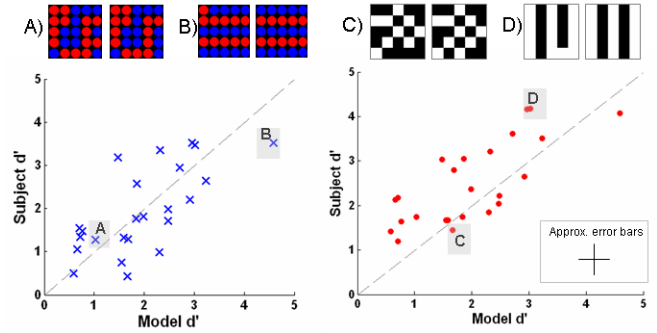

Figure 3: The fit of our probabilistic model to the observers’ data with $K=4$ in the model for Experiments 1 and 2. Each point is the d' for a pair of displays. Approximate error bars are shown for both the subjects and model, calculated by bootstrapping standard errors. Example of both a hard and easy pairs of displays is shown for each experiment.

a 750ms blank period; then the second display was flashed up for 750ms in a different screen location. Observers’ task was simply to say whether the two flashed displays were the same or different (See Figure 1). Each display was presented to each observer in both a “same” and “different” trial, so observers completed 48 trials each, with the entire experiment lasting approximately 4 minutes. The order of the 48 trials was randomly shuffled for each subject. Observers were paid 30 cents for their time.

Results

For each display we computed a d' , measuring how difficult it was to detect the change in that display (averaged across observers). Performance in Experiments 1 and 2 was highly similar, as the correlation in the display-by-display d' was $r=0.91$ between the two experiments. Thus performance was collapsed across both experiments for the remaining analyses.

On average, human observers d' was 2.18 (S.E. 0.06) suggesting they were quite good at detecting changes on these displays. Since the displays contain 25 dots, this d' corresponds to a Cowan’s K of nearly 16.1 dots if the items are assumed to be represented independently and with no summary information encoded (Cowan, 2001). This is nearly 5 times the number usually found in simpler displays and thus represents a challenge to standard models of change detection and visual working memory capacity.

Importantly, our claim is not that observers remember 16 individual dots. Instead, our model provides an alternative explanation. The model achieves the same performance as people ($d'=2.18$) with a K value of only 4, thus encoding only four specific dots in addition to the display’s gist (model $d'=1.2, 1.8, 2.05, 2.25$ at $K=1, 2, 3, 4$). This is because the model does not represent each dot independently: instead, it represents both higher-order information as well as information about specific dots. The model thus aligns nicely with both previous work from visual working memory suggesting

a capacity of 3-4 simple items (Luck & Vogel, 1997; Cowan, 2001) and also with data from the literature on real-world scenes which suggests a hierarchical representation with both gist and item information (e.g. Lampinen et al., 2001).

In addition to describing overall memory capacity, we can also examine the difficulty of particular displays. Previous models of change detection treat all displays as interchangeable, since they choose which objects to encode at random and do not represent any summary information about the display. They thus make no predictions about which particular changes will be hard or easy to detect. However, observers reliably find it more difficult to detect change in some displays than others, as measured both by averaging 200 split-half correlations on d-prime ($r=0.75$) and by bootstrapping standard errors on observers' d-prime (see Figure 3).

Our model does not treat each item independently, and chooses which items to encode by making strategic decisions based on the display's gist. Thus, our model does make predictions about the difficulty of detecting particular changes. In fact, the correlation between the model's difficulty with individual displays and the human performance on these displays was quite high (overall: $r=0.71$, $p<0.0001$; Exp.1: $r=0.65$, Exp.2: $r=0.73$; See Figure 3). Thus, the model's simple gist representation captures which changes people are likely to detect and which they are likely to miss.

Discussion

We here present a formal model of change detection which relies upon probabilistic inference to make predictions about visual working memory. The model takes into account the hierarchical nature of memory typically found in real-world scenes. It successfully predicts the display-by-display difficulty of visual working memory displays, indicating which changes observers will find easy to detect and which they will find difficult. The model also converges with the standard visual working memory literature on an estimate of 3-4 individual objects remembered, even in more complex patterned displays.

Importantly, the model recovers previous models of visual working memory capacity as a special case, and thus captures the properties of those models in displays with no higher-order information. However, by formulating change detection in terms of probabilistic inference, we can make much richer models of working memory than those typically used to calculate capacity in visual working memory experiments.

Non-independence in Visual Working Memory

While almost all experiments on visual working memory treat the items to be remembered as independent units, there are several exceptions (e.g., Jiang, Olson, & Chun, 2000; Sanocki & Sulman, 2008; Jiang, Chun, & Olson, 2004; Vidal, Gauthier, Tallon-Baudry, & Oregan, 2005). The most prominent exception to this assumption of independence is the work of Jiang et al. (2000), who suggested that the spatial context of other items is important to simple change detection tasks. On

displays where the item that changed is presented in the context of the other items present at encoding, observers perform better at change detection (Jiang et al., 2000). This suggests the items are not represented independently of their spatial context. This is compatible with the encoding of both summary information and specific items used in our probabilistic model.

In addition, previous work by Brady et al. (2009); Brady and Alvarez (2010) demonstrates that observers can be induced to encode displays with colored dots using statistical regularities present between the dots, rather than treating each dot separately. Observers not only use information about co-occurrence between items to form more compressed representations of these displays (Brady et al., 2009) but also encode the displays at multiple levels of abstraction, combining both an overall summary of the display and information about particular dots (Brady & Alvarez, 2010).

More broadly, the idea that memory encoding and retrieval are based on information represented at multiple levels of abstraction is common in the literature on reconstructive memory (Bartlett, 1932). Recent computational models similar in spirit to the one presented here have formalized this in both the domains of object size memory (Hemmer & Steyvers, 2009b) and more recently in the combination of gist and specific objects in real-world scenes (Hemmer & Steyvers, 2009a).

Chunking, Perceptual Grouping and Gist

One of the most popular explanations for observers' better-than-expected performance with more complex stimuli is chunking, or forming larger units out of smaller subsets of the stimuli (Miller, 1956; Cowan, 2001). In this framework, performance on our displays of patterned dots could be a result of observers' remembering only 3-4 independent items from the display and not encoding any overarching gist or structure. Instead, the items they remember would simply consist of multiple dots grouped into single items. This explanation has been proposed, for example, to explain why observers are better than expected at empty-cell localization tasks using patterned stimuli much like ours (Hollingworth, Hyun, & Zhang, 2005) and why some displays are remembered more easily than others in same/different tasks (Howe & Jung, 1986).

This kind of chunking could potentially explain observers' performance on our displays. However, our preliminary work with a model that partitions the display into contiguous regions of the same color and remembers K of these regions suggests that such a model does not adequately explain performance in the current experiments. Instead, such a model either fails to capture the pattern of human errors or requires memory for an overly large number of regions ($K>5$) to achieve human levels of performance. However, future work is needed to examine models that perform such grouping or chunking and compare them with models, like ours, that represent the displays at multiple levels of abstraction.

Model of Gist

In the model the "gist" is encoded using Markov Random Fields, and thus the only information that can be represented are local spatial continuity properties of the colors in the display (similarity between horizontal and vertical neighbors). Obviously, this is too impoverished to be a fully accurate model of human visual memory, even for such simple dot displays. For example, we could draw letters or shapes in the dot patterns, and people would recall those patterns well by summarizing them with a gist-like representation. Our model cannot capture such representations. However, we believe that our model nonetheless represents a step forward in understanding how people make use of such gist during change detection.

Abstract

Eye-movement research on expert visual artists suggests that experts in this particular domain differ from novices in their strategies for encoding to-be-rendered stimuli. However, it remains unclear if such differences are specific to the domain of expertise or independent of it (i.e., if the different strategies are utilized only in relation to perception with goals specific to rendering, or if they generalize to visual perception of any stimulus with perceptual goals other than rendering). Experiment 1 examined eye-movement strategies utilized by experts and novices when rendering familiar and novel stimuli. Experiment 2 examined performance in a recognition task that also utilized novel stimuli. Results suggest that experts possess both domain-specific *and* domain-independent advantages, in that they have more efficient visual encoding abilities both when rendering and not. The results of a concurrent analysis suggest a link between the encoding advantage and schizotypy, which is correlated with creative advantage, as well as with a neural profile of left hypofrontality. Implications for a two-stage model of creativity are discussed.

Keywords: Expertise; far transfer; schizotypy; visual art; creativity.

Introduction

Only in the presence of a meaningful configuration of stimulus features do experts in various domains, including chess (Chase & Simon, 1973), cars (Curby, Glazek, & Gauthier, 2009), and digit strings (Ericsson & Kintsch, 1995) outperform novices in terms of recall performance. Theoretically, long-term memory plays a role in such a domain-specific expert advantage (Ericsson & Delaney, 1999): Repeated practice yields a hierarchically organized memory structure for a class of stimuli, into which a stimulus representation can easily be encoded, provided that the stimulus generally fits the pattern with which an expert is familiar. Furthermore, as expertise increases, so does the number of features, or chunks, that the structure can accommodate. Such a structure would, *ipso facto*, not exist for a novel stimulus. Based on this account of expertise development, expert visual artists (henceforth *experts*) should perform as poorly as control participants (henceforth *novices*) when rendering novel stimuli and when performing perceptual tasks independent of rendering.

However, there is evidence that expertise unique to the domain of visual art confers an advantage that transfers

outside of what is familiar, e.g., mathematics performance in elementary school (Luftig, 1994), math and verbal SAT scores (Vaughn & Winner, 2000), visual analysis of out-of-focus pictures and novel stimuli, and mental rotation of three-dimensional objects (Kozbelt, 2001). Expertise in visual art may transcend a rendering-specific advantage, as creating drawings or paintings from life (henceforth *renderings*) requires visual analysis of objects in one's environment. Such visual analysis may generalize to visual perception in general (i.e., to situations where there is no rendering requirement, just streams of visual stimulation). In addition to examining rendering performance, the current experiments are designed to shed light on how experts and novices process novel stimuli under the perceptual goal of recognition.

A potential mechanism underlying an expert advantage in encoding visual information is also examined. Divergent thinking is considered a mechanism central to creativity (e.g., Burch, Pavelis, Hemsley, & Corr, 2006; Mednick, 1962; Miller & Tal, 2007; Schuldberg, 2000-2001; but see Weisberg, 2006, for a different view). It benefits from access to multiple associates (i.e., thoughts, ideas, etc. that come from memory and/or the environment) as starting points for creative synthesis; the more qualitatively-different associates a person has access to, the more likely it is that she will find a meaningful, novel combination in them (insight), then create a tangible product (elaboration).

In normal participants, environmental sources of stimulation outside of a point of focus are attenuated or blocked from consciousness (e.g., Lubow & Gewirtz, 1995). However, such blocking has been shown to be detrimental to creativity; individuals who were less likely to block out a task-irrelevant stream of stimuli were more likely to be creative, as measured by lifetime creative achievement (Carson, Peterson, & Higgins, 2003). If experts encode visual stimuli more rapidly than novices, they might then have access to more of them as associates in working memory, thus potentially boosting their divergent thinking capacity.

Individuals with schizotypic personality disorder (SPD), an attenuated form of schizophrenia, are also more likely to not attenuate irrelevant streams of stimulation (Baruch, Hemsley, & Gray, 1988). This population has a particular pattern of cortical activity: Left hypofrontality, whereby left

prefrontal cortical (PFC) function is attenuated (Buchsbaum et al., 1997; Raine et al., 2002). Left PFC activity is associated with two types of processing pertinent to the current study. First, left PFC function has been shown to play a role in translating modality-specific information into abstracted information (e.g., Anderson, Qin, Yung, & Carter, 2007). Normal left PFC function is associated with a lack of accuracy in rendering, and accurate rendering emerges when left PFC function is suppressed using transcranial magnetic stimulation (Snyder et al., 2003). These findings strongly suggest that left hypofrontality plays a major role in accurate rendering, potentiating it via a lack of interference in the signaling among sensory pathways and motor control centers. Second, increased bilateral PFC function is associated with creativity. Jung et al. (2010) found a negative correlation between lifetime creative achievement and left prefrontal cortical thickness. Carlsson, Wendt, and Risberg (2000) found that highly creative participants (as judged by the Creative Functioning Test) utilized right PFC to a significantly larger extent than low-creative participants, who utilized only left PFC, when coming up with alternate uses for a brick. The responses in that study were not rated as varying in creativity between the groups, implying that creative individuals utilize the right hemisphere to a greater extent than non-creative individuals in any kind of task.

Elevated levels of SPD in experts would be consistent with a pattern of left hypofrontality, which may underlie both rendering and creative abilities.

Experiment 1: Domain-Specific Performance

Several inferences can be made regarding cognitive processing on the basis of tracking eye movements. Theeuwes, Olivers, and Chizk (2005) showed that maintenance of the spatial location of an item in working memory only (i.e., without its presence in the field of vision) causes saccades (i.e., eye movement trajectories) to deviate in the direction of the maintained item. Tremblay, Saint-Aubin, and Jalbert (2006) showed that participants' use of eye movements as overt rehearsal was not only a default strategy used to maintain spatial position and serial order of dots presented on a computer screen, but also that denying subjects use of such a strategy caused a significant decrease in accuracy of recall of order of presentation. Under unconstrained conditions, experts reference (i.e., move their eyes from paper to stimulus during rendering) to-be-rendered stimuli significantly more frequently than novices (Cohen, 2005; Tchalenko, 2009). Experimentally manipulating the refresh rate (i.e., alternately illuminating either the stimulus or drawing pad every 1, 5, or 15 s) affected blindly-judged accuracy of experts' renderings; lower refresh rates (i.e., stimulus visible only every 15 s) yielded significantly less accurate renderings (Cohen, 2005). The manipulation had no effect on novices' accuracy. However, these results apply only to relatively complex stimuli, including faces (Cohen, 2005) and standing nudes (Tchalenko, 2009). For rendering straight and curved individual lines and squares, there do not appear to be

differences in eye movement patterns between experts and novices under unconstrained conditions (Tchalenko, 2007).

Therefore, in addition to the dimension of novelty, the content of a stimulus can be operationalized along a continuum of complexity. This experiment is the first to explicitly manipulate novelty and complexity in a rendering task and record the effect on eye movement strategies of experts and novices. If experts possess a visual encoding advantage, they should encode familiar and novel stimuli by utilizing the same cognitive strategy (as evidenced by similar eye movement patterns), while novices should utilize distinct strategies for encoding familiar and novel stimuli of varying complexity.

Method

Stimuli and Apparatus Stimuli rated as most familiar (Snodgrass & Vanderwert, 1980), and ones that are entirely novel (Chinese ideograms) were used. Within each of these categories, complexity was manipulated. Stimuli rated as most familiar were sorted according to rated complexity and the 10 simplest and 10 most complex were selected. The 10 familiar simple stimuli had a mean complexity rating of 1.60 out of 5 ($SD = 0.25$), and the 10 familiar complex stimuli had a mean complexity rating of 3.78 out of 5 ($SD = 0.31$), a significant difference ($p < 0.001$).

Unique Chinese ideograms were selected as novel stimuli, and their features (i.e., number of line segments) counted. The set of 10 novel simple stimuli had a mean of 5.50 features ($SD = 0.51$), and the set of 10 novel complex stimuli had a mean of 13.85 features ($SD = 1.66$), a significant difference ($p < 0.001$).

Thus, complexity was explicitly controlled for both novel and familiar stimuli in order to examine its effect on eye movement behavior.

Stimuli were presented using E-Prime software, version 2.0 on a Tobii 1750 eye tracker (Psychology Software Tools, Pittsburgh, PA) set to 1024 x 768 pixels screen resolution, sampling eye position at 50 Hz and with a screen refresh rate of 50 Hz. The eye tracker was calibrated at the outset of each session prior to data collection to ensure reliable eye tracking. Participants rendered using a stylus on the screen of a tablet PC running CogSketch software, version 1.131 with a simplified graphic user interface (SILC, Chicago, IL).

Participants Novices ($n = 8$, mean age = 19.9 years, three males) were recruited from Temple University's undergraduate subject pool, and given the option of course credit or cash for their participation. Experts ($n = 8$, mean age = 30.1 years, two males) were recruited using flyers posted around the Philadelphia community, and had to meet the following criteria: Have at least five years of formal art training, be at least 18 years old, and must draw or paint more than once a week, all this information being gathered via e-mail or telephone interviews prior to participation. Experts were compensated with cash.

All novices were screened for art expertise following their experimental session. All participants were screened for proficiency in reading, writing, and speaking Chinese¹.

Procedure Factor 1 (between-subjects) was expertise (novice or expert participant). Factor 2 (within-subjects) was stimulus familiarity (familiar or novel), which pertains to the presence or absence of long term representations: No subjects possess long-term representations of novel stimuli, and all subjects possess representations of familiar stimuli. Factor 3 (within-subjects) was stimulus complexity (simple or complex stimulus). Participants were informed that they had 60 s to render each of the 40 stimuli as accurately as possible, with the opportunity to rest between trials. If a participant finished rendering before 60 s elapsed, she pressed the space bar on the keyboard in front of the monitor. If she did not finish, the stimulus disappeared once 60 s elapsed. Following a practice trial to provide familiarization with the drawing stylus and tablet, all participants rendered all 40 stimuli in randomized order. The dependent variables were percentage of time spent per trial with eyes on the on-screen image (i.e., visual encoding of a stimulus), and mean duration of eyes on the on-screen stimulus. An on-screen epoch was operationalized as 60 consecutive ms or more of the eyes looking at the rectangular area subsuming a stimulus.

Results

An examination of eye movements to and away from to-be-rendered stimuli during rendering yielded a significant main effect of expertise ($F(1, 14) = 6.43, p < .05$), with novices' total encoding time significantly longer than experts' (see Figure 1A). A significant main effect of stimulus complexity was evidenced, as well ($F(1, 14) = 46.08, p < .001$; see Figure 1B). There was also a significant interaction between stimulus complexity and stimulus novelty ($F(1, 14) = 6.96, p < .05$), which resulted from a significant difference between familiar complex and novel complex stimuli ($t(15) = 2.47, p < .05$), and a lack thereof between familiar simple and novel simple stimuli (see Figure 1B).

In order to examine the above effects in more detail, individual epoch durations were analyzed. There was a significant main effect of expertise ($F(1, 14) = 7.79, p < .05$); experts' epochs were significantly shorter than novices' (see Figure 1C). As with overall encoding time, there was a significant main effect of stimulus complexity ($F(1, 14) = 56.85, p < .001$), with longer epochs for complex stimuli (see Figure 1C). There was also a main effect of stimulus novelty ($F(1, 14) = 79.29, p < .001$), with shorter epochs for novel stimuli (see Figure 1D). Of central importance were three significant interactions. The first of these was complexity by expertise ($F(1, 14) = 4.67, p < .05$; see Figure 1C); the second was novelty by expertise ($F(1, 14) = 21.16, p < .001$ see Figure 1D), and finally, complexity by novelty

Figure 1: Effects of A) expertise, and B) stimulus type on total encoding time; C) stimulus complexity, and D) familiarity on epoch duration. Error bars represent one standard error.

by expertise ($F(1, 14) = 7.08, p < .05$). Essentially, as stimulus complexity and novelty changed, so did the novices' encoding strategy, which was also the case for experts, albeit to a significantly lesser extent (see Figures 1C and 1D).

Discussion

The results support the hypothesis that stimulus novelty and complexity have differential effects on processing strategy. The significant three-way interaction is of most interest, in that the effects of stimulus complexity and novelty on encoding strategy were different for experts and novices. As can be seen in Figure 1 C and D, both experts' and novices' encoding strategies were affected by stimulus complexity and novelty in a similar fashion. However, the experts evidenced an attenuation of the differences caused by novel and complex stimuli. These results suggest that visual art training is associated with an advantage in encoding novel and complex stimuli when the goal of perception is rendering.

The absence of long-term representations affected experts less than novices, suggesting that experts use less top-down processing (associated with PFC), or use it more efficiently, than novices when rendering.

The results suggest that experts approach equal efficiency at encoding familiar and novel visual stimuli regardless of complexity when visual encoding is linked to the goal of domain-relevant action. In fact, these results indicate that experts encode novel stimuli as though they are familiar, at least when compared to novices.

Experiment 2: Domain-Independent Performance

Experiment 1 showed that novices require longer epochs than experts in order to effectively encode novel and complex stimuli when rendering. The experts' advantage

¹ One participant fluent in Chinese, excluded from analyses, evidenced patterns very similar to the expert group.

may or may not disappear if the domain-specific task of rendering is absent.

In order to examine whether this expert advantage can be observed in a task that does not entail an expertise-based motor component, in Experiment 2 the domain-specific requirement of rendering was removed from the perceptual task, and replaced by a binary stimulus recognition task. It was hypothesized that experts require less encoding time than novices to correctly identify a stimulus as being the same as or different from a briefly-encoded novel stimulus. However, there may be a complexity-based limit on this encoding advantage; thus, the advantage was predicted to be more pronounced for simple novel stimuli than for complex novel stimuli.

Method

Stimuli and Apparatus Eighty Chinese ideograms were used as novel stimuli. Forty were simple and 40 complex. The stimuli used in this experiment were unique (i.e., none overlapped with the stimuli used in Experiment 1). Stimuli were presented on the same computer monitor used in Experiment 1. Eye movements were not recorded in this experiment.

Participants The same participants that took part in Experiment 1 took part in Experiment 2. The order of experiments was counterbalanced across participants.

Procedure Experiment 2 consisted of a binary judgment recognition task, as follows. At the outset of each trial, explicit written instructions appeared on the computer screen for the participant to keep her eyes focused on the screen so as to avoid missing the briefly-presented stimulus, which appeared upon her pressing the space bar. The stimulus was on-screen for a variable amount of time (50, 125, 200, or 275 ms)², randomly selected by the computer. Then, following a 1500 ms interval, a second stimulus appeared, which was either the same ideogram, or the same ideogram with one of four slashes superimposed over it. The first ideogram may have had a superimposed slash, as well. The presence of a slash was randomly selected by the computer. This randomization yielded relatively equal numbers of trials for same and different conditions, as well as for all four encoding durations. Participants responded as to whether the second ideogram was the same as or different from the first ideogram by pressing "F" or "J" on the keyboard, respectively (the keys' meanings were displayed on-screen), with explicit instructions to use one index finger for each key. There were four practice trials, followed by eight sets of 10 trials each, with a prompt to take a rest between each set. Sets of trials alternated between simple and complex ideograms. The dependent variable was the proportion of correct answers (same or different) for each encoding duration.

² Pilot data obtained from a sample of novices ($n = 23$) indicated that these intervals should yield meaningful variation.

Results

The results of Experiment 2 are summarized in Figure 2. Non-parametric tests were used due to violations of normality and homogeneity of variance in some of the distributions. There was a significant difference for complex stimulus recognition between experts and novices at 125 ms ($U = 46.5$, $p < .01$). Likewise, for simple stimuli, there was a marginally significant difference between experts and novices at 200 ms ($U = 67.0$, $p = .06$). Furthermore, experts attained above-chance performance for all but the shortest encoding duration, whereas novices did not.

Figure 2: Rates of correct recognition of novel stimuli. 0.5 indicates chance performance.

Discussion

The results of Experiment 2 extended the results of Experiment 1, in that experts significantly outperformed novices at shorter encoding durations. The fact that a difference emerged at 200 ms for simple stimuli indicates that experts' advantage is somewhat limited; experts and novices were equally poor at encoding simple novel stimuli at short durations. Nevertheless, experts were able to encode simple novel stimuli significantly better than novices when given 200 ms or more, whereas novices required at least 275 ms to close the gap. Furthermore, when encoding complex novel stimuli, experts at least evidenced the ability to deviate from chance performance, whereas novices did not. This indicates that, although the experts' advantage appears to be limited, it does confer an advantage when encoding dense, unfamiliar patterns.

Clearly, experts' visual encoding advantage is not limited to rendering, insofar as in Experiment 2, experts were denied any synergistic boost from perceiving with the goal of rendering. Even with a lack of the rendering component, experts' encoding was superior, as evidenced by their higher performance on the recognition task.

Relation of Expertise to Schizotypy: Implications for the Neuroscience of Creativity

The question remains: What cognitive operations can experts perform while novices are still encoding?

Consistent with left hypofrontality in experts, novices encode visual information and abstract it, while experts use the same time to encode the same information and either plan motor commands (Experiment 1), or perform other cognitive tasks (Experiment 2), potentially including divergent thinking. In order to lend support to the theory that left hypofrontality underlies experts' more efficient encoding, self-report data on SPD were obtained, with the hypothesis that experts would evidence higher levels of SPD, an indirect measure of left hypofrontality.

Method

Stimuli, Apparatus, and Participants The schizotypal personality questionnaire, form B (SPQ-B; Raine & Benishay, 1995) was administered to assess schizotypal traits in the expert and novice samples. The SPQ-B is a reliable, 22-item binary judgment questionnaire that assesses three factors: Cognitive-perceptual aberrations, (ideas of reference, magical thinking, unusual perceptual experiences, and paranoid ideation), interpersonal dysfunction (social anxiety, lack of close friends, blunted affect, and paranoid ideation), and disorganization (odd behavior and odd speech). It was presented on the same computer as used in Experiments 1 and 2. Twenty eight novices and 18 experts filled out the questionnaire as part of ongoing investigations.

Results

For the disorganized factor, experts responded affirmatively to significantly more questions than novices ($t = 2.46, p < .05$). For questions that load onto the cognitive-perceptual factor, experts responded affirmatively marginally significantly more than novices ($t = 1.86, p = .09$). There was no difference between the groups on the interpersonal factor.

Discussion

Experts evidenced a pattern of elevated SPD relative to novices. There was no difference between experts and novices on the interpersonal factor, but there was a significant difference found on the disorganized factor, and a marginally significant difference on the cognitive-perceptual factor. These data provide a potential mechanism for experts' ability to render accurately, despite requiring less time to encode visual information. Hypoactive left PFC does not over-abstract stimulus representations (i.e., its functioning is attenuated) in expert cognition, allowing experts to perform well at modality-specific tasks (drawing is visual, writing is verbal, etc.).

This finding also has implications for creativity. Not only does left hypofrontality allow for modality-specific stimulus representation, it allows for attentional disinhibition. Thus, experts have better access to more visual associates upon which they can perform divergent thinking operations, and thus make *creative* modality-specific products.

General Discussion

Visual artists encode novel visual information more efficiently than control participants, both within the domain of rendering and in at least one task outside of it. This ability to transfer an encoding advantage outside of a domain of expertise implies that expert visual artists are prepared to perceive the unknown similarly to the way that novices perceive the familiar. However, novices' variable encoding strategies are only *attenuated* in experts, suggesting that training in visual art may allow for perceiving novel information in a manner only *similar* to that for familiar information. More extensive training may be associated with encoding strategies for novel and familiar stimuli that are indistinguishable. This possibility is of importance to the field of education, as students can be trained to encode novel information potentially as efficiently as familiar information. Neural plasticity caused by musical training has been demonstrated (Hyde et al., 2009), so there is potential for advantageous left hypofrontality to be an effect of visual art training.

With less time required to fully encode a novel stimulus, cognitive resources are free to be utilized for additional operations upon it and previously-encoded or recalled stimuli, including divergent thinking operations. In Experiment 1, experts encoded stimuli on average 157 ms faster than novices. In Experiment 2, experts attained levels of recognition that novices required an additional 75 ms to attain. Ecologically speaking, that additional processing time can be used to attend to other streams of stimulation, then make a creative connection. This process can be referred to as insight, and is distinct from elaboration, the phase during which the creative insight is turned into a tangible product. Martindale and colleagues (Martindale & Hasenfus, 1978; Martindale, Hines, Mitchell, & Covello, 1984) showed distinct brain activation patterns (as measured by electroencephalogram) during each of these two phases. The current results extend this two-stage theory of creativity; insight may be dependent upon processing on the scale of tens or hundreds of milliseconds, time made available by efficient encoding.

The results of the SPQ-B are consistent with the hypothesis that experts' creativity is based on attentional disinhibition, which allows them to make connections between far-flung associates; making distant connections on the basis of rapid encoding may be responsible for experts' self-reports of their speech or behavior being perceived by others as odd, as well as for having unusual perceptual experiences.

In order to more fully understand expert cognition, work currently under way by the authors examines experts' abilities to retain and manipulate novel visual information.

Melody Recognition: Effects of Articulation Format

Stephen Wee Hun Lim (gmslwhs@nus.edu.sg)

Winston D. Goh (psygohw@nus.edu.sg)

Department of Psychology, National University of Singapore

Block AS4, 9 Arts Link, Singapore 117570

Abstract

Various surface features – timbre, tempo, and pitch – influence melody recognition memory, but articulation format effects, if any, remain unknown. For the first time, these effects were examined. In Experiment 1, melodies that remained in the same, or appeared in a different but similar, articulation format from study to test were recognized better than were melodies that were presented in a distinct format at test. A similar articulation format adequately induced matching. Experiment 2 revealed that initial perceptual (dis)similarity as a function of the location of articulation (mis)match between two instances of the melody did not accurately determine discrimination performance. An important boundary condition of the matching process was defined: Whether matching occurs depends on the physical quantity, rather than location, of fit between the memory trace and the recognition probe, suggesting a global matching advantage effect.

Keywords: Melody recognition memory; articulation format effects; global matching advantage

Introduction

When we hear a piece of music, we detect and occasionally remember phrases, motifs, themes, syncopations, suspensions, tonic chords, cadences, and so on. We recognize the instrument playing the melody, or even identify with the emotions of the specific musician performing the work. To this end, what exactly is the nature of mental representations that underlie the music experience? To address this question, it is useful to first recognize that there are two kinds of information in music, namely *abstract structure* and *surface characteristics* (Trainor, Wu, & Tsang, 2004). The *abstract structure* entails the relative pitches and ratios of the durations between adjacent musical notes, regardless of the individual note's absolute pitch level or length *per se*. *Surface characteristics*, in contrast, contain the non-structural aspects of the music, such as absolute pitch, tempo, and timbre. Both the abstract structure and surface characteristics contribute towards musical interpretation. Representing the abstract structure enables recognition of a melody across different performances, and musical variations of a motif within a musical composition (Large, Palmer, & Pollack, 1995). For example, *Happy Birthday* retains its identity and is readily recognized even when it is played or sung in various keys and tempos, or by different voices or instruments. Yet, these very surface characteristics lead us to identify the specific musician and unique performance of the work, defining the emotional

interpretation of that rendition. While Raffman (1993) has suggested that only the abstract structural information is encoded into long-term memory (LTM), others have reported that surface features, such as timbre (e.g., Peretz, Gaudreau, & Bonnel, 1998) and tempo (e.g., Halpern and Müllensiefen, 2008), are also encoded into LTM during a melody recognition task.

In music, the way a melody is articulated shapes its surface appearance. In the extant literature that examined the effects of surface characteristics on melody recognition performance, it is surprising that no study has explored the effects of articulation format, even though it is a feature that is commonly manipulated by both composers and performers. Trained musicians commonly define articulation as whether the music (e.g., melody) is played in a *legato* (i.e., continuous) or *staccato* (i.e., detached) format. Because no one has studied the influence of articulation on melody recognition, our initial motivation was to add to that literature. Thus far, memory representations that subserve explicit recognition of melodies appear to be formed by a highly specialized association that binds together characteristics such as timbre and tempo with melody identity. It is thus attractive to ask whether the articulation feature is tied to a melody's identity and computed during the perceptual analysis of the melodic input. By addressing this question, we hope to explicate more fully the central idea that variability in surface features, along with the idealized canonical structure of music, is important in music perception and processing.

To examine the effects of articulation format on melody recognition, we designed the melody to occur either fully in *legato* form, fully in *staccato* form, or in mixed articulation format (i.e., a combination of *legato* and *staccato* components). When the melody was played in *staccato* form, the duration of each note in the melody was manipulated to last 10% of the full duration when the note was played in *legato* form. The schematic of the eight different articulation formats is shown in Figure 1. These formats are coded as *l*, *s*, *a*, *b*, *c*, *d*, *e*, and *f*. The *legato* and *staccato* formats are abbreviated as format *l* and *s*, respectively, while the six mixed-articulation formats follow an alphabetical system of coding for ease of reference. Each set of four boxes represents sequentially the four bars of the melody respectively.

Taking format *f* for instance, the melody opens in *staccato* form (i.e., the notes of the melody are articulated by the instrument in a disjointed fashion) for the first bar, switches to *legato* form (i.e., the notes are now articulated smoothly

in a continuous manner) by the second bar, returns to *staccato* mode in the third bar, and finally closes with a long-sounding note in the final bar.

Experiment 1

In Experiment 1, we asked two questions: (1) Is articulation feature information retained in LTM, and (2) what is the role of feature similarity in melody recognition memory? Our first goal was to investigate the effects of manipulating articulation context on melody recognition. The hypothesis was that to the extent that articulation format information is not erased from, but is in fact preserved in, LTM, discrimination performance ought to improve when old melodies are repeated in the same articulation format, as compared to when the melodies appeared in a distinct articulation format during the recognition stage.

In addition, we recognized that extant studies that examined surface feature effects have used test stimuli that were denoted as either of the same or different format, neglecting effects that could arise from varying magnitudes of intermediate perceptual differences. For instance, Peretz *et al.* (1998) presented melodies in timbres at test that were either the same as, or distinct from, those used at study; Halpern and Müllensiefen (2008) made the tempo changes in altered tunes “large enough to be perceptible” (p. 1378). Effects of fine-grained perceptual details of surface features, such as tempo or timbre, have been somewhat overlooked, so it is unclear whether these details actually contributed to the disparate surface feature effects observed in the literature. As such, a second goal was to assess the contribution of fine perceptual details in melody recognition memory, by including a similar-articulation-format condition. We speculated that to the extent that articulation similarity constitutes an integrated part of the matching and retrieval processes involved in melody recognition, performance ought to improve even when old melodies are tested with a different *but similar* articulation format, as

compared to when the melodies appeared in a distinct articulation format.

Method

Participants Forty-seven introductory psychology students participated for course credit.

Materials The stimulus set contained 48 novel monophonic melodies (see Figure 2 for samples). An equal number of four-bar melodies were composed in the tonality (key) of C major, C minor, G major, or G minor. The melodies started either on the tonic, mediant, or dominant, but always ended with a single long note on the tonic of their home key. Each melody was written in simple triple or simple quadruple time, lasting approximately six seconds or 7.2 seconds respectively. The melodies were constructed using the *Finale 2009* software, and saved as .wav sound files.

Figure 2: Samples of the 48 melodies used.

Prior to conducting Experiment 1, we first derived a multidimensional “articulation map” using MDS techniques (Kruskal & Wish, 1978) that shows the similarity relations between the individual articulation formats that will be used as the stimulus materials. This procedure was necessary to ensure that the selection of specific articulation formats for

Figure 3: Two-dimensional MDS solution for eight articulation formats.

use in the subsequent main experiments can be based on objective measures of the degree of perceived similarity among different articulation formats. Sixteen students from the same population sample but who did not participate in the main experiments rated the pairwise similarity of the eight articulation formats across four different melodies using a 7-point Likert scale. The two-dimensional MDS solution (Kruskal's stress = .15, $R^2 = .85$) for the eight articulation formats appears in Figure 3. The interpretation is that the further away two articulation formats are positioned from each other in space, the more perceptually distinct they are. Two different combinations of articulation formats were selected for melody presentation. For each combination, the articulation formats are listed in the order that constitutes the same-, similar-, and distinct-articulation context conditions, respectively: (1) *l, b, s* and (2) *s, f, l*. These sets were created for counterbalancing purposes described in the procedure.

Apparatus Computers equipped with 16-bit sound cards were used for the experiment. Participants received the signals through a pair of Beyerdynamic DT150 headphones at approximately 70 dB SPL. The stimuli were presented using E-prime 1.2, and data were collected using the PST Serial Response Box (Schneider, Eschman, & Zuccolotto, 2002), with the left- and right-most buttons of the button-box labelled *No* and *Yes* respectively.

Design The 48 melodies were divided equally into two lists. One list was designated to consist of old melodies while the other to consist of new melodies. At study, all the 24 old melodies were presented using a single articulation format. In the test phase, the 24 new melodies were divided among three articulation formats, where eight melodies were assigned to be presented in the same format, eight in a similar format, and the remaining eight in a distinct format. For the 24 old melodies, likewise, eight were assigned to the same-articulation context condition, eight to the similar-articulation context condition, and the remaining eight to the distinct-articulation context condition (see Table 1).

Procedure Half of the participants were randomly assigned to listen to melodies played by the clarinet, while the other half were randomly allocated to listen to melodies played by

the violin. The session consisted of two parts – the memorization phase and the recognition phase. The forthcoming recognition test was made known to participants before the memorization phase started. Participants were told to silently memorize each melody that was played through the headphones. At the start of each trial, a ready prompt was displayed on the monitor for one second, after which it was deleted. One second later, a melody was played over the headphones; the melody was repeated 800 ms following its first presentation. Participants then pressed the space key to proceed to listen to the next melody. This sequence persisted until all 24 melodies had been presented. The melody presentation sequence was randomized across participants.

Following the memorization phase, participants were first presented with versions of two well-known melodies – *Mary had a little lamb* and *London bridge is falling down* – that varied in their articulation formats to clarify the definition of “form”. After which, the recognition test began. On each trial, the ready prompt appeared for one second and disappeared. 800 ms later, the question *Did you hear this melody in Part 1?* was displayed, and a single melody was played through the headphones. Participants were told to press the *Yes* button on the Serial Response Box if they thought they had heard the melody earlier, regardless of the original “form” (i.e., articulation format) that the melody was presented in. Otherwise, they were told to press the *No* button. Participants were told to respond as accurately as possible. No feedback was provided on any of the trials. A new trial was started after a button response.

Results and Discussion

Table 2 presents the pattern of results for d' performance across the three articulation-context conditions. There was a reliable main effect of articulation context, $F(2, 90) = 3.94$, $MSe = 0.36$, $p < .05$. Pairwise comparisons revealed that participants were significantly better at discriminating melodies presented with the same articulation format than they were at discriminating melodies presented with a distinct articulation format, $t(46) = 2.42$, $p < .05$; participants also performed better when melodies appeared in a similar articulation format than they did when melodies appeared in a distinct format, $t(46) = 2.03$, $p < .05$.

Table 1: Summary of Experiment 1's Design

Memorization Study melodies	Recognition					
	Test melodies (Old)			Test melodies (New)		
	Articulation format context					
	Same	Similar	Distinct	Same	Similar	Distinct
	<i>Set combination 1 articulation formats</i>					
1	l	b	s	l	b	s
24	8	8	8	8	8	8
<i>Set combination 2 articulation formats</i>						
s	s	f	l	s	f	l
24	8	8	8	8	8	8

Discriminability did not differ between the same- and similar-articulation context conditions, $t < 1.05$. This pattern of results indicates that discriminability increased significantly so long as melodies were tested in at least a similar articulation format.

Table 2: Discrimination Performance (d') Across Articulation-Context Conditions in Experiment 1.

	Articulation context		
	Same	Similar	Distinct
<i>M</i>	0.97	0.90	0.64
<i>SD</i>	0.66	0.56	0.67

The present data revealed an advantage in melody recognition for same-articulation repetitions over distinct-articulation presentations. There was also an advantage in melody recognition for similar-articulation presentations over distinct-articulation presentations. An interpretation based on the the now-classic encoding specificity framework (Tulving & Thompson, 1973) is apt. Under this framework, the effectiveness of a retrieval cue depends on its degree of relatedness to the encoding of an item at first. Our view is that surface (articulation) and structural attributes of a melody are stored together in the LTM trace. Melody recognition is reliable when a specific match between the episodic memory trace and the probe occurs, but is hampered when there is a mismatch.

The comparison of shared properties between the memory trace and the probe implies that item similarity *per se* constitutes an integral part of the retrieval process. In fact, the degree of similarity among the features of the exemplar traces in memory and the target probe forms a central aspect in exemplar models of memory and categorization (Gillund & Shiffrin, 1984; Hintzman, 1988). Memory theorists have assumed that memory for a stimulus is really memory for features contained in that stimulus. The global matching approach (see Clark & Gronlund, 1996) suggests that these features in a test item, when matched with the features that have earlier been stored in memory, evoke a familiarity signal. Specifically, the greater the degree of match is, the stronger the signal will be. In our case, when a melody was re-played in the same or in a similar articulation format at test, there are many overlapping features between the articulation formats of the two melody instances from study to test. These overlaps presumably contribute to a strong sense of familiarity signal evoked by resemblance to the studied melody (see Cleary, 2004). In contrast, when the melody appeared at test in a distinct format, there are few overlapping features with the melody's original format. As such, the familiarity signal is presumably weaker, which hinders melody discrimination.

The present experiment suggests that when matching occurs, melody recognition performance is reliable at test. Experiment 2 was designed to establish an important boundary condition which determines whether this matching process would prevail (or fail).

Experiment 2

A first examination of the articulation similarity scaling solution shown in Figure 3 reveals that the greater the amount of *physical* articulation match between two instances of a melody, the more similar they were perceived to be. For instance, formats *d* and *f*, each containing two bars of *staccato* component, were perceived as similar to each other. But a closer look at the scaling solution reveals that only when the articulation format of two instances of the melody matched *at the melody's onset* would the two instances of the melody be perceived as similar to each other. This interpretation can explain why format *e* was perceived as rather different from formats *d* and *f* even though each of these formats contained two bars of *staccato* component. This observation is intriguing because two articulation formats, given the same quantitative amount of articulation match, could in fact be perceived as different from each other due to the fact that the match did not occur at the melody's onset.

We therefore pursued a third question here: Would this perceptual dissimilarity between two instances of the melody (e.g., in formats *d* and *e*) due to the location of the (mis)match hamper discrimination performance during the test stage, even when both instances contain the exact same quantity of articulation match (e.g., two bars of *staccato* component)? The goal was to illuminate the underlying nature of the matching process in melody recognition memory, and we hypothesized that to the extent that perceptual dissimilarity, as a function of the location of (mis)match in format, affects matching between study and test, discrimination performance ought to be hampered when old melodies that were originally played in, say, format *s* are repeated in format *e* (i.e., perceptually dissimilar format) at test, as compared to when the melodies are repeated in format *d* or *f* (i.e., perceptually similar format) at test, although formats *d*, *e*, and *f* each contains the exact same quantity (i.e., two bars) of *staccato* component.

Method

Participants Sixty-four psychology undergraduates participated. None had participated in Experiment 1.

Materials, Apparatus, Design, and Procedure The materials and procedures were essentially the same as those of Experiment 1, with a slight modification in materials. Based on Figure 3, four different combinations of articulation formats were selected for melody presentation. For each combination, the articulation formats are listed in the order that constitutes the same-, similar-, and distinct-articulation context conditions respectively: (1) *s*, *d*, *e*, (2) *s*, *f*, *e*, (3) *l*, *b*, *a*, and (4) *l*, *c*, *a*. Set combination was counterbalanced across participants.

Results and Discussion

Table 3 presents the pattern of results for d' performance across the three articulation-context conditions. There was no reliable main effect of articulation context, $F < 1.23$.

Discriminability between the same-, similar-, and distinct-articulation context conditions did not differ reliably. Articulation format did not influence performance.

Table 3: Discrimination Performance (d') Across Articulation-Context Conditions in Experiment 2.

	Articulation context		
	Same	Similar	Distinct
M	1.13	0.94	1.09
SD	0.67	0.78	0.70

Experiment 1 suggested that articulation properties are bound with the melody's structural identity. Surface feature information of the melody is first encoded and stored in the memory trace, and later used to retrieve the melody. Because a same- or similar-feature repetition constitutes an exact, or at least a close, match with the memory trace for the old melody, the trace becomes more salient than the other competing traces, enhancing discrimination performance. On the other hand, a distinct-feature presentation would not match with the trace for the old melody, thus performance is hampered. The interpretation is that given a retrieval cue that coincides with the initial encoding of the melody in terms of its surface properties, the cue would help the melody to be recovered at test.

But Experiment 2 revealed that initial perceptual (dis)similarity, as a function of the location of feature (mis)match between two instances of the melody, did not accurately determine discrimination performance. When two instances of the melody are perceived as different from each other from study to test, matching presumably would not occur. Yet, some form of matching must have occurred despite the perceptual mismatch because the overall discrimination performance (in the distinct articulation condition) was good, average $d' = 1.09$.

Values of d' between 1 and 2 usually represent good yes-no recognition performance (Neath & Surprenant, 2003, p. 202). To further justify that this was good performance, we conducted three planned comparisons on the d' data. The first and second comparisons established that the data sets between Experiments 1 and 2 were comparable: Performance in the same-articulation conditions, as well as performance in the similar-articulation conditions, across both experiments did not differ, $t_s < 1.28$, $p_s > .21$. The third comparison used performance in Experiment 1's distinct articulation condition as baseline, and revealed that performance in Experiment 2's distinct-articulation condition reliably exceeded performance in this baseline condition, $t(109) = 3.44$, $p < .01$, implicating good discrimination performance in this case.

Thus, the logical inference is that whether matching would occur is likely to be contingent on the absolute physical quantity of match between the memory trace and the recognition probe per se, rather than the perception of dissimilarity due to the location of (mis)match in the feature attributes. These data defined an important boundary

condition of matching observed in melody recognition under which matching would (or would not) be successful.

General Discussion

Several studies have demonstrated that the alteration of the initial part of a sound can affect the recognition of musical instruments (e.g., Berger, 1964; Grey & Moorer, 1977). These findings suggest that temporal features are important in timbre perception and music processing at large. Yet, Experiment 2 suggests that altering the initial part of the articulation format (i.e., at the onset of a melody) did not influence discrimination performance. In explaining these data, we offer a global matching advantage interpretation which finds its roots in Gestalt psychology. A basic position of the Gestalt view is that a whole is qualitatively different from the complex that one might predict by considering only its parts. Under this view, wholes are organized prior to perceptual analysis of their properties and components in perceptual organization. Navon (1977) proposed that perceptual processing starts with global structuring and later moves towards more fine-grained analysis. This proposal was termed as the *global precedence hypothesis*. This hypothesis has been tested by studying the perception of hierarchical patterns in which larger figures are constructed by suitable arrangements of smaller figures.

An example is a set of large letters constructed from the same set of smaller letters having either the same identity as the larger letter or a different identity (see Figure 4). The larger letter is considered a higher-level unit relative to the smaller letters, which are, in turn, lower-level units. Properties of the higher-level unit are considered more

Figure 4: An example of Navon's (1977) type hierarchical stimuli. Large Es and Hs are composed using small Es and Hs.

global than properties of the lower-level units by virtue of their position in the hierarchical structure. In a typical experiment, observers are presented with such stimuli and are required to identify the larger (i.e., global) or the smaller (i.e., local) letter in different trials. *Global advantage* is observed, where the global letter is identified faster than the local letter.

Our view is that an analogous global advantage mechanism operates in the matching process found in melody recognition. The general articulation format of the melody (i.e., whether the melody is overall presented in a *staccato* or *legato* format) is considered a higher-level unit relative to the specific format of individual bars, which are, in turn, lower-level units, and properties of the higher-level unit are considered more global than properties of the lower-level (local) units based on their position in the hierarchical structure. In order for matching to occur, that there is a *global* match based on the *absolute quantity* of match between the memory trace and the recognition probe *per se* is more critical, as compared with whether there is a *local* match between the articulation format at the onset of the test melody and the format at the onset of the study melody. Once global matching attains, melody discrimination performance is enhanced.

The present global matching advantage hypothesis can be verified in a future study that manipulates the overall (global) and local matches in, say, timbre between two instances of a melody, by specifically altering the timbre at various temporal points (e.g., the onset) of the melody. Others could assess the effects of surface features that have yet to receive attention, such as the use of ornaments or phrase boundaries. More broadly, future investigations can extend to the domain of speech perception. There had been considerable work which argued for a commonality between music and speech processing (see Patel, 2003), and comparing these two processes can lead to an understanding of wider (and potentially shared) principles of perceptual categorization and temporal organization across brain areas (McMullen & Saffran, 2004; Patel, 2003). Thus, it is of interest whether the present effects would emerge in speech. There is a large body of data suggesting that talker's voice, a surface feature of spoken language, is encoded into LTM. Specifically, old words were recognized better when they were tested in a voice that matched with the original voice that originally spoke the word at study, than when the voices did not match (see Goh, 2005 for a review). Yet, the boundaries that permit (or prevent) this match in a speech context are not well defined. It is worthwhile to explore the extent to which speech recognition performance is driven by the absolute match in the physical properties of voice between two instances of speech and/or the location of match *per se* (e.g., in a sentence context).

On the Relationship Between Entropy and Meaning in Music: An Exploration with Recurrent Neural Networks

Greg Cox (grcox@indiana.edu)

Department of Psychological and Brain Sciences, Indiana University
1101 E. Tenth St., Bloomington, IN 47405 USA

Abstract

Meyer (1956) postulated that meaning in music is directly related to entropy—that high entropy (uncertainty) engenders greater subjective tension, which is correlated with more meaningful musical events. Current statistical models of music are often limited to music with a single melodic line, impeding wider investigation of Meyer’s hypothesis. I describe a recurrent neural network model which produces estimates of instantaneous entropy for music with multiple parts and use it to analyze a Haydn string quartet. Features found by traditional analysis to be related to tension are shown to have characteristic signatures in the model’s entropy measures. Thus, an information-based approach to musical analysis can elaborate on traditional understanding of music and can shed light on the more general cognitive phenomenon of musical meaning.

Keywords: Music cognition; neural networks; information theory; entropy.

Introduction

Music is an intriguing artifact of human culture, and one of the challenges in music cognition is to explain how music is capable of having meaning for the listener. Much music carries meaning by virtue of associations to non-musical things like stories and literature (Rimsky-Korsakov’s *Sheherazade*), visual imagery (Mussorgsky’s *Pictures at an Exhibition*), environmental sounds (taxi horns in Gershwin’s *An American in Paris*), symbols (the “cross” motif in the Fugue in C-sharp minor from Book I of J. S. Bach’s *Well-Tempered Clavier*), and the meaning of text or lyrics. However, music theorists and cognitive scientists have been particularly concerned with investigating music that lacks text and that does not explicitly refer to anything non-musical.¹

Meyer (1956) postulated that meaning in music arises from the ability of a musical event to imply or refer to other *musical* events that are expected to follow it. In a later work, he summarized his hypothesis:

Musical meaning arises when an antecedent situation, requiring an estimate as to the probable modes of pattern continuation, produces uncertainty as to the temporal-tonal nature of the expected consequent. (Meyer, 1957, p. 416)

Within a particular style, a given musical event—e.g., a dominant chord—is expected to be followed by another musical event—e.g., a tonic chord, making for an authentic cadence.

¹Of course, even non-referential music is sure to remind a listener—consciously or not—of something other than the music he or she is currently hearing. However, these non-musical associations tend to vary widely between individuals and as such cannot be relied upon as a basis for musical meaning.

These expectations can also be violated or ambiguous—perhaps the dominant chord is followed by a submediant chord, making for a deceptive cadence. In such cases, a listener experiences tension which is manifested both in subjective reports (Krumhansl, 1996) and in physiological affective responses (Steinbeis, Koelsch, & Sloboda, 2006). Tension and its associated affective qualities—reflecting uncertainty—can thus be a signature of musical meaning.

Beyond suggesting a direct link between musical meaning and tension, Meyer’s definition is readily formalized via the concept of entropy, which is a measure of both uncertainty and information content (more information is necessary to describe something that is difficult to predict). Other music theorists have made use of entropy measures in a variety of ways, including the analysis of structure in atonal music (Hiller & Fuller, 1967), stylistic variation in tonal music (Knopoff & Hutchinson, 1981), and differences between musical styles (Margulis & Beatty, 2008).

While most music theoretical studies of information in music have focused on gross properties of style or large segments of music, recently, modeling techniques from cognitive science have been brought to bear on Meyer’s notion of musical meaning. Markov models and recurrent neural networks enable researchers to quantify entropy and other information measures by specifying the underlying predictive model a listener might have. Measures of information content in Markov models of music can predict structural boundaries that correspond to those assigned by human listeners to monophonic (single-part) music in the minimalist style (Potter, Wiggins, & Pearce, 2007; Abdallah & Plumbley, 2009).

However, structural boundaries are only a part of musical meaning. If meaning is related to subjective tension arising from uncertainty—i.e., entropy—it should be possible to correlate instantaneous measures of entropy (an “entropy profile”) with momentary affective responses to music. For instance, an authentic cadence is a point of repose and thus should be correlated with lower entropy. A dramatic climax should be correlated with a high value of entropy (a local maximum) as it represents a large amount of tension. Human-derived entropy profiles for Bach chorale melodies (Manzara, Witten, & James, 1992) are in accord with these intuitions.

It is also likely that different dimensions of music (e.g., pitch, rhythm, harmony) contribute differently to tension and to entropy. This notion is embodied in multiple viewpoint models (Conklin & Witten, 1995), although since these models have only been applied to monophonic music, they tend to focus on pitch to the exclusion of rhythmic, harmonic, and

contrapuntal dimensions. A study of entropy as a correlate of tension should address more than just single melodic lines, since harmony and counterpoint are critical dimensions along which music can meaningfully vary.

The present study investigates the extent to which entropy can serve as a general measure of tension—and thus meaning—in music. To that end, I present a recurrent neural network as a predictive model of polyphonic (multiple-part) music and compare entropy measures derived from the model with traditional music theoretical analysis. I show that features of the traditional analysis related to subjective tension have particular signatures in the model’s entropy measures, supporting the hypothesis that entropy underlies musical meaning.

A Recurrent Neural Network for Music Prediction

Recurrent neural networks (RNNs) have been fruitfully used as models of sequential prediction in many domains. In music research, they have been used to compose monophonic music both with (Mozzer, 1994) and without (Todd, 1989) accompanying harmonic progressions, and to model the acquisition and perception of tonal harmony (Bharucha & Todd, 1989).

Although Markov models have seen wider—and, arguably, more productive—application in monophonic music than have RNNs, Markov models are less well suited to modeling polyphonic music. Monophonic music is easily translated into a sequence of discrete symbols drawn from a finite alphabet. It is much less clear, however, how one might translate polyphonic music into a language appropriate for a Markov model, as such music includes multiple pitch sequences updating at different rates with varying degrees of independence. For instance, to describe just the pitch transitions of a four-part piece where each part spans a diatonic octave (eight possible pitches), a naïve first-order Markov model would require a state space with $8^4 = 4096$ points and a transition matrix with $4096^2 = 16777216$ entries, and this does not even include any information about rhythm!² Further, in any realistic training set, only a small portion of the number of possible transitions will be represented, leading to problems of over-fitting and lack of generalization (though these problems can be solved in some domains with the smoothing techniques described by Pearce & Wiggins, 2004). RNNs tend to avoid these problems, since they do not require enumerating and/or representing all state transition probabilities, but rather the weights of the network represent only those dependencies necessary to minimize prediction error. In addition, since the RNN must learn its own internal representation of the input, it will naturally converge toward representations that capture the generalities in the training set.

It should be emphasized that, as with a Markov model of music, no literal psychological reality is meant to be ascribed to the structure and training procedure of a RNN. Rather, the

²By making certain independence assumptions, it is possible to simplify a Markov model greatly, but it is not in general possible to know, *a priori*, what those assumptions should be.

Figure 1: Schematic of the recurrent neural network used in this study, assuming 4 distinct parts. See text for details.

network should be seen only as a statistical model that mirrors the *function*—not necessarily the *form*—of whatever predictive model a human listener has acquired through musical experience. The resulting trained network does not—indeed, cannot—represent a listener’s *entire* understanding of music in general, but is limited to representing the expectations of a listener who is familiar with a piece of music and/or its style.

Architecture

The architecture of the RNN used in this study is shown in Figure 1. As in Elman (1990), the network is presented with the current state of the music, $x(t)$, and is trained—via back-propagation through time with a single time step (Rumelhart, Hinton, & Williams, 1986)—to produce the state of the music at the next time step, $x(t+1)$, at its output layer. Output layer units use a logistic activation function $f(net) = 1/(1 + \exp(-net))$, where *net* is the net input to the unit. Successive layers are fully interconnected.

Time Musical time is divided into discrete “time steps” of equal length, and the input, $x(t)$, describes all musical events (pitches and note onsets) occurring during that time step.

Input/Output Representation The input at time t , $x(t)$, is the concatenation of several vectors representing, for each part (i.e., distinct instrument or timbre, e.g., violin, piano, etc.) in a piece of music, the part’s state along two dimensions: pitch and rhythm. The pitch dimension is represented in a localist fashion, with one unit corresponding to each absolute pitch (in twelve-tone equal temperament) that could occur in a part, including a unit representing silence or a “rest”. At the input layer, a pitch unit is active (1) if it is currently sounding and zero otherwise; at the output layer, a pitch unit’s activity represents the degree to which that pitch is expected at the next time step. The pitch state vector $\pi_p(t)$ for part p at time t may thus be expressed $\pi_p(t) = \langle \pi_{p0}, \pi_{p1}, \dots, \pi_{pn}, \pi_{pREST} \rangle$ for possible pitches $0 \dots n$ and the special *REST* “pitch”. The input layer also contains a set of units representing all pitches that are sounding at the

current time across all parts, to allow for generalization of pitch content between parts. However, the network is only trained to predict the pitches of each part individually, not this aggregate pitch content.

An additional unit for each part represents its state along the rhythmic dimension: this unit is active (1) when the current time step contains a note onset within that part, and is otherwise inactive (when the part is silent or sustaining a previous pitch). At the output layer, this unit can be interpreted as the probability $\rho_p(t+1)$ that part p will contain a note onset at time $t+1$. Note that the assumption of independence between rhythm and pitch in the input/output representation permits the analysis of each component separately. However, independence of representation does not guarantee probabilistic independence, as both pitch and rhythm units are treated equally in the network's internal representation in the hidden layer.

Hidden Layer Hidden unit activations are a function of the current input, the hidden layer at the previous time step (also called the “context” layer), and each unit's own prior activation. The activation of hidden unit h_i at time t is

$$h_i(t) = \tau_i f(\sum_j w_{ij} x_j(t) + \sum_k w_{ik} h_k(t-1)) + (1 - \tau_i) h_i(t-1),$$

where $f(\cdot)$ is the logistic activation function described above, w_{ij} is the weight from input unit j to hidden unit i and w_{ik} is the weight from context unit k to hidden unit i . The different time constants τ_i cause the hidden units to change at varying rates over time, permitting the representation of multiple time scales at the hidden layer (Mozer, 1992).

For simplicity, I assume that the number of hidden units with time constant τ is $N_\tau = \lfloor \tau N_1 \rfloor$ where N_1 is the number of units with $\tau = 1$ and $\lfloor \cdot \rfloor$ is the floor function, ensuring that there will be only a finite number of hidden units and time scales represented. In the simulations reported here, each τ is the reciprocal of either a power of 2 or a power of 3, i.e., $\tau = 2^{-\gamma}$ or $\tau = 3^{-\gamma}$ for $\gamma = 0, 1, 2, \dots$. The choice of time constant scales based on 2 and 3 derives from the predominant metrical subdivisions (duple and triple meters) in Western music, which is the domain of the current study. Thus, the hidden layer best represents information at time scales that are likely to be most salient.

Measures of Entropy

Although there are many ways to measure entropy within the current modeling architecture of the RNN, I will focus on four simple measures, three of which are used in the subsequent musical analyses. For any part p , the pattern of activity over its pitch units (including the “rest” pitch) at the output layer, π_p , can be normalized to sum to one, such that it can be considered a probability distribution over pitches. Then, the entropy with regard to pitch in part p at time t is $H_p^{pitch}(t) = -\sum_{i=0}^{n.REST} [\pi_{pi} \log_{(n+1)}(\pi_{pi})]$, where the base of the logarithm normalizes the entropy to the range from zero to one. Similarly, the entropy with regard to rhythm in part p at time t is $H_p^{rhythm}(t) = -\rho_p(t) \log_2(\rho_p(t)) - (1 - \rho_p(t)) \log_2(1 - \rho_p(t))$.

To measure entropy over the entire ensemble rather than within each part, an aggregate pitch probability vector $\pi^* = \langle \pi_0^*, \pi_1^*, \dots, \pi_n^* \rangle$ is created, where $\pi_i^* = C \sum_{p=0}^P \pi_{pi}$, i.e., the sum of the probability assigned to pitch i by each of the P parts, normalized (by constant C) to sum to one. The entropy of π^* can then be computed. The rhythmic entropy of the ensemble is computed over the joint distribution of the onset probabilities of each part. Pitch entropy represents uncertainty about *what* pitches will occur, while rhythmic entropy represents uncertainty about *when* those pitches will occur.

Long-Term and Short-Term Models

As in work with multiple viewpoint models of music (Conklin & Witten, 1995), for each piece of music to be analyzed, two of the above-described networks are trained. The first network is trained on a representative sample of a particular style of music and is meant to represent more global stylistic characteristics acquired by the listener over a longer time span, hence it is called the long-term model (LTM). A second network is trained on just a single piece of that style and is meant to represent knowledge of that piece in particular acquired over less time, hence it is called the short-term model (STM). This distinction is akin to that between “schematic” (LTM) and “veridical” (STM) knowledge made in Justus and Bharucha (2001). Both models produce patterns of activation over output units representing the expected pitch and rhythmic state of each part. These patterns can be combined to form an aggregate prediction from both the STM and LTM models³. Following Pearce, Conklin, and Wiggins (2005), this combination is a weighted geometric mean of the output activations for each dimension of each part of each model, where the weight is inversely proportional to the entropy of the activity over the relevant dimension of each part. For example, the aggregate activation of pitch π_i in part p (aggregate rhythm activation is analogous) would be

$$\bar{\pi}_{pi} = \left[(\pi_{pi}^{STM})^{\frac{1}{H_{STM}^{pitch}}} (\pi_{pi}^{LTM})^{\frac{1}{H_{LTM}^{pitch}}} \right]^{\frac{1}{\frac{1}{H_{STM}^{pitch}} + \frac{1}{H_{LTM}^{pitch}}}}.$$

The effect of combining the STM and LTM in this way is to emphasize “points of agreement” between them. For example, if they both strongly predict a particular pitch, the aggregate activity ascribed to that pitch will be very high. If one model is ambivalent (high entropy) while the other is certain (low entropy) of a particular pitch, the aggregate activity will accrue to the pitch of which one model is certain. If both models are certain but disagree, activity will be diffused over all possible pitches, leading to high entropy of the aggregate STM-LTM prediction.

³Justus and Bharucha (2001) found that schematic (LTM) and veridical (STM) knowledge made independent contributions to musical expectations; their results are consistent with a weighted geometric mean of those two sources of information.

Applying the Network: Haydn's String Quartet Op. 20, No. 3, First Movement

Because Markov models are already well-suited to modeling monophonic music and RNNs have already been shown to deal well with monophonic melodies, even those with accompanying harmonic progressions, I wanted to explore polyphonic music that did not have a simple “melody plus chords” texture—in other words, music that has been difficult to model with previous approaches. There is also an inherent difficulty in correlating entropy with tension, since tension in a listener is not directly observable. As such, I will consider tension as it is normatively described by traditional music theoretical analysis. The analytical procedure described below has been replicated with a variety of corpora, including Bach chorales, Chopin piano preludes, and Schönberg's *Pierrot Lunaire*, with similar results regarding the relationship between entropy and traditional accounts of tension. To show how an analysis of entropy relates to traditional approaches, I report here the results of a single analysis in detail.

The Op. 20 string quartets of Joseph Haydn share many stylistic characteristics—for example the use of “sonata form”, a typical classical dramatic form, in the first movement of each quartet. Yet despite the regularities among the quartets and between their first movements in particular, they contain many deviations from standard practice. Both global regularities and local idiosyncrasies contribute to the dramatic content of these pieces and make them prime targets for analysis.

The third quartet, in G minor, is particularly dramatic, containing prolonged periods of tension, metrical ambiguity, and various surprising moments. I used the above-described RNN model to calculate measures of entropy for each time step in the first movement of this quartet. I then compared these measures to features derived from a music theoretical analysis of the piece in terms of its formal and dramatic structure.

Training

All pieces on which the RNN were trained were encoded as MIDI files, with each instrument (two violins, viola, and cello) assigned to a different part and thus separately represented in the RNN's input and output layers. In total, 247 units were used to represent the input (pitch and rhythm units for all four parts separately, as well as the aggregate pitch content) and 177 units were used in the hidden layer. The back-propagation learning rate parameter was set at 0.0625 and time steps were set at sixteenth-note duration.

The LTM was trained on the first movements of all six quartets in Op. 20 (19006 total time steps). All pieces of the training set were transposed to either C-major or C-minor as appropriate to eliminate effects of absolute pitch (since the model uses a localist pitch representation). The LTM was trained in cycles, during each of which it was trained on all six training pieces in random order. Training continued until mean accuracy—defined as the mean probability assigned to each time step in the training pieces—did not change by more than 0.0001 for 10 consecutive cycles. In all, the LTM was

trained for 2000 cycles and achieved a final accuracy over the entire training set of 0.276 (range: 0.179 to 0.383).

The STM was trained on only the first movement of Op. 20, No. 3 (4332 total time steps). Using the same stopping criterion, the STM was presented with this movement 2500 times and achieved a final accuracy of 0.751. The combined LTM and STM models, which produced the output analyzed below, achieved an accuracy of 0.456 on the movement.

Simulations were also conducted which varies the number of hidden units, learning rate, and size of the LTM training corpus (for example, by including a wider selection of Haydn string quartet movements from Op. 17). The only major effect of these variations was that accuracy was improved with additional hidden units, but the form of the entropy profiles remained the same; specifically, major points of inflection were all at the same place and in the same direction.

Analysis of Entropy Profiles

The pitch and rhythmic entropy profiles derived from the combined STM and LTM are shown in Figure 2. Only the first repeat of the exposition (the first section of a sonata form piece; mm. 1-94) is shown, as this will be the focus of the subsequent analysis. Lacking a principled method of integrating pitch and rhythmic entropy, they are here considered separately, although both are assumed to contribute to a listener's subjective sense of tension. To enable the analysis of trends in the entropy measures, they were smoothed by convolving the raw entropy measures with an exponentially-decaying impulse response filter with weights $\psi(t) = e^{-\lambda t}$, where decay constant $\lambda = \frac{1}{32}$ corresponds to a mean lifetime of four measures (32 time-steps). Thus, the values shown in Figure 2 represent a “memory” of the instantaneous entropy that emphasizes the last four measures. The following analysis owes much to the work of Drabkin (1999), particularly pp. 105-111. Additional analytical material may be found in Grave and Grave (2006), especially pp. 190-192.

The only perfect authentic cadence in the exposition occurs at the end of the first phrase in m. 7, where there is a clear local minimum in pitch entropy as well as a low plateau in rhythmic entropy⁴. Mm. 8-26 effect a modulation from the home key of G minor to its relative major, B♭, all the while increasing the tension for a strong resolution to a B♭ harmony. This increase in tension is mirrored by increasing pitch and rhythmic entropy, where pitch entropy reaches a local maximum on the second beat of m. 24 with the introduction of a novel unison figure that prolongs the tension until the B♭ resolution in m. 27.

The second theme group (mm. 27-40) maintains a consistent pitch entropy while rhythmic entropy builds until the cello's eighth-note pulse disappears in m. 34, leaving just a high violin melody with the other instruments holding chords in long rhythmic values. The decrease in rhythmic entropy is

⁴In simulations with Bach chorales (not reported here), resolutions of authentic cadences also correspond to local minima in entropy measures while deceptive cadences produce no change or an increase in entropy.

Figure 2: Ensemble pitch and rhythm entropy profiles for the exposition (mm. 1-94) of Haydn Op. 20, No. 3, first movement.

interrupted in mm. 37-38, when pitch changes become staggered between the instruments. Mm. 41-52 are more transitory and fragmented, with a large drop in pitch entropy during the violin solo in mm. 50-51 (greater certainty arising from predicting fewer separate parts). The long, regular rhythmic durations of mm. 53-59 continue the drop in rhythmic entropy while the chromatic harmonies increase pitch entropy until a break is reached at a deceptive cadence in m. 60.

This is followed by an F-major statement in mm. 61-64, then in mm. 65-66 by an “utter non sequitur—a fortissimo fanfare, poised on a first-inversion B \flat triad, with no compelling relationship to the immediately preceding or following material” (Grave & Grave, 2006, p. 190). This surprising event is naturally accompanied by a spike in both rhythmic and pitch entropy. Contrary to what might be implied by the B \flat fanfare—strong thematic material emphasizing the new key of B \flat —we are instead treated in mm. 67-70 to the opposite: a softer, tonally ambiguous reprise of mm. 61-64. Mm. 67-70 are at a softer dynamic, played by solo violin instead of the entire quartet, and in a more restricted and chromatic melodic range. This unexpected consequent is assigned the highest pitch entropy in the entire exposition.

Rhythmic entropy continues to build until a resting point is reached at m. 70 on an unclear tonality. The succeeding violin solo and its accompaniment in mm. 71-77 is metrically ambiguous, implying a triple meter when in fact the duple meter still prevails. In this instance, the gradually diminishing ensemble rhythmic entropy is not in accord with this ambiguity, which should result in a higher rhythmic entropy for this passage. However, the rhythmic entropy of the individual parts, shown averaged in Figure 3, does show the expected staggered increase from mm. 71-77.

The remainder of the exposition is on more solid tonal and metrical footing. Of particular interest is the jump in pitch entropy in mm. 85-86, corresponding to another instance of the unison figure from mm. 24-25 and serving the same purpose—to prolong tension before reaching a harmonic resolution—and producing the same effect on the entropy profile—an increase in pitch entropy whilst rhythmic

Figure 3: Rhythmic entropy averaged between parts for mm. 71-79 of Haydn Op. 20, No. 3, first movement.

entropy is unaffected. Although rhythmic entropy reaches a local maximum at m. 90 and begins to fall after a constant eighth-note pulse is established in the violins, pitch entropy increases toward the end of the exposition, reflecting the fact that the end of the exposition can be followed by either a repeat of the exposition (return to m. 1) or the start of the next section. In both cases, the rhythmic surface is the same, but the pitches are different and are assigned to different instruments, thus it is logical that there would be more uncertainty about pitch than rhythm at the end of the exposition.

Discussion

Analyses like the one presented above show that entropy derived from a predictive model of music can correspond to dramatically important features of music. Specifically, the entropy measures employed are sensitive to the calming effect of cadences (m. 7), the build-up of tension prior to resolutions (mm. 8-26), differential effects of textural change (mm. 27-60), and the shocking effects of interruptions (mm. 24-25, 85-86) and their consequents (mm. 65-70). Because a listener’s subjective sense of tension is also affected by these features, this suggests a relationship between entropy and tension—and thus, perhaps, to musical meaning.

It is, perhaps, remarkable that such a relationship may be found, given the limitations of the current model. The model includes no information about dynamics, timbre, and expressive timing. A more realistic pitch representation, while in-

creasing the model's complexity, might also improve its performance (Mozer, 1994). Further, the use of a RNN at all imposes severe limitations on the approach outlined in this paper. While RNNs enable the analysis of music that is not amenable to other modeling techniques, they are slow to train, limited in the size of the corpus on which they can be trained, and, in the form presented here, cannot generalize to other ensemble types. The application of computational cognitive models to music is still in its infancy, and future research is sure to improve upon the techniques explored thus far. Future work must also compare model-derived entropy measures with human tension judgments (as in Krumhansl, 1996). This will elaborate on the relationship between entropy and tension, including the contributions of different sources of uncertainty (e.g., pitch and rhythm) to overall tension.

Even given the limited state of our current knowledge, it is possible to show that meaningful musical features correlate with features of musical entropy, given an appropriate predictive model. If human listeners have a similar predictive model "in mind"—consciously or not—as they listen to music, this provides great insight into the nature of music cognition and creation. The reasons why certain patterns recur within a style and that listeners have consistent responses to those patterns and violations thereof are not arbitrary—they can be understood in terms of prediction and uncertainty. With the advent of formal cognitive models, we can leverage this principle to better understand music that resists conventional analysis, for example, styles with few examples (e.g., the oeuvre of many idiosyncratic modern composers) or for which there is insufficient access to primary sources (e.g., historical and ethnomusicological studies). While more sophisticated methods will allow us to better elucidate the nature of entropy in music, it is clear that Meyer's (1956) thesis is still a viable approach to understanding the nature of meaning in music.

Abstract

People react differently to stress. According to the Cognitive Motivational Relational Theory by Lazarus and Folkman, the appraisal of stress and the emotions related to it determine whether people cope with stress by focussing on altering the situation (problem focussed) or on changing the emotional consequences of the events (emotion focussed). These different coping strategies have different effects on the long term. The coping process can be described in a formal dynamic model. Simulations using this model show that problem focussed coping leads to better coping skills and higher decrease of long-term stress than emotion focussed coping. These results also follow from a mathematical analysis of the model. The presented model can form the basis of an intelligent support system that uses a simulation of cognitive processes in humans in stressful conditions.

Introduction

Stress is simply a reality of nature where forces from the outside world affecting the individual. It comes in many forms and affects people of all ages and all walks of life. The individual responds to stress in ways that affect the individual as well as their environment. Hence, all living creatures are in a constant interchange with their surroundings, either physically or behaviorally. In general, stress is generally considered as being synonymous with distress and dictionaries defined it as “physical, mental, or emotional strain or tension” or “a condition or feeling experienced when a person perceives that demands exceed the personal and social resources the individual is able to mobilize” (Beck, 1987; Folkman, 1984).

However, human has its own mechanism to adapt with this adversity. Through a process known as coping, our cognitive skill will evaluate the situation mentally. If the situation is threatening, then the human will decide how to deal with the situation, and what skills can be used. If the demands of the situation outweigh the resources human has, then it will be labeled as “stressful” and he or she will react with the classical stress response and vice versa (Carver et al., 1989). It is essential to consider that everyone sees situations differently and has different coping skills. For this reason, no two people will respond exactly the same way to a given situation. Understanding this coping ability is an

essential ingredient for developing a software agent that is capable of providing the right intervention towards stressed individuals (Aziz et al., 2010). Therefore there is a need for a virtual human agent model that has this capability. In this paper, virtual human agents are computer model of people that can be used as substitutes for “the real person” in a virtual environment, with a specific focus on simulating human coping behaviors during the formation of stressful events. Although there has been several work in computational models of human stress, little work has been done in modeling coping strategies, with a few exceptions in (Marsella and Gratch, 2003; Marsella et al., 2009).

This paper focuses exclusively on the formal model for dynamics in coping process, as it is one of the essential components in the development of a software agent that is able to monitor individuals’ conditions during stressful events (Aziz & Treur, 2009). In the next section, the underlying principles in coping during stress are discussed (Section 2). From this perspective, a formal model is designed and formulated (Section 3). Later, in Section 4, simulation traces are presented to illustrate how this model satisfies the expected outcomes in long-term stress. In Section 5, a detailed mathematical analysis is performed, to identify equilibria in the model. Finally, Section 6 concludes the paper

Underlying Concepts in Coping

The cognitive theory that governs the underlying principle of this work is based on Cognitive Motivational Relational Theory (CMRT) as in Lazarus and Folkman (1984). This theory explains the role of distinctive positive and negative emotions in the stress appraisal process. Essentially, it conceptualized a transactional process in which the person and the environment are viewed as being in a dynamic and bidirectional relationship, where the essence of cognitive appraisal and coping provides a critical mediator between stressful person-environment and health outcomes.

Dynamics in Cognitive Appraisal Process and Coping Strategies

The cognitive approach to coping is based on a mental process of how the individual appraises the situation. Cognitive appraisal can be viewed as the evaluation of the

significance of what is happening in the person-environment relationship (Lazarus, 1991). Normally, it is also related to the *intensity of the stressful events*, a condition where several factors such as *situational demands* (pressure), *personal resources* (i.e; support), and *negative events* play important roles (Aziz et al., 2009; Lazarus & Folkman, 1984). Having the stressful events in motion, individual appraises two types of appraisals; the primary and the secondary. The primary appraisal is made when the individual makes a conscious evaluation of the matter at hand of whether it is a sense of harm or a loss, a threat or a challenge. It is an evaluation process of what is at stake for a person's well being. From this first process, the situation can be appraised either as harm/loss, threatening, challenging or benign (Folkman et al., 1986). *Harm* or loss refers to a condition where damage has already occurred, while *threat* refers to damage, but an anticipated one (*imminence of harm*) and it is more to a risk assessment part (Kessler, 1997). *Challenging* differs from threat in term of how persons are viewing it where it has a positive tone compared to threat. When stressful events were appraised as irrelevant or as *benign*, it will offer the chance to preserve or enhance wellbeing as it does not initiate the stress process as there is no potential threat to overcome. In addition, this appraisal process also involves an array of *personality attributes* such as values, commitments, and beliefs about oneself and the environment in defining the condition that the individuals are facing through (Uehara et al., 1999). Later this process will determine individuals' emotion perception; *negative*, *positive* or *neutral* emotion (Folkman, 1984). Negative emotion is related to perceiving *harm* and *threat*, while position emotion is attributed to perceiving *challenge* (Lazarus, 1991). Neutral emotion is triggered when individual perceives the condition as *benign* (Noh, 2003).

In the second appraisal, the persons evaluate whether they have the resources to deal with the incoming stressors. It is commonly related to the emotional attribution, where a positive and neutral emotion results in *acceptance* and *change*, while the negative emotion triggers *holdback* behavior (Lazarus, 1991). During this stage, several coping strategies are evaluated. Coping strategies refer to the specific efforts, both behavioral and psychological, that people employ to either be in charge of, tolerate, reduce, or minimize stressful events. According to the CMRT model, there are two types of coping strategies have been distinguished, namely; *problem-focused coping* and *emotion-focused coping*. A problem-focused coping is associated with aggressive interpersonal efforts to alter the situation, as well as rational efforts to get the problem solved (Carver et al., 1989). Contrary to this, emotion-focused coping strategies (thinking rather than acting to change the person-environment relationship) entail efforts to regulate the emotional consequences of stressful or potentially stressful events (Pruchno & Resch, 1989). It is typically include distancing, escape avoidance, and seeking for social comforts.

Several findings showed that the type of coping strategies can be derived, depending on what was at stake (primary appraisal) and what the coping options were (secondary appraisal) (Lazarus, 1991; Ntoumanis et al. 2009). It means, when people feel that they are capable of changing the situation into something better (high perception of acceptance and change), and then a problem-focused coping is chosen. In contrast, when the conditions are considered not amenable to change (high perception in holdback) then emotion-focused coping is used. In addition to this, problem focused coping strategies may give an individual greater perceived control over their problem, while emotion focused coping strategies may more often lead to a reduction of control over the perceived events. All these strategies can be proven useful, but many individuals feel that problem-focused coping represent a more effective means of coping in adversities (Uehara, 1999). In addition to this, in a long run, emotion focused coping is associated with outcomes that people found unsatisfactory (*exhaustion in coping*) that later will increase long-term stress, and problem focused coping is associated with satisfactory outcomes (*improved coping skills*) (Clarke & Tanya, 2009). Furthermore, in psychological distress, problem focus coping strategies appear reliably to produce better emotional adjustment to chronically stressful events than do emotional focused strategies (Pruchno & Resch, 1989; Uehara, 1999).

In short, the following dynamics can be identified from the literature; (1) the intensity of the stressful events will lead to coping appraisal, (2) the perception of event regulates emotional attribution, (3) the emotional attribution will trigger a coping strategy, (4) a long-term overwhelming dependency in emotion-focused coping will lead to the exhaustion in coping, and (5) a problem-focused coping will improve the coping ability.

The Virtual Human Agent Model

Based on the analysis of the cognitive dynamics in coping appraisal and strategy as given in the previous section, it is possible to specify computational properties for the virtual human agent model. These computational properties are represented in a way that allows simulating how an individual is coping when experiencing stressors, and what are the consequences of that action. All of these concepts (and their interactions) are discussed in the following paragraphs in this section.

Formalizing the Cognitive Model Relationships

In the formalization, the dynamic concepts discussed in the previous section are translated into several interconnected nodes. Figure 1 depicts the global interaction between these nodes. The nodes are represented as variables that can have values ranging from 0 (low) to 1 (high). The interaction will determine the new value of it, either by a series of accumulations or an instantaneous interaction for each node.

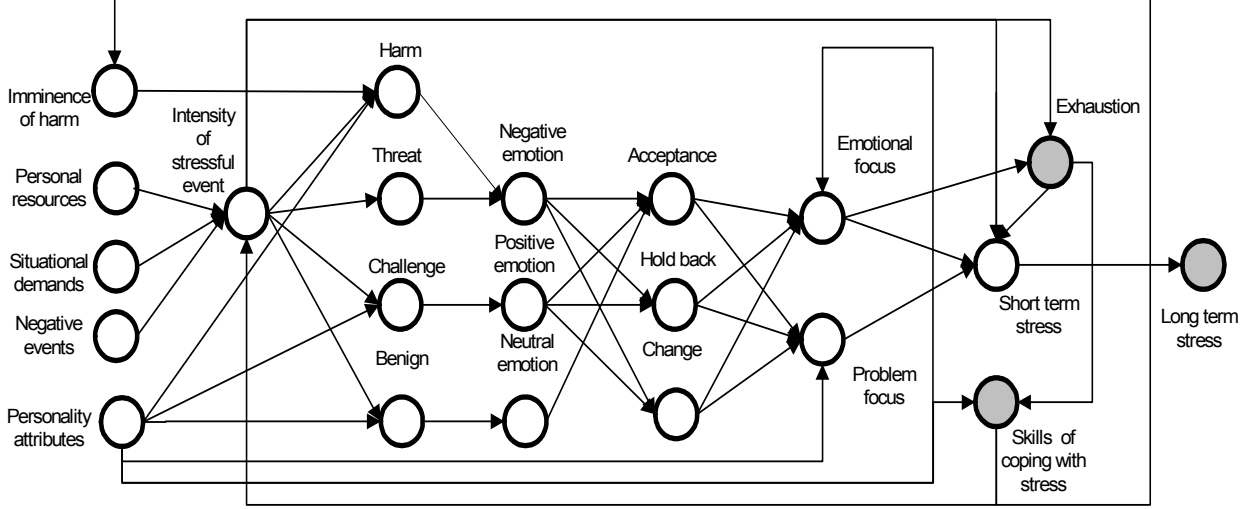

Figure 1: Global relationships of variables involved in the coping process

The description of these formalizations is described in the following. Together, this results in a dynamic model. This model involves a number of instantaneous and some temporal relations. The dark nodes represent concepts that have temporal relationships with the incoming nodes, in which the change is specified for a time interval between t and $t + \Delta t$

Stressor Events, Intensity of Stressful Event, and Imminence of Harm In the model, the stressor events (e) (negative events) are generated by simulating potential effects throughout t time using w weighted sum of three types of events; life (le), chronic (ce), and daily (de) events. The role of these factors in the model is to represent a series of events. The intensity of stressful event (IsE) represents the degree of stress encountered by a person related to his or her situational demands (SiD), and stressor events ($NeVt$), regulated by the proportion factor β_e . In addition, the intensity of a stressful event will be reduced if the coping skills (ScS) and personal resources (PeS) are high. Imminence of harm (ImH) can be measured by combining both concepts in perceived harm (PeH) (from the environment), and coping skills (ScS).

$$NeV(t) = w_1.le(t) + w_2.ce(t) + w_3.de(t), \quad \sum w = 1 \quad (1)$$

$$IsE(t) = [\beta_e.NeV(t) + (1-\beta_e).SiD(t)].(1-ScS(t)).(1-PeS(t)) \quad (2)$$

$$ImH(t) = PeH(t).(1-ScS(t)) \quad (3)$$

Harm, Threat, Challenge, and Benign The level of harm (HrM) is determined by the proportional contribution ϕ_h on the imminence of harm, and intensity of the stressful event. The intensity of the stressful event also related to threat (ThT). For both cases, in harm and threat, there is a negative relation with personality attributes. On the contrary, challenge (ChL) and benign (BnG) are positively related with good personality attributes (PrA), and negatively with the intensity of stress. Here parameters α_c and ψ_b represent

the proportional factor for both challenge and benign respectively.

$$HrM(t) = [\phi_h.ImH(t) + (1-\phi_h).IsE(t).ImH(t)].(1-PrA(t)) \quad (4)$$

$$ThT(t) = IsE(t).(1-PrA(t)) \quad (5)$$

$$ChL(t) = \alpha_c.PrA(t) + (1-\alpha_c).(1-IsE(t)).PrA(t) \quad (6)$$

$$BnG(t) = \psi_b.(1-IsE(t)) + (1-\psi_b).PrA(t) \quad (7)$$

Negative, Neutral, and Positive Emotion When the harm and threat is perceived, a fraction from those two parts (by a proportional factor β_n) is contributed as a negative emotion (NgE). The notion of positive (PsE) and neutral (NuE) emotion is represented through a proportional factor of τ_p in challenge and ρ_e in benign respectively.

$$NgE(t) = \beta_n.HrM(t) + (1-\beta_n).ThT(t) \quad (8)$$

$$PsE(t) = \tau_p.ChL(t) \quad (9)$$

$$NuE(t) = \rho_e.BnG(t) \quad (10)$$

Acceptance, Holdback, and Change Positive and neutral emotion increases the acceptance (AcP) level by a proportional factor γ_a , while negative emotion works in a opposite way. Holdback (HdB) depends on the relation between negative and positive emotion. Change (ChG) uses the same concepts as in holdback but with the opposite relation.

$$AcP(t) = \gamma_a.PsE(t) + (1-\gamma_a).NuE(t).(1-NgE(t)) \quad (11)$$

$$HdB(t) = (1-PsE(t)).(NgE(t)) \quad (12)$$

$$ChG(t) = PsE(t).(1-NgE(t)) \quad (13)$$

Emotional and Problem Focused Coping Emotional focused coping (EmF) is determined using the presence of acceptance, holdback and change. Using this relation, emotion focused coping decreases when either acceptance or change increases. However in problem focused coping (PrF), coupled with personality attributes, those factors

provide a positive effect. Parameters η_e and γ_p regulate the contribution preferences for both specifications respectively.

$$EmF(t) = [\eta_e.(1-AcP(t)).HdB(t) + (1-\eta_e).HdB(t)].(1-ChG(t)) \quad (14)$$

$$PrF(t) = [\gamma_p.PrA(t) + (1-\gamma_p).AcP(t)].(1-HdB(t)).ChG(t) \quad (15)$$

Short-term stress, Long-term stress, Exhaustion, and Coping Skills The notion of short-term stress (StS) models a relation between coping styles (regulated by μ_s), and a combination of exhaustion and intensity in stressful events (regulated by a proportional rate γ_s) and will influence the level of long-term stress (LtS) in a long run. The formation of exhaustion (ExH) is modelled using the presence of emotion-focused coping and the intensity of stressful events. The level of coping skills (ScS) is influenced by the exhaustion and personality attributes. The rates of change for all temporal relationships are determined by flexibility parameters β_{ltS} , ψ_e , and ϕ_s respectively.

$$StS(t) = [1 - (\mu_s.EmF(t) + (1-\mu_s).PrF(t))] . (\gamma_s.ExH(t) + (1-\gamma_s).IsE(t)) \quad (16)$$

$$LtS(t+\Delta t) = LtS(t) + \beta_{ltS} . [Pos(StS(t) - LtS(t)).(1-LtS(t)) - Pos(-(StS(t) - LtS(t))).LtS(t)].\Delta t \quad (17)$$

$$ExH(t+\Delta t) = ExH(t) + \psi_e . [Pos((IsE(t) - ExH(t)).(1-ExH(t))) - Pos(-(IsE(t) - ExH(t))).ExH(t)].EmF(t).\Delta t \quad (18)$$

$$ScS(t+\Delta t) = ScS(t) + \phi_s . [Pos(ExH(t) - ScS(t)).(1-ScS(t)) - Pos(-(ExH(t) - ScS(t))).ScS(t)].PrA(t).\Delta t \quad (19)$$

The operator Pos for the positive part is defined by $Pos(x) = (x + |x|)/2$, or, alternatively; $Pos(x) = x$ if $x \geq 0$ and 0 else.

Example Simulation Traces

In this section, the virtual human agent model of coping has been executed to simulate a number of scenarios with a variety of different conditions of individuals. Two example scenarios are shown: an individual with a tendency to choose problem focused coping (**A**), and an individual with a tendency to choose emotional focused coping (**B**). The initial settings for the different individuals are the following (PrA , PeH , SiD , PeS); **A** (0.8, 0.5, 0.5, 0.8), and **B** (0.2, 0.5, 0.8, 0.1). In all cases, the long term stress, exhaustion, and coping skill value are initialized at 0.3.

Corresponding to these settings, the level of severity is set at 0.5, defining that any individuals scoring higher than 0.5 in their long-term stress and exhaustion levels will be considered as experiencing difficulties in coping. These simulations used the following parameters settings: $t_{max}=1000$ (to represent a monitoring activity up to 42 days), $\Delta t=0.3$, all proportional and flexibility rates are assigned as 0.5 and 0.9 respectively. These settings were obtained from several systematic experiments to determine the most suitable parameter values in the model.

Result # 1: Simulation Trace for Repeated Stressor Events During this simulation, each type of individual has been exposed to an extreme stream of stressor events, with a moderate alteration between each corresponding event. Figure 2 depicts the comparison between the conditions of individual *A* and *B* during repeated stressors. In this simulation trace, it is visible that individual *A* has developed better coping skills. For this reason, an individual *A* recovers much faster from long-term stress compared to other individuals.

Figure 2. Simulation traces for repeated stressor in (a) individual *A* (b) individual *B*

Note that the individual *B* shows a repeated increasing pattern that may lead to potential long-term stress. As a consequence of this condition, an individual *B* will experience difficulty if that individual is having constant exposure towards stressors in a long run

Result # 2: Simulation Trace for Fluctuated Stressor Events This simulation trace shows two types of periods, one with a very high constant and with a very low constant stressor event. These events occurred in a constant behaviour for a certain period of time (approximately within 20 days).

Figure 3. Simulation traces for fluctuated stressor in (a) individual A (b) individual B

Also here it can be seen (in Figure 3) that individual B gets into long-term stress much faster than individual A. Moreover, even at the end of the simulation time, the long term stress level of individual B is still slightly higher than individual A. Furthermore, in contrast with individual B, individual A has his/her coping skills improved throughout time.

Mathematical Verification

This section addresses the formal analysis of the agent model and the simulation results presented above by means of a mathematical analysis of the equilibria of the model. The equilibria describe situations in which a stable situation has been reached. Those equilibria are interesting as it should be possible to explain them using the knowledge of the domain that is modelled [2]. As such, the existence of reasonable equilibria is an indication for the correctness of the model. To analyze the equilibria, the available temporal and instantaneous equations are filled with values for the model variables such that the derivatives or differences between time point t and $t + \Delta t$ are all 0. The dynamic part of the model written in differential equation format is as follows:

$$dLtS(t)/dt = \beta_{lts} \cdot [\text{Pos}(StS(t) - LtS(t)) \cdot (1 - LtS(t)) - \text{Pos}(-(StS(t) - LtS(t))) \cdot LtS(t)] \quad (20)$$

$$dExH(t)/dt = \psi_e \cdot [\text{Pos}(IsE(t) - ExH(t)) \cdot (1 - ExH(t)) - \text{Pos}(-(IsE(t) - ExH(t))) \cdot ExH(t)] \cdot EmF(t) \quad (21)$$

$$dScS(t)/dt = \phi_s \cdot [\text{Pos}(ExH(t) - ScS(t)) \cdot (1 - ScS(t)) - \text{Pos}(-(ExH(t) - ScS(t))) \cdot ScS(t)] \cdot PrA(t) \quad (22)$$

For an equilibrium it has to hold that all of the derivatives are zero:

$$dLtS(t)/dt = dExH(t)/dt = dScS(t)/dt = 0$$

Assuming β_{lts} , ψ_e and ϕ_s nonzero, this provides the following equilibrium equations:

$$\text{Pos}(StS - LtS) \cdot (1 - LtS) - \text{Pos}(-(StS - LtS)) \cdot LtS = 0 \quad (23)$$

$$[\text{Pos}(IsE - ExH) \cdot (1 - ExH) - \text{Pos}(-(IsE - ExH)) \cdot ExH] \cdot EmF = 0 \quad (24)$$

$$EmF = 0$$

$$[\text{Pos}(ExH - ScS) \cdot (1 - ScS) - \text{Pos}(-(ExH - ScS)) \cdot ScS] \cdot PrA = 0 \quad (25)$$

$$PrA = 0$$

Table 1 shows which cases can be distinguished. For example, notice that always $\text{Pos}(x) \geq 0$, so (23) is equivalent to;

$$\begin{aligned} \text{Pos}(StS - LtS) \cdot (1 - LtS) &= 0 \\ \text{Pos}(-(StS - LtS)) \cdot LtS &= 0 \end{aligned}$$

This provides cases;

$$(StS \leq LtS \vee LtS = 1) \wedge (StS \geq LtS \vee LtS = 0) \quad (26)$$

This can be logically rewritten into;

$$\begin{aligned} (StS \leq LtS \wedge StS \geq LtS) \vee (StS \leq LtS \wedge LtS = 0) \vee \\ (LtS = 1 \wedge StS \geq LtS) \vee (LtS = 1 \wedge LtS = 0) \end{aligned}$$

The latter case cannot exist, and as $0 \leq StS \leq 1$ the other three cases are equivalent to $StS = LtS$. Similarly the cases for (24) and (25) can be found as shown in Table 1.

Table 1: Equilibrium Equations

(1)	(2)	(3)	Combined
$StS = LtS$	$EmF = 0$	$PrA = 0$	$StS = LtS$, $EmF = PrA = 0$
		$ExH = ScS$	$StS = LtS$, $EmF = 0$, $ExH = ScS$
	$IsE = ExH$	$PrA = 0$	$StS = LtS$, $IsE = ExH$, $PrA = 0$
		$ExH = ScS$	$StS = LtS$, $IsE = ExH = ScS$

Note that for each of the distinguished cases, further information can be found about the equilibrium values of other variables using the other non-dynamic-equations. For example, from $EmF = 0$ by (14) it follows that $ChG = 1$ or $HdB = 0$. This condition illustrates the generic condition that a problem-focused individual that encounters stressful events will never develop long term stress that typically caused by a prolonged dependency on emotion-focused focus coping (Aziz & Treur, 2009; Ntoumanis et al, 2009; Pruchno & Resch, 1989). From another condition $PrA = 0$, by (6) it follows that $ChL = 0$ represents a condition when an individual with negative personality attributes tend to appraise stressful events not as a challenge later will trigger emotion-focused coping (Clarke & Tanya, 2009; Uehara et

al. 1999). Both of these conditions can be found in our simulation results.

Conclusion

In this paper, we have presented a formal temporal model for the cognitive process of coping with stress as described in the informal Cognitive Motivational Relational Theory by Lazarus and Folkman. This theory explains the role of positive and negative emotions in the stress appraisal process, which results in either a problem focused coping strategy or an emotional focused coping strategy. The theory also describes the effect of the different strategies on the long term stress.

The resulting model has been used for two simulations of two persons with different personality characteristics in two different scenarios that describe the level of external sources of stress over time. The simulation traces exhibit patterns that are expected in this domain: problem focused coping leads to better coping skills and higher decrease of long-term stress than emotion focused coping. These results also follow from a mathematical analysis of the model, in which the equilibria of the model are determined to identify the stable situation in the model.

The resulting model can be considered as a virtual human agent model, in the sense that it is a computer models of a person that can be used as a substitute for the real person in a virtual environment. This could provide the basis for a intelligent support system, in which the system should be able to understand the coping process of the persons to which support is provided.

Abstract

In this paper an adaptive integrative ambient agent model is introduced incorporating estimation of a human's interactive dynamics of believing and feeling. The integrative agent model is equipped with a dynamical model which describes how the strength of a belief depends both on information obtained and emotional responses on the belief. In addition, the agent model integrates an adaptation model to tune parameter values representing personal characteristics. In a simple personalised case it is shown how the ambient agent model is able to assess a person's state and use this assessment to interact in a personalised manner.

Keywords: Integrative agent, believing, feeling, adaptive

Introduction

An important and interesting recent class of applications for software/hardware agents can be found in Ambient Intelligence: the area of ambient or pervasive systems; e.g., (Aarts, Collier, Loenen, Ruyter, 2003; Aarts, Harwig, Schuurmans, 2001; Riva, Vatalaro, Davide, Alcañiz, 2005). One of the more ambitious challenges in this area is to create ambient agents with an appropriate awareness of the (mental) states of humans. Human-aware ambient agent systems can be taken to perform a certain type of mindreading or to possess what in the psychological and philosophical literature is called a Theory of Mind; e.g., (Gärdenfors, 2003; Goldman, 2006). As developed during the evolutionary human history, mindreading addresses different types of mental states, such as intention, attention, belief or emotion states; e.g., see (Gärdenfors, 2003). Inspired by these facilities available in nature, ambient agent models can be developed that have mindreading capabilities for one or some of these types of mental states. However, it is more and more acknowledged that such mental states can be quite dynamic and often interact with each other intensively. To obtain an adequate ambient agent model, dynamical models describing such dynamics and interaction has to be integrated within the agent model.

Human-aware ambient agent systems equipped with the ability to reason about the different types of mental states can be applied in the area of personalised customer relationships and marketing. A recent trend is to dig deeper into the clients' minds and lives. The work reported here focuses on the dynamics and interaction of an individual client's beliefs and emotions and integrates models for these dynamics in an ambient agent model to provide effective intelligent marketing strategies by a better understanding of the cognitive and affective system of the client. In their

generation process beliefs trigger emotional responses that result in certain feelings. In a reciprocal manner, the generated feelings affect the belief as well; for some literature on such reciprocal interactions between cognitive and affective states, see, for example, (Eich, Kihlstrom, Bower, Forgas, and Niedenthal, 2000; Forgas, Goldenberg, and Unkelbach, 2009; Niedenthal, 2007; Schooler and Eich, 2000; Winkielman, Niedenthal, and Oberman, 2009).

In this paper, a computational dynamic model is adopted from (Memon and Treur, 2009) that models the client's reciprocal interaction between feeling and believing. This model is based on neurological theories on the embodiment of emotions as described, for example, in (Damasio, 1994, 1996, 1999, 2004; Winkielman, Niedenthal, and Oberman, 2009). More specifically, in accordance with, for example (Damasio, 1999, 2004), for feeling the emotion associated to a belief a converging recursive body loop is assumed. A second converging feedback loop introduced in the model, inspired the Somatic Marker Hypothesis (Damasio, 1994, 1996), involves the interaction back from the feeling to the belief.

This dynamical model is integrated within an ambient agent model to enable the agent to assess the strength of the belief and feeling, and to intervene when desired. As a personal characteristic represented by a parameter indicating a bias of the belief in a positive or negative direction, is hard to determine at forehand, the ambient agent is equipped with an adaptation model to adjust the value of this parameter over time. This results in an adaptive integrative agent model that learns to estimate the human's belief and feeling better and better over time.

To illustrate the model, the following example scenario is used. A person (client) develops strong (false) beliefs due to strong negative feelings (of insecurity) about a product offered by the bank, for example, buying bonds or shares. The ambient agent estimates the level of belief and feeling of the client related to this insecurity. When the client becomes too insecure, i.e., the emotion level goes above certain threshold, the ambient agent can take measures in order to achieve a reduction of the insecure feeling, e.g., by providing information that makes the client feel more secure.

In this paper, first in Section 2 the dynamical model for the interaction between belief and feeling is described. In Section 3 the ambient agent model is described which integrates the dynamical model. Section 4 describes the parameter adaptation model integrated within the agent. Section 5 presents some simulation results. Finally, Section 6 is a discussion.

Belief and Emotion

In this section a computational model for the interaction between believing and feeling is briefly discussed, as adopted from (Memon and Treur, 2009). As any mental state in a person, a belief state induces emotions felt within this person, as described by Damasio (1999; 2004, p. 93):

belief → preparation for bodily response → bodily response
 → sensing the bodily response → sensory representation of the bodily response → feeling

As a variation, an ‘as if body loop’ uses a direct causal relation: preparation for the bodily response → sensory representation of the bodily response; as a shortcut in the causal chain. The body loop (or as if body loop) is extended to a recursive body loop (or recursive as if body loop) by assuming that the preparation of the bodily response is also affected by the state of feeling the emotion: feeling → preparation for the bodily response; as an additional causal relation. Within the model used in this paper both the bodily response and the feeling are assigned a level, expressed by a number; for example, the strength of a smile and the extent of happiness.

Although beliefs in an idealised rational agent might only depend on informational sources, real life persons may, for example, have a more optimistic or pessimistic character and affect their beliefs accordingly. To model this a causal relation: feeling → belief; is added. Therefore two recursive loops result, as shown in Figure 1. From a neurological perspective the existence of a connection from feeling to belief may be considered plausible, as this may be developed based on a general Hebbian learning mechanism (Hebb, 1949; Bi and Poo, 2001) that strengthens connections between neurons that are activated simultaneously. Another type of support for a connection from feeling to belief can be found in Damasio’s Somatic Marker Hypothesis; cf. (Damasio, 1994, 1996; Bechara and Damasio, 2004; Damasio, 2004). This is a theory on decision making which provides a central role to emotions felt. Each decision option induces (via an emotional response) a feeling which is used to mark the option. Usually the Somatic Marker Hypothesis is applied to provide endorsements or valuations for options for a person’s actions. However, it may be considered plausible that such a mechanism is applicable to valuations of internal states such as beliefs as well.

The hybrid dynamic modelling language LEADSTO used subsumes qualitative and quantitative causal relationships, and dynamical systems; cf. (Bosse, Jonker, Meij and Treur, 2007). Within LEADSTO the temporal relation $a \rightarrow b$ denotes that when a state property a occurs, then after a certain time delay (which for each relation instance can be specified as any positive real number), state property b will occur. A dedicated software environment is available to support specification and simulation.

An overview of the model for believing and feeling is depicted in Figure 1. Note that the precise numerical relations between the indicated variables V shown are not expressed in this picture. The detailed specification of the model can be found in (Memon and Treur, 2009).

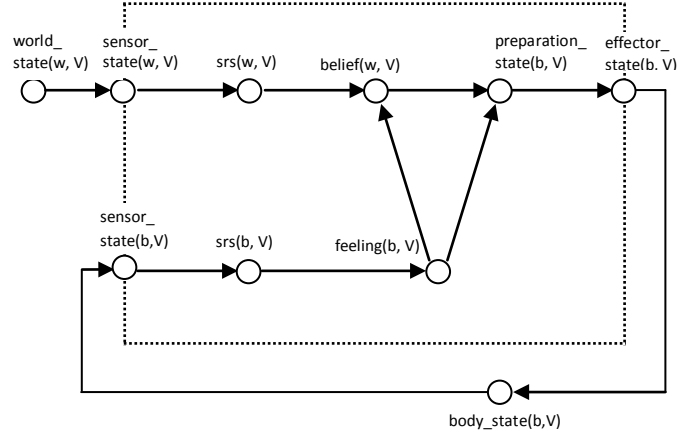

Figure 1: Dynamical model for belief and feeling

As an example, the dynamic property for the process for belief generation is described. The level for the belief is calculated based on a function $g(\beta, V_1, V_2)$ of the original levels, where β is the personal characteristic (with values from 0 to 1) indicating positive or negative bias for the belief.

LP3 Generating a belief for a feeling and a sensory representation

If a sensory representation for w with level V_1 occurs,
 and the associated feeling of b with level V_2 occurs
 and the belief for w has level V_3
 and β_1 is the person’s orientation for believing
 and γ_1 is the person’s flexibility for beliefs
 then a belief for w with level $V_3 + \gamma_1 (g(\beta_1, V_1, V_2) - V_3) \Delta t$ will occur.

has_state(human, srs(w, V_1)) &
 has_state(human, feeling(b, V_2)) &
 has_state(human, belief(w, V_3))
 → has_state(human, belief(w, $V_3 + \gamma_1 (g(\beta_1, V_1, V_2) - V_3) \Delta t$))

For the function $g(\beta, V_1, V_2)$ the following was taken:

$$g(\beta, V_1, V_2) = \beta(1 - (1 - V_1)(1 - V_2)) + (1 - \beta)V_1V_2$$

Dynamic property LP4 describes the emotional response to a belief in the form of the preparation for a specific bodily reaction. This dynamic property uses the same combination model based on $g(\beta, V_1, V_2)$ as above.

LP4 From belief and feeling to preparation of a body state

If belief w with level V_1 occurs
 and feeling the associated body state b has level V_2
 and the preparation state for b has level V_3
 and β_2 is the person’s orientation for emotional response
 and γ_2 is the person’s flexibility for bodily responses
 then preparation state for body state b will occur with level $V_3 + \gamma_2 (g(\beta_2, V_1, V_2) - V_3) \Delta t$.

has_state(human, belief(w, V_1)) &
 has_state(human, feeling(b, V_2)) &
 has_state(human, preparation(b, V_3))
 → has_state(human, preparation(b, $V_3 + \gamma_2 (g(\beta_2, V_1, V_2) - V_3) \Delta t$))

The Ambient Agent Model

Within the integrative ambient agent model, the model for the dynamics of belief and feeling is embedded in order to enable the agent to reason about this process, and to assess the person’s beliefs and feelings. In psychology, this capability is often referred to as mindreading or Theory of Mind (e.g., Gärdenfors, 2003). The embedding uses the format that the causal relationships of the model described in

Section 2 above are transformed into relationships for beliefs of the ambient agent on mental states of the person. In order to achieve this, the idea of recursive modelling is used; e.g., (Marsella, Pynadath and Read, 2004). This means that the beliefs that agents have about each other are represented in a nested manner. Each mental state is parameterized with the name of the agent considered, thus creating concepts like

```
has_state(human, feeling(b, 0.5))
has_state(AA, performed(add_pos_info))
```

In addition, a number of meta-representations are introduced. For example, `has_state(AA, belief(has_state(human, feeling(b, 0.7))))` states that the ambient agent (AA) believes that the human has a feeling level of 0.7 for b. The following are the resulting agent local properties (ALP) that specify the processes within the ambient agent. The first property specifies how the agent AA observes that the human senses external information.

ALP1 Observing the human's sensing external information

If the human senses external information,
then the ambient agent AA will observe this.

```
has_state(human, sensor_state(externalinfo, V))
→ has_state(AA, observed(
    has_state(human, sensor_state(externalinfo, V))))
```

ALP2 Generating a belief for the human's sensing

If the ambient agent AA observes that the human senses an external information,
then it will generate a belief on it.

```
has_state(AA, observed(
    has_state(human, sensor_state(externalinfo, V))))
→ has_state(AA, belief(
    has_state(human, sensor_state(externalinfo, V))))
```

ALP3 Generating a belief for a sensory representation

If AA believes that the human senses external information,
then it will generate a belief that the human will have a sensory representation for this.

```
has_state(AA, belief(
    has_state(human, sensor_state(externalinfo, V))))
→ has_state(AA, belief(has_state(human, srs(externalinfo, V))))
```

ALP4 From sensory representation and feeling to belief

If AA believes that the human has a sensory representation for external information with level V_1
and AA believes that the human has feeling b with level V_2 ,
and the belief for w has level V_3
and β_1 is the person's estimated orientation for emotional response
and γ_1 is the person's flexibility for bodily responses
then it will generate the belief that the human's belief with level $V_3 + \gamma_1 (g(\beta_1, V_1, V_2) - V_3) \Delta t$ will occur

```
has_state(AA, belief(
    has_state(human, srs(externalinfo, V1)))) &
has_state(AA, belief(has_state(human, feeling(b, V2)))) &
has_state(AA, belief(has_state(human, belief(w, V3))))
→ has_state(AA, belief(has_state(human,
    belief(w, V3 + \gamma_1 (g(\beta_1, V_1, V_2) - V_3) \Delta t))))
```

ALP5 From belief and feeling to preparation of a body state

If AA believes that the human has a belief for w with level V_1
and AA believes that the human has feeling b with level V_2 ,
and the preparation for body state b has level V_3
and β_2 is the person's orientation for emotional response
and γ_2 is the person's flexibility for bodily responses
then it will generate the belief that the human's preparation state for body state b will occur with level $V_3 + \gamma_2 (g(\beta_2, V_1, V_2) - V_3) \Delta t$.

```
has_state(AA, belief(has_state(human, belief(w, V1)))) &
has_state(AA, belief(has_state(human, feeling(b, V2))))
has_state(AA, belief(has_state(human, preparation(b, V3)))) &
→ has_state(AA, belief(has_state(human,
    preparation(b, V3 + \gamma_2 (g(\beta_2, V_1, V_2) - V_3) \Delta t))))
```

ALP6 From preparation to body modification

If AA believes that the human's preparation state for body state b with level V occurred,
then it will believe that the human's body state will have level V .

```
has_state(AA, belief(has_state(human, preparation(b, V))))
→ has_state(AA, belief(has_state(human, effector_state(b, V))))
```

ALP7 From body modification to modified body

If AA believes that the human's body is modified with level V ,
then it will believe that the human's body is showing b with level V .

```
has_state(AA, belief(has_state(human, effector_state(b, V))))
→ has_state(AA, belief(has_state(human, body_state(b, V))))
```

ALP8 Sensing a body state

If AA believes that the human's body is showing b with level V ,
then it will believe that the human will sense this body state.

```
has_state(AA, belief(has_state(human, body_state(b, V)))) →
has_state(AA, belief(has_state(human, sensor_state(b, V))))
```

ALP9 Generating a sensory representation of a body state

If AA believes that the human has sensed body state b with level V ,
then it will believe that the human has a sensory representation for body state b with level V .

```
has_state(AA, belief(has_state(human, sensor_state(b, V))))
→ has_state(AA, belief(has_state(human, srs(b, V))))
```

ALP10 From sensory representation of body state to feeling

If AA believes that the human has a sensory representation for body state b with level V ,
then it will believe that the human has feeling b with level V .

```
has_state(AA, belief(has_state(human, srs(b, V))))
→ has_state(AA, belief(has_state(human, feeling(b, V))))
```

In addition, a number of other rules have been established to model the behaviour of the human and the ambient agent, and its effect on the world:

ALP11 Intervention by the Ambient Agent

If AA believes that the human has feeling b with level V which is higher than a certain threshold th_1 ,
then it will add some positive information to the external environment

```
has_state(AA, belief(has_state(human, feeling(b, V)))) &  $V \geq th_1$ 
→ has_state(AA, performed(add_pos_info))
```

ALP12 Effect of intervention in the world

As long as AA does not add some positive information to the external environment,
then positive information will remain 0.

```
not has_state(AA, performed(add_pos_info))
→ added_pos_info(0)
```

As soon as AA adds some positive information to the external environment, it will be available in the environment.

```
has_state(AA, performed(add_pos_info))
→ added_pos_info(0.2)
```

The Adaptation Model

Characteristics of a human, used as parameters in a dynamical model (such as the β used in the belief generation in the model described above) are often not easy to determine at forehand, and can only be given to the agent as initial beliefs. This section describes a method by which an agent is able to adapt these beliefs concerning human characteristics to the real characteristics. Using the dynamical model with parameter values as represented by these initial beliefs, the agent predicts the human belief and feeling state, up to a certain time point. When at that time point, for example by observation, information is obtained about the real value of this belief or feeling state, this is used

as input for the adaptation process. The agent adjusts the belief on the human characteristic, to reduce the difference between predicted and real value.

For reasonable adjustments, information is required on how a change in parameter value affects the difference between predicted and real value of the variable that is considered; this is called the sensitivity of the variable value for the parameter value. The *sensitivity* S of variable X (e.g., the belief or feeling level) for parameter P (e.g., the β used in belief generation) is the number such that a change ΔP in the value of parameter P will lead to a change ΔX in X which is (approximately) proportional to ΔP with S as proportion factor: $\Delta X = S \Delta P$. This is an approximation which is more accurate when the Δ 's are taken small. To determine a sensitivity S the following approximation method is used. A small change ΔP in the parameter is used to make an additional prediction for X , and based on the resulting difference ΔX found in the two predicted values for X , by $S_{X,P} = \Delta X / \Delta P$ the sensitivity S can be estimated. Once the sensitivity and a deviation ΔX between estimated and observed level have been determined, the value W of the parameter P is adjusted by ΔP in the following manner (with α the adaptation speed):

$$\Delta P = \alpha * (1 - W) * (-\Delta X / S_{X,P}) \quad \text{if } -\Delta X / S_{X,P} \geq 0$$

$$\Delta P = \alpha * W * (-\Delta X / S_{X,P}) \quad \text{if } -\Delta X / S_{X,P} \leq 0$$

This has been specified in LEADSTO-format as follows.

ALP13 Calculating change ΔX in predicted belief X

If AA believes that the human has a sensory representation for external information with level V_1
 and AA believes that the human has feeling b with level V_2 ,
 and AA believes that the predicted belief for w has level V_3
 and β_1 is the person's estimated orientation for emotional response
 and γ_1 is the person's flexibility for bodily responses
 and the change to be made in person's estimated β_1 is V_4
 then it will generate the predicted belief for w with
 level $V_3 + \gamma_1 (g(\beta_1 + V_4, V_1, V_2) - V_3) \Delta t$
 has_state(AA, belief(as_state(human, srs(externalinfo, V1)))) &
 has_state(AA, belief(has_state(human, feeling(b, V2)))) &
 has_state(AA, belief(predicted_belief(w, V3)))
 → has_state(AA, belief(predicted_belief(w, V3 + $\gamma_1 (g(\beta_1 + V_4, V_1, V_2) - V_3) \Delta t$)))

ALP14 Generating sensitivity

If AA believes that the predicted belief for w has level V_1
 and AA believes that the human has a belief for w with level V_2
 and the change to be made in person's estimated β_1 is V_3
 then AA will generate the belief for sensitivity by $(V_1 - V_2) / V_3$
 has_state(AA, belief(predicted_belief(w, V1))) &
 has_state(AA, belief(has_state(human, belief(w, V2))))
 → has_state(AA, belief(sensitivity, (V1 - V2) / V3))

ALP15 Calculating deviation

If AA believes that the human has a belief for w with level V_1
 and AA believes that the observed human belief is V_2
 then AA will generate the belief that the deviation between estimated and observed belief is $(V_1 - V_2)$
 has_state(AA, belief(has_state(human, belief(w, V1)))) &
 has_state(AA, belief(observed_human_belief, V2))
 → has_state(AA, belief(deviation, V1 - V2))

ALP16 Adapt estimated beta

If AA believes the estimated beta is V_1
 and AA believes that the deviation between estimated and observed belief is V_2

and AA believes that the sensitivity is V_3
 and $-V_2 / V_3 > 0$
 and α is the adaptation speed
 then AA will generate the belief in an estimated beta with
 level $(\alpha * (1 - V_1) * (-V_1 / V_3) + V_1)$
 has_state(AA, belief(estimated_beta(V1))) &
 has_state(AA, belief(deviation, V2)) &
 has_state(AA, belief(sensitivity, V3)) &
 - V2 / V3 > 0
 → has_state(AA, belief(estimated_beta($\alpha * (1 - V_1) * (-V_1 / V_3) + V_1$)))
 If AA believes estimated beta is V_1
 and AA believes that the deviation between estimated and observed belief is V_2
 and AA believes that the sensitivity is V_3
 and $-V_2 / V_3 \leq 0$
 and α is the adaptation speed
 then AA will generate the belief in an estimated beta with
 level $(\alpha * V_1 * (-V_1 / V_3) + V_1)$
 has_state(AA, belief(estimated_beta(V1))) &
 has_state(AA, belief(deviation, V2)) &
 has_state(AA, belief(sensitivity, V3)) &
 - V2 / V3 <= 0
 → has_state(AA, belief(estimated_beta($\alpha * V_1 * (-V_1 / V_3) + V_1$)))

Simulation Results

Based on the model described in the previous section, a number of simulations have been performed within the LEADSTO simulation environment (Bosse, Jonker, Meij and Treur, 2007). The model was tested in a small scenario, involving an ambient agent and a human (indicated by AA and human, respectively). The agent model was equipped with the model to estimate human's emotion level. The central emotion used in the scenario is insecurity for the particular product, as discussed in Section 1. In order to simulate this, every now and then certain events take place, which influence the level of insecurity of the human either positively (e.g., some good news about the product published in a newspaper) or negatively (e.g., some friend informed him about his own past bad experience with that product). To model this behavior, the following property has been used:

ALP17 Generating a sensor state for external information

If a sensor state of external information of level V_1 occurs
 and the ambient agent has added some positive information V_2 , has flexibility η
 and some positive information V_3
 and some negative information V_4 is present from the environment,
 then the human will sense external information with level
 $(V_1 - \eta * (V_2 + V_3) * V_1 + \eta * V_4 * (1 - V_1))$.
 has_state(human, sensor_state(externalinfo, V1)) &
 added_pos_info(V2) &
 flexibility(η) &
 positive_externalinfo(V3) &
 negative_externalinfo(V4)
 → has_state(human, sensor_state(externalinfo, ($V_1 - \eta * (V_2 + V_3) * V_1 + \eta * V_4 * (1 - V_1)$)))

Here positive_externalinfo and negative_externalinfo represent the positive and negative events that are occurring randomly in the environment which influence the insecurity level of the human. For the example simulations the probability for the positive events to occur has been taken 0.8 and for negative events to occur is 0.3. The main goal of the ambient agent is to estimate the level of insecurity of the human. To this end, it starts with some initial values of the human's belief and feeling levels, and then keeps on updating this, using the

Figure 2: Simulation 1: the estimated β is higher than the real β

Figure 3: Simulation 2: the estimated β is lower than the real β

strategies explained earlier. him some positive information about the product). When it is estimated that the human becomes too (unreasonably) insecure, the ambient agent can take measures to calm him down (e.g., informing

Some example simulation traces (under different but fixed parameter settings) are illustrated in Figures 2 and 3 (here the time delays within the temporal LEADSTO relations were taken 1 time unit). In all of these figures, where time is on the horizontal axis, the upper part shows the time periods, in which the binary logical state properties hold (indicated by the dark lines); for example, `added_pos_info`. Below this part, quantitative information is provided about the human's actual belief and feeling level, and the ambient agent AA's estimation of this belief and feeling level, respectively. Values for these levels for the different time periods are shown by the dark lines. Note that only a selection of the relevant state properties is shown.

The first trace (see Figure 2), shows a situation in which the estimated β (0.95) is substantially higher than the real β (0.7), as indicated in the upper part of Figure 2. As shown in the figure, the ambient agent AA estimates the level of emotion of the human too high so that it is too early in adding the positive information indicated in the upper part by state property: `has_state(AA, performed(add_pos_info))`, at time point 52.

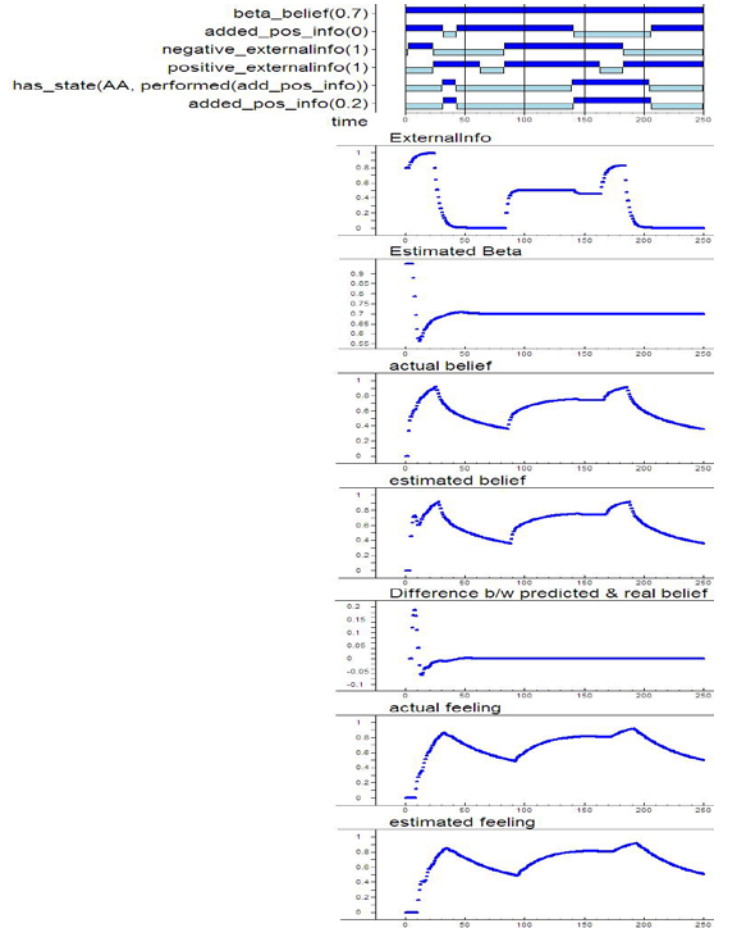

Figure 4: Simulation 3: the estimated β is adapted and approximates the real β

The second trace (see Figure 3) shows a situation in which the estimated β (0.45) is substantially lower than the real β (0.7), as indicated in the upper part of the Figure 3. As shown in the figure, the ambient agent AA estimates the level of emotion of the human much too low, so that it is too late in adding the positive information, indicated in the upper part by state property: `has_state(AA, performed(add_pos_info))`, at time point 128. This is too late, because, as shown in the actual emotion graph below, the human's emotion level has gone too high already at time point 118.

In Figure 4 a simulation trace is shown where the parameter β is adapted to the person. Here the initial value of β is too high (0.95) compared to the actual value (0.7). To compensate for that, the adaptation model first reduces the estimated value to below 0.6, after which it almost monotonically approximates the real value 0.7.

Discussion

To function in a knowledgeable manner, ambient agents (e.g., Aarts, Collier, Loenen, Ruyter, 2003; Aarts, Harwig, Schuurmans, 2001; Riva, Vatalaro, Davide, Alcañiz, 2005) need a model of the humans they are supporting. Such a model enables them to perform a form of mindreading (e.g., Gärdenfors, 2003; Goldman, 2006). The ambient agent model presented here focuses on mindreading concerning the interaction between beliefs and emotions, based on neurological theories that address this interaction. A belief usually triggers an emotional response and may also depend on this emotional response, as, for example, shown in literature such as (Eich et al., 2000; Forgas et al., 2009; Niedenthal, 2007; Schooler and Eich, 2000).

The ambient agent model presented uses a computational model of this interaction, adopted from (Memon and Treur, 2009). For feeling the emotion, based on elements taken from (Damasio, 1999, 2004; Bosse, Jonker and Treur, 2008), a converging recursive body loop is included in the model. As a second loop the model includes a feedback loop for the interaction between feeling and belief. The causal relation from feeling to belief in this second loop was inspired by the Somatic Marker Hypothesis described in (Damasio, 1994, 1996; Bechara and Damasio, 2004), and may also be justified by a Hebbian learning principle (cf. Hebb, 1949; Bi and Poo, 2001). Both the strength of the belief and of the feeling emerge as a result of the dynamic pattern generated by the two loops.

The adaptive integrative agent model equipped with the dynamical model for the dynamics of belief and feeling was specified in the hybrid dynamic modelling language LEADSTO, and simulations were performed in its software environment; cf. (Bosse, Jonker, Meij, and Treur, 2007). An adaptation model was integrated within the agent to be able to tune beliefs on the human's characteristics used as parameters in the dynamical model to the real characteristics. Here feedback can be used when at times the human reveals his or her belief or feeling. To evaluate the ambient agent model in human experiments is left to future work.

Abstract

We describe artificial subtle expressions (ASEs) as an intuitive notification methodology for artifacts' internal states for users. We prepared two types of audio ASEs: one was a flat artificial sound (flat ASE), and the other was a sound that decreased in pitch (decreasing ASE). These two ASEs were played after a robot made a suggestion to the users. Specifically, we expected that the decreasing ASE would inform users of the robot's lower level of confidence in its suggestion. We then conducted a simple experiment to observe whether the participants accepted or rejected the robot's suggestion based on the ASEs. The results showed that they accepted the robot's suggestion when the flat ASE was used, whereas they rejected it when the decreasing ASE was used. We thereby concluded that the ASEs succeeded in conveying the robot's internal state to users accurately and intuitively.

Keywords: Artificial subtle expressions (ASEs); Complementary; Intuitive; Simple; Accurate.

Introduction

Although human communications are explicitly achieved through verbal utterances, paralinguistic information (e.g., pitch and power of utterances) and nonverbal information (e.g., facial expressions, gaze direction, and gestures) also play important roles (Kendon, 1994). This is because one's internal state is deeply reflected in one's paralinguistic and nonverbal information. In other words, other people can intuitively and easily understand a person's internal state from such information when it is expressed (Cohen et al., 1990). Recently, some researchers have reported that very small changes in the expression of such information, called subtle expressions (Liu & Picard, 2003), significantly influence human communications, especially in the conveyance of one's internal state to others. For example,

Ward (2003) reported that the subtle flections of the pitch information in speech sounds reflect one's emotional states even when contradicted by the literal meanings of the speech sounds, and Cowell & Ayesh (2004) offered a similar argument in terms of facial expressions.

It is therefore believed that such subtle expressions can be utilized to help humans easily understand an artifact's internal state because humans can intuitively understand such subtle expressions. For example, Sugiyama et al. (2006) developed a humanoid robot that can express appropriate gestures based on a recognition of its situation, and Kipp & Gebhard (2008) developed a human-like avatar agent that can control its gaze direction according to the user's gaze direction. However, since these researchers tried to implement subtle expressions on artifacts (e.g., humanoid robots or dexterous avatar agents), it resulted in considerably high implementation costs.

In contrast to the above approaches, Yamada & Komatsu (2006) and Komatsu & Yamada (2007) reported that simple beeping sounds from a robot with decreasing/increasing frequency enabled humans to interpret the robot's negative/positive states. Funakoshi et al. (2008) also reported that the robot's blinking LED could convey to users a robot's internal state (processing or busy) for the sake of reducing the occurrence of speech collisions during their verbal conversations. It then seemed that such simple expressions (beeping sounds or blinking LEDs) from artifacts could play a similar role to the subtle expressions of humans, so we named these expressions in artifacts "Artificial Subtle Expressions (ASEs)," referring to artifacts' simple and low-cost expressions that enable humans to estimate the artifacts' internal state accurately and intuitively. We stipulate that the ASEs should

simultaneously meet two design and two functional requirements.

Specifically, the two design requirements are as follows:

- **Simple:** ASEs should be implemented on a single modality. This is expected to lower the implementation cost.
- **Complementary:** ASEs should only have a complementary role in communication and should not interfere with communication's main protocol. This means that the ASEs themselves do not have any meaning without a communication context.

The two functional requirements are as follows:

- **Intuitive:** ASEs should be understandable by humans who have no prior knowledge of the ASEs.
- **Accurate:** ASEs should convey the designer's intended meanings accurately. Specifically, ASEs should convey the internal states of the artifact just as subtle expressions do in nonverbal information by humans.

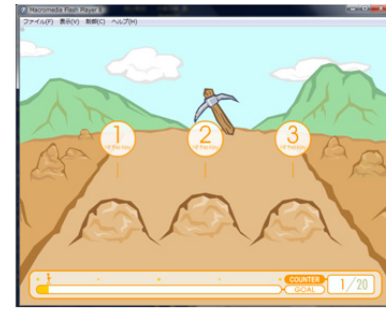

In this study, we focused on audio ASEs. Related studies with audio ASEs include those that proposed simple and effective information to convey specific meaning to users, e.g., "earcon (Blattner, 1989)" or "auditory icon (Gaver, 1989; Gaver, 1997)". These earcons and auditory icons play an effective role in informing users of specific meanings as communication's main protocol, while ASEs play a complementary role for the main protocol. This is the significant difference between ASEs and earcons or auditory icons.

In this paper, we investigated whether the ASEs could convey the artifacts' internal state to the users accurately and intuitively; specifically, we created audio ASEs that were intended to meet the two design requirements and investigated whether they also met the two functional requirements by conducting a simple psychological experiment.

Experiment

Setting

We used a "treasure hunting" video game as an experimental environment to observe participants' behavior (Figure 1). In this game, a game image scrolls forward on a straight road, with small hills appearing along the way. A coin is inside one of three hills, while the other two hills have nothing. The game ends after the player encounters 20 sets of hills, and the approximate duration of this video game is about three minutes. The purpose is to get as many coins as possible. In this experiment, the participant was awarded 1 point for each coin that s/he found. The participants in this experiment were informed that 1 point was equivalent to 50 Japanese yen (about 50 US cents) and that after the experiment they could use their points to purchase some stationery supplies (e.g., file holders or USB flash memory) of equivalent value.

1. Encountering three hills

2. Selecting the 2nd hill
(but not knowing whether this selection was right or not)

3. Walking to
the next three hills

Figure 1: Treasure hunting video game.

The position of the coin in the three hills was randomly assigned. In each trial, an artifact placed next to the participants told them in which position it expected the coin to be placed. The artifact placed next to the participants was the MindStorms robot (LEGO Corporation, see Figure 2). The robot told the participant the expected position of the coin using its speech sounds. The participants could freely accept or reject the robots' suggestions. In each trial, even though the participants selected one hill from among three, they did not know whether the selected hill had the coin or not (actually, the selected hill just showed a question mark and a closed treasure box, as depicted in the center of Figure 1). The participants were informed of their total game points only after the experiment.

Figure 2: MindStorms Robot.

Utilized ASEs

Figure 3: Speech sound “ni-ban (no.2)” and decreasing ASE.

Figure 4: Flat and decreasing ASEs (duration: 0.5 second).

We implemented the audio ASEs in the robot’s speech sounds. In this experiment, the robot expressed Japanese artificial speech sounds to tell the expected position of the coin; that is, “ichi-ban (no. 1),” “ni-ban (no. 2),” and “san-ban (no. 3).” These artificial speech sounds were created by

the text-to-speech (TTS) function of “Document Talker (Create System Development Company).” Just 0.2 seconds after these speech sounds, one of the two simple artificial sounds was played as the ASE (Figure 3). These two ASEs were triangle wave sounds 0.5 seconds in duration, but their pitch contours were different (Figure 4); that is, one was a flat sound (onset F0: 400 Hz and end F0: 400 Hz, called “flat ASE”), and the other was a decreasing one (onset F0: 400 Hz and end F0: 250 Hz, called “decreasing ASE”). These ASE sounds were created by “Cool Edit 2000 (Adobe Corporation).” Komatsu & Yamada (2007) reported that the decreasing artificial sounds expressed from the robot were interpreted as negative feelings by humans; therefore, we intended that the decreasing ASE would inform users of the robot’s lower confidence in the suggestions as the robot’s internal state.

Here, the main protocol of the robot was to tell the expected position of the coin, while the ASE protocol was to indicate the robot’s confidence level in a complementary manner. The two ASE sounds were created quite easily by simply editing the consumer software. Thus, the ASEs met the two design requirements, that is, simple and complementary. Therefore, to confirm whether the ASEs were able to convey the robot’s internal states to the users accurately and intuitively, we needed to investigate whether the utilized ASE met the two requirements for functioning, that is, being intuitive and accurate.

Procedure

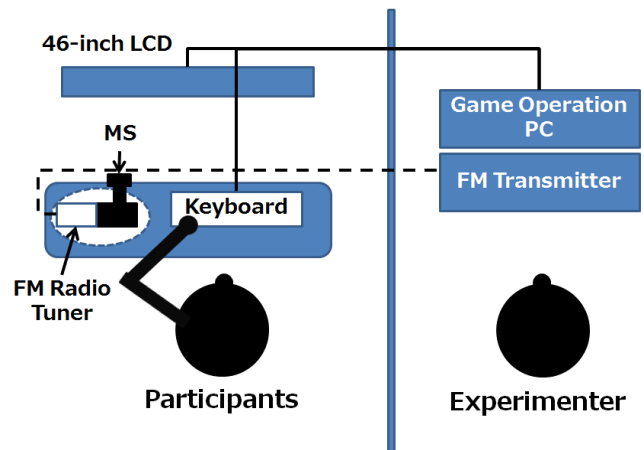

Figure 5: Experimental setting.

Nineteen Japanese university students (10 men and 9 women; 22 – 25 years old) participated. The treasure hunting video game was projected on a 46-inch LCD in front of the participants, and the robot was placed in front of and to the right of the participants, with the distance between them being approximately 50 cm (see Figures 5 and 6). The sound pressure of the robot’s speech sounds at the participants’ head level was set at about 50 dB (FAST, A). The robot’s speech sounds with the ASEs were remotely controlled by the experimenter in the next room using the Wizard of Oz (WOZ) method. Before the experiment started,

the experimenter told the participant the setting and purpose of the game. However, the experimenter never mentioned or explained the ASEs. Therefore, the participants had no opportunity to acquire prior knowledge about the ASEs. Among the 20 trials, the robots expressed the flat ASE 10 times and the decreasing ASE 10 times. The order of expression for these two types of ASEs was counterbalanced across participants. Actually, the robot told the exact position of the coin in all 20 trials, but the participants did not know whether or not the robot was telling the right position because the participants were not able to find out whether the selected hill had the coin or not. If the participant actually knew whether or not the selected hill had the coin just after their selections, they would have associated the ASE with the robot's performance, e.g., whether or not the robot pointed to the right position. Thus, this experimental setting, where the participants were not notified of whether the selected hill was correct or not, was intended to reduce such associations and to clarify the effect of the ASEs on the participants' behavior.

Figure 6: Experimental Scene

The purpose of this experiment was to observe the participants' behavior as to whether they accepted or rejected the robot's suggestions in terms of the types of ASEs used. We assumed that *the participants would accept the robot's suggestion when the flat ASE was added to the speech sounds while they would reject the suggestion when the decreasing ASE was used*. If we could observe these phenomena, we could recognize that the utilized ASE had succeeded in conveying the robot's internal state to the participants accurately and intuitively; that is, the ASE had successfully met all four requirements. In addition, after the experiment, we conducted interviews to determine whether or not the participants had noticed the ASEs and, if so, how they had interpreted them.

Results

To investigate the effect of the ASEs on participants' behavior, we calculated the rejection rate, indicating how

many of the robot's suggestions the participants rejected for 10 flat ASEs and 10 decreasing ASEs. For all 19 participants, the average rejection rate of the 10 flat ASEs was 1.73 (SD=1.51), while the rejection rate of the 10 decreasing ASEs was 4.58 (SD=2.43, see Figure 7). These rejection rates for the 10 flat ASEs and 10 decreasing ASEs were analyzed using a one-way analysis of variance (ANOVA) (within-subjects design; independent variable: type of ASE, flat or decreasing, dependent variable: rejection rate). The result of the ANOVA showed a significant difference between the two groups ($F(1,18)=13.38$, $p<.01$, (**)); that is, the robot's suggestions with the decreasing ASE showed a significantly higher rejection rate compared to those with the flat ASE. Therefore, the ASEs significantly affected the participants' behavior, and we found evidence supporting our previously mentioned assumption. The most interesting point was that the ASEs affected the behavior of the participants without their being informed of the meaning or even existence of the ASEs.

Figure 7: Rejection rate for all 19 participants.

In the interview sessions, 5 out of the 19 participants said that they immediately realized the meanings of the ASEs after the robot's speech sounds and that they utilized these ASEs when it came to accepting or rejecting the robot's suggestions, e.g., "I felt that the decreasing artificial sounds meant that the robot had less confidence in its answer." However, the remaining 14 participants said that they did not notice the existence of the ASEs. Here, if there were significant differences between flat and decreasing ASEs in their rejection rate, the ASEs were interpreted by these 14 participants unconsciously. In this case, we strongly argue that the ASEs were able to convey the robot's internal state to the participants accurately and intuitively. For these 14 participants, the average rejection rate of 10 flat ASEs was 2.28 (SD=1.73), while the rejection rate of the 10 decreasing ASEs was 3.43 (SD=1.59, see Figure 8). These rejection rates were analyzed using a one-way ANOVA (within-subjects design; independent variable: ASE type, flat or decreasing, dependent variable: rejection rate). The result of the ANOVA showed a significant difference between them ($F(1,13)=4.98$, $p<.05$, (*)); that is, the robot's suggestions

with the decreasing ASE had a significantly higher rejection rate compared to those with a flat ASE, even though these participants did not notice the existence of the ASEs. To sum up, the results of this experiment clearly show that the utilized ASEs succeeded in conveying the robot's internal states to the participants accurately and intuitively; that is, the ASEs succeeded in meeting all four requirements.

Figure 8: Rejection rate for 14 participants who did not notice ASEs.

Discussion

Future Applications

As a result of the experiment, we could confirm that the robot's suggestions with the decreasing ASEs showed a significantly higher rejection rate compared with those with flat ASEs. Moreover, these ASEs were interpreted by the participants even though they were not informed of the meaning or even the existence of the ASEs. Therefore, our experiment clearly showed that the utilized ASEs succeeded in conveying the robot's internal states to the participants accurately and intuitively.

Currently, we are planning to implement the ASEs in various kinds of spoken dialogue systems such as ATMs and automatic telephone reservation systems. Specifically, we are now focusing on car navigation systems' speech sounds; the reason for this is that current car navigation systems still sometimes give poor driving routes to users. However, if this navigation system's confidence level regarding the route instruction is not very high, the instructions of speech sounds with ASEs could implicitly convey a lower confidence level. If the ASEs are still effective in such situations, they could be utilized in various situations in which artifacts have to convey their internal states to users.

In our experiment, we only focused on the internal state of the artifact in order to convey to users its level of confidence in its own expressed information. However, we are planning to investigate which kinds of internal states could be conveyed to the users by means of ASEs. For example, it is expected that the artifacts should also convey other kinds of internal states, such as feelings or conditions,

and the confidence level in interpreting the user's expressions. This consecutive study would also contribute to expanding the applicability of ASEs to various interactive situations.

Advantage of utilizing ASEs

It is said that the most significant advantage in utilizing ASEs is the lower implementation cost compared to utilizing human-like expressions. Therefore, it is expected that many applications in human-computer interaction or human-robot interaction will be able to include the ASEs quite easily. In addition to the lower cost, we believe that the advantage of utilizing ASEs includes the possibility of solving several problems such as those reported in the above research areas.

So far, it has been strongly believed that most robots or on-screen agents required to interact with users should have a human-like appearance and produce human-like expressions. However, we feel that these research directions have had two difficulties; one is the implementation cost mentioned above, and the other is that users have unexpected attitudes or impressions toward human-like artifacts; i.e., artifacts having a human-like appearance have a higher possibility of diving them into the "uncanny valley" (Mori, 1970). Moreover, users are likely to overestimate the artifacts' ability when it has a human-like appearance or expressions, so they would be disappointed if these artifacts were to demonstrate unpredictable or poor behavior (Komatsu & Yamada, 2010).

Therefore, our approach that the artifact should not produce human-like expressions but artifact-like ones to convey its internal state to the users has succeeded in proposing a novel research approach in the research area of human-computer interaction or human-robot interaction in order to resolve the above issues. Now we are planning to conduct a consecutive study to compare ASEs to human-like expressions in terms of users' cognitive load or cost-benefit relationships. Comprehending the advantages and disadvantages of these two expressions (ASEs and human-like expressions) would constitute a design methodology for artifacts' expressions in order to achieve smooth interaction between users and artifacts.

Conclusions

In this paper, we investigated whether the ASEs could convey artifacts' internal states accurately and intuitively to users; specifically, we created audio ASEs intended to meet the two requirements for design, and we investigated whether these ASEs met the two requirements for function by conducting a simple psychological experiment. As a result of this experiment, the robot's suggestions accompanied by decreasing ASEs showed a significantly higher rejection rate compared with those accompanied by flat ASEs. Moreover, these ASEs were accurately interpreted by participants even though they were not informed of the meaning or even the existence of the ASEs.

Therefore, our experiment clearly showed that the utilized ASEs succeeded in conveying the robot's internal states to the participants accurately and intuitively; that is, the ASEs succeeded in meeting all four requirements. Thus, we confirmed that simple and low-cost expression ASEs could be utilized as an intuitive notification methodology for artifacts to convey their internal states to users through paralinguistic or nonverbal information.

Abstract

Various Artificial Intelligence semantics have been developed to predict when an argument can be accepted, depending on the abstract structure of its defeaters and defenders. These semantics can make conflicting predictions, as in the situation known as floating reinstatement. We argue that the debate about which semantics makes the correct prediction can be informed by the collection of experimental data about the way human reasoners handle these critical cases. The data we report show that floating reinstatement yields comparable effects to that of simple reinstatement, thus supporting preferred semantics over grounded semantics. Besides their theoretical value for validating and inspiring argumentation semantics, these results have applied value for developing artificial agents meant to argue with people.

Keywords: Argumentation; Semantics; Nonmonotonic reasoning; Behavioural Experiment;

Introduction

Argumentation has become a very fertile area of research in Artificial Intelligence (Rahwan & Simari, 2009), where a highly influential framework for studying argumentation-based reasoning was introduced by Dung (1995). An *argumentation framework* is simply a pair $AF = \langle \mathcal{A}, \rightarrow \rangle$ where \mathcal{A} is a set of arguments and $\rightarrow \subseteq \mathcal{A} \times \mathcal{A}$ is a defeat relation between arguments. This approach abstracts away from the origin of individual arguments and their internal structures, and focuses instead on the defeat relationship between them.

Figure 1 shows an example textual argument and its corresponding graph structure. This structure is the canonical example for the notion of *reinstatement*. In particular, while argument A is defeated by argument B , the presence of C reinstates A since C undermines A 's only defeater.¹

Given an argument framework (or graph), a semantics assigns a *status* to each argument. Classically, we distinguish between arguments that are *accepted* and those that are not (Dung, 1995). In some cases, all semantics agree on the result. For example, in Figure 1, all classical argumentation semantics agree that we should accept C (for lack of any counter-argument), reject B (because there is a good reason

¹While many notions of defeat exist, here we adopt the simple notion of *undercutting*: the defeater's conclusion explicitly negates the defeated argument's premise.

Textual argument:

A: Tweety flies because it is a bird.

B: Tweety does not fly, because it is a penguin.

C: The observation that Tweety is a penguin is not reliable.

Graphical structure:

Figure 1: Defeat structure with reinstatement

to), and accept A (since every objection to it has been defeated). When there are cycles, different semantics may prescribe different results.

These semantics typically come from a normative perspective, which relies on intuition and ad hoc hypothetical examples as to what constitutes correct reasoning. We will argue that there are limits to relying solely on this approach, and we will advocate the use of psychological experiments as a methodological tool for informing and validating intuitions about argumentation-based reasoning.

In this paper, we apply this experimental method to the problem of floating reinstatement. We will show that psychological experiments can help to evaluate these various semantics, and can provide unique insights even when all formal semantics are in agreement. Not only can these insights inform current and future semantics, but they are relevant to the design of software agents that can argue persuasively with humans, or provide reliable support to human evaluation of arguments (e.g., on top of argument diagramming tools).

Abstract Argumentation Frameworks

This section contains technical background only, whose outline is the following. Figure 1 displays the canonical graph of simple reinstatement, whereas Figure 2 displays the canonical graph of floating reinstatement. The main question is, in both cases, whether A can be accepted. For simple reinstatement, A is accepted by preferred as well as grounded semantics (to be defined below). For floating reinstatement, A is not accepted by grounded semantics, but is accepted by preferred

Figure 2: The canonical graph of defeat and floating reinstatement. Argument A is defeated by B, which is itself defeated by C as well as D, although C and D are mutual defeaters.

semantics. Additionally, preferred semantics also accept C and D in the (formally defined) ‘credulous’ sense, but not in the ‘sceptical’ sense.

We now lay bare the technical background required to arrive at these conclusions. We begin with Dung’s (1995) abstract definition of an argumentation framework.

Definition 1 (Argumentation framework). *An argumentation framework is a pair $AF = \langle \mathcal{A}, \rightarrow \rangle$ where \mathcal{A} is a set of arguments and $\rightarrow \subseteq \mathcal{A} \times \mathcal{A}$ is a defeat relation. An argument α defeats an argument β iff $(\alpha, \beta) \in \rightarrow$, also written $\alpha \rightarrow \beta$.*

The directed graphs displayed in Figures 1 and 2 will be our running examples all through the article. The critical issue with these examples is whether argument A can be accepted in spite of being defeated by argument B.

For a given set S of arguments, S^+ is the set of arguments that are defeated by the arguments in S . Formally, $S^+ = \{\beta \in \mathcal{A} \mid \alpha \rightarrow \beta \text{ for } \alpha \in S\}$. Conversely, for a given argument α , the set α^- is the set of all arguments that defeat α . Formally, $\alpha^- = \{\beta \in \mathcal{A} \mid \beta \rightarrow \alpha\}$.

Definition 2 (Conflict-freeness). *Let $\langle \mathcal{A}, \rightarrow \rangle$ be an argumentation framework and let $S \subseteq \mathcal{A}$. S is conflict-free iff $S \cap S^+ = \emptyset$.*

In other terms, a set of arguments is *conflict free* if and only if no argument in that set defeats another.

Definition 3 (Defence). *Let $\langle \mathcal{A}, \rightarrow \rangle$ be an argumentation framework, let $S \subseteq \mathcal{A}$, and let $\alpha \in \mathcal{A}$. S defends α if and only if $\alpha^- \subseteq S^+$. We also say that argument α is acceptable with respect to S .*

In other terms, a set of arguments *defends* a given argument if and only if it defeats all its defeaters.

Example 1. *In the graph displayed in Figure 1, the set $\{A, C\}$ is conflict free, but the set $\{A, B\}$ is not, and neither is the set $\{B, C\}$. Because the set $\{C\}$ defeats all the defeaters of A, we can say that the set $\{C\}$ defends argument A. In the graph displayed in Figure 2, the only conflict-free sets (apart from trivial ones containing single arguments) are $\{A, C\}$ and $\{A, D\}$. Either one of the sets $\{C\}$, $\{D\}$, or $\{C, D\}$, defends A against all its defeaters.*

Figure 3: Single (complete, grounded, and preferred) extension in simple reinstatement. Accepted arguments are shaded.

Figure 4: The two (complete, preferred) extensions in floating reinstatement. Accepted arguments are shaded.

We now define the *characteristic function* of an argumentation framework.

Definition 4 (Characteristic function). *Let $AF = \langle \mathcal{A}, \rightarrow \rangle$ be an argumentation framework. The characteristic function of AF is $\mathcal{F}_{AF}: 2^{\mathcal{A}} \rightarrow 2^{\mathcal{A}}$ such that, given $S \subseteq \mathcal{A}$, we have $\mathcal{F}_{AF}(S) = \{\alpha \in \mathcal{A} \mid S \text{ defends } \alpha\}$.*

Applied to an argument set S , the characteristic function returns the set of all arguments defended by S . Because we are only dealing in this article with one argumentation framework at a time, we will use the notation \mathcal{F} instead of \mathcal{F}_{AF} .

We now turn to various so-called *extensions* that can characterise the collective acceptability of a set of arguments. Essentially, these extensions provide different possible ways to group self-defending arguments together. These extensions will be used subsequently to define the argument evaluation criteria that we study empirically in this paper.

Definition 5 (Complete/grounded/preferred extensions). *Let S be a conflict-free set of arguments in framework $\langle \mathcal{A}, \rightarrow \rangle$.*

- *S is a complete extension iff $S = \mathcal{F}(S)$.*
- *S is a grounded extension iff it is the minimal complete extension with respect to set inclusion.*
- *S is a preferred extension iff it is a maximal complete extension with respect to set inclusion.*

S is a complete extension if and only if *all* arguments defended by S are also in S (that is, if S is a fixed point of the operator \mathcal{F}). There may be more than one complete extension, each corresponding to a particular consistent and self-defending viewpoint.

Example 2. *In the graph displayed in Figure 1, the set $\{C\}$ is not a complete extension, because it defends A without including it. The set $\{B\}$ is not a complete extension because it includes B without defending it against C –see Figure 3. The only complete extension is $\{A, C\}$. The graph displayed in Figure 2 has two complete extensions, $\{A, C\}$ and $\{A, D\}$ –see Figure 4.*

A grounded extension contains all the arguments in the graph that are not defeated, as well as all the arguments

which are defended directly or indirectly by non-defeated arguments. This can be seen as a non-committal view (characterised by the *least* fixed point of \mathcal{F}). As such, there always exists a unique grounded extension.

Example 3. *The graph in Figure 1 has only one complete extension, $\{A, C\}$, which is also its grounded extension. The graph in Figure 2 has two complete extensions $\{A, C\}$ and $\{A, D\}$, but none of this is the grounded extension, because there is no node in the graph that is initially undefeated. In that case, the grounded extension is the empty set.*

A preferred extension is a bolder, more committed position that cannot be extended (by accepting more arguments) without causing inconsistency. Thus a preferred extension can be thought of as a maximal consistent set of hypotheses. There may be multiple preferred extensions, and the grounded extension is included in all of them.

Example 4. *The graph in Figure 1 has only one complete extension, $\{A, C\}$, which is also a preferred extension. The graph displayed in Figure 2 has two complete extensions $\{A, C\}$ and $\{A, D\}$, and both qualify as preferred extensions.*

Now we can define the status of an individual argument within the graph, that is, we can define criteria for accepting or not each individual argument. The main question in this paper is whether people evaluate a reinstated argument sceptically or credulously in accordance with the definition below.

Definition 6 (Argument status). *Let $\langle \mathcal{A}, \rightarrow \rangle$ be an argumentation framework, and $\mathcal{E}_1, \dots, \mathcal{E}_n$ its extensions under a given semantics. Let $\alpha \in \mathcal{A}$ and $i = 1, \dots, n$.*

- α is accepted in the sceptical sense iff $\alpha \in \mathcal{E}_i, \forall \mathcal{E}_i$.
- α is accepted in the credulous sense iff $\exists \mathcal{E}_i$ where $\alpha \in \mathcal{E}_i$.
- α is rejected iff $\nexists \mathcal{E}_i$ such that $\alpha \in \mathcal{E}_i$.

Under the grounded semantics, any argument that belongs to the unique grounded extension is accepted both in the credulous and the sceptical sense, and any argument that does not belong to the unique grounded extension is rejected. Under the preferred semantics, an argument is sceptically accepted if it belongs to all preferred extensions; but it can also be credulously accepted if it belongs to at least one preferred extension. If an argument is neither sceptically nor credulously accepted, it is rejected.

Example 5. *The graph displayed in Figure 1 has only one complete extension, $\{A, C\}$, which is grounded as well as preferred. As a consequence, arguments A and C are accepted by grounded as well as preferred semantics, both in the credulous and sceptical sense. The graph displayed in Figure 2 has an empty grounded extension, which means that no argument should be accepted under a grounded semantics. Under a preferred semantics, though, two extensions are identified, $\{A, C\}$ and $\{A, D\}$. From these extensions, only A can be accepted in a sceptical sense, but A, C, and D can all be accepted in a credulous sense.*

What Validates a Semantics?

As established above, different semantics can have different takes on which arguments can be accepted within a given argumentation framework. The question then arises of evaluating the different claims made by different semantics.

Most semantics for argumentation-based reasoning in Artificial Intelligence are based on intuition as to what constitutes correct reasoning. This intuition is informed by specific (hypothetical or real) argumentation scenarios in which a particular semantics draws the desired intuitive answer. This *example-based approach* (to borrow a term from Baroni & Giacomin, 2007) is problematic, since one can often construct other examples with the same logical structure, in which the proposed semantics draws counter-intuitive conclusions. For example, Horty (2002) famously devoted a whole paper to demonstrate counter-intuitive results with floating conclusions in default reasoning. Baroni and Giacomin (2007) made a compelling case for the limitations of the example-based approach, noting that even in relatively simple examples, there might not be a consensual intuition on what should be the correct conclusion. In parallel, Prakken (2002) observed that intuitions about given examples were helpful for generating new investigations, but less helpful as critical tests between different semantics.

To overcome the limitations of the example-based approach, a number of authors recently advocated a more systematic, axiomatic, *principle-based* approach. In this approach, alternative semantics are evaluated by analysing whether they satisfy certain principles, or quality postulates. Such postulates include the *reinstatement criterion*, according to which an argument must be included in any extension that reinstates it, and *directionality criterion* which requires that an argument's status should only be affected by the status of its defeaters (Baroni & Giacomin, 2007).

The principle-based approach provides a significant improvement over the basic example-based approach, since it enables claims that transcend individual examples and characterise semantics more generally. The source of the general postulates, however, is still the researcher's intuition as to what correct reasoning ought to be. In sum, most of the extent validation of various argumentation semantics, example-based or principle-based, relies on normative claims based on intuition. We now suggest that this normative-intuitive perspective could be adequately complemented with descriptive, *experimental* evidence about how people actually reason from conflicting arguments.

The Experiment-based Approach

There is a growing concern within the Artificial Intelligence community that logicians and computer scientists ought to give serious attention to cognitive plausibility when assessing formal models of reasoning, argumentation and decision-making. For example, Benthem (2008) strongly supports the rise of a *new psychologism* in logic at large, arguing that although logicians and computer scientists have tended to go by

intuition and anecdotal evidence, formal theories can be modified under pressure from evidence obtained through careful experimental design.

Pelletier and Elio (2005) also argued extensively for the importance of experimental data when formalizing default and inheritance reasoning, arguing that default reasoning is particularly psychologistic in that it is *defined* by what people do. Their own results have been complemented by a dynamic experimental literature consisting of controlled tests of human default reasoning (e.g., Bonnefon, Da Silva Neves, Dubois, & Prade, 2008; Ford & Billington, 2000; Pfeifer & Kleiter, 2009).

Finally, and in close relation to the problems of simple and floating reinstatement that we have introduced in the previous section, Horty (2002) implicitly appealed to descriptive validation when highlighting the issues that floating conclusions raise for sceptical semantics:

There is a vivid practical difference between the two skeptical alternatives. [...] Which alternative is correct? I have not done a formal survey, but most of the people to whom I have presented this example are suspicious of the floating conclusion (p.64).

We believe that the field of computational argumentation can indeed benefit from the same kind of formal surveys that have been conducted in the field of default reasoning, and that have been generally called for in Artificial Intelligence. To our knowledge, only very few articles have explicitly sought to inform formal models of argumentation with experimental evidence, and these experimental data have only been collected in relation to the specific issue of argumentation-based decision making (e.g., Dubois, Fargier, & Bonnefon, 2008). What we offer in this article is an experimental investigation of the basic issue of how people reason from the complex argument structure corresponding to floating reinstatement, and whether one of the current available semantics can capture their reasoning.

Recently, we conducted experiments on the simple reinstatement structure, across a varied set of linguistic contents (Madakkattel, Rahwan, Bonnefon, Awan, & Abdallah, 2009). Our study revealed that participants reasoned in a way that reflected the formal notions of defeat and reinstatement: Their confidence in an argument *A* decreased when it was attacked by an argument *B*, but bounced back up when *B* itself was attacked by a third argument *C*. These findings are in agreement with grounded as well as preferred semantics (and others). What neither semantics could predict, though, is the finding that the recovery of argument *A* was not complete when reinstated by argument *C*: Confidence in *A* in presence of *B* and *C* did not raise back to its former level, when *A* was presented alone.

Our present study offers an experimental comparison of the simple reinstatement structure to the more complex structure known as floating reinstatement, shown in Figure 2. The present study seeks to answer the following questions: Does floating reinstatement restore the confidence in the conclusion of argument *A*, and does it do so to the same extent as

simple reinstatement? (A ‘yes’ to both questions would go against the predictions of grounded semantics.) If so, does the effectiveness of floating reinstatement require that participants manifest a preference for either *C* over *D* or *D* over *C*? (A ‘yes’ would provide support to the predictions of credulous preferred semantics, a ‘no’ would provide support to the predictions of sceptical preferred semantics.)

Method

Forty-seven participants were randomly approached in offices, shopping malls, and open spaces in Dubai. Participants read an introduction to the task, informing them that the purpose of the experiment was to collect information about how people thought, that the task included no trick question, and that they simply had to mark the answer that they felt correct. They were randomly assigned to two experimental groups corresponding to simple and floating reinstatement, respectively, then solved 12 problems, following a 3-level, 4-measure within-participant design.

The 3-level independent variable was the *Pattern* of the problem (Base, Defeated, Reinstated). In the Base pattern, participants were only presented with argument *A*; in the Defeated pattern, participants were presented with arguments *A* and *B*; finally, in the Reinstated pattern, participants were presented with the three arguments *A*, *B*, and *C* (in the simple reinstatement group) or with the four arguments *A*, *B*, *C*, and *D* (in the floating reinstatement group).

The linguistic contents of arguments *A*, *B*, *C*, and *D* were taken from four different argument sets (see Appendix). All participants saw each argument set in its Base, Defeated, and Reinstated versions. The order of argument sets within the questionnaire was counterbalanced across participants (two different orders), but the order of Pattern within each argument set was fixed across the experiment. Participants had to answer every problem, in the order they appeared in the questionnaire, without looking at the next problem in the questionnaire. For each problem, participants had to assess the conclusion of argument *A*, using a 7-point scale anchored at *certainly false* and *certainly true*.

In addition, participants rated their understanding of each problem (‘How clearly did you understand the problem?’) on a 7-point scale anchored at *Not at all* and *Completely*. Lastly, participants in the floating reinstatement group answered the following question about the four reinstated problems: Do you think that (i) *C* is a better argument than *D*, (ii) *D* is a better argument than *C*, or (iii) *C* and *D* are about equally good?

Results

Figure 5 displays the average confidence in the conclusion of *A*, as a function of Pattern and Type of reinstatement, averaged across the contents and participants. The visual inspection of Figure 5 already suggests that the results are very similar for the two groups. This preliminary intuition was confirmed by the results of a mixed-design analysis of variance, using the confidence in the conclusion as a dependent

Figure 5: Reinstatement is as effective in its floating form as in its simple form. Confidence in the conclusion of an argument decreases when the argument is defeated, and is then imperfectly restored when its defeater is itself defeated, whether by a single argument (simple reinstatement) or by two mutually defeating arguments (floating reinstatement).

variable, pattern as a 3-level within-subject predictor (Base, Defeated, Reinstated), the type of reinstatement as a 2-level between-group variable (Simple, Floating), and four measures corresponding to the four linguistic contents.

The multivariate test detected a significant effect of Pattern, $F(8, 38) = 6.1$, $p < .001$, $\eta_p^2 = .56$. It did not, however, detect a significant main effect of Type of reinstatement $F(4, 42) < 1$, $p = .79$, $\eta_p^2 = .04$, nor a significant interaction between Pattern and Type, $F(8, 38) = 1.2$, $p = .32$, $\eta_p^2 = .20$.

The overall effect of Pattern reflected a successful defeat followed by a successful reinstatement. As shown by contrast analysis, confidence ratings in the Defeated condition were significantly lower than ratings in the Base condition, $F(1, 45) = 34.9$, $p < .001$, $\eta_p^2 = .44$, and this difference was not moderated by the Type of reinstatement (there is indeed no reason that it should be), $F(1, 45) < 1$, $p = .67$, $\eta_p^2 < .01$. The confidence ratings in the Reinstated condition were significantly greater than in the Defeated condition, $F(1, 45) = 13.7$, $p < .001$, $\eta_p^2 = .23$, and this difference (more interestingly this time) was not moderated by the Type of reinstatement, $F(1, 45) < 1$, $p = .60$, $\eta_p^2 < .01$. Just as in our earlier study (Madakkattel et al., 2009), reinstatement is not perfect, as ratings in the Reinstated condition remain significantly lower than in the Base condition, $F(1, 45) = 9.0$, $p < .01$, $\eta_p^2 = .17$. Again, there is no evidence whatsoever of a moderation by Type of reinstatement, $F(1, 45) < 1$, $p = .92$, $\eta_p^2 < .01$.

So far, results suggest that floating reinstatement has an effect that is identical to classic reinstatement. We further note that although subjects found the floating reinstatement problems slightly harder to understand than the simple reinstatement problems, this difference appeared to play no role in the ratings they gave for their confidence in the conclusion. The average understanding rating was 4.6 (SD = 1.1) for simple reinstatement problems, compared to 4.0 (SD = 0.9) for floating reinstatement problems, $t(45) = 2.0$, $p = .05$. How-

ever, a regression analysis seeking to predict acceptance of reinstated arguments on the basis of problem understanding, Type of reinstatement (dummy coded, 1 for floating), and the interaction term between these two predictors, failed to find any significant effect. The interaction term in particular achieved a standardized β of .19, non-reliably different from zero, $t = 0.32$, $p = .75$.

The effectiveness of floating reinstatement does not appear to result from the subjects manifesting a preference for one of the mutually defeated arguments. We conducted four repeated-measure analyses of variance, one for each argument set, with conclusion acceptance as a dependent variable, pattern as a 2-level predictor (Defeated, Reinstated), and preference as a dummy coded between-group variable (0 for subjects who said the two mutually defeating arguments were equally good, 1 otherwise). The interaction term between pattern and preference did not achieve statistical significance in any of the four analyses, all F s in the 0.5 – 1.5 range, all p s in the .23 – .48 range.

Discussion

We applied the experimental approach to understand how people deal with floating reinstatement in argument-based reasoning, a case that has puzzled theoreticians for many years. Our results suggest that, empirically speaking, floating reinstatement works exactly as well as simple reinstatement. Participants' confidence in an argument A decreased when it was attacked by an argument B , but bounced back up when B itself was attacked by two mutually defeating arguments C and D . These results clearly speak in favour of preferred semantics. Results also suggest that the sceptical version of preferred semantics might be more cognitively plausible than the credulous version, since the effect of floating reinstatement was not dependent on participants showing a preference for one of the two mutually defeating arguments. This question is not yet settled, though, since the data do not make it clear whether participants would be willing to commit to accepting one of the mutually defeating arguments C and D . This aspect requires further investigation.

Besides their theoretical value, our results also have applied value for developing agents that are meant to argue with human users. We already know that artificial agents can achieve better negotiation results with human users when they do not play normative equilibrium strategies, but rather adopt boundedly rational strategies inspired from human behavioural data (Lin, Kraus, Wilkenfeld, & Barry, 2008). Generally speaking, we may expect that artificial agents may similarly be more successful when arguing with human users, if they can anticipate human reactions to various abstract argumentation frameworks. With that goal in mind, our results suggest that artificial agents may be better off avoiding discussion that may reveal a defeater, even if the agent has a counter-argument to that defeater; but should be ready to use floating reinstatement as well as simple reinstatement in order to neutralise a defeater raised by the human user. These kinds

of heuristics can be incorporated into a decision-theoretic model of a persuasive agent that interacts with users using natural language (e.g. to promote a healthy diet (Mazzotta, Rosis, & Carofiglio, 2007). Going beyond our specific results, by building up a corpus of argument structures and how they are evaluated, it may be possible to use machine learning techniques to build models that predict how people will react to novel argument structures.

Independently of our specific results, we hope to have convinced the reader that the wealth of scientific methodology from psychology can give a new perspective on the problems raised when formalising argumentation and developing argument evaluation semantics. We hope that our claims and findings can prompt researchers working on the computational modelling of argument to explore new avenues of investigation inspired by, and validated against, empirical evidence from psychology and cognitive science.

We also hope to have excited cognitive scientists about the growing literature on formal models of argumentation. These models, and their associated normative properties, have great potential in complementing existing research on human reasoning, and providing conceptual means for dealing with highly complex inference structures.

Materials

Argument Set 1

- (A) Cody does not fly. Therefore, Cody is unable to escape by flying.
- (B) Cody is a bird. Therefore, Cody flies.
- (C) Cody is a rabbit. Therefore, Cody is not a bird.
- (D) Cody is a cat. Therefore, Cody is not a bird.

Argument Set 2

- (A) Smith does not follow American spelling. Therefore, Smith writes ‘colour’ instead of ‘color’.
- (B) Smith speaks American English. Therefore, Smith follows American spelling.
- (C) Smith was born and brought up in England. Therefore, does not speak American English.
- (D) Smith was born and brought up in Australia. Therefore, does not speak American English.

Argument Set 3

- (A) The car did not slow down. Therefore, the car approached the signal at the same speed or higher.
- (B) Louis applied the brake. Therefore, the car slowed down.
- (C) Louis applied the accelerator instead. Therefore, Louis did not apply the brake.
- (D) Louis applied the clutch instead. Therefore, Louis did not apply the brake.

Argument Set 4

- (A) Stephen is not guilty. Therefore, Stephen is to be free from conviction.
- (B) Stephen was seen at the crime scene at the time of the crime. Therefore, Stephen is guilty.
- (C) Stephen was having dinner with his family at the time of crime. Therefore, Stephen was not seen at the crime scene at the time of the crime.
- (D) Stephen was watching football with his friends in the stadium at the time of the crime. Therefore, Stephen was not seen at the crime at the time of the crime.

Optimizing Learning Environments: An Individual Difference Approach to Learning and Transfer

Daniel M. Belenky (dmb83@pitt.edu)

Timothy J. Nokes (nokes@pitt.edu)

Learning Research and Development Center

Abstract

Prior work has found that the type of learning activity (direct instruction or invention) interacts with achievement goals (mastery or performance-oriented) such that invention tasks can help facilitate mastery goal adoption and knowledge transfer (Belenky & Nokes, 2009). In the current study, we investigated how robust the effect is, and whether explicit manipulations of the task goals can produce a similar effect. We conducted an experiment with 98 college students in which achievement goals were measured, while task goals and task structure were manipulated between subjects. Results indicated that task structure was generally a more effective way of influencing which achievement goals are adopted within a learning activity. However, task goals that promoted an evaluative context interfered with transfer for mastery-oriented learners from invention activities. The results are interpreted in relation to theories of regulatory fit and multiple goal hierarchies.

Keywords: learning; transfer; skill acquisition; motivation; achievement goals.

Student's achievement goals have a large influence on their behaviors and experiences in academic settings. The literature surrounding Achievement Goal theory shows that these goals lead to very different patterns of affect, interest and achievement (e.g., Harackiewicz et al., 2005). However, this literature has not focused on how the goals influence what is learned. That is, although "achievement" is frequently measured as an outcome, it is almost always done at a coarse-grain level, such as final grades in a course. It is not clear how different achievement goals (mastery versus performance) are related to different kinds of learning, such as learning procedural skills, simple facts, or conceptual knowledge.

To begin to address this gap, Belenky & Nokes (2009) examined how achievement goals impact the type of knowledge gained from different kinds of instruction. That study found that mastery-oriented learners do better on transfer measures, regardless of whether the mastery-orientation came from a stable predisposition or whether the open-ended structure of an "invention" task led to mastery-oriented feelings and goals in the specific context. Conversely, performance-oriented learners did better on skill acquisition when the instruction seemed to match their goals, by presenting a well-structured, simple task through direct instruction.

This initial work has provided evidence that task structure interacts with existing achievement goals to influence learning. In the current work we examine whether direct

manipulations of task goals through instructions can change the ways students learn, similar to the effect of task structure. If directly manipulating task goals produces similar effects, it would offer a more direct way of encouraging students towards desired learning outcomes (whether towards transfer or skill). However, it is possible that achievement goals within a learning activity are not under conscious control, and task structure has more influence on how a student engages than instructions that attempt to prompt a particular achievement goal. It is also possible that task structure and task goals operate independently, leading to a three-way interaction in the adoption of achievement goals based on students' prior dispositions. This study explores these possibilities.

Background

Research on achievement goals has focused on two main aims; classifying what the goals are and then correlating those with predictors and outcomes. The prevailing classification is a 2 x 2 framework that has been well-validated (Elliot & McGregor, 2001). This framework separates the evaluative criterion (mastery or performance) from the valence (approach or avoidance), which results in four separable goals (mastery-approach, mastery-avoidance, performance-approach, performance-avoidance). Mastery goals refer to ones in which a person is basing his evaluation on the skill or competence he is trying to develop (that is, in comparison to an expectation or prior ability), while performance goals refer to evaluating oneself based on a normative standard (that is, in comparison to others). Approach goals refer to seeking out positive outcomes, while avoidance goals refer to averting negative ones. For example, a mastery-approach goal is one in which a person is seeking to improve his ability or knowledge, based on an internally-referenced criterion ("My aim is to completely master the material in this class"), while a performance-avoidance goal is one in which a person is seeking to not look bad compared to others ("My aim is to avoid doing worse than other students;" see Elliot & McGregor, 2001). Students can have different levels of each of these goals, and studies have validated that these four goals are separate factors (Elliot & McGregor, 2001). Because we are most interested in studying how different paths of *successful* learning affect what knowledge is gained, our work focuses on mastery-approach and performance-approach goals.

Mastery-approach (MAP) goals have been correlated with a host of positive outcomes, such as intrinsic motivation, interest, better self-regulation, and deeper strategy use.

However, MAP goals are generally unrelated to achievement scores (usually operationalized as exam scores or final grades). Performance-approach (PAP) goals have been correlated with some positive outcomes, such as perseverance, task engagement, enjoyment and topic interest, as well as some negative outcomes, such as test anxiety, poor help-seeking and, most importantly for the current study, shallow cognitive strategies. PAP goals are also positively correlated with achievement scores (see Elliot, 1999 for a review). One potential reason that MAP goals are unrelated to achievement scores but PAP goals correlate positively could be due to the type of knowledge being assessed on achievement measures. Scores on a final exam, for example, may reflect a person's ability to recall factual information (a performance-oriented outcome) more than a deep conceptual understanding (a mastery-oriented outcome).

Belenky & Nokes (2009) examined the possibility that different types of knowledge were being generated due to students' existing achievement goals. This work found that MAP goals led to more flexible use of knowledge on a transfer assessment, while PAP goals led to better procedural skill with a formula. That study also showed that an ill-structured, invention-based learning task promoted mastery-goal adoption. This goal adoption was particularly beneficial for those who entered the study low in MAP goals; this group performed one standard deviation better than low-MAP counterparts who completed a well-structured, direct instruction-based approach.

The paradigm and tasks used in the current work are based on previous work on "Preparation for Future Learning" (Belenky & Nokes, 2009; Schwartz & Martin, 2004). This paradigm allows one to measure a person's ability to use knowledge acquired in one situation to help learn in a new situation. The work that established this paradigm contrasted two types of learning activities, direct instruction and invention (Schwartz & Martin, 2004). The direct instruction condition was similar to a well-structured, "tell-and-practice" style of pedagogy, where a student is shown a method and asked to use it to solve similar problems. The invention activity was modeled on a form of "discovery learning" where students are asked to construct their own knowledge in an open-ended, ill-structured problem. All students were given a subsequent transfer problem on an extension of the concept. Half of the students from each of the group were given a learning resource (a worked example) embedded in the assessment, while half were not (see Figure 1). They found that only those students who had invented and were given the worked example showed large improvements in the ability to solve a transfer problem. Belenky & Nokes (2009) found evidence that this benefit was due, at least in part, to the adoption of different goals. Support for this view was based on a questionnaire given right after the learning activity showing that students given invention activities were more concerned about their understanding of the concepts than those given tell-and-practice activities, as well as a benefit in transfer

Figure 1. The general Preparation for Future Learning paradigm which measures the ability to transfer from an initial learning experience to a later one.

performance among those students who entered the study low in MAP goals but performed invention activities as opposed to those who performed tell-and-practice activities.

The current study further explores the issue of how achievement goals influence and are influenced by different task structures, by using the same tasks and adding task instructions to try and directly manipulate the achievement goals students adopt. We have evidence that goal adoption, whether due to individual dispositional differences or task structure, influences the form of the knowledge gained from instruction. The robustness of this effect is being examined, by adding the factor of task instructions to the framework.

Hypotheses

We are investigating how explicit, task-based goal instructions influence the effects of existing achievement goals and task structure on learning and transfer. We predict that the task structure will have a larger effect than the task-based instructions on which achievement goals students adopt and their impact on learning and transfer. However, there are several possibilities for interesting interactions between task structure, task goals, and existing achievement motivations. We are most interested in exploring whether there is evidence for a "multiple-goals" framework (Harackiewicz et al., 2002) or a "regulatory fit" viewpoint (Higgins, 2005).

The multiple goals hypothesis states that a mix of performance-approach and mastery-approach goals is optimal for learning (Harackiewicz et al., 2002). If this hypothesis is correct then we would expect that crossing mastery and performance goals would promote the best overall learning. Alternatively, a "regulatory fit" view states that the alignment of task structure, task-based goals and dispositional orientations should facilitate the best learning (Higgins, 2005). This suggests that matching students' goals with instructions that support pursuit of those goals would improve learning, (e.g., mastery-oriented achievement goals with invention tasks and mastery-oriented instructions). If this is the case, we would also expect to see that incongruous goals would harm learning. We will examine these possibilities by assessing three-way interactions

between existing goals, task structure and instructions on different learning outcomes.

We also predict replications of our basic prior findings that invention activities promote more mastery-oriented learning behaviors and feelings than tell-and-practice. We also predict that existing mastery-approach goals will lead to better transfer, while performance-approach goals will lead to better performance on a skill measurement.

Methods

This study closely followed the methods and materials of prior studies (Belenky & Nokes, 2009; Schwartz & Martin, 2004). Participants completed a pre-test, went through a series of learning activities on basic statistical concepts, and then took a post-test in a 2-hour laboratory session. They were given questionnaires at the beginning, middle, and end of the experiment.

Participants

Ninety-eight undergraduates from the University of Pittsburgh participated in this study ($M = 19.4$ years old, $SD = 2.5$ years) in exchange for course credit.

Design and Materials

This study had a 2 (task structure: invention or tell-and-practice) \times 2 (task goal: mastery-oriented or performance-oriented instructions) between-subjects design. Materials were presented as packets in binders. These packets consisted of an initial questionnaire; a pre-test; learning activities (with an activity questionnaire after the first one); a post-test; and final questionnaires, including a demographic sheet.

Learning Materials

The learning materials consisted of one activity on mean deviation, instruction on the correct calculation of mean deviation (a narrated PowerPoint video), and then a new activity on standardization. The first learning activity presented four different data sets representing the spread of a number of pitches thrown by different pitching machines. The students' task was to decide which of the machines is the most reliable. The invention and tell-and-practice students both attempted this problem, but the instructions each received was different. The tell-and-practice group was given a worked example demonstrating how to calculate mean deviation immediately prior to attempting to solve this problem. The invention group was not given this worked example, and was instructed "Your task is to invent a procedure for computing a quantity that expresses the variability for each of the pitching machines and decide which is most reliable. There is no single way to do this, but you have to use the same procedure for each machine, so it is a fair comparison." Both groups were given access to scrap paper and a calculator during this activity.

The video demonstrated a brief introduction on variability before walking through the calculation of mean deviation in a worked example. This was followed by two simple problems to work on, with solutions demonstrated to make sure students understood the basics of the formula.

The structure of the standardization activity was similar to the mean deviation activity. The invention group was asked to evaluate which of two world records was "more shattered," given two small data sets and the corresponding world record for each. The tell-and-practice group was given the exact same problem to solve, but was first shown how to graphically arrive at a solution, by divvying up a visual representation of the distributions through a worked example.

We manipulated task goals through instructions. Immediately below the tell-and-practice or invention instructions, participants saw instructions about the purpose of the task. These were constructed to spur participants towards either a mastery or performance orientation while working on the learning activities. The motivation goal instructions were modeled on previous work that had experimentally manipulated goals (i.e., Elliott & Dweck, 1988; Elliot & Harackiewicz, 1996). The mastery goal instructions were: "Many people see problems like this one as a challenge, and feel like they are developing their skill to solve these types of problems. While working on this problem, you may make mistakes and feel a little confused at times, but in the end you will have learned some things and developed your skill to solve problems like this one." The performance goal instructions were: "This problem assesses your mathematical ability. People who can solve this problem generally have the capability to solve similar problems. While working on this activity, you can gauge how good you are at these types of math problems." These were presented underlined, to make them more salient.

Test Materials

The pre-test consisted of three items: a skill measure, a data representation problem, and a transfer problem. The post-test contained isomorphic versions of these problems, as well as an adaptive use and a qualitative reasoning problem. We will only focus on the transfer and skill measures here. The skill measures presented small data sets and explicitly asked the participants to calculate mean, mode, median and mean deviation. The transfer problems were both word problems that presented descriptive statistics for two data distributions and one exceptional score from each, and asked which individual score was more impressive. While similar to the standardization activity, this problem assesses transfer because it requires reasoning from descriptive statistics, not raw data, and because simpler heuristic processing would lead to an incorrect answer (i.e., reasoning about range, or because one value is higher than the other).

The skill measure was scored dichotomously as a 0 if incorrect, while a 1 was awarded if the student flawlessly used the formula. All other problems were coded as a 0 if incorrect, 1 if conceptually correct but there was a computational error, and 2 if the answer was conceptually and computationally correct. For the transfer problem, this meant calculating standardized scores and using them to decide which value was more impressive.

The test also included a worked example on how to calculate a standardized score. This was presented just like

the other test problems, and described a situation in which one would want to calculate a standardized score to compare values from different samples. The text then introduced the formula to do so and computed the values for the data presented. This was followed by a second, very simple data set, and asked the students to use the formula on these data. The worked example always came at least two problems before the transfer problem, so if a student used the formula on the transfer problem, it was because they noticed that it applied and could recall it, not due to temporal contiguity.

Motivation Measures

To assess achievement goals, we used the Achievement Goal Questionnaire (AGQ; Elliot & McGregor, 2001). This 12-item scale has 3 items for each of the 4 achievement goal constructs. We focus only on mastery-approach and performance-approach goals in this study. The questions were phrased to be specifically about math classes, and were assessed on a 7-point Likert scale. Cronbach's alphas for each of the scales was high (MAP = .839, PAP = .932). There was also an activity questionnaire, which was the same as that used in Belenky & Nokes (2009). This 8-item measure asked about student's focus and affect while working on the first learning activity. At the end of the study, the participants completed additional questionnaires – the AGQ again, and a questionnaire we developed to assess how students reflected on and our goal manipulations.

Procedure

The study was run in groups of up to six participants in a two-hour laboratory session, with all participants working individually. Inside the packet was: an initial questionnaire; a pre-test; a learning activity; the activity questionnaire; space to work on problems presented in the video; another learning activity; a post-test; a final set of questionnaires; a demographics sheet. Participants took as long as they needed to complete the questionnaires, with no one taking longer than three minutes for any one questionnaire. Both learning activity and the video took fifteen minutes each. Participants were given five minutes for each test item.

Results

Our hypotheses focused on the conceptual replication of earlier findings, as well as exploring how explicitly manipulating task goals and task structure would influence learning. First, we assess whether task structure and instructions influenced students' self-reported experiences during the learning activity. Then, we examine the competing "regulatory fit" and "multiple-goals" hypotheses

by looking at the interactions of existing goals, learning tasks, and instructions.

Motivational effects on questionnaires

On the activity questionnaire, administered directly after the first learning problem, there were telling differences between responses from the invention and tell-and-practice groups (see Table 1). Namely, students who invented felt more concerned with understanding, challenged, and frustrated, $F_s(1, 94) > 6.87, p_s < .01$. While frustration is generally considered a negative outcome, it may signal to a student a lack of understanding that drives further cognitive engagement. Notably, there were no differences due to our task goal manipulation, nor interactions. This is evidence that the structure of the task led to very different experiences for the learner, both in terms of affective response and goals adopted, and that this structure has more influence on goal adoption than explicit instructions about the purpose of the task.

We also asked a similar set of reflective questions at the end of the experiment. The only observed significant differences were that students who completed invention tasks reported being able to be more creative, while those who received mastery instructions reported enjoying the activity more. There was also an interaction between the experimental manipulations on the item "it was a challenge to come up with the correct solution." This interaction was driven by the lower ratings on this item provided by those who completed the tell-and-practice activities with performance- oriented task goal. This manipulation seems to have led students to feel less challenged, even compared to the students who completed the same activity but were told that the task could help them improve. The results from the reflective questionnaire seem to suggest that manipulations of goals do not produce large differences in students' conscious, reflective experience of learning.

Interactions

We predicted that we would see three-way interactions between existing achievement goals, task structure, and task goals, specifically looking at performance-approach goals (PAP) when considering skill acquisition and mastery-approach goals (MAP) for transfer. To assess the effect of existing achievement goals, we performed a median split within each experimental group on the performance-approach and mastery-approach construct scores, based on the initial questionnaire, administered at the start of the experiment. We used the mean deviation skill measurement as the dependant variable in a 2 (task structure) x 2 (task

goal instructions) $\times 2$ (high or low performance-approach) ANOVA. There was no effect of instructional goal, $F(1, 88) < 1$, *ns*, but there was an effect of task structure, $F(1, 88) = 4.09$, $p < .05$, with tell-and-practice leading to better performance (77% correct) than invention (57% correct). There was also a significant effect for PAP goals; those high in PAP goals (77% correct) did better than those who entered low in such goals (56% correct, $F(1, 88) = 4.59$, $p < .05$). However, the experimental manipulations did not interact with existing goals, nor was the three-way interaction significant, $F_s(1, 88) < 2.48$, *ns*. For learning a simple skill, the dispositional goal of being able to perform leads to better acquisition, as does a well-structured learning task.

To look at transfer, an adjusted score was calculated. This value is the post-test score minus pre-test score on two isomorphic transfer problems, which were counterbalanced. Participants who were at ceiling on pre-test were taken out of subsequent analyses of transfer, as they already had knowledge of the formula, and when it applies. No effect of either task structure or task goals on transfer performance was found. Invention activities produced the same level of transfer as tell-and-practice, as did mastery task goals and performance task goals, and there was no interaction between these factors, $F_s(1, 70) < 1.16$, *ns*. However, students high in MAP goals did better ($M = 1.36$, $SD = .84$) than those low in MAP goals ($M = .90$, $SD = .94$) on the measure of transfer, $F(1, 70) = 5.85$, $p < .05$. When paired with the result that PAP goals lead to better skill, this is clear evidence that existing student goals affect the type of learning students exit instruction with. There was also a significant three-way interaction, $F(1, 70) = 4.36$, $p < .05$ (see Figure 2). This interaction is due to the invent structure and performance task goals condition behaving differently than all of the other conditions in terms of the effect of existing MAP goals. In the other conditions, high MAP goals produce better transfer than low MAP goals, as per the main effect. However, within the invention/performance-oriented cell, those low in MAP goals did slightly better than those high in MAP goals ($M_s = 1.18, .9$, $SD_s = .98, .88$, respectively). It appears that an ill-structured environment like the invention activity, when presented in an evaluative

context, changes the pattern of learning a mastery-oriented student might normally engage in, harming their ability to flexibly transfer their knowledge.

Discussion

This study examined whether explicit task goals would affect learning the same way task structures have been shown to. The evidence shows that they do not. Task structure was a bigger determinant in the learning outcome, as evidenced by the main effect of a well-structured domain helping with skill acquisition, and the difference in goal adoption on the activity questionnaire, which showed differences based on task structure, but not based on the task goals received. It seems that telling students which goal to adopt is not a particularly effective way to change learning behaviors or affect, and that task structure is a better way to change a student's focus during an instructional event.

The results provide strong evidence that existing student achievement goals change what a student learns during the course of instruction. Those high in performance-approach goals did better on skill measures, regardless of which task structure they learned with, while those high in mastery-approach goals did better on the transfer measure. These differences on their own are illuminating in light of the null effects for mastery-approach goals on achievement measures (see Harackiewicz et al., 2002). This may be due to the types of measures used when achievement is measured in schools. A grade on the test at the end of the semester may reflect factual knowledge that a performance-oriented student has been more focused on attaining than the deep understanding a mastery-oriented student focused on.

Finally, this work also examined whether having multiple goals would help one to learn, or if incongruous goals would produce a poor "fit" and interfere with successful learning. Within a given outcome (i.e., skill or transfer), we do not see evidence that multiple goals are best. On the skill measure, we see no interaction between existing goals, task structure and instructional goals. For transfer, we see evidence for a "regulatory fit" model, where a task goal that did not fit with the task structure and an existing achievement goal harmed learning. The focus on ability created by performance-oriented instructions may have

changed the way in which these students would have normally processed the material, which, based on the performance of their equivalent group who received mastery-oriented instructions, and from our prior study, would have performed much better. The evaluative context brought on by the performance instructions appears to have fundamentally changed the way these students engaged in the learning activity, producing worse transfer. Though we have discussed this in terms of regulatory fit, this adverse effect could also be due to anxiety, or the use of simpler learning strategies related with performance goals (Elliot, 1999).

Conclusion

The study of student motivation has much to offer researchers focused on *how* students learn. It seems naïve to believe that the goal a student has in a learning environment does not influence the form and utility of the knowledge generated, and this line of work is bearing this out empirically. Specifically, research has found that the way information is represented and processed will have an effect on how that information is used to solve new problems and learn new concepts (e.g., Nokes & Ohlsson, 2005). A student's goals for a learning environment can be a catalyst for different types of processing and representations, as demonstrated by performance-approach goals predicting performance on measures of skill and mastery-approach goals predicting performance on transfer tests.

That we can reliably show these differences in a laboratory setting seems to be evidence that these results have high external validity, as student goals should be even more salient in authentic academic environments than in the lab. Also, while our attempts to manipulate these goals did not produce effects similar to existing achievement goals, stronger interventions conducted over longer periods of time may have very profound effects on student learning, especially when they succeed in changing the goal itself (i.e., Blackwell, Trzesniewski, & Dweck, 2007).

Within a task, it appears that making the learning goals, task structure, and instructions as coherent as possible promotes better learning. Those high in mastery-approach goals who invented were disrupted by instructions which placed the task into a more evaluative context. While the results within a given learning measure (e.g., skill or transfer) do not support a "multiple-goals" viewpoint, the study as a whole does. The separation of skill and transfer seems to illustrate one potential mechanism in support of a multiple-goals viewpoint, which claims that a combination of performance-approach and mastery-approach goals is optimal (Harackiewicz et al., 2002). Our work illustrates that having both goals would allow for the development of efficient skills at routine aspects (i.e., performance-approach goals lead to improved formula use) as well as innovative ability to use the underlying concept (i.e., mastery-approach goals lead to improved transfer). This combination of efficiency and innovation is hypothesized to be necessary for adaptive expertise, a desired outcome of education

(Hatano & Inagaki, 1986). If the multiple-goals viewpoint is correct, a critical question left to examine is if students flexibly switch between these goals, and how they do so. It may be that the time course is a critical factor in explaining why, across a semester, multiple goals may be optimal. A more fine-grained, microgenetic study of when and how each goal contributes could shine light on this possibility.

Future work should also further explore the mechanisms by which achievement goals affect the type of learning done. It could be due to different representations used and formed and/or different types of learning strategies (i.e., self-explanation versus rehearsal). Achievement goals remain an important individual difference to consider, and one that could greatly impact how we can use cognitive science to improve education.

Abstract

Prior research has found that while people are generally quite poor at recognizing when a new situation is structurally similar to a known case, comparison of two analogous cases greatly improves the likelihood of achieving such recognition. Our study examines the effects of varying the similarity between these compared cases, both featurally and structurally. We find that between-case similarity has a significant impact on transfer, and that these effects interact with characteristics of the learner.

Introduction

Our minds are filled with valuable knowledge that we are unable to use. This is particularly true of what might be the most valuable knowledge of all: general principles that can be applied across a wide range of situations. Research in analogy has repeatedly found that principles that are learned in one context often fail to be retrieved when an individual is confronted with a deeply related situation that differs in concrete or contextual ways (e.g., Gentner, Rattermann & Forbus, 1983; Gick & Holyoak, 1983; Ross, 1984). For example, in Gick and Holyoak's classic (1980; 1983) analogy studies, individuals attempting to solve an insight problem routinely failed to recognize that the problem was analogous to one they had been taught earlier (unless given an explicit hint), and therefore failed to make use of their relevant knowledge. For both theoretical and practical reasons, researchers are keenly interested in finding ways to overcome this kind of impediment.

One approach that has shown great promise is simply asking learners to compare two different examples of a principle (e.g., Gick & Holyoak, 1983; Loewenstein et al, 2003; Gentner et al, 2003; Rittle-Johnson & Star, 2007). For example, Loewenstein and colleagues (2003) conducted research with MBA students enrolled in a course on negotiation. Some of the students compared two specific cases involving a "contingency contract," a useful but sometimes counterintuitive negotiation technique. Other students received the same two cases, but read and analyzed them separately, without any explicit comparison. The researchers found that students who had compared cases were nearly three times more likely to apply the relevant principle to a new case than those students who had analyzed the cases separately. Consistent with prior findings of poor analogical transfer in general, the students who had read but not compared cases performed no better on the transfer task than those who had received no training.

Results such as these point to the potential power of comparison. The most common explanation for these effects is that structural alignments generated when comparing two concrete examples serve to highlight meaningful structural commonalities between them, while simultaneously taking the focus away from elements that are extraneous or irrelevant (e.g., Markman & Gentner, 2000). This, in theory, allows a more explicit representation of the structure or principle itself, making it easier to recognize when it arises in new situations.

However, a great deal remains unknown about the factors that make comparison successful in transfer. Particularly, there is a surprising lack of research on how the relationship between the *compared* cases (such as their similarity) may influence the representations that are formed during comparison. Given that the similarities and differences between the cases are the basis for the knowledge that comparison is presumed to generate, this would seem to be a critical area for study.

For instance, will transfer to new situations be best when the features of the compared cases are relatively similar to one another, or when their content is more dissimilar? There are empirical reasons to predict either of these outcomes. Evidence for "conservative generalization" (Medin & Ross, 1989) suggests that the comparison of two examples that share significant surface commonalities may lead to a representation in which many of these irrelevant features are retained. If so, one of the primary assumed benefits of comparison—a more general representation—may be lost. Comparison of dissimilar cases may therefore lead to representations with broader generalizability. On the other hand, comparisons between overtly similar cases are likely to be less cognitively demanding, and may therefore help to "boot-strap" early learning processes. Consistent with this possibility, Kotovsky and Gentner (1996) found that young children were better able to perform matches on the basis of abstract structural commonalities after performing a similar task involving more perceptually similar stimuli.

A related issue is the effect of the similarity of the structures themselves. Most studies focusing on comparison and transfer have made use of cases with essentially identical relational structures. However, there are reasons to suggest that structural variation may be beneficial as well. For instance, some research has shown that comparing two "near-miss" cases (Winston, 1975), which are identical except for a crucial structural difference, may improve transfer (e.g., Gick & Paterson, 1992). This approach may be particularly effective when an individual needs to

discriminate examples of a specific structure from other non-matching cases, as is generally the case in the real world.

The current study examines the impact of both featural and structural similarity in compared cases. Additionally, unlike previous studies, our design requires participants to discriminate different kinds of structures, which may be a more ecologically valid way of assessing the benefits of comparison. Finally, in contrast to previous research that has concentrated on analogical transfer in college-age students, our study uses 7th and 8th grade students in a science class. Children may be more prone to concrete interpretations of scenarios, and thereby miss connections between deeply related scenarios. Given the importance of students appreciating deep principles (e.g. diffusion, order from randomness, and our current topic of interest – feedback loops), it is particularly important to know how children's understanding of principles is influenced by superficial and deep similarities between scenarios.

Experiment

Participants

90 students from a public middle school participated in this study, as part of their regular class time in a General Science course. The group included both 7th- and 8th-grade students ($n = 49$ and 41 , respectively) from six class periods. Roughly half of the students ($n = 47$) were part of the school's Accelerated Learning Program (ALPs), which is composed of students passing a science achievement test.

Materials and Design

We led the students' class sessions for two days. The first day involved general instruction on the concept of complex systems, including several real-world examples of such systems. This instruction did not include any specific discussion of feedback systems, our target principle. The experiment itself was conducted on the second day.

The overall design of the experiment was as follows: Brief instruction on feedback systems was followed by a pre-test, in which students classified specific scenarios as examples of positive or negative feedback, and answered inference questions about those cases. Students then interacted with two computer simulations, each of which could vary in terms of its content domain (biology or economics) and the type of feedback system it represented (positive or negative). These variations represented the experimental manipulation in the study. Afterwards, students explicitly compared and contrasted the simulations they had completed. Finally, the classification and inference task was administered a second time, as a post-test.

The initial instruction included brief descriptions of positive and negative feedback systems, and included an example of each. These definitions and examples were available to students throughout the experiment.

Pre-test and post-test The pre-test and post-test materials were designed to assess students' understanding of feedback systems, particularly the ability to discriminate positive and negative feedback systems. These materials included eight brief scenarios (averaging 50 words apiece), each describing

a real-world phenomenon. Four of these scenarios represented positive feedback systems, and four represented negative feedback systems. For example, one scenario was the following:

The lynx is a natural predator of the hare. When lynx populations are small, hare populations increase rapidly. This makes the lynx population increase, since food is plentiful. However, a large lynx population reduces the number of hares, which ultimately brings the lynx population back down. This cycle repeats every ten years or so.

After reading each scenario, participants classified it as an example of either a positive or negative feedback system by selecting a response from a 5-point scale: *Definitely negative, Probably negative, Don't know, Probably positive, Definitely positive*. They also answered one multiple-choice inference question about each scenario. For example:

As the lynx population decreases, the population of rabbits should: [Increase / Decrease]

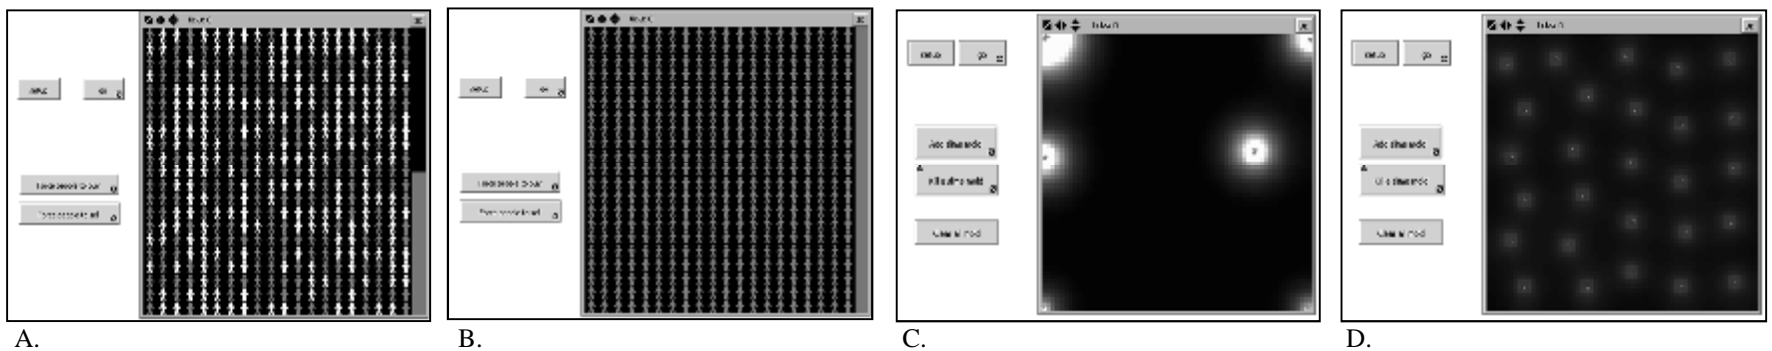

Identical items were given at pre-test and post-test. However, in order to minimize explicit memorization and reference to previous answers, students were not informed about the post-test until later in the experimental session.

Computer simulations. All students interacted with two computer simulations demonstrating feedback behavior. These were implemented in NetLogo (Wilensky, 1999), a software package for developing agent-based simulations. Each of the simulations depicted either a positive or a negative feedback system, and each instantiated one of two domains: biology (specifically, interacting slime mold cells) or economics (a simple stock market). This resulted in four relevant simulation types: Biology Positive, Biology Negative, Economics Positive, and Economics Negative. Two versions of each type were created, differing in cosmetic ways. This allowed some students to interact with two different versions of the same type without repeating an identical simulation. The main theoretical focus of our study was on the effects of the similarity between simulations; that is, whether the domain and/or feedback type were the same or different for each participant.

Each simulation began with a brief description of its behavior. For instance, the Economics Positive simulation presented the following introductory description:

*"This simulation involves a small economic system. People in this system buy stocks, and they pay attention to what other people are doing. When they see someone else buying a stock, they are more likely to want to buy it themselves. When they see someone else **selling** a stock, they are more likely to sell it themselves. This creates a **POSITIVE FEEDBACK LOOP**. People buying the stock leads to even **more** people buying it. People selling the stock leads to even more people **selling** it."*

The presentation of the simulation was strictly guided although interactive, instructing students to perform specific actions and then to observe the resulting effects

Box 1: Simulations.

The **economic** (stock market) simulations begin (Frame A) with the 420 agents evenly divided between owning the stock (dark; red in the original simulation) and not owning the stock (white). A bar on the right side of the screen indicates the proportion of the agents currently owning the stock. While the simulation is running, each agent will buy or sell the stock with some specified probability. In the Positive Feedback version of the simulation, the probability of buying rather than selling is a positive function of the overall ownership of the stock. As more agents own the stock, the likelihood of new agents purchasing the stock increases. Conversely, as fewer agents own the stock, the likelihood of other agents selling the stock increases. Because of this, random initial fluctuations in stock ownership tend to be amplified over time, and the system quickly moves toward the extremes, resulting in either ownership by all agents or ownership by no agents (Frame B). In the Negative Feedback version, the probability of an agent buying the stock is a *negative* function of overall ownership. Therefore, increased overall ownership makes agents more likely to sell the stock, while decreased overall ownership makes agents more likely to buy. This tends to create homeostasis in the system. As the ownership of the stock begins to increase or decrease, the market quickly “corrects” itself and maintains an even proportion of owners and non-owners (as in Frame A).

In the course of the simulation, students are instructed to force a proportion of the agents to buy or sell the stock. This is accomplished by selecting the appropriate button on the left side of the screen, then clicking and dragging across the agents. These interactions serve to highlight the way that the system responds to small imbalances, by either amplifying them (positive feedback) or reducing them (negative feedback). Additionally, students are explicitly reminded at one point during the simulation that it is an example of a positive or negative feedback system. For instance, those in the Negative Feedback version were told: “Observe how this system is a negative feedback loop. People buying the stock leads to other people selling it, and people selling the stock leads to other people buying it. This tends to keep the system in balance, without allowing too many people to own or not own the stock at once.”

The **biological** (slime mold) simulations begin with 27 agents (mold cells) randomly distributed on the screen. While the simulation is running, each cell moves about the screen probabilistically, and secretes a chemical that remains for a short period of time in its current location. In the Positive Feedback version, cells are attracted to this chemical, and their likelihood of moving toward a location increases with the quantity of the chemical there. Over time, this results in the cells grouping into a small number of clusters (Frame C), since more cells in a given location leads to a greater amount of the chemical there, attracting even more individuals. (Chemical density is reflected by the brightness of a location). In the Negative Feedback version, cells tend to be repelled by the chemical, and are therefore more likely to move to locations where less of the substance is present. This results in the cells attempting to maintain a maximal distance from one another, leading to a relatively homogenous distribution across the field (Frame D).

During the simulation, users are instructed to add additional mold cells to the system, by selecting the “Add slime mold” button and clicking in the desired location on the screen. They are asked at various points to observe the relative effects of clustering these new cells close together versus spreading them out in the space. They are also reminded at one point that the simulation is an example of positive or negative feedback, and why. For example, users in the Positive Feedback version were told: “Observe how this system is a positive feedback loop. Cells produce the chemical in a certain location, which brings other cells to that location, which leads to even *more* of the chemical there. This tends to bring the cells together into large clusters.

on the system. For example, students in the Economics simulations were instructed at various times to force a proportion of the agents to buy or sell the stock and observe the results. At one point during each simulation, students were explicitly reminded of which type of feedback system the simulation portrayed (positive or negative), and specifically why this system's behavior reflected that feedback type. After being guided through several relevant actions, students were encouraged to interact freely with the system. Each simulation lasted approximately five minutes. Box 1 provides a detailed description of the simulations.

After completing both simulations, students were instructed: "Now we would like you to compare the two simulations that you just interacted with. Please write about the ways in which the two simulations were similar and different from each other, especially in terms of the way that they behaved." There was no time restriction on the comparison phase. After comparison, all students completed the classification and inference task again.

Predictions. The primary variable of interest is the change in performance between pre-test and post-test. There are several potential predictions about how this variable might be affected by the comparisons that students make. First, prior work on the effects of comparing analogous cases (e.g., Loewenstein et al, 2003) leads us to expect an overall improvement in classification and inference performance, reflecting generally stronger representations of the principles underlying feedback systems. Given that all students are explicitly comparing cases that share a feedback structure, it seems likely that their understanding of such structures should improve on average.

We also predict that the *kinds* of comparisons made may affect performance. Comparing two systems involving the same type of feedback (i.e., both positive or both negative) could lead to a bias in the interpretation of new cases. For instance, a student comparing two simulations involving negative feedback may be more likely to classify new cases as examples of negative feedback at post-test.

Another way in which the kind of comparison may matter is in whether it provides an appropriate balance between the *compatibility* (ease of alignment) and the *generalizability* of the two simulations. As discussed, the similarity of the compared cases may have two opposing influences on transfer. Cases that are more similar to one another may be easier to align, and may therefore provide a more straightforward basis for learning about their shared underlying structure. On the other hand, highly similar cases may artificially restrict students' representations of the relevant principles, leading them to only recognize the structure in new situations that are concretely similar to the learned cases. Less similar comparison cases may therefore lead to better generalization of the principles. We predict that learning will be optimal when dissimilarity on one dimension is "scaffolded" by relatively high similarity on another dimension. In the current context, we would predict relatively good performance from those comparing different feedback types in the same domain (e.g., Biology Positive and Biology Negative). In this case, the relevant differences in the positive and negative systems should be particularly

highlighted because the concrete features of the simulations are otherwise highly similar. Likewise, strong performance is predicted for individuals comparing the same feedback type across different domains (e.g., Biology Positive and Economics Positive), since the same underlying principles can be observed across more diverse contexts, presumably supporting broader generalization.

We are also interested in potential effects of individual differences between students, and how these may interact with comparison. For instance, it is possible that students in accelerated classes will tend to focus more on the underlying principles of the simulations, and will therefore be less influenced by perceptual variation between them.

Results

Our data yielded several informative findings. Surprisingly, however, most of our initial predictions were not borne out. We first examined the overall improvement of the students between pre-test and post-test. Calculating improvement simply as post-test performance minus pre-test performance, there was no evidence of any improvement on average, either in classification ($M = .03$, $t(89) = 0.52$, *n.s.*) or inference ($M = .01$, $t(89) = 0.78$, *n.s.*).

Next, we examined possible bias effects in classifications. Specifically, we predicted that individuals who had compared two cases representing the same kind of feedback system (i.e., either two positive cases or two negative cases) would become more disposed to classify new cases as instances of that particular type. For each of these students ($n = 43$), we calculated bias as the shift toward whichever end of the classification scale matched the type of feedback cases that the student had compared. This measurement did not differ from zero ($M = .01$, $t(42) = 0.23$, *n.s.*).

There was also no evidence for the kind of interaction between structural and featural similarity that we had predicted (analysis below). Neither of the conditions that included one similar dimension and one dissimilar dimension showed any improvement (see Figure 1). However, our analysis did reveal several significant results.

We conducted a 2 (Feedback similarity: Same v. Different) \times 2 (Domain similarity: Same v. Different) \times 2 (ALPs: Accelerated v. Regular classes) ANOVA on the improvement scores. The omnibus test indicated reliable differences between groups for the classification task, $F(7, 82) = 2.27$, $p < .05$. (No effects were found for the inference task on this or any other analysis discussed). Specifically, the test revealed main effects for both Feedback similarity ($F(1, 82) = 4.02$, $p < .05$) and Domain similarity ($F(1, 82) = 6.18$, $p < .05$). In both cases, improvement was greatest when dissimilar cases were compared. Interestingly, for both dimensions of similarity, performance actually decreased numerically at post-test when similar cases were compared (Feedback: similar = $-.07$, dissimilar = $.13$; Domain: similar = $-.08$, dissimilar = $.16$). This fact explains the absence of the predicted improvement in overall performance: increased scores associated with comparing dissimilar cases were largely offset by *decreased* scores resulting from the comparison of similar cases. As seen in Figure 1, the greatest improvement was seen in students who compared cases involving both different feedback

Figure 1: Post-test improvement, by condition

types and different domains, while the least improvement (actually negative) was seen in those whose comparisons involved the *same* domain and feedback type. Improvement by those in the Different-Different condition was reliably greater than zero ($M = .26$, $t(19) = 2.22$, $p < .05$). Those in the Same-Same condition were marginally less than zero ($M = -.21$, $t(21) = 1.79$, $p < .10$). No effect of membership in the accelerated class was observed ($F(1, 89) = 0.33$, $n.s.$).

The influences of structural and featural similarity therefore appear to reflect independent main effects. However, these two effects did not apply equally across all individuals. Interestingly, students in non-accelerated classrooms showed large effects of Domain similarity ($t(42) = 2.83$, $p < .01$), but no evidence of any influence from the similarity of the feedback types that were compared ($t(42) = 0.04$, $n.s.$; see Figure 2). In contrast, the ALPs students were influenced by Feedback similarity ($t(46) = 2.38$, $p < .05$) but not Domain similarity ($t(46) = 0.38$, $n.s.$).

Discussion

Several conclusions are suggested by these data. First, the results are consistent with previous characterizations of explicit comparison as a powerful cognitive process that may have an important impact on the acquisition of generalizable principles. Under the right conditions, participants in our study improved reliably in their ability to classify new cases, even in very dissimilar domains. However, our data also suggest that the situation is more complex than is generally proposed, and that comparison is not uniformly beneficial. In fact, on average, explicit comparison by the students was not associated with any improvement at all at post-test. Under some circumstances, there were even trends suggesting that students might be negatively impacted by the comparison process (although these effects were not reliable, they were large enough to effectively offset any overall benefits of comparison). These results highlight the importance of exploring the comparison process more deeply, and attempting to establish the factors that influence comparison-based learning. The remainder of our findings begin to address these issues, exploring aspects of both the compared materials and the learners themselves.

Our study varied both the structural similarity (whether the systems involved the same or different feedback types) and the surface similarity (same versus different content

domain) of the compared simulations. We predicted that learning would be optimal when dissimilarity along one dimension was “balanced” by higher similarity on another dimension, which we believed would facilitate alignment while still highlighting important structural features. This prediction was based in part on the approach that has generally been taken in the literature: either presenting the same underlying structure in dissimilar contexts (e.g., Loewenstein et al, 2003), or using “near-miss” cases involving the same content but slightly varying the relevant structure (e.g., Gick & Paterson, 1992). In contrast to our expectations, however, we found that post-test improvement was greatest when the cases were less similar to one another on both dimensions of similarity.

Of course, it is important not to over-interpret the results from one task and set of materials. Each dimension was only tested at two levels, one of which was very high similarity. It is possible (even likely) that these effects do not reflect a simple linear relationship between dissimilarity and transfer, but that there is in fact some optimal similarity level beyond which learning and transfer will decline. Regardless, our results do clearly indicate that the similarity of the compared cases—and not simply the similarity between the learning and transfer cases—is a critical factor influencing whether or not relevant knowledge will be successfully learned and applied. Furthermore, our results highlight the importance of using materials that will maximize the generalizability of the learned representations, and suggest that this factor may often be more important than attempting to facilitate alignment through high similarity.

Perhaps the most interesting—and challenging—finding from our study is the way in which properties of the comparison cases appear to interact with individual differences between learners. Transfer by the students in accelerated classes was influenced by the structural similarity between the cases, but not at all by the similarity of the domains involved. In contrast, structural similarity had no impact on students in regular classes, but learning in these individuals was significantly affected by domain similarity. This finding raises important issues about the effects of comparing cases.

The benefits of comparison are generally attributed to its ability to focus attention on relevant aspects of cases while

Figure 2: Post-test improvement for accelerated and regular classes.

backgrounding less relevant features. This is, in fact, a mechanism that likely frequently occurs. However, it is important to be mindful of the ways in which differences in individuals' representations of the cases will influence which aspects of the situations are highlighted, and to recognize that these do not always correspond with those that the experimenter may consider "relevant." While membership in the accelerated classes is certainly based on a number of interrelated factors—motivation, achievement, intelligence, ability to focus—it is clear that some difference between the groups is causing them to attend to different aspects of the simulations. These differences appear to have a stark impact on the effects of comparison.

Although more work will be necessary to establish the exact basis of these differences, it seems likely that the ALPs students are better able to look past the immediate surface features of a simulation, and to focus instead on its underlying structural relationships. There are many reasons that this might be the case. For instance, these individuals might be coming to the task with richer background knowledge about the systems that are being presented, and therefore have more cognitive resources available for learning. Consistent with this explanation, students in the accelerated classes had reliably greater performance at pre-test, prior to the primary instruction ($t(89) = 4.60, p < .001$). It is also possible that these students have adopted different learning strategies, and are more likely to view all instructional cases as examples of some relevant principle rather than simple facts to be learned independently. Bassok and Holyoak (1989, Experiment 3) found that individuals appeared to acquire the exact same material more concretely or more abstractly based on the specificity of the context in which it was presented. It is possible that successful students have learned to take advantage of this cognitive flexibility by deliberately treating new materials as instantiations of deeper principles, rather than ends in themselves. Previous research has found that experts tend to weigh structural similarities more than superficial similarities (Novick, 1988). The current results extend this finding; even non-experts that are generally high achieving in science show similar tendencies. As such, there appear to be domain-general individual differences in sensitivity to structure that go beyond expertise in a particular domain.

Future research will provide more insight into the exact processes underlying these differences, but our results make clear that characteristics of the learner must be considered when using comparison as an instructional tool. As our data show, cases that lead to reliable gains in one population may foster no improvement at all in another (even very similar) group.

Conclusions

Our knowledge is only valuable to the extent that we are able to make use of it. In previous research, the simple act of comparing two analogous situations has been shown to be extremely valuable in this regard, freeing up concepts that were otherwise bound to a specific context and allowing them to be employed in a much wider range of situations.

The current research shows, however, that these processes may interact in complex and unexpected ways with the

features of the cases that are compared and with individual differences in the learner. Our results begin to establish some of the factors that influence the efficacy of comparison, and point the way to future research that may further help us take advantage of this powerful cognitive tool.

Abstract

Achieving and understanding effective transfer of learning requires a careful analysis of the hidden knowledge and skills to be transferred. We present an experiment that tests a subtle prediction of such an analysis. It concluded that a critical difficulty in students' learning to translate algebra story problems into symbolic expressions is in learning the grammar of such expressions. We hypothesized that exercises requiring students to substitute one algebraic expression into another would enhance students' algebraic grammar knowledge. This hypothesis led to a counter-intuitive prediction that learning to symbolize story problems could be better enhanced through practice on dissimilar looking substitution exercises than through practice on more similar looking story problems. We report on an experimental comparison involving 303 middle school students that supports this prediction. We discuss how having learners externalize a uniform abstract form and get interactive feedback on it may be important factors in enhancing transfer.

Keywords: cognitive task analysis; transfer; grammar learning; mathematics education.

Introduction

Humans learn language before they have a language to use to learn. Might the learning processes that make this amazing feat possible, like the capability to learn grammatical structures through experience without explicit instruction, be useful for other kinds of learning tasks? Once children have acquired language, are the cognitive functions employed in language learning no longer useful? For instance, as students take courses in complex academic topics, like algebra, does all that brain matter for language learning have nothing to do? Or is it possible that some of the same implicit learning mechanisms employed in language learning are useful for learning math and science?

This paper does not aim to provide conclusive answers to these questions, however, it does provide a compelling demonstration that grammar learning processes may be important in learning mathematics. Students may engage in such learning without explicit awareness and such implicit learning may be more prevalent in academic learning than is generally recognized (e.g., Alibali & Goldin-Meadow, 1993; Landay & Goldstone, 2007). In earlier work, we performed a cognitive task analysis of the important task domain of "symbolization", that is, the ability to model problem situations or "story problems" in algebraic symbols

(Heffernan & Koedinger, 1997; 1998). Table 1 shows examples of symbolization problems, which ask students to translate a story problem into an algebraic expression. The obvious potential connection between language learning processes and this task is in learning to read and comprehend story problems. While such learning is indeed a significant challenge for elementary students (Cummins, Kintsch, Reusser, & Weimer, 1988), our past data provided evidence that comprehending story problems is no longer a major sticking point for most beginning algebra students.

This claim can be illustrated by an analogy to foreign language translation: Translating a story problem to algebra is like translating English to Greek. For an English speaker, the difficulty in translating to Greek is not comprehending the English, but generating the Greek. Similarly, the challenge for older students in a beginning algebra course is much less in understanding the English in which the story problems are written and more in being able to express that understanding algebraically, that is, in the language of algebra.

One indication that comprehension of algebra story problems is not a major sticking point for beginning algebra students comes from Heffernan and Koedinger's (1998) data showing that students can solve story problems (produce a value for the dependent or "y" variable when a value for the independent or "x" variable is given) much more accurately (63% correct) than they can symbolize (write an equation relating x and y) a story problem (18% correct). Since solving requires comprehension of the story, the performance difference is suggestive that symbolizing is problematic for students in ways beyond the demands of sentence comprehension. A second indication presents a contrast with a difficulty experienced by Artificial Intelligence systems programmed to solve story problems, namely that of understanding the arithmetic relationships between quantities described in the story (Bobrow, 1968). We created problems where natural implicit descriptions of such relationships (e.g., "Ms. Lindquist teaches 62 girls. Ms. Lindquist teaches b boys.") are supplemented (Heffernan & Koedinger, 1997) or replaced (Koedinger, Alibali, & Nathan, 2008) with explicit descriptions (e.g., "The number of students Ms. Lindquist teaches is equal to the number of boys plus the number of girls."), which are much easier for a program to process. We found, however, that providing such explicit descriptions does not

Table 1. Eight two-step symbolization items in order from easiest to hardest.

name	Item	Answer
cds	Mary opened a new music store. She got CDs delivered on her first day. She got 5 truck loads of CDs delivered. Each truck that arrived dropped off 12 boxes. Each box she received had c CDs. Write an expression for how many CDs were delivered that first day.	$5*12*c$
mcдона	Mike starts a job at McDonald's that will pay him 5 dollars an hour. Mike gets dropped off by his parents at the start of his shift but he takes a taxi home that costs him 7 dollars. Mike works an h hour shift. After taking into account his taxi ride, write an expression for how much he makes in one night.	$5*h-7$
children	John and his wife Beth have been saving to give their 5 children presents for the holidays. John has saved 972 dollars for presents and Beth has saved b dollars. They give each child the same amount. Write an expression for how much each child gets.	$(972+b)/5$
sisters	Sue made 72 dollars by washing cars to buy holiday presents. She decided to spend m dollars on a present for her mom and then use the remainder to buy presents for each of her 4 sisters. She will spend the same amount on each sister. Write an expression for how much she can spend on each sister.	$(72-m)/4$
students	Ms. Lindquist is a math teacher. Ms. Lindquist teaches 62 girls. Ms. Lindquist teaches f fewer boys than girls. Write an expression for how many students Ms. Lindquist teaches.	$62+62-f$
rowboat	Ann is in a rowboat on a lake. She is 800 yards from the dock. She then rows for m minutes back towards the dock. Ann rows at a speed of 40 yards per minute. Write an expression for Ann's distance from the dock.	$800-40m$
trip	Bob drove 550 miles from Boston to Pittsburgh to visit his grandmother. Normally this trip takes him h hours, but on Tuesday there was little traffic and he saved 2 hours. Write an expression for what was his average driving speed.	$550/(h-2)$
jacket	Mark went to the store to buy jackets that cost d dollars. When he got there the store was having a sale of $1/3$ off the usual prices. Write an expression for how much the jacket cost him.	$d-1/3*d$

significantly improve the performance of beginning algebra students (77% on explicit vs. 79% on implicit in Koedinger, Alibali, & Nathan, 2008 and 53% vs. 50%, respectively, in Heffernan & Koedinger, 1997).

A third indication that problem comprehension is not a major sticking point identifies difficulties on the production side of the translation process (i.e., going from understanding to the target language, Algebra in this case) rather than the comprehension side (i.e., going from the source language, English story problems, to understanding). Heffernan and Koedinger (1997) contrasted the two-step problems shown in Table 1 (e.g., see the *students* problem in the fifth row) with matched one-step counter parts (e.g., see the first two rows in Table 2 for the one-step counterparts of the two-step *students* problem). In each matched set, the two one-step problems are designed to have essentially the same content as the two-step problem. Using the *students* problem as an example, the two-step problem requires the solver to understand that 1) the total number of Ms. Lindquist's students is the sum of the number of girls and number of boys and 2) that the number of boys is difference between the number of girls and the variable f . The one-step problem "a" in Table 2 requires understanding of first of these relationships and the other one-step problem "b" requires understanding the second of these. Heffernan and Koedinger (1997) found that student performance on symbolizing two-operator problems was significantly worse (40% correct) than combined performance on two matched one-operator problems (62% correct). (Note that average performance on a single one-operator problem is even better at 79% correct.)

The comprehension demands of the two one-operator problems are quite similar to that of the two-operator problem as the words and sentences used in each are substantially overlapping if not quite identical. The production demands, however, have an important difference. To correctly produce the algebraic expression for the one-step problems, $62+b$ and $62-f$, learners need only acquire the mental equivalent of the grammar rule "expression \Rightarrow quantity operator quantity". However, this syntactic knowledge is not sufficient to produce two-operator symbolic expressions, like $62+62-f$. To do so, requires the acquisition of knowledge equivalent to additional grammar rules that allow for an expression to be embedded inside another expression. More formally, producing two-operator symbolic expressions requires the equivalent of grammar rules like "expression \Rightarrow quantity operator expression" and "expression \Rightarrow expression operator quantity". Figure 1 illustrates how the first two of the three grammar rules above can combine to produce two-operator expressions like $62+62-f$.

Figure 1: Grammar tree for a two-operator expression.

To be sure, we are not saying that students need to learn such grammar rules explicitly, but simply that they need to implicitly acquire the skills that are consistent with the patterns these rules describe. But the difference between two-step and one-step performance implicates such syntactic skill. In other words, that students are significantly worse at solving a single two-step problem than they are at solving both of the matched one-step problems is evidence that they lack implicit knowledge of grammar for combining expressions. There are alternative hypotheses to be sure (some of which were explored in Heffernan & Koedinger, 1997, 1998), but a strong test is to use this hypothesis to design purportedly better instruction and test whether it is indeed better.

So, for instruction, the ideal would be to find a task that isolates learning of these implicit “hidden” grammar rules. A task that does so is a substitution exercise, as illustrated in the last row of Table 2. This task requires students to produce of two operator expressions (and thus should exercise the hidden grammar rules) but without any of the requirements of comprehending a two-step story problem.

This leads us to a counter-intuitive hypothesis that instruction (substitution) that looks unlike the target objective (two-operator story problem symbolization) is going to lead to learning and transfer and, further, may do so better than instruction (one-operator story symbolization) that looks much more like the target objective. In particular, we hypothesize that practice on substitution exercises will transfer to better performance on translating algebra story problems into symbolic expressions. We will measure improvement by examining the differences on posttest two-step symbolization items between students who do substitution problems embedded within a problem set and students who only practice one-step symbolization problems within the problem set. As a pretest, both the treatment and control conditions begin with a measure of their ability to write one-step expressions before being presented with a two-step problem.

Method

The experiment was implemented inside the ASSISTment system and run in middle school classrooms in an urban school district outside of Boston, MA. The ASSISTment system is a web-based computer tutor authoring and delivery system designed to be used for both formative assessment and instruction (Razzaq et al., 2007). Instruction is provided by feedback on errors, on-demand hints, and scaffolding questions that reduce a problem into its components much like a simplified version of a Socratic dialogue.

Materials and Design

The materials for this study were the eight two-step story problems shown in Table 1 along with matched one-step and substitution items for each as illustrated in Table 2. This produces a pool of 32 items of which students saw 16 in one of two versions. Items were placed into the versions

so that students never saw an item that has the same answer (or answer part) as another. The items were organized in three phases: 1) five pre-test items, 2) seven integrated instructed and post-test items, and 3) four filler items. The first two phases are relevant to the study design and are illustrated in Table 3. (The filler items are the one-step or substitution items the other condition received as instruction and were included to collect data on item difficulty.)

Table 2. The matched one-step problems (a & b) and substitution problem (c) for the two-step *student* item.

	Item	Answer
a	Ms. Lindquist is a math teacher. Ms Lindquist teaches 62 girls. Ms Lindquist teaches b boys . Write an expression for how many students Ms. Lindquist teaches.	$62+b$
b	Ms. Lindquist is a math teacher. Ms Lindquist teaches 62 girls. Ms Lindquist teaches f fewer boys than girls. Write an expression for how many boys Ms. Lindquist teaches.	$62-f$
c	Substitute $62-f$ for b in $62+b$ Write the resulting expression.	$62+62-f$

In the pre-test phase, both groups did the same four one-step problems (labeled a or b in Table 3) depending on which version of the problem set received, followed by one two-step problem (labeled 0 in Table 3) depending on which version and order received. We created two “versions” to be evenly matched in difficulty by selecting two-step problems going down this list, cds, sisters, students, and jackets for version A and mcdonalds, children, rowboat, and trip for version B. Version A, then, had one-step and substitution items corresponding with cover stories mcdonalds, children, rowboat, and trip and vice versa for version B. We also created two orders of each version by reversing the sequence of the two-step problems, easy to hard (0, 1,2,3) vs. hard to easy (3,2,1,0). Thus, we expected order to have a significant effect on a pre-post comparison and controlled for it in the analyses below.

In the integrated instruction and post-test phase, students started with two instructional problems (either ab or cc in Table 3) and then alternated between two-step problems (1-3 in Table 3) and further instructional problems. As noted above, the four instructional problems come from the four base cover stories not used for the two-step problems, whether version A or B. The instructional problems corresponded with condition, one-step problems for the one-step condition and substitution problems for the substitution condition. For the one-steps, which come in a-b pairs (as illustrated in Table 2), two of type a and two of type b were selected from the four available cover story sets.

The two-step problems were ordered by difficulty based on a pilot study with students from the same grade and district and this order, from easiest to hardest, is shown in Table 1.

Table 3. Sequence of items for both conditions.

Condition	Pre-test	Instruct & test
One-step	abab0	ab1a2b3
Substitution	abab0	cc1c2c3

a & b = one-step, c = substitution, 0-3 = two-step

Given the nature of the ASSISTment system, all items are both assessment items (based on students' first response) and instructional items (based on feedback, hints, and scaffolding questions that may follow an incorrect response). The only difference between the two conditions is the placement of the substitution versus one-step items during the instruction.

Participants

The original data included 318 middle school students (N=158 one-step practice, N=160 substitution practice) using an on-line system during the 08-09 school year. The final data set included only those subjects who completed all 16 of the items in the problem set (four two-step, eight one-step, and four substitution) for a total of 303 participants (N=154 one-step, N=149 substitution).

Measures

The pre-test was designed to assess students' prior knowledge of translating story problem to algebraic expressions. It was the first five items in the item sequence and consisted of four one-step items and the first one two-step item. A pre-test measure was computed as the average of the two-step score and the average of the four one-step scores, thus appropriately giving more weight to the two-step item that is the goal of instruction. The posttest score was computed as the average of the scores on the last three two-step items. All pre and post-test scores were based on students' first attempt at an item such that either an incorrect entry or a hint request counted as an error.

Results

To test the main hypothesis that instruction on substitution tasks leads to better transfer of learning to two-step symbolization problems than does instruction on one-step symbolization problems, we performed an ANCOVA with pre-test as a covariate, condition and item order (easy-to-hard vs. hard-to-easy) as factors, and post-test as the dependent variable. As noted above, we included the order factor because of its obvious likely influence. We found significant effects of both factors, condition ($F(1,299) = 4.45, p < .05$) and order ($F(1,299) = 39.57, p < .001$), and of the pre-test covariate ($F(1,299) = 78.62, p < .001$). We found no other significant effects when we explored more complex models involving problem set version and the possible two- and three-way interactions with condition, version, and order.

Not surprisingly, high pre-tests are associated with higher post-tests and the easy-to-hard order yields lower post-test

scores. With regards to condition, students in the substitution condition had similar pretest scores ($M=.56$) as students in the one-step condition ($M=.57$); however, the substitution group posttest scores ($M=.39, SD=.35$) were higher than the one-step group scores ($M=.33, SD=.33$). We used the ANCOVA results to compute adjusted posttest scores ($M=.39$ for substitution, $M=.32$ for one-step) and an effect size (Cohen's $d = .29$).

How Does Substitution Practice Help

To better understand how substitution practice may enhance learning of algebra symbolization skills, we investigated the errors students made on the posttest items. A common error category on two-step symbolization problems is to provide a 1-operator answer, for instance, "62-f" rather than "62+62-f". This error is consistent with a student whose only algebra grammar knowledge is "expression => quantity operator quantity". We hypothesized that substitution practice should aid the acquisition of grammar rules that allow for embedded expressions, like "expression => quantity operator expression". The addition of such knowledge should reduce the 1-operator responses to two-step problems.

We coded incorrect solutions in four error categories: 1-operator, 2-operator, missing parentheses, or hint/other. The most common error for both conditions is a 1-operator error. We found that the one-step group produces the 1-operator error (34%) somewhat more often than the substitution group (30%). This difference is larger for some problems and, in particular, appears to account for improved performance on four of the problems (cbs, students, rowboat and trip) on which the one-step group is 9% worse than the substitution group (23% vs. 32%) and makes 12% (47% vs. 35%) more 1-operator errors. We found no consistent differences between conditions for 2-operator or hint/other errors. Three post-test problems require parentheses (sisters, children and trip) and on these, missing parentheses errors account for condition differences. The one-step group is 8% (34% vs. 42%) worse on these problems than the substitution group and makes 12% (25% vs. 13%) more missing parentheses errors.

We did not discuss parentheses in our brief characterization of the algebra grammar above, but the correct use of parentheses is clearly an important part of algebra expression structure. Consistent with the hypothesis that substitution practice should enhance algebra grammar learning, we indeed found a reduction in missing parenthesis errors in the substitution group relative to the one-step group.

One way grammar learning can be achieved is through the kind of implicit or non-verbal statistical learning mechanisms that are presumably used in first language acquisition. If these mechanisms are in part responsible for algebra grammar learning (see Li, Koedinger & Cohen, 2010 for a demonstration of the feasibility of such), then we might expect to see more frequent use of grammatical forms seen by those students who have seen such forms more

frequently. Indeed, the one-step group sees 1-operator expressions more frequently and generates such expressions more frequently on post-test problems than the substitution group. In contrast, the substitution group sees more expressions with parentheses and generates such expressions more frequently on post-test problems than the one-step group.

In fact, these patterns appear not only in student errors, as discussed above, but also in their correct responses. On some two-step posttest problems (cds, students, and jackets) it is possible to produce a correct 1-operator solution (e.g., “60c” for $5 \times 12c$, “124-f” for “ $62+62-f$ ”, $2/3 \times d$ for $d-1/3 \times d$). The one-step group, despite doing generally worse on these problems (23% vs. 31%), actually produces twice as many correct 1-operator solutions as the substitution group (7.2% vs. 3.5%). It is also possible for students to produce correct answers that include parentheses on problems that do not require them (e.g., “ $62+(62-f)$ ”). Again, consistent with the hypothesis that statistical properties of learning, like frequency, are operative even in formal domains like algebra, we find that the substitution group has more correct solutions that involve unnecessary parentheses than the one-step group (15% vs. 9.3%).

An astute reader may wonder about the following alternative interpretation of the observed overall differences in learning. Might the one-step group’s experience generating 1-operator solutions simply be interfering with production of 2-operator solutions needed for correct performance on the two-step post-test problems? Or, to put it in more stark terms, might students in the substitution group simply be learning a shallow bias to generate 2-operator solutions and the one-step group students simply learning a shallow bias to generate 1-operator solutions? It is first worth emphasizing that, because of the instructional scaffolding for all on the two-step problems, neither group was exclusively seeing one response type or the other.

Certainly though, part of our hypothesis is that a shift in bias is causing improvement, but that that shift is in probabilities on implicit grammatical structure knowledge not in shallow or surface features. To be better, the substitution group students must not only avoid generating 1-operator solutions (note that they are not so easily biased that they stop making 1-operator errors), but also learn how to generate correct 2-operator solutions, including appropriate use of parentheses. If substitution group students were simply shallowly biased toward 2-operator solutions, we would expect them to perform worse on the four one-step problems they were given in the filler phase than the one-step group did on the same problems during instruction. In fact, both groups were 72% correct on one-step problems. Thus, the substitution group was not blindly over-generating 2-operator solutions.

Discussion and Conclusion

When we think about learning and transfer, it is tempting to think just in terms of the observable tasks between which transfer may occur. However, the vehicle of transfer is the

knowledge the learner acquires from a source task and transfer occurs to the extent that that knowledge is relevant and employed in the target task (cf. Singley & Anderson, 1989). Careful cognitive task analysis regarding the underlying nature of the knowledge demands of tasks can thus provide insight into how best to achieve transfer. We presented an experiment that tested a subtle prediction of a prior data-driven cognitive task analysis. That analysis suggested that comprehending story problems tends not to be a major source of difficulty for students learning to translate story problems to algebra. Instead, learning to produce longer symbolic expressions is a more significant challenge and that students must acquire more sophisticated algebra grammar knowledge to meet this challenge. We hypothesized that practice on substitution tasks would assist students in extending their algebra grammar and, counter-intuitively, that such practice would yield better transfer to story problem symbolization than practice on simple story symbolization would. A classroom-based study with some 300 middle school students provided support for this hypothesis.

It may seem surprising that we found transfer from instruction on symbolization tasks, which have little natural language content, to story problem tasks and, even more, that such transfer is greater than from instruction on story problem tasks themselves (albeit simpler ones). After all, the literature and theory on analogical transfer (e.g., Gentner, 1983; Gick & Holyoak, 1983) suggests that people are particularly sensitive to surface features and have great trouble transferring experience from one situation (e.g., converging radiation treatment) to another with dissimilar surface features (e.g., converging military forces). How, then, does the instruction used in this study apparently help students acquire a relevant deep structure and transfer it from substitution tasks to surface-dissimilar story problem symbolization tasks?

An important observation here is that while these task categories (substitution and two-step story) do not have common surface features in their stimulus structure, they are similar in their response structure. The answer in both cases is a two-operator algebraic expression. To be sure, the correct responses to the instructional problems (analogical sources) and post-test problems (analogical targets) are not identical, nor even similar in surface characteristics -- for instance, “ $800-40x$ ” has little or no surface similarity with “ $62+62-f$ ”. However, the structure of these responses, whether generated from a story problem or a substitution problem, is similar in underlying grammatical form (“expression \Rightarrow quantity operator expression”).

Similarity in response structure is not enough to produce transfer. The well-known convergence tasks of Gick and Holyoak (1983) have an arguably similar response structure, yet learners show little transfer between such tasks under most instructional variations. What may be critical is that the learner externalizes the response, gets feedback and support to get the response right, and the external form is abstract and uniform (e.g., if a common converging arrow

diagram was used in response to convergence tasks). In this study, the demands of both substitution and symbolization problems put the solution response into the world where it can be "re-perceived" (c.f., Goldstone, Landy, & Son, in press). Further, the kind of interactive instruction we employed (use of the ASSISTment tutor) guarantees that students get the response right before moving on. By generating, or at least perceiving a correct response, students may (implicitly) engage the same perceptually-grounded, similarity-based generalization processes on the response that they use on the task stimulus. Thus, they may develop better mental representations, whether grammar rules or "perceptual chunks" (Chase & Simon, 1973), of those response representations. Further, it may be important to the transfer result that the response representation is a uniform abstraction (i.e., algebraic expressions). This concise, unadorned representation may make it easier for pattern recognition mechanisms to learn the deep patterns (i.e., the algebraic grammar rules) needed for transfer (c.f., Kaminski, Sloutsky, & Heckler, 2008).

More practically, this research illustrates how a general instructional principle like starting simple (or mastery-based learning, Bloom, 1984) may not be effective if it is not accompanied with a careful cognitive task analysis of the target subject matter domain. Instruction that helps students master parts before helping them master the whole may seem obvious, however, what seem like "parts" on the surface may not be the right "cognitive parts" a learner needs to acquire. It is not particularly hard to identify the part-whole relationship between one-step and two-step story problems. Thus, the control condition in this study is not a straw man, but a reasonable application of part-task training principles and is representative of sequencing in math textbooks.

It is not *a priori* obvious, however, that substitution tasks are a "part" of two-step story problem symbolization. We came to that conclusion after a data-driven cognitive task analysis (cf., Clark, Feldon, van Merriënboer, Yates, & Early, 2007) that involved the analytic use of computational modeling (e.g., the grammar rule analysis). We believe that there is great promise for greatly improving the efficiency and effectiveness of instruction, even in well-investigated domains like algebra, through a combination of domain-general instructional principles and such detailed cognitive task analysis.

Abstract

This paper investigates the idea that it is not just the content of what students learn that influences transfer, but also how learning and transfer contexts are linguistically framed. In a one-on-one tutoring experiment we manipulated framing while controlling for several known transfer mechanisms. We contrasted an expansive framing in which students are positioned as contributing to larger conversations that extend across time, places, people, and topics, with its opposite. We then measured the degree to which high school biology students transferred knowledge from a learning session about the cardiovascular system to a transfer-of-learning session about the respiratory system. We found that students in the expansive condition were more likely to transfer: (a) facts, (b) a conceptual principle, and (c) a learning strategy from one system to another.

Keywords: Transfer-of-learning; Linguistic framing; Social interactions and learning; Human tutoring; Self-explaining

Introduction

Transfer-of-learning, or the application of something learned in one context to another context, is one of the most important but difficult issues in cognitive science and education (e.g. Gick & Holyoak, 1983; Lave, 1988; Lobato, 2006). As Barnett and Ceci (2002) explain, “there is little agreement in the scholarly community about the nature of transfer, the extent to which it occurs, and the nature of its underlying mechanisms.” This paper focuses on an instructional mechanism that has rarely been investigated systematically: the linguistic *framing* of learning contexts (Engle, 2006). In this paper, we report the first experimental study of this mechanism in an educational context: a tutoring experiment testing whether framing affects transfer.

Framing Contexts as a Mechanism for Transfer

Most research on transfer mechanisms does not focus on *contexts* or their framing, but on the nature of the *content* students transfer. For example, the importance of comparing multiple examples to form generalizations is often emphasized (e.g. Gick & Holyoak, 1983; Gentner, Lowenstein & Thompson, 2003). When context is addressed, the focus is on similarities between objective features of learning and transfer contexts, like their physical locations and who is present (e.g. Catrambone & Holyoak, 1989; Spencer & Weisberg, 1986).

Our approach to the relationship between context and transfer investigates the idea that otherwise objectively similar contexts can be linguistically framed as different

social realities (e.g. Duranti & Goodwin, 1992; van Dijk, 2008) that may encourage or discourage transfer (Engle, 2006; Laboratory for Comparative Human Cognition [LCHC], 1983; Greeno, Smith & Moore, 1993; Hammer et al., 2005). As Pea (1987, p. 647) explained, “contexts [that matter for transfer] are *not* defined in terms of physical features of settings, but in terms of the *meanings* of these settings constructed by the people present.”

We use the term *framing* to refer to the linguistic processes of establishing these social realities (e.g., Tannen 1993). For explaining transfer, the framing of boundaries of learning and transfer contexts is particularly important as it affects which contexts students view as being relevant sites for using what they have learned. For example, when a teacher introduces a lesson as providing students entry into knowledgeable roles within communities they plan to participate in throughout their lives, the social boundary of the lesson expands to encompass additional contexts for which each student’s understanding of the lesson will be relevant. In contrast, the teacher could have introduced the same lesson as only relevant to the next day’s quiz, thus framing it as divorced from other contexts-of-use.

Here we investigate the hypothesis that transfer is more likely when learning and transfer contexts are framed *expansively* as opportunities for students to actively contribute to larger conversations that extend across times, places, people, and activities (Engle, 2006). The boundaries of expansive contexts are framed as wide-ranging and permeable to increase the contexts that can become linked with them (Floriani, 1994; Gee & Green, 1998). Additionally, learners become positioned as authors who share their knowledge more generally. Thus, learners learn under the assumption that they will be expected to transfer what they learn to other contexts (LCHC, 1983; Pea, 1987). In potential transfer contexts they act under the assumption that they are accountable for using what they know from other times, places, and people (Greeno et al., 1993; Pea, 1987).

Existing Evidence About Framing and Transfer

Few studies have empirically investigated potential connections between framing and transfer. Hammer et al. (2005) showed that when two transfer contexts were re-framed as being about active sense-making rather than the replication of knowledge, students transferred-in their prior knowledge in ways that helped them understand physics concepts. Engle (2006) showed how a classroom case of

successful transfer that occurred despite weak content-based supports could be explained by a teacher's expansive framing of time, participants, and roles. Finally, Hart and Albarracin (2009) found that people were more likely to repeat an action they had just engaged in—the most basic form of transfer that there is—if they were prompted to describe it using a progressive verb tense that frames it as a continuing activity (“I was doing...”) versus a perfective tense that frames it as a completed action (e.g., “I did...”).

A Tutoring Experiment to Investigate the Effects of Framing on Transfer

We conducted a tutoring experiment using a 2x2 design with framing condition (expansive vs. its opposite, bounded) as a randomized variable and student population (first year General Biology vs. Advanced Placement [AP] Biology) as a fixed variable included to assess the generality of effects across populations. To reduce pre-intervention differences between conditions, matched pairs of students from the same classes who performed similarly on a screening test were randomly assigned to each framing condition (Shadish, Cook & Campbell 2002). Each student participated individually in a 3-4 hour learning session about the cardiovascular system on one day followed by a 1-2 hour transfer-of-learning session about the respiratory system the next day. Each session's order was: instructions, pre-test, tutoring, survey, and post-test. In all conditions we aimed to strongly support learning while moderately supporting transfer via known instructional mechanisms.

Participants and Their Originating Biology Classes

24 biology students from the same Northern California high school participated in the experiment, 14 from General Biology and 10 from AP Biology, with half of each population assigned to each condition. Instruction in both biology courses was generally consistent with a bounded framing. Students took notes from lectures, the textbook, and educational movies, and teachers evaluated their ability to correctly recall individual facts from these sources. The AP course may have been framed somewhat expansively by its implicit linking to the end-of-year AP exam and college.

Similarities in Procedures Across All Participants

We controlled for objective features of the contexts in which tutoring occurred as well as elements of instruction commonly known to affect learning and transfer.

Objective Features of Context On day 1, the tutor was the first author and the videographer was a research assistant. On day 2, the tutor and videographer were different research assistants. Both days of the study occurred in the same laboratory room, but the student, tutor, and videographer were located in different places on each day.

Target Content to Transfer The learning goal for the first day was to have all students master the same facts and principles about the cardiovascular system. Transfer to the

respiratory system would be assessed on day 2. For facts, students learned the sequence of body parts through which blood flows—a sequence that overlaps with where oxygen travels within the respiratory system. This material is necessary for forming correct mental models of each system (Chi et al., 1994; Liu & Hmelo-Silver, 2009). For principles, students learned that *pressure differentials* determine the direction of blood flow in the cardiovascular system, which applies to gas movement in the respiratory system and fluid flow more generally. They also learned that a large collective *surface area* increases diffusion across capillaries, which applies to increasing the rates of diffusion across alveoli in the respiratory system as well as chemical reactions, heat transfer, and many other processes.

Tutoring Methods The foundation of day 1's tutoring was having each student self-explain the same text and diagrams about the cardiovascular system (Chi et al., 1994, 2001). This method, which promotes learning and transfer (e.g. Chi et al., 1994; Rittle-Johnson, 2006), also allowed us to reduce and control for the tutor's role as provider of content. Drawing on methods established in prior research (Chi et al., 1994; McNamara, 2004), we first trained students to self-explain using an unrelated science text, and then asked them to read each sentence from the cardiovascular system text out loud and self-explain it. Although most students self-explained without difficulty, if the tutor observed a student only paraphrasing (cf. Hausmann & vanLehn, 2007), she prompted for a more elaborate explanation.

Self-explaining was supplemented by having students:

1. Identify key body parts from the text on diagrams.
2. Answer questions about structures, behaviors, functions, and their relationships (Goel et al., 1996).
3. Draw diagrams to represent their evolving models of the cardiovascular system (Ainsworth & Loizou, 2003).
4. Interact with a gestural or physical model for each target principle.

Tutoring about the respiratory system on day 2 was less guided. Students were first asked to anticipate what they would need to learn about the respiratory system. They were then given as long as they wished to “think aloud” while reviewing a text (adapted from Hmelo-Silver & Pfeffer, 2004), hypermedia system (identical to Liu & Hmelo-Silver's 2009), and diagrams. They were also provided with pen and paper, but not required to use it, which provided an opportunity for them to transfer the learning strategy of drawing diagrams from day 1. Each student was also asked to: (a) explain a lung model representing pressure differentials, and (b) explain why there are so many alveoli in the lungs, which relates to the surface area principle.

Known Instructional Supports for Transfer Use of known transfer mechanisms was controlled for all students in ways designed to avoid floor and ceiling effects. All students received the same: (a) overlapping surface linguistic cues between learning and transfer contexts (Catrambone, 1998), (b) examples of each principle (e.g. Gick & Holyoak, 1983), (c) comparisons between those

examples (e.g. Gentner et al., 2003), and (d) level of abstraction of statements of each principle (e.g. Reeves & Weisberg, 1994). No students were given any direct hints (e.g. Anolli et al., 2001; Gick & Holyoak, 1983), nor was the respiratory system mentioned prior to day 2.

Operationalization of the Framing Manipulation

We manipulated the framing of five key aspects of contexts: *who*, *when*, *where*, *what*, and *how* (Engle, 2006). Here we provide illustrations of each framing in classrooms and then in the experiment, with each sentence presenting the more bounded framings first and the more expansive ones second.

Who Is Involved? Lessons can be framed as just involving the teacher and each student, or as being relevant to a much larger community in the classroom and beyond. In our experiment, we framed the student as interacting separately with each tutor versus collectively with the whole research team and anyone else students mentioned.

When Is It Happening? The temporal horizon of a lesson can be framed as an isolated event that has been completed or as part of an ongoing activity that will be continuing. In our experiment, we framed each day as separate studies that consisted of separate completed sub-events versus as one ongoing study that extended across the two days and beyond to other times students mentioned as being relevant to them.

Where Is It Happening? Lessons can be framed as only being relevant to the particular classroom or as also being relevant to other settings like the rest of the school, the local community, a workplace, etc. We framed tutoring as being contained to the room versus being relevant throughout the university and anywhere else students mentioned.

What Is the Scope of the Activity? Two lessons can be framed as being relevant to separate classes, topics, or curriculum units; or as being part of the same larger subject area, unit or topic. In our experiment, we framed each day as a separate tutoring session about a different topic versus part of a pair of tutoring sessions about a larger topic.

How Are Learners Positioned Intellectually? In lessons, learners can be framed as disconnected recipients reporting about the ideas of others or as authors and respondents who take ownership of their own ideas. In our experiment, we framed the learner as a spokesperson for the text versus as the author of his or her own ideas about the body.

Instruments

Post-tutoring Survey To measure whether students detected the intended framing and their general level of motivation during tutoring, the videographer asked each student to complete a survey during a break after tutoring. The tutor was out of the room during its administration.

Cardiovascular System Pre/Post Test At the start and end

of day 1's tutoring session, a written pre/post test (adapted from Chi et al., 1994) measured students' knowledge of the target facts and principles about the cardiovascular system that could be applied to the respiratory system.

Respiratory System Pre/Post Test To measure transfer we devised analogous written assessment questions about the respiratory system. The fact question and the first question about each principle comprised the three-item screening test used to select students to participate in the study.

Analytical Methods

We coded assessments at all five time points—screening, pre-cardiovascular, post-cardiovascular, pre-respiratory, and post-respiratory. Coding was done blind to condition and not by the first author.

We assessed transfer of facts and principles using three different but partially overlapping measures in order to measure converging evidence of transfer effects. *Transfer-of-knowing* is when a student *knows* something about one topic that they apply later to a related topic. It was measured by calculating the proportion of material included in either of the cardiovascular tests that re-appeared in the respiratory system pre-test. *Transfer-of-learning* is when a student *learns* something about one topic that they apply later to a related topic. It was measured by calculating the proportion of material that appeared in the cardiovascular system post-test but not in its pre-test that then re-appeared in the respiratory system pre-test. Finally, *transfer-after-exposure* is when a student increases the extent to which they use a set of ideas with one topic after being *exposed* to those same ideas with a related topic. It was measured by calculating the proportion of material not known in the respiratory screening test that was included in the same parts of the respiratory pre-test.

We measured transfer of the learning strategy of diagram drawing by simply recording which students spontaneously chose to draw diagrams during day 2's tutoring.

Results

Students Perceived Differences in Framing

Day 1's survey indicated that students generally perceived the intended differences in framing. Students in the expansive condition perceived greater use of expansive framing than those in the bounded condition ($F(1,19)=10.6$, $p < .01$), a large effect (Cohen's $d = 1.4$). There was no interaction effect or main effect of population. Follow-up analyses found that students were most aware of the framing of intellectual positioning and temporal horizon.

No Differences in Other Factors Affecting Transfer

There were no significant differences between conditions in common factors affecting learning and transfer. Prior knowledge, as measured by the screening test, was similar across groups. There also were no differences in time spent learning or in responses to the motivation question ("how

much did you care about learning the cardiovascular system?”). Perhaps most importantly, there were no differences by condition in how much students learned the facts and principles whose transfer serves as the main outcome of this study.

Differences by Condition in the Transfer of Facts

To assess the transfer of facts, we examined responses to a question on each corresponding test that required listing the body parts that *oxygenated* blood (cardiovascular system) or *oxygen* (respiratory system) passes through between the lungs and the body's cells. Because these two paths involve the same 10 body parts we assessed transfer by counting how many were listed in each test and comparing them.

For transfer-of-knowing, there was a large main effect of condition (see Fig. 1, error bars are SEM), with students in the expansive condition transferring 42% of facts they knew while those in the bounded condition only transferred 21% of them ($d = .89$; $F(1,20) = 4.37$, $p = .04$). There were no population nor interaction effects. For transfer-after-exposure, there was also a large main effect of condition ($d = .94$), with students in the expansive condition listing 20% more facts than they had during the screening test while students in the bounded condition listed only 3% more facts ($F(1,19)=4.82$, $p = .04$; Fig. 1). Again, there were no other effects. For transfer-of-learning, there was a trend of more transfer for expansive (36%) versus bounded (13%) conditions ($F(1,20)=3.27$, $p = .09$; Fig. 1), with no other effects found.

Figure 1: Greater transfer of facts in expansive condition.

Partial Evidence for Differences by Condition in the Transfer of Principles

To measure degree of transfer for principles, we divided each principle into a set of propositions that could be included in student responses to analogous questions at each testing occasion. There were 12 codeable propositions relevant to the differential pressure principle and 11 codeable propositions relevant to the surface area principle (91% agreement; Kappa = .82).

For the differential pressure principle, there was a large main effect ($d = .95$) of condition on transfer-of-knowing

($F(1,20) = 5.42$, $p = .03$), with no interaction effect or main effect of population (see Fig. 2). Students in the expansive condition transferred much ($M = 78\%$) of what they knew while those in the bounded condition transferred only about half ($M = 55\%$). For transfer-of-learning, there was a trend for students in the expansive condition to transfer more than the bounded condition (74% vs. 46%; $F(1,21)=3.04$, $p=.098$; see Fig. 2). Upon further examination of the data, however, we suspect this trend was driven by the General Biology students. There were no differences between groups in transfer-after-exposure. Thus, we found a statistically reliable effect of framing for one of the three measures of transfer for the differential pressure principle.

Figure 2: Generally greater transfer of the differential pressure principle in the expansive condition.

In contrast, for the surface area principle there were no main or interaction effects on transfer when measured in each of the three ways. Although the observed means did favor the expansive condition with the transfer-of-knowing measure, there is no reliable evidence that framing affected students' propensity to transfer what they knew or learned about the surface area principle.

Differences by Condition in the Transfer of the Learning Strategy of Drawing Diagrams

Figure 3: Greater transfer of the strategy of drawing diagrams in the expansive condition.

On the basis of a 2x2x2 loglinear analysis, students in the expansive condition were much more likely to draw diagrams than those in the bounded condition ($G^2(2) = 8.28$, $p = .02$). Only 1 of the 12 students in the bounded condition drew diagrams while 7 of the 12 students in the expansive condition did so (see Fig. 3). There was a trend of this effect being greater for General Biology than AP Biology students ($G^2(4) = 8.52$, $p = .07$).

Discussion

We found compelling initial evidence that framing may in fact influence transfer. Students in the expansive condition were more likely than those in the bounded condition to transfer: (a) the learning strategy of drawing diagrams; (b) facts they knew or (c) had been exposed to; and (d) what they knew about the differential pressure principle. In addition, (e) General Biology students in the expansive condition were more likely to transfer what they learned about the differential pressure principle.

The fact that several large effects of framing on transfer were found within a small-scale experiment suggests that it is likely that framing does play an important role in transfer. Also framing does not appear overly specialized in terms of what kinds of transfer it can influence. In this study it affected the transfer of facts, principles, and strategies while in prior research it influenced the transfer of actions, experiences and explanatory schemes (Engle, 2006; Hammer et al., 2005; Hart & Albarracin, 2009).

In future research it will be important to investigate whether it is the framing of one particular aspect of contexts that is responsible for the effects or whether all are necessary. For example, is the manipulation of intellectual positioning as authors versus spokespersons the most important, or is it the way in which time and other aspects of settings are framed as being linked with each other? If more than one aspect of expansive framing matters, does each one make its own independent contributions or is the whole greater than the sum of its parts? To address these questions, future experiments can manipulate each aspect of framing alone and in coordination. This will simultaneously advance understanding of how exactly framing works, provide replication of the effects reported here, and guide educators about which aspects of framing to focus on.

Although transfer of the differential pressure principle was found, no differences were detected across conditions in any kind of transfer of the surface area principle. This contrast opens up issues about how framing may interact with other mechanisms for supporting transfer. This could suggest that framing's effects on transfer may be found only when there is at least some minimal level of content-based support for transfer. In this study, we provided more examples and comparisons for the differential pressure principle than the surface area principle. However, this outcome could also be due to the fact that the surface area principle is arguably more complex. To distinguish between these possible interpretations, follow-up experiments could

cross content-based support with framing while controlling for principles.

More generally it is possible that the framing of learning contexts in an expansive manner makes it more likely that students assume they will need to transfer what they have learned, which may prompt them to make better use of those content-based supports for transfer that are available to them (Engle, 2006). For instance, students learning with an expansive framing may be more likely to bring in multiple examples from a wide range of contexts. In anticipation of applying what they are learning, they may also be more likely to make systematic comparisons between multiple examples to form abstract generalizations. Although tracking which examples, comparisons, and generalizations students made was beyond the scope of this study, it would be a compelling focus of future investigation. Future investigations also should more systematically probe whether motivational variables like utility, relevance, and importance mediate these effects (Pugh & Bergin, 2006).

What is potentially so powerful about expansive framing is that it is much less targeted and content-specific than previously studied instructional supports for transfer. Because of this, it may be easier for teachers to implement expansive framing than instructional supports for transfer that rely on sophisticated content knowledge. In addition, as students come to regularly orient to learning activities in an expansive fashion, one would expect them to make greater use of prior knowledge more generally as they become increasingly accountable for sharing what they know across connected contexts.

At the same time, we do not claim that expansive framing is the be-all and end-all for instruction. Our informal observations of the tutoring sessions and broader theoretical considerations suggest that there may be costs as well as benefits of expansive framing for both learning and transfer. For example, we observed a few students in the expansive framing condition that brought in so much prior knowledge while self-explaining that they became overwhelmed or had difficulty focusing on what the text could contribute to their understanding. Thus, it may make sense for the starts and ends of lessons and curriculum units to be framed more expansively, but to use a less expansive framing when students need to focus on learning particular new material. Also, expansive framing should ideally be paired with activities in which students critically evaluate the knowledge they transfer in for its relevance and validity.

In closing, this study provides converging evidence that framing is an important instructional mechanism to consider when trying to enhance transfer, one that can potentially affect the transfer of many different kinds of knowledge.

Abstract

We build on a philosophical account of personal identity (Parfit, 1984) which argues that the degree of concern one has for one's future self may be scaled by the degree of "psychological connectedness"—overlap in properties such as beliefs, values, and ideals—held between one's current and future self. We pose participants with tradeoffs between consuming a benefit in the near future versus consuming more of that benefit in the distant future. When people's sense of connectedness with their future self is reduced, they make impatient choices.

Introduction

Many of the most important and difficult decisions we face in life hinge on the same underlying dilemma: how to choose when trading off consumption or happiness in the immediate future with (more) consumption or happiness delayed to the more distant future. Research on such dilemmas has been broadly defined as concerning choices between one option with higher immediate benefits but lower (or negative) long-term utility and another with lower immediate benefits but higher long-term utility. People's widely documented tendency to prefer smaller rewards sooner over larger rewards later has been characterized as revealing short-sightedness or impatience (Elster, 1979).

In this paper, we focus on a fundamental question raised by the literature on intertemporal choice: why do people's choices often seem so short-sighted or impatient, and why do people differ in their degree of impatience, as inferred from the choices they make? In particular, we will focus on a subset of such dilemmas—intertemporal choices in which the tradeoffs between short and long-term benefits are made explicit—as an ideal setting in which to investigate the decision processes leading to impatience in decision making across a wide range of future-directed thought and behavior. Economists and psychologists have extensively studied how people make these kinds of intertemporal choices, and have offered metrics for judging the degree to which behavior conforms to or diverges from normative and descriptive models.

Much of the work on intertemporal choice has centered on the specific issue of temporal discounting: how people choose between smaller amounts of money or other goods in the immediate future and larger amounts of money or goods to be received at a later date (see Frederick, Loewenstein, and O'Donoghue, 2002 for a detailed review). In this context, the discount rate, the degree to which an outcome loses value by being delayed for a given period of time, can be interpreted as

a measure of impatience (Ainslie 1975). Thus, we can restate the general question of (im)patience in intertemporal choices as asking why people exhibit such *high discount rates* (compared to market interest rates or some other norm) in their behavior and to provide a partial account for why people exhibit such different discount rates from each other.

We will argue that our understanding of what constitutes a reasonable discount rate (or, more generally, prudent vs. impatient choices) has been limited by the implicit assumption that people should maximize the utility of a constant self over one's lifetime. The philosopher Derek Parfit (1984) proposed an alternative view: that a decision about consuming now or later should depend not only on the temporal distance between events, but also on the perceived continuity between one's present and future selves. In this view, the degree of concern one has for one's future self should be scaled by the degree of "psychological connectedness"—overlap in properties such as beliefs, values, and ideals—held between one's current and future self. These properties have been proposed to define the mental ties between selves that comprise identity over time (Lewis, 1983; Perry, 1972).

We employ the notion of psychological connectedness—drawn from a literature in which there is an ongoing debate over its specifically *normative* implications (Parfit, 1984; see Dancy 1997 for dissenting views)—to test a *descriptive* account of people's intertemporal choices. In our view, the greater the perceived connectedness to the future self, the greater people's willingness to defer benefits to the future self, all else equal. Conversely, feeling disconnected from the future self will undercut the general motivation to preserve resources for the future self, causing a reduction in patience that is distinct from other factors that affect valuations of present and future outcomes.

Evidence for high discount rates

In the context of intertemporal choice, impatience (or short-sightedness) is exhibited by consistently choosing sooner-smaller options even when the latter option is more than large enough to compensate for the delay (per some normative standard). Normative models (Koopmans, 1960) indicate that the premium needed in order to forego receiving money sooner rather than later (i.e. the discount rate) should depend primarily on how much interest could be earned on the money in the intervening time, taking into account liquidity constraints and economic factors such as inflation. In contrast,

empirical research has found that actual behavior is generally more impatient than what would be predicted by these views.

Numerous studies have attempted to estimate discount rates, using field and experimental studies, real and hypothetical outcomes, and a range of elicitation methods. Frederick et al. (2002) summarize the literature as characterized by a “predominance of high discount rates—discount rates well above market interest rates.” In addition to experimental studies with hypothetical choices, they review field study evidence for high discount rates (i.e. impatience) in everyday decisions, such as people’s preferences for lower priced appliances with substantially higher long-term usage costs and military employees’ preferences for a large lump-sum payment over an annuity representing a higher than market interest rate.

Heterogeneity in discount rates

Of the research that has shed light on high discount rates, the primary focus has been on moderators of discount rates, both across people and across decision contexts. While generally high, discount rates have been shown to be sensitive to the specific experimental elicitation methods used (e.g. choice, willingness-to-pay, matching, titration of indifference points). Discount rates have been found to exhibit reasonably high test-retest reliability as individual traits (Simpson & Vuchinich, 2000), but vary systematically by demographics (Green et al., 1994) as well as by individual differences in how people think about the long-term implications of their choices (Strathman et al., 1994).

This large literature on interpersonal differences in discounting provides correlational evidence that people often have fundamentally differing discount rates, often in ways that map onto more generalized short-sightedness. However, the behavioral correlates of discounting (e.g. higher discounting among alcohol or drug abusers), in particular, raise questions as to potential confounds and the order of causality.

Connectedness to the future self and discounting

In this paper, we propose that the notion of connectedness to the future self is fundamental for understanding impatience, shedding light on why discount rates are generally high, why some people are more impatient than others, and what kinds of interventions may lead to higher or lower discount rates. In doing so, we draw on the views of philosopher Derek Parfit, who has theorized that changes over time in the psychological properties that comprise one’s identity should warrant a reduction in concern for a later self:

“We care less about our further future... because we know that less of what we are now—less, say, of our present hopes or plans, loves or ideals—will survive into the further future... We may, because of this, act knowingly against our own long-term self-interest... [If] what matters holds to a lesser degree, it cannot be irrational to care less.” (Derek Parfit 1976, p. 99)

In this view, the future self, given an extremely large reduction in connectedness, may be reasoned about almost as a distinct individual. We do not mean to overstate the analogy of regarding the future self as you would regard another—in our account, rather, the future self is seen as a continuation of

the current self, to varying degrees. The future instantiations of the self may be seen as nearly identical to the current self, or they may be substantially different, and we will argue that this perceived degree of continuity leads to differences in patience.

In extending the notion of connectedness to a descriptive account of impatience, we define connectedness between the current self at time t_0 and a future self at time t_1 as the proportion of the defining psychological features of the current self believed to persist in the self that will exist at time t_1 . Consistent with the recent empirical literature on how people judge the continuity of identity over time (Nichols & Bruno, in press; Rips, Blok, & Newman, 2006), connectedness between current and future selves hinges specifically on the stability of one’s defining psychological properties over the time interval.

In our view, a person values future outcomes in proportion to how much she believes that the current self’s important psychological characteristics will persist in the future self. When people feel highly connected to the future self, benefits received by the future self are valued much as if they were received by the present self. However, when a discontinuity in identity is perceived, deferred benefits accrue to a disconnected future self (i.e., a somewhat different person), and this outcome is valued less than having those benefits consumed by the present self. Thus, when people are faced with explicit intertemporal tradeoffs, their allocations of benefits to the future selves are driven, in part, by how psychologically connected they feel to those future selves. As a result, decisions that might appear short-sighted (i.e. characterized by placing a low weight on future consequences or having an inflated discount rate) may instead merely reflect an unwillingness to share resources with a future self who is evaluated to be substantially different from the current self.

A few studies have examined correlations between people’s perception of the continuity of their identity over time and the choices they make. Ersner-Hershfield and colleagues have shown that people who perceive less continuity with the future self show greater devaluation of money (Ersner-Hershfield, Wimmer, & Knutson, 2009; cf. Frederick 2002) and tend to have accrued fewer material assets in their lives (Ersner-Hershfield et al., 2009). Bartels and Rips (2010) investigated the role of connectedness in non-constant discount rates over time and found that declines in a given persons’ discount rates over time—a pattern often referred to as “hyperbolic discounting” (Ainslie, 1975)—correlated with perceived reduction in their own connectedness over time.

In this paper, we provide the first direct, experimental evidence that changes in connectedness to the future self across individuals causes differences in patience for real choices and that the influence of connectedness on patience is distinct from other factors already identified in the literature as impacting people’s relative timing preferences.

Study 1

In Study 1, we investigate the effect of manipulating connectedness on subsequent hypothetical choices between either the immediate receipt of a gift card or a gift card bundled with an additional payment to delay receipt. After

reading either that identity changes radically in early adulthood (especially during the college years) or that the core features of one's identity are fixed in early childhood (and stable during college), participants made a set of hypothetical choices between receiving a gift certificate later in the day, or receiving it in a year along with an additional payment to compensate for the delay. If disconnectedness from the future self is a driver of discounting, then anticipating changes in the properties that comprise one's identity will make people more impatient, and participants exposed to the instability message should require a larger delay premium than participants exposed to the stability message.

Method

One hundred seven undergraduates were approached in a dining hall on campus and agreed to fill out a short survey for a chocolate square. We manipulated connectedness (high vs. low, between subjects) by inducing the belief that the identity of the future self will either change or not change from one's current identity. Specifically, in the high-connectedness condition, participants began by reading a short description of "recent research" suggesting that young adulthood is characterized by stability in identity (e.g., "the important characteristics that make you the person you are right now... are established early in life and fixed by the end of adolescence"). In the low-connectedness condition, participants read about instability (e.g., "the important characteristics that make you the person you are right now... are likely to change radically in young adulthood."). Then, participants wrote a short summary of the passage they read. Data from four participants were dropped from further analysis because they left this response blank or because their paraphrasing indicated misunderstanding or noncompliance.

Next, participants in both conditions were asked to imagine being given a \$120 gift certificate. We used two different retailers, Target and Expedia, to ensure the generalizability of results. They were then asked to make a series of choices between receiving the gift certificate later that day vs. receiving the gift certificate one year later and being paid an extra amount for the delay, using eight dollar values (0, 17, 34, 51, 69, 86, 103, and 120). Participants then answered two kinds of manipulation checks: an assessment of connectedness and a rating of the believability of the passage they had read. To assess connectedness, we asked participants to "think about the important characteristics that make you the person you are now—your personality, temperament, major likes and dislikes, beliefs, values, ambitions, life goals, and ideals and circle the one diagram out of the six below that best reflects your opinion about the degree of connectedness between the person you are now and the person you will be in a year, where no overlap means 'completely different' and complete overlap means 'exactly the same.'" Participants circled one of the six sets of Euler circles representing connectedness, which were coded as numeric scores.

Results and Discussion

Manipulation checks. Participants who read about stability rated themselves as more connected ($M = 4.43$, $SD = 0.73$) than did participants who read about instability ($M = 4.00$, $SD = 1.07$; $t(1,102) = 2.39$, $p < .05$), suggesting that our manipulation was effective in promoting perceptions of one's own identity as more (or less) stable over time and therefore more (or less) connected to one's future self. Believability of the stability and instability passages did not differ ($t < 1$).

Relating perceived (in)stability to discounting. Our measure of patience was the number of deferred options (waiting one year for the gift certificate) chosen out of the eight given, such that larger values indicated greater patience. Participants in the high-connectedness conditions were more patient, requiring a smaller delay premium, on average (\$49, inferred from $M = 5.14$), than did participants in the low-connectedness conditions (\$68, inferred from $M = 4.04$). A 2 (Condition: High/Low Connectedness) \times 2 (Good Type: Target/Expedia) ANOVA, finds the expected main effect of Connectedness ($F(1,100) = 9.21$, $p < .01$); neither the effect of good type nor the interaction term reached significance ($F_s < 1$). These results demonstrate both that perceived connectedness to one's future self can be directly manipulated, and, more importantly, that increasing perceived connectedness to the future self increases patience.

Study 2

Study 1 shows that disconnectedness causes impatience, as revealed by the premium people demand to delay receiving an award. Implicit in these choices is that people are depriving their future selves of potential resources, in order to consume sooner. However, it is not necessarily the case that people think of such tradeoffs in terms of allocating resources, and they may instead think in terms of fair rates of return for delay or other factors. In fact, the literature has shown that framing matters in such choices: while people are generally willing to accept compensation to wait to consume, they are much less willing to actually pay to speed up an outcome, due to the pain of paying and other factors (Loewenstein, 1988). We have argued that reduced connectedness impacts preferences due to a reduced willingness to share resources with a future self who is evaluated to be substantially different from the current self. In our view, the effects of connectedness should persist even when it is made explicit to participants that they have to, in effect, deprive their future self of resources in order to consume now, thereby highlighting the future consequences of impatience. In this study, we test whether disconnectedness causes impatience so pronounced that people actually are willing to spend their own money in order to consumer sooner.

The results of Study 1 show that over periods of time where one might reasonably expect meaningful change in the properties that comprise one's identity, providing information that highlights the likelihood of decreased connectedness leads to more impatience. Note, however, that the way in which people's perceived connectedness was manipulated relied on participants in different groups being presented with different information. A potential concern, then, is that participants' choices may have reflected a lay theory about what the appropriate effect of changes in identity on patience should be,

rather than reflecting their true preferences. Study 2 addresses this concern in two ways: (i) we pose participants with a decision involving real economic outcomes, and (ii) we manipulate connectedness while keeping the information content the same across the two conditions.

In this study, we used the inferences that participants reached from a metacognitive cue to manipulate their sense of connectedness to the future self. Specifically, we drew from the work on “accessibility experiences” (Schwarz, 2004) to indirectly manipulate people’s perceptions of the stability of their identity, by asking them to judge how difficult it would be to generate either 2 or 10 reasons why their identity will remain very stable over the next 12 months. Participants asked to imagine how difficult it would be to generate two reasons should find the task easy, and therefore have no reason to doubt the stability of their identity. Conversely, participants in the 10 reasons condition should anticipate that the task would be more difficult, and are likely to use this anticipated difficulty as a cue to question the stability of their identity, yielding a feeling of low connectedness.

Method

As part of a larger study, one hundred five graduating seniors filled out an online survey 1-2 weeks before their graduation in return for \$4 and entry into a lottery for which they could receive a real gift certificate.

All participants were presented with a passage that described the effect of college graduation on the stability of one’s identity as mixed. Participants in the high-connectedness condition were then asked to judge (on a 7-point scale) how easily they could generate 2 reasons why their own identity would remain very stable over the next 12 months (i.e., before and after graduation), after reading that most participants were able to generate 2 reasons in a previous study. In the low-connectedness condition, participants judged how easily they could generate 10 such reasons, after reading that most participants previously had been able to generate 10 reasons.

Lastly, they read that they had been entered into a lottery for a gift card. They read:

“The drawing will occur in two weeks, and if your survey is chosen, you will receive a \$95 Amazon.com gift card either in one year, or you can pay to receive it immediately after the drawing is held in two weeks.

What is the maximum amount that you would be willing to pay now to be able to use the \$95 gift card immediately?”

Results and Discussion

Manipulation checks. Participants in the 2 reasons (high-connectedness) condition rated the reason-generation task as relatively easy ($M = 5.28$, $SD = 1.51$) compared to the ratings of the participants in the 10 reasons (low-connectedness) condition ($M = 4.58$, $SD = 1.81$; $t(103) = 2.15$, $p < .05$).

Relating perceived (in)stability to willingness to pay to expedite gift certificate. Participants in the 10 reasons (low-connectedness) condition were willing to pay more to speed up receipt of the gift certificate ($M = \$14.83$, $SD = 15.96$) than were participants in the 2 reasons (high-connectedness) condition ($M = \$9.49$, $SD = 8.99$; $t(103) = 2.16$, $p < .05$). In

other words, participants made to feel disconnected from the future self were significantly more impatient—as in the previous study, they strongly preferred to allocate benefits to their sooner, more connected self over their later, less connected self. Unlike the previous study, making impatient choices did not merely imply being less generous to the future self, but rather required the participants to, in effect, deprive their future self of resources in order to consume sooner, thus highlighting the long term consequences of impatient choices.

Study 3

The studies above provide the first evidence that directly manipulating connectedness systematically affects people’s patience for the outcomes they will receive. Next, we test whether naturally-occurring individual differences in perceived connectedness to the future self relate to individual differences in patience. One goal was to rule out the possibility that the observed effects on impatience could be attributed to highlighting the notion of connectedness for our participants prior to their choices, by extending the findings to more natural contexts in which people might or might not spontaneously reflect on connectedness when making choices. Recall that in the prior studies, we manipulated perceived connectedness and then asked for people’s preferences. In this study, we instead employed a re-contact methodology. In the first stage, we measured connectedness (without manipulating it). Three weeks later, in a separate study, we re-contacted participants and collected preference data followed by measures of other psychological constructs known to affect intertemporal choice.

The second goal of this study was to assess the impact of several other variables that could contribute to possible alternative explanations for our findings. In particular, we assess whether intertemporal preference is affected by connectedness, even when we control for natural variation in several psychological factors, distinct from connectedness, that have been linked to patience in the literature. Furthermore, by simultaneously assessing the relationship of individual differences in connectedness and these alternative psychological factors with patience, we can gauge how large an impact connectedness has on patience relative to the impact of other important psychological factors..

In order to test whether rated connectedness has a unique influence on patience when controlling for other potentially explanatory variables, we included measures of (i) degree of “projection bias”, (ii) future anhedonia, (iii) time perception, (iv) reward responsiveness, and (v) non-planning impulsiveness at the end of the second survey.

Projection bias is a measure that captures whether people believe that specifically their *tastes and preferences* will be different in the future (Loewenstein et al. 2003), which might lead people to consume sooner, rather than later, if they think delayed benefits might not fit the future self’s tastes. “Future anhedonia” refers to an affective forecasting phenomenon where people view both positive and negative outcomes as less extreme the farther into the future these outcomes occur. Viewing both positive outcomes as less extreme when delayed

to the farther future may cause people to consume benefits sooner, when their positive qualities are more intense (Kassam et al., 2008). Time perception has been implicated by Zauberman et al. (2009) as a partial explanation for hyperbolic discounting and for high discount rates in the near future. In this view, the proportion of value retained over a given delay is linearly-related to the *perceived* duration of the delay, rather than the actual duration.

Lastly, people who score high in reward responsiveness (degree of desire induced by a reward; Carver & White, 1994) may be more susceptible to factors that induce impulsivity in discounting tasks, and non-planning impulsiveness (inability to resist temptation; Patton, Stanford, & Barratt, 1995) has been linked to higher discount rates (Hinson, Jameson, and Whitney 2003).

We argue that psychological connectedness predicts intertemporal choice over and above these other contending variables, and it does so even in a context in which the idea of connectedness to the future self is not brought to mind by the study's procedure. So, this study assesses the contribution of connectedness to patience, relative to the influence of several other relevant psychological factors.

Method

Ninety four undergraduates participated in the first round of data collection, 57 of whom agreed to participate in the second round of data collection when re-contacted. Participants in the first survey were paid \$1 for their time, and those who agreed to participate in the second survey participated in exchange for entry into a lottery for a \$50 gift certificate.

First survey. Participants gave three sets of connectedness ratings. First, as in Study 1, they circled the pair of Euler circles that best represented their perceived degree of connectedness. Next, participants were asked to think again about these identity-comprising properties and to rate connectedness on a 0 to 100 scale. Finally, participants were asked to draw a mark on a line to rate their connectedness. The multiple measurement procedures enabled us to limit the impact of elicitation method-specific biases.

Second survey. Approximately three weeks later, we re-contacted our participants, offering them an opportunity to participate in a second round of data collection. They were first presented with a titration task, in which they made real choices between receiving a \$50 gift card for Amazon.com (if their survey was chosen) in a week, when the drawing would be held, or receiving a larger-valued gift card in a year (\$50, 58, 66, 74, 82, 90, 98 or 106). Next, they responded to items which measured (i) projection bias, (ii) future anhedonia, (iii) time perception, (iv) reward responsiveness, and (v) non-planning impulsiveness.

Results and Discussion

We combined the three connectedness ratings (Euler circles, similarity rating, and line scale) into an index of connectedness which yielded high internal reliability ($\alpha = .91$). We used this index, along with the alternative variables, to predict people's discounting, as expressed in their choices of gift certificates.

Our measure of patience is simply the number of deferred, larger rewards chosen. We first correlated patience to each predictor variables individually; then conducted a multiple regression, including all predictor variables simultaneously.

Our index of psychological connectedness in the first survey was significantly correlated with patience for receiving a gift card, as measured three weeks later ($r = .29, p < .05$). In addition, projection had a marginally significant effect ($r = -.24, p < .10$), such that those who anticipated that their tastes would change exhibited less patience. None of the other measures had a significant correlation with patience in the gift card task.

More importantly, connectedness predicts patience in a multiple regression ($\beta = .78, p < .05$) controlling for the other factors which have been shown, in other circumstances, to exert their own influences on patience (but which were not significant in this regression). This finding is particularly striking, given that we measured each construct (connectedness and patience) uncontaminated by the other construct, due to the three week delay between the two measures. Thus, the fact that psychological connectedness remains a significant predictor of patience, even when all of the factors are entered in the regression simultaneously (model $R^2 = .20$), provides strong evidence for both the distinctiveness and pervasiveness of psychological connectedness as an explanation for discounting.

Summary and Conclusions

The three studies described here show that people's beliefs about the stability of the important characteristics that determine their identity over an interval of time also determine the patience they exhibit over that interval. People who perceive relatively less connectedness to their future selves require a larger delay premium to wait for a gift card, pay more to expedite receipt of a gift card, and are more likely to favor smaller-valued gift cards over larger-valued, delayed gift cards than people who feel highly connected to their later selves. Perceived connectedness, in turn, can be influenced by exposure to information regarding the variability of identity-comprising characteristics over time and by the ease with which reasons for expecting stability over time can be generated. We found that both manipulated and measured perceptions of connectedness influence intertemporal choice, even when connectedness is not brought to mind in the testing session. Moreover, in the last study, connectedness was shown to be a unique, and in our data, the strongest predictor of discounting compared to other psychological factors.

Taken together, these results shed light on a heretofore under-represented explanation of discounting, and one that is quite well-grounded theoretically (Parfit, 1984): A powerful determinant of people's future-oriented preferences, plans, and behavior is the person they expect to be when outcomes are realized. When this later person is more closely connected to the current self in terms of sharing important psychological properties, the decision maker is more motivated (consciously or not) to act patiently—that is, in a manner that reflects greater consideration of the later self's welfare.

To our knowledge, the current studies are the first to manipulate perceived connectedness to a later self and the first

to assess the descriptive adequacy of this determinant of discounting against the adequacy of other determinants. It is important to note, however, that temporal discounting is likely to be multiply-determined. There have been several attempts to integrate these multiple determinants in models of discounting (e.g., Killeen, 2009), but because none of the existing models accommodate how inferences about continuity of self over time affect preference, none explicitly account for the effects we have demonstrated. A model designed to capture our effects would need to incorporate a parameter which represents the degree of connectedness, such as the proportion of the defining characteristics of the current self's psychological make-up believed to persist in the future self at future points in time. Discounted utility would then be scaled by this parameter, representing the partiality towards more connected selves which we hypothesize and provide evidence for.

The key intuition of our framework that is absent from other accounts of discounting is that "impatience" can be the result of simply allocating less to a future self that is seen, to varying degrees, as a continuation of the current self. And notably, by our account, allocating less utility to a less connected later self is thus not necessarily a mistake. However, in those contexts where it is a mistake—for example, where people consistently fail to maintain their plans in advance of temptation (e.g., under-saving relative to budgetary allowances)—fostering the sense that what matters most in defining us persists over time may help us persist in achieving important goals, including those that most help us maintain what defines us.

WIN!! vs. win:

Impact of “Outcome” Salience on Illusion of Control

Abstract

In contingency judgment tasks (CJT) people typically overestimate their control over an outcome. We hypothesized that this outcome density effect (a type of illusion of control) may be due to an attentional bias toward positive outcomes, which may lead one to ignore negative outcomes and thus to underestimate their occurrence. In order to directly test this hypothesis, we manipulated the outcome's salience in a CJT, inducing participants to focus on either positive or negative outcomes. Results showed that enhancing the salience of positive outcomes (wins) enhanced participant's judgment of control more so than enhancing than of negative outcomes (losses). Moreover, when positive outcomes were salient, participants overestimated the amount of money they had earned during the experiment. In sum, the salience of the “outcome event” affected both judgment of control and memory for positive, more than for negative events, implying that attentional mechanisms may play an important role in the illusion of control phenomenon.

Keywords: Illusion of Control; Density Outcome Effect; Salience; Attention; Memory; Mood.

Introduction

The desire for control is widespread across both normal (see Keinan, 2002) and psychiatric (e.g. Moulding & Kyrios, 2007) populations, often leading to magical thinking, superstitious behavior and distortion of reality (e.g. Bar-Hillel & Neter, 1996). According to Taylor and Brown (1988), although correlating with psychiatric disorders (e.g. Reuven-Magril, Dar & Liberman, 2008), a moderately amount of positively distorted self-perceptions and expectations about the future might be functional in preserving mental health, through maintaining an adequate self-esteem. An important aspect of any adaptive behavior is the ability to selectively attend to salient or relevant information (Bradley, 2009). In fact, biased attention leads to distorted perception, often observed in major clinical disorders such as, depression (e.g., Leyman et al., 2007) and anxiety (e.g., Bradley et al., 1998). The present study focuses on the role of attentional biases in the establishment of cognitive illusions, specifically, the illusion of control (Langer, 1975).

Jenkins and Ward (1965) observed that in an active contingency judgment task (CJT), where participants had to judge the contingency between their action and an outcome, the perceived control correlates with the desired outcome's

density instead of the actual contingency. In an active CJT, observers typically have to perform an action (e.g., pressing a button) to which it may, or may not follow a desirable outcome. After the task they are asked to judge to what extent their action affected the outcome. The key finding is that people tend to base their judgment of control on the frequency of reinforcement instead of on the objective evaluation of the actual contingency (Jenkins & Ward, 1965). In other words, high outcome's density leads to a higher judgment of control, while lower outcome's density leads to an underestimation of control.

According to a study conducted by Alloy and Abramson (1979), only non-depressed individuals show the outcome density effect, while depressed subjects tend to estimate their control more realistically. Alloy and Abramson (1979) argued that the lack of the outcome density effect in depression (depressive realism) indicates that depressed people are “sadder but wiser” than non-depressed people. While non-depressed individuals seem to succumb to positive illusion, depressed people lack this illusion and show a more accurate judgment of the contingency between their actions and external effects. The outcome density effect has been referred to as a type of “illusion of control” (see Alloy & Abramson, 1979). In the illusion of control (Langer, 1975) people overestimate their chance to success, ignoring the objective evaluation of the actual contingency.

Only few studies (e.g., Msetfi et al., 2005) have proposed a link between the lack of illusion of control in depressed individuals and an attentional dysfunction. Msetfi and colleagues (2005) observed that differences between depressed and non-depressed individuals disappear at long inter trial intervals (ITI). They suggested that depressed people might be deficient in exploring all the contextual elements, due to an attentional deficit. This conclusion is supported by studies showing attentional deficits in depression (e.g. Paelecke-Habermann, Pohl & Leprow, 2005). Similarly, Allan, Siegel and Hannah (2007) suggested that differences between depressed and non-depressed people might rely on a change in the decision criterion related to the salience of the outcome (i.e. the one with lower density rate as in the case of low density outcome), instead of a distorted perception of contingency.

Here we suggest an alternative hypothesis, that illusion of control is due to an attentional bias toward positive outcomes, which may lead one to selectively ignore

negative outcomes, thus, to underestimate their occurrence. There is a growing number of studies showing that major depression is characterized by an impairment of selective attention (e.g., Purcell et al., 1997), increased sensitivity to negative reinforcement (Pizzagalli et al., in press) and enhanced brain response to negative feedback (Santesso et al., 2008). Moreover, Nelson and Craighead (1977) showed that depressed individuals recall the frequency of the negative feedback more accurately than non-depressed individuals. An attentional bias toward negative outcomes could enhance the memory for negative feedback and therefore, improve the performance in the judgment task.

In their Experiment 3, Alloy and Abramson (1979) implicitly manipulated attention, associating either positive outcome with a monetary winning or negative outcome with a money loss, separately. Illusion of control was observed only when the positive outcome was associated with a monetary winning. It has now been documented that monetary rewards have strong effects on the attentional system (e.g., Della Libera & Chelazzi 2009), thus it is likely that the value assigned to the outcomes may have modulated the attentional pull of these events. Specifically, the money loss associated with the negative outcome may have encouraged the observer to attend to the negative outcomes, eliminating the bias and therefore, the illusion of control. On the other hand, emphasizing the salience of positive outcomes should enhance the bias, therefore leading to an increase of the illusion.

The goal of the present study was to directly test the hypothesis that attentional mechanisms are involved both in the judgment of control and in the memory for events, in the CJT. We asked observers to estimate their control over an outcome in an active CJT, by pressing one of two buttons in the attempt to maximize their winnings. In the present experiment, although the relative density of the outcome changed ($P(O) = .25$ or $.75$), the actual control (ΔP)—defined as the difference between the probability of the outcome given an answer and the probability of the outcome given the other answer—was zero.

We manipulated attention by means of the outcome's salience by having two salience conditions (blocked between subjects): a condition in which the negative outcome was perceptually more salient than the positive outcome, and a condition in which the positive outcome was more salient than the negative outcome. In order to evaluate whether attention also affects the memory representation for winning and losses, we also asked participants to estimate the amount of money they thought they won in the experiment. Predictions are straightforward: if illusion of control is modulated by a natural tendency to neglect negative outcomes, an increase of the negative event's salience should accompany a reduction of the illusion. On the contrary, an enhancement of positive event's salience should enhance the illusion. If the same attentional bias also affects memory for positive and negative events, we also expect salience to affect the perceived money winning or loss.

Method

Participants

Fifty-four females and 43 males (age = 21 ± 3) participated in the experiment. All participants had normal or corrected to normal vision, signed an informed consent before the experiment and were paid \$8 per hour. Participants assigned to the high reward rate condition were given extra \$5 at the end of the experimental session.

Stimuli and Materials

Stimuli (Figure 1) were presented on a 21-inch monitor running at 85Hz. All stimuli were white unless otherwise specified, and they were displayed on a black background. All writings were typed in white, Helvetica font. The fixation point appeared in the center of the monitor, and consisted of a cross sign subtending 0.6° visual angle. The "get ready" message appeared at fixation and occupied 1° visual angle vertically and 16° horizontally. The countdown numbers subtended about $1^\circ \times 2^\circ$ visual angle and replaced fixation, when displayed.

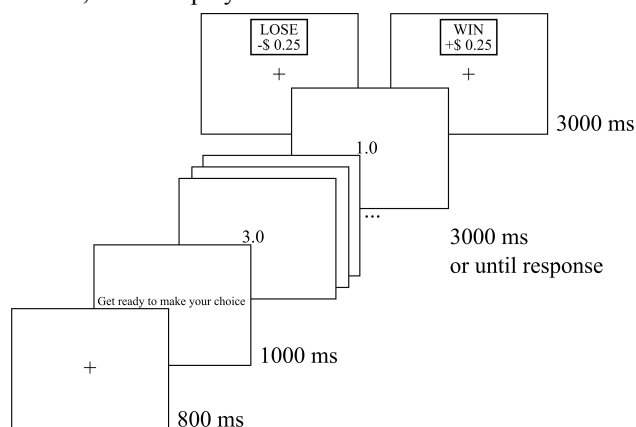

Figure 1. Stimuli used in the contingency judgment task.

The outcome display consisted in a box ($6.4^\circ \times 4.4^\circ$ visual angle) located 6° above the fixation point. One of two messages could be displayed inside the box: the word "WIN" presented above the amount of money actually won on that trial, or the word "LOSE" above the amount of money lost on the trial (see Figure 1). On salient trials, the outcome boxes were very similar to the boxes on regular trials, with the only difference that the inner part was red and the outline was yellow; the font size was also increased.

Visual Analogue Mood Scales (VAMS) We used the VAMS to assess the mood of participants in the experiment. In this procedure, six positive adjectives are presented. The bottom of the page contained the question: "How do you feel right now?". Below the question, the adjectives: "Pleased", "Cheerful", "Optimistic", "Contented", "Satisfied" and "Happy" are displayed. Underneath each adjective there was a 100mm long line. Participants were verbally instructed to draw a mark along the line, at the point that best described their feelings, in that particular

moment. Score varies from 0 to 100, with “Not at all” at the left-most position in the line, and “Very much” at the right-most position. Intermediate values correspond to intermediate states.

General procedure

Upon arrival to the lab, participants were asked to sign an informed consent and to fill out the first VAMS. Through the whole exchange, the experimenter acted very friendly, using a cheerful attitude and trying to set up a positive interaction. Participants then watched a 5 minutes long, pleasant movie after receiving a treat (i.e., a candy). After the video, they were asked to recall a happy memory. The goal of these manipulations was to improve participants’ mood (e.g. Rottenberg, Raye & Gross, 2007), because it has been shown that positive mood enhances the illusion of control (Alloy, Abramson & Viscusi, 1981). Importantly, it was not our goal to study the effects of mood on the illusion of control, but simply to maximize the magnitude of the effect, so that we could in turn study modulations of this magnitude by our attention manipulations. Once these manipulations were completed, participants filled out a second VAMS and then, performed the CJT. A subset of participants also completed a third VAMS after the CJT.

Procedure

Participants sat in a comfortable chair, positioned at 56cm from the monitor and located in a dim-lighted, thermo-regulated room. Given that realistic circumstances enhance illusion of control (Matute, 1996), participants were told that they had the actual opportunity to win money depending on their button pressing, and they were asked to make an effort in order to figure out the best strategy to win more money. They were suggested to explore the use of the two buttons as much as possible. This was meant to discourage participants from adopting the strategy of pressing only one of the two buttons. Such strategy would not be desirable in this type of task because it would inflate the participant’s perceived control. Even if the instruction were clear and effective (only two subjects pressed the same button throughout the whole task), uncontrolled imbalance was taken into account.

Each trial (Figure 1) begun with a fixation point, which participants were instructed to look at. One second later, a “Get Ready” message appeared (also 800 ms in duration). Following this message, participants were given 3 seconds to make a choice between two keyboard buttons (“c” or “n”). During this time, there was a numerical countdown display on the monitor, with the numbers 10 counting down towards one, three times in a row. The countdown stopped after 3 repetitions or upon the subject’s response. This procedure had the purpose to maximize the illusion of control, which has been shown to increase using stopping devices (Ladouceur, & Savigny, 2005). Participants were simply asked to press a button during the countdown.

After the response, a box appeared for 3000 ms to tell participants whether they won or lost \$0.25. If no response

was detected, a warning message appeared and a new trial began.

After the task participants were asked to judge both, how much control they had over the outcome on a scale from 0 (no control) and 100 (complete control). Intermediate values corresponded to intermediate judgments of control. In addition, they had to indicate the total amount of dollars they believed to have earned throughout the whole experiment.

Design

Participants were randomly assigned to one of the six possible conditions (each made-up of 40 trials). There were two levels of reward frequency: low reward rate, in which the relative density of the positive outcome $P(W)$ was 0.25—i.e., the negative outcome occurred 75% of the trials—and a high reward rate, in which the relative density of the positive outcome $P(W)$ was 0.75—i.e., the negative outcome occurred 25% of the trials. One half of the participants were assigned the low reward rate condition and the other half was assigned the high reward rate condition. Within each group, one third of the subject were assigned to the control condition (identical salience for win and loss feedback messages), one third were assigned to the condition in which the negative outcomes (the loss events) were salient (the loss salient condition) and the remaining third received the one in which the positive outcomes (the win events) were salient (the reward salient condition).

Independently of the reward rate, the CJT gave participants no control ($\Delta P=0$). That is, the reward rate varied independently from which button the participant decided to press.

Data analysis

Six people were excluded from the analysis because of missing data; one was excluded for participating in the experiment twice and another one was excluded for providing an unrealistic answer about the winning’s amount.

In order to evaluate the effectiveness of our mood induction procedure, and to rule out the possibility that our results could be caused by mood differences, a mixed ANOVA was carried out on the VAMS scores (before mood induction, after mood induction) with reward rate (low, high) and salience (control, loss salient, reward salient) as factors.

In order to evaluate the effect of attention on the outcome density effect, judgments of control and win were analyzed using a between-subjects ANOVA with reward rate (low, high) and salience (control, loss salient, reward salient) as factors. VAMS scores collected after mood inductions were included as covariate.

Judgments of control were corrected for the actual amount of control that participants experienced during the task, by means of the formula adapted from Allan (1980):

$$\Delta P = P(W | C) - P(W | \sim C)$$

where $P(W|C)$ is the relative probability to win by pressing one button (“c”) and $P(W|\sim C)$ is the relative probability to win by pressing the other button (“n”). Judgments of control were also analyzed using a series of t-tests, in order to evaluate whether they differed from zero (correct estimation of control).

Judgments of winnings were corrected for the actual amount of money won during the CJT, so that positive values correspond to an overestimation of winnings and negative values correspond to an underestimation of the winnings.

Results

Mood The 3 (mood; before mood induction, after mood induction, after task) by 2 (reward rate; low, high) by 3 (salience; control, loss salient, reward salient) ANOVA on VAMS scores for happiness showed a significant effect of mood induction ($F_{2,132}=10.3$; $p<.001$). Happiness after mood induction (mean = 82 ± 16.15) increased by 12%, when compared to the first assessment (mean = 70 ± 19.29 ; $p<.001$) and decreased again after the experiment ($p<.001$). More important, there was a significant interaction ($F_{2,132}=4.8$; $p<.01$). Post hoc tests showed that, after the CJT, the mood in the high reward rate groups was higher than the one in the low reward rate ($p<.001$). Mood decreased by 26% after the CJT in the low reward rates groups ($p<.01$), while in the high reward rate condition it remained higher than the first assessment ($p<.001$) but it did not change with respect to the second assessment ($p>.05$).

Judgment of Control as a function of reward rate and Outcome Salience The 2 (reward rate; low, high) by 3 (salience; control, loss salient, reward salient) ANCOVA on judgments of control (corrected by the actual control, ΔP) showed a significant effect of the reward rate ($F_{1,90}=25.23$; $p<.001$). Participants assigned to the high reward condition (mean = 22.19) reported higher perceived control than the ones assigned to the low reward rate condition (mean = -4.19). The interaction between reward rate and salience showed a tendency towards significance ($F_{2,90}=2.91$; $p=.06$). In order to better understand this result, we ran an ANCOVA using reward rate (low, high) and only two levels of reward salience (control, loss salient). This analysis only showed an effect of the reward rate ($F_{1,58}=8.32$; $p<.01$). Participants who performed the high reward condition (mean = 15.41) reported higher perceived control than the ones assigned to the low reward rate condition (mean = -2.97). The interaction between reward rate and reward salience was not significant ($F<1$). A second analysis focused on the reward-salient results: we ran an ANCOVA with factors reward rate (low, high) and two levels of salience (control, reward salient). This analysis showed an effect of the reward rate ($F_{1,64}=22.9$; $p<.001$), with groups assigned to the high reward condition (mean = 23.66) reporting higher perceived control than the ones assigned to the low reward rate condition (mean = -5.08). More importantly, the interaction between reward rate and reward salience was significant, $F_{2,64}=6$; $p<.05$ (see Figure 2).

Further post hoc analyses revealed that this significant interaction was reflecting the fact that the group assigned to the [high reward rate, reward salient] condition reported higher perceived control ($F_{2,31}=7.1$; $p<.01$) than the other groups.

Further analysis on the judgment of control, using Student’s t-test, showed that none of ratings of control for the groups in low reward conditions differed than zero (all $ps>.05$). Moreover, judgments of control expressed by participants assigned to the high reward rate condition were significantly higher than zero only when the positive outcome ($p<.001$) was salient; when none of the outcomes was salient there was a tendency to significance ($p=.06$) while when the negative outcome was salient the judgments of control were no significantly higher than zero ($p=.08$).

Figure 2. Reported judgment of control corrected by the actual control experienced during the task.

Winnings results The 2 (reward rate; low, high) by 3 (salience; control, loss salient, reward salient) ANCOVA on the difference between the reported and the actual winnings showed a significant effect of the reward rate ($F_{1,90}=41.1$; $p<.001$).

Figure 3. Errors in perceived money won, corrected for the actual winning displayed by a) salience and b) reward rate. Positive values indicate overestimation and negative values indicate underestimation of winnings.

The groups assigned to the low reward condition (mean = 4.39; corrected for the actual winning) overestimated their winnings more than the ones assigned to the high reward rate condition (mean = 0.03). The analysis also showed an effect of salience ($F_{2,90}=3.04$; $p<.05$; Figure 3), with overall larger overestimation errors in the reward salient condition (mean = 3.5) compared to control and loss salient conditions (mean = 1.6, mean = 1.4, respectively). The interaction between reward rate and salience was not significant ($F<1$). Post hoc tests showed that the group assigned to the reward

salient condition overestimated their winnings more than the ones assigned to the loss salient condition ($p < .05$); moreover, the difference between the control condition and the reward salient condition also tended towards significance ($p = .06$), but failed to reach it due to relatively larger variability in that condition, compared to the loss salient condition.

Discussion

The aim of this study was to evaluate the role of attention in the outcome density effect. We hypothesized that, if the illusion of control is caused by an attentional bias toward the positive outcome, increasing the negative outcome's salience should reduce the illusion. On the other hand, salient positive outcomes were expected to enhance the illusion.

The results partially confirmed our hypotheses: judgments of control were indeed inflated when the positive outcomes were made more salient; yet, judgments of control were unaffected by the salience of the loss outcomes.

Overall, our results replicated the traditional outcome density effect (Jerkins & Ward, 1965). Judgments of control of participants who were often rewarded were higher than those of participants who received fewer rewards. Furthermore, participants in the high reward rate condition tended to overestimate the control they exerted over the outcome ($p = .06$).

The enhancement of perceived control when the positive outcome occurs often and when it is more salient than the negative one, is in accordance with the hypotheses that attention modulates the illusion of control: the increased salience of positive outcomes likely attracted attention towards those events, enhancing a baseline bias towards attending to those events in the first place, increasing the illusion of control. That said, it is also important to note that equivalent salience manipulations on the feedback of "loss" events did not significantly modulate neither the illusion of control nor the perceived winnings in the task.

Our mood induction procedure was successful in enhancing the general mood in participants. Importantly, differences in the mood of participants across groups were not responsible for the differences observed in perceived control or winnings, since no difference in participant's mood was observed across conditions.

There may be several reasons why our salience manipulation failed to influence the illusion of control in the loss salient condition. It is possible that the specific colors we chose in our manipulation may have interacted differently with the perceptions of gain and loss. There is a lifetime associations between yellow and cautious behavior and red with maximum levels of hazard (see Williams and Noyes, 2007; for a review). If the observers interpreted the color of the outcome as a warning clue, it is possible that this encouraged them to abandon a risk taking strategy, which is common in gamblers and known to be correlated with illusion of control (Fenton-O'Creevy et al., 2003). Moreover, results showing that red color facilitates

cognitive tasks in which negative stimuli are involved (Mehta, & Zhu, 2009) suggest that positive and negative salient outcomes may have been processed differently. Specifically, red may have increased accuracy in remembering the occurrence of the negative outcomes only. That said, this would not explain why the illusion grew in size in the reward condition. Lastly, it is well known that gains and losses are perceived asymmetrically to begin with (Kahneman & Tversky, 1979). As such, it is possible that loss aversion may have been at play in our experiment, making participants in the loss salient conditions overall more cautious than in the reward salient condition, or turned them into more "objective" assessors of the events (much like in the "depressed realism" effect). In contrast, participants in the reward salient condition may have been more prone to get excited about their winnings, inducing something like a positive-mood amplification of the illusion of control effect. Overall, the asymmetry in the effects of event salience on perceived control and perceived winnings has strong implications in terms of understanding some aspects of gambling behavior: in most gambling situations, loss events have little salience, whereas win events tend to be very salient. This may be contributing to increase levels of illusion of control in gambling scenarios (like slot machines), and further, our results suggest that simply increasing the salience of the loss events (making them as bright and noisy as win events) may be insufficient to counteract the increased illusion of control arising from salient win events.

A reverse outcome density effect was observed in the winning ratings. On the one hand, participants generally overestimated the amount of money won in the experiment. On the other hand, the biggest mistake in overestimating the amount of money was observed in the low reward rate condition (i.e., when the win events happened more rarely). This result, although surprising, could be due to a bias induced by the experimental procedure: subjects signed an informed consent in which they were promised a fixed amount for the experimental session, plus the possibility to increase their earnings for the day. This manipulation is intended to increase the illusion (Matute, 1996), but could have caused participants to be skeptical on the actual possibility to lose money during the experiment, encouraging them not to state a money loss.

A particularly striking result was the salience effect observed on the winnings recall. When the positive outcome was salient, participants overestimated the winnings more than in either of the other two conditions (salient loss outcome and control conditions). This result was independent of the reward rate and, although preliminary, might also be potentially relevant to gambling. Winnings are often exaggerated and amplified by means of lights, sound and colors and the saliency is not necessarily commensurate to the actual winning. This may not only increase the gambler's tendency to overestimate its own control over the situation but also to remember inflated winnings throughout the gambling experience.

In sum, in line with our initial hypothesis, attentional biases seem to partly contribute to the illusion of control phenomenon. Salience of the outcome, in fact, modulated both the contingency judgment and the memory for winnings. These results are promising and have potentially important implications for the understanding of cognitive mechanisms underlying gambling behaviors.

Abstract

Base-rate neglect, the tendency of adults to ignore the prior probability of an event, has been well-studied over the past decades. However, the evidence for base-rate neglect and its theoretical implications are still debated. We argue that such lack of agreement comes from the mistaken assumption that performance unequivocally reflects cognitive processes. We adopt a different viewpoint, namely that performance reflects existing constraints in the person-task relation. To test whether this viewpoint is appropriate for performance in base-rate problems we manipulated the constraints available in the task's response options. With a highly constraining response mode adults are expected to exhibit the classic base-rate neglect, with little variability in their performance as procedural factors are manipulated. However, with a less constraining response mode performance is expected to be more variable and more susceptible to subtle changes in the task procedure. Results support this view, demonstrating non-linear context effects in decision making.

Keywords: rationality; adult reasoning; context effects.

Introduction

Consider the following problem:

"In a study 1000 people were tested. Among the participants there were 5 engineers and 995 lawyers. Jack is a randomly chosen participant of this study. Jack is 36 years old. He is not married and is somewhat introverted. He likes to spend his free time reading science fiction and writing computer programs. What is most likely? (a) Jack is a lawyer (b) Jack is an engineer."

Based on the description of Jack, you may be tempted to think that he is an engineer; after all, he is introverted, he enjoys reading science fiction, and he writes computer programs. Indeed, a vast majority of adults would agree with you (De Neys & Glumicic, 2008). However, the statistical information provided in the problem indicates otherwise. Given that Jack was randomly selected from a study consisting of far more lawyers than engineers (995 vs. 5), it follows that Jack is most likely a lawyer.

This type of decision-making problem has a long history in the literature on reasoning, stretching back to the classic studies of Daniel Kahneman and Amos Tversky (1973). Despite nearly four decades of research featuring these base-rate problems, discussions concerning the task are still going strong. Take, for example, the disagreement about the influence of presenting statistical information as frequencies

rather than one-case probabilities. Some argue that presenting problems in terms of frequencies has more ecological validity and, therefore, improves performance on the task (Cosmides & Tooby, 1996; Gigerenzer & Hoffrage, 1995; Hoffrage, Gigerenzer, Krauss & Martignon, 2002). Others have suggested that gains in performance are not attributable to the frequency format alone, but to presentation formats that encourage the formation of a set inclusion mental model (Evans, Handley, Perham, Over & Thompson, 2000).

Or consider the discussion about how to characterize the cognitive processes that take place as the task is solved. Is human reasoning subserved by two distinct processes (c.f., Evans, 1984; 2007; Kahneman & Frederick, 2002; Stanovich & West, 2000), one being heuristic while the other is analytic? If so, how do these processes function in relation to one another? Is one of these processes the default, aided by the other process only in the case of conflict? Or is the dual-process approach presenting a false dichotomy altogether?

There is even disagreement about whether base-rate neglect implies a shortcoming of the human mind or a sophisticated adaptation. Some suggest that neglect of base-rate information is an indication of humanity's underlying irrationality (Nisbett & Borgida, 1975), while others argue that the exact same performance reflects adaptive processes that maximize efficiency in decision making (Gigerenzer & Brighton, 2009).

Similar disagreements in how to interpret performance have been documented in virtually all of adult cognition, including memory, attention, decision making, and learning (for a review see Van Orden, Pennington, & Stone, 2001). It is rather the norm than the exception to disagree about which task might best reflect natural reasoning, or how to best characterize underlying cognitive processes. These disagreements are symptomatic of an assumption that performance in a task allows direct inferences about cognitive structures or cognitive processes that are at work (for full arguments, see Kloos & Van Orden, 2009; Van Orden & Kloos, 2003). Only if performance is thought to be transparent to the underlying cognitive architecture can details of the task context be argued about. But this assumption, known also as the 'effect = structure' fallacy, has been shown to be faulty (e.g., Gibbs, 1994; Lakoff, 1987). An alternative is the assumption that performance reflects a unique person-task relation, one that cannot be

reduced to the person (or the task) alone (e.g. Gibson, 1979).

The idea that performance reflects non-reducible person-task units has been formalized in the idea of constraints that reduce degrees of freedom for action (Kloos & Van Orden, in press). If a task context is highly constraining (e.g., there are only two answer options, one of which is understood to be correct), then we expect to see formulaic, uniform performance – as if a stable cognitive structure or process is operating. If, however, a task context is less constraining (e.g., the person is presented with many answer options or believes that there is no right or wrong answer), performance is likely to be affected by idiosyncratic aspects of the person's history, miniscule changes in the procedure and seemingly irrelevant aspects of task instructions or stimuli. The resulting difference in performance does not reflect different cognitive processes but rather a different coupling between the person and the task.

In the current paper we investigate whether the idea of constraints could help shed light on performance in a base-rate neglect task (c.f., Kahneman & Tversky, 1973). Adult participants had to determine the likelihood of a certain event, given base-rate information (the a priori statistical probability of a certain event) and individuating information (the stereotypical probability of the event). The crucial manipulation was in the answer options: Participants were presented either with highly constraining multiple-choice answer options (*multiple-choice condition*), or they were presented with less constraining open-ended answer options (*open-ended condition*). We also manipulated a superficially irrelevant factor, namely the order in which information was presented: In *Order 1*, base-rate information appeared first, before the individuating information; and in *Order 2*, base-rate information appeared second, after the individuating information. If constraints, rather than cognitive structure, decide the performance in a task, then our constraints manipulation should matter. In particular, one would expect performance to be more susceptible to order changes in the less constraining task (open-ended response options) than in the more constraining task (multiple-choice response options). A recall task was added at the end of the experiment that had the same response mode across conditions. This allowed us to determine the degree to which conditions differed in how information was encoded.

Method

Participants

Participants were 24 undergraduate students from the University of Cincinnati (10 men, 14 women) who volunteered their time in return for course credit. The mean age of participants was 19.25 years ($SD = 3.43$). One additional adult was tested and excluded from the final sample due to apparent confusion with task procedures.

Materials and Procedure

Participants were tested individually in a quiet room. The testing session consisted of a decision-making task, an unannounced recall task, and a brief exit survey. As was done in a recent study by De Neys and Glumicic (2008), participants were asked to think aloud while solving the decision-making problems. Participants were introduced to the experiment and the thinking-aloud procedure with the following script used by De Neys and Glumicic:

“In this experiment we try to find out how people solve everyday reasoning problems. Therefore, we ask you to “think aloud” when you’re solving the problems. You should start by reading the complete problem aloud. When you’re solving the problem you have to say everything that you’re thinking about. All of the inferences you’re making, all the comments that you’re thinking of, basically everything that is going through your mind, you have to say aloud. You should be talking almost continuously up until the point that you have answered the question. Try to keep thinking aloud the whole time. If you are silent for a while I will ask you to continue to voice your thoughts.”

Participants were then given the opportunity to ask questions concerning the thinking aloud procedure. Once the participants were ready to move on, the experimenter began the audio recording and presented the decision-making task. Using the same problem set developed by De Neys and Glumicic (2008), the decision-making task consisted of 18 separate decision-making problems, each containing base-rate information and individuating information. The order of problems was randomized, and the problems were organized in booklet form. The first page of each booklet featured a set of instructions which corresponded to the response mode of the featured problems. Participants in the multiple-choice condition received the following instructions, again adapted from De Neys and Glumicic (2008):

“In a big research project a number of studies were carried out where short personality descriptions of the participants were made. In every study there were participants from two population groups (for example, carpenters and policemen). In each study one participant was drawn at random from the sample. You’ll get to see the personality description of this randomly chosen participant. You will also get to see the number of people in each of the two population groups. Finally, you will be asked to indicate which population group the participant most likely belongs to (policemen, for example) by circling a response.”

Only the last sentence was modified for participants in the open-ended condition. It read: “Finally, you will be asked to write the probability that the randomly chosen participant belongs to one of the population groups (policemen, for example).” Participants were asked to read the instructions aloud and were given the opportunity to ask questions regarding the task. Participants then began the decision-making task.

The base-rate information featured a brief description of a sample of 1000 people who were said to have taken part of a study. The sample consisted of two groups of people which were grossly disproportionate in number. For example, base-rate information in one problem stated: ‘In a study 1000 people were tested. Among the participants there were 5 sixteen-year olds and 995 fifty-year olds. Ellen is a randomly chosen participant of this study.’ Other ratios used were 996 to 4 and 997 to 3.

The individuating information provided a description of an individual who was randomly selected from the featured sample of 1000 people. For instance, given the base-rate example provided above, the individuating information was described as: ‘Ellen likes to listen to hip hop and rap music. She enjoys wearing tight shirts and jeans. She’s fond of dancing and has a small nose piercing.’

In a third of the trials, base-rate information was pitted against individuating information; the description of the selected person was stereotypic of an individual from the smaller group of the sample (like in the example above). These trials were *incongruent* because the stereotypic associations did not match the most probable option according to the base-rate information.

Alternatively, in another third of the trials, base-rate information matched with the individuating information. That is to say, individuating information was stereotypical of an individual from the larger group of the sample. These trials were considered *congruent*. Finally, the remaining six problems did not feature stereotypes of either population group and, therefore, were considered *neutral* problems.

In order to determine how adults combine base-rate with individuating information, each set of information was followed by a question. In the multiple-choice condition, participants had to select the most probable event out of two options. For example, given the information provide above, the test question was: ‘What is most likely? (a) Ellen is sixteen (b) Ellen is fifty’. The answer options (a) and (b) were counterbalanced, such that answer option (a) matched with the base-rate information in half of the trials, while answer option (b) matched with the base-rate information in the other half of the trials.

In the open-ended condition participants were asked to write the probability of the event. For example, the question from the base-rate and individuating information above was: ‘What is the probability that Ellen is sixteen?’ or ‘What is the probability that Ellen is fifty?’ Half of the questions inquired about the smaller sub-group of the sample and the other half inquired about the larger sub-group of the sample.

In the open-ended response mode additional instructions were occasionally provided. For example, if participants were unsure of how to express their answers, the experimenter explained that probabilities are typically expressed as fractions, decimals or percentages. If participants wrote responses such as “the probability is high,” the experimenter requested a more specific, numerical response. Finally, in instances where participants

responded with ranges such as “50-70%,” the experimenter instructed participants to provide a more precise response.

At the conclusion of the task the audio recording was stopped. The experimenter then checked the decision-making task to ensure that none of the problems were overlooked. After a short break of about a minute, participants were presented with an unannounced recall task and were instructed to answer the questions to the best of their ability. As was done in the De Neys and Glumicic (2008) study, participants solved four recall questions for each corresponding decision-making problem. The first two questions tested recall of base-rate information, and the second two tested recall of individuating information. All four questions were printed on one page. The pages were once again stapled into a booklet and followed the same order with which the decision-making problems were presented. The following is an example of the recall task:

One of the problems you just solved concerned Ellen whose description was drawn at random from a sample of fifty-year olds and sixteen-year olds. Try to answer the following questions.

Exactly how many sixteen-year olds were there in the study?

Exactly how many fifty-year olds were there in the study?

Circle the correct statement:

- a. Ellen likes to knit
- b. Ellen listens to hip hop
- c. Ellen shops at thrift stores
- d. Ellen drives a truck

Circle the correct statement:

- a. Ellen speaks German
- b. Ellen plays the trumpet
- c. Ellen does not have a job
- d. Ellen has a small nose piercing

After completing the recall task participants were presented with an exit survey that measured the participants’ perceptions of the task.

Design

There were two different orders (Order 1: Base-rate First; Order 2: Base-rate Second) and two answer modes (Multiple-choice condition; Open-ended condition). Participants were randomly assigned to one of the four resulting experimental groups. Each participant solved six incongruent problems, six congruent problems, and six neutral problems. Recall was identical across groups.

Results

Our first analysis pertains to participants’ performance in the multiple-choice condition. It was scored according to whether the normatively correct option was selected (i.e., the answer option that corresponded to the largest

population group). Responses were collapsed across trials within problem type (incongruent, congruent, neutral), yielding three proportion-correct scores for each participant. Figure 1A displays the means of these scores for the multiple-choice condition as a function of problem type and order. A mixed-design 2 x 3 ANOVA (with problem type as the within-subject factor and order as the between-subject factor) revealed a significant effect of problem type, $F(2, 20) = 101.42, p < .001$, but no significant effects of order or order interaction, $ps > .4$. As expected, below-chance performance was obtained for the incongruent problems ($M = 0.19, SE = 0.05$), while performance was at ceiling (or above chance) for congruent problems ($M = 1.00$) and neutral problems ($M = 0.83, SE = 0.11$). The order in which information was presented had no effect on performance in this condition.

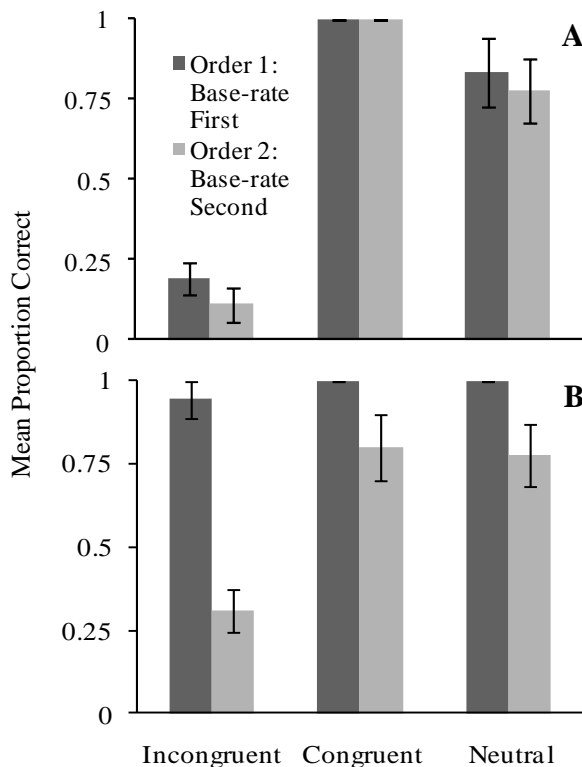

Figure 1: Mean proportion of correctly answered problems as a function of problem type and order. A: multiple-choice condition. B: open-ended condition. Error bars display standard errors.

A very different picture emerges when adults were given a continuum of response options (opened-ended condition). Responses to the prompt for each trial were first scored to match the multiple-choice scoring system. Probabilities below 50% were scored as correct for questions that pertained to providing the probability that the individual is a member of the smaller population group. Alternatively, probabilities above 50% were scored as correct for

questions that pertained to providing the probability that the individual is a member of the larger population group. Responses of 50% were not included in the following analysis. This resulted in the exclusion of three of 108 responses in Order 1 and six of 108 in Order 2.

Figure 1B displays the mean proportion of correct responses in the open-ended condition as a function of problem type and order. A mixed-design 2 x 3 ANOVA (with problem type as the within-subject factor and order as the between-subject factor) revealed not only the expected significant effect of problem type, $F(2, 20) = 10.04, p < .001$, but also a significant effect of order, $F(1, 10) = 52.90, p < .001$, and a significant interaction, $F(2, 20) = 6.30, p < .01$. Problem type affected performance only in Order 2, $F(2, 10) = 9.05, p < .01$, with below-chance performance on incongruent problems ($M = 0.31, SE = 0.06$), and above-chance performance on congruent problems ($M = 0.80, SE = 0.10$) and neutral problems ($M = 0.78, SE = 0.09$). In Order 1, however, problem type did not affect performance, $F < 1.0, p < .4$, with participants performing at or near ceiling on all problem types ($M = .98, SE = .02$).

One critique of the above analysis is that the assumption of homogeneity of variance was not met across problem types. A Levene's test of equality of error variances revealed significant difference in variance for the congruent and neutral problem types ($ps < .01$), undermining the results of the parametric tests for these problem types. For this reason, we focus only on the incongruent problem type in the next analysis. Recall that this problem type is the more relevant problem type in the base-rate literature because it demonstrates the base-rate neglect. A 2 x 2 between-subjects ANOVA, with response mode (multiple-choice; open-ended) and order (Order 1, Order 2) as between-subject factors, replicates the results of our previous analyses. It revealed a significant effect of response mode, $F(1, 20) = 69.45, p < .001$, a significant effect of order, $F(1, 20) = 39.53, p < .001$, and a significant interaction effect, $F(1, 20) = 23.28, p < .001$.

To account for performance in the open-ended condition on a continuum, and thus to get a more accurate sense of the data, we computed the distance of responses from the normatively correct probability. For example, if a participant responded with "30%" when the normatively correct response 0.5% or lower, the resulting score would be 29.5%. These scores were once again collapsed across trials within a problem type, yielding three mean distance scores for each participant. Figure 2 shows the mean scores as a function of problem type and order.

A mixed-design 2 x 3 ANOVA (with problem type as the within-subject factor and order as the between-subject factor) revealed a significant effect of problem type, $F(2, 20) = 11.17, p < .001$, a significant effect of order, $F(1, 10) = 33.41, p < .001$, and a marginally significant interaction, $F(2, 20) = 3.04, p < .07^1$. Once again, a significant effect of

¹ The interaction might not have reached significance due to unequal variances between the two orders, found for each of the problem types (Levene's Test: $Fs(1,10) > 11.8, ps < .01$).

problem type was found for Order 2, $F(2, 10) = 8.81$, $p < .01$, but not for Order 1 ($p > .13$).

Figure 2: Mean distance from normatively correct probability as a function of problem type and order in the open-ended condition. Error bars display standard errors.

Finally, performance in the open-ended condition was scored in a third way, this time according to whether the response violated the rules of normative probability. For example, if the base-rate information listed a ratio of 3 to 997, probability judgments above 0.3% were scored as incorrect (assuming the question pertained to providing the probability that the individual is a member of the smaller population group). A mixed-design 2 x 3 ANOVA (with problem type as the within-subject factor and order as the between-subject factor) revealed a significant effect of order $F(1, 10) = 26.35$, $p < .001$, no significant effect of problem type, $p > .4$, and no significant interaction, $p > .4$. As Figure 3 illustrates, average performance across problem types was higher for Order 1 ($M = .81$, $SE = .12$) than for Order 2 ($M = .06$, $SE = .12$).

Figure 3: Mean proportion of normatively correct answers as a function of problem type and order (Order 1: Base-rate First, Order 2: Base-rate Second) in the open-ended condition. Error bars display standard error.

Thus far we have shown that the pattern of responses on the decision-making task varied with response mode (multiple-choice vs. open-ended). In the multiple-choice condition order had no effect on performance. But in the open-ended condition, no matter how data was scored, order had a highly significant impact.

One could argue that the difference between conditions is spurious, due to perhaps extraneous factors pertaining to small sample size. Our analysis of participants' base-rate recall provides reason to doubt these possible objections. Bear in mind that recall took place at the end of the experimental session, and the task employed the same response mode for all participants. Thus, if the effect of response mode in base-rate problems was spurious due to small sample size, then we would expect to see differences among conditions in the recall task as well.

Performance on recall of the base-rate information was scored according to whether participants correctly identified the relative size of each group (i.e., which group was larger and which group was smaller). A 2 x 2 x 3 mixed-design ANOVA was conducted, with condition and order as the between-subject factors and problem type as the within-subject factor. Importantly, there was no significant difference and no significant interaction ($F_s < 2.47$, $p_s > .13$), with above-chance performance for each group (assuming a chance probability of 0.5), single-sample $t_s > 2.2$, $p_s < 0.05$. Figure 4 provides the individual means for response mode and problem type, collapsed across order.

Figure 4: Mean proportion of correct recall as a function of response mode and problem type. Error bars display standard error.

Summary and Discussion

A commonly used base-rate problem was adapted in the current experiment to manipulate the constraints of the task context. Adults participated in one of two conditions that differed only in whether the base-rate problems had a constraining multiple-choice response mode, or a less constraining, opened-ended response mode. Patterns of performance across base-rate problems differed markedly as a function of our manipulation.

In the multiple-choice response mode participants demonstrated the classical base-rate neglect without being affected by superficial changes in the order in which the information was presented to them. Conversely, in the open-ended response mode participants neglected base-rate information only in one of the order conditions, when base-rate information was presented after individuating information (Order 2). In the reverse order, when base-rate information was presented before individuating information (Order 1), participants took base-rate information into account.

Note that Order 1 is the common way in which information was presented to participants in previous research (e.g., De Neys & Glumicic, 2008; Kahneman & Tversky, 1973). Accordingly, we did indeed replicate the previous findings when the multiple-choice response mode was used. But when the response mode was less constraining, the superficial changes in order made a difference in performance. Performance in the recall task provides reason to doubt the possibility that these differences are spurious effects of some sort. Participants in all groups performed above chance on the recall task, independently of how the information was presented in the decision-making problems.

The results of the present investigation underscore the idea that performance cannot be uniquely attributed to cognitive structures or processes. Any plausible cognitive structure that could be responsible for the current findings would be post-hoc and rather complex, given that even irrelevant changes in order affected performance. A constraints view, in contrast, could readily explain our results. It predicts, a priori, that the tightening of degrees of freedom cuts down on idiosyncratic variability in performance and the impact of seemingly superficial factors. Our findings suggest that adults are neither rational nor irrational reasoners. Instead, their performance reflects a coupling with the task, and thus says as much about the task as about the reasoner.

Abstract

This article proposes a method by which anchoring effects can be mathematically modeled. Anchoring effects are a type of assimilation effect; so this article proposes using Anderson's (1965; 1981) integration model to model anchoring effects, as it is typically used to model other assimilation effects. The difficulty in using the integration model is that doing so requires that the modeler knows or is able to estimate participants' unbiased estimates (i.e., what their estimates would have been had they never seen the anchor) and this information is not available from conventional anchoring effect paradigms. A method for estimating unbiased estimates is proposed. This method is used to estimate unbiased estimates for a set of anchoring effect data and the integration model is fit to these data. This article closes by speculating on possible theoretical insights into anchoring effects that might be gleaned by using the proposed methodology and possible practical applications.

Anchoring Effects

The goal of this paper is to propose a method by which anchoring effects can be mathematically modeled. The ability to mathematically model anchoring effects might be useful both for differentiating among theoretical models of anchoring effects and for calculating likely practical applications of anchoring effects in situations such as negotiations (e.g., Chapman & Bornstein, 1996; Galinsky & Mussweiler, 2001), auctions (Ku, Galinsky, & Murnighan, 2006), and pricing (Northcraft & Neale, 1987). These possible applications of the proposed model will be discussed in the General Discussion section.

In anchoring effects, estimates of an unknown value are assimilated towards an arbitrary numeric value called the anchor. For example, in a well-known study, Tversky and Kahneman (1974) asked participants to judge whether African nations represented a higher or lower percentage of UN-member nations than an anchor and then to estimate the actual percentage. Estimates were assimilated towards the anchor. When the anchor was 10% of UN-member nations, the median estimate was assimilated downward toward 10% to equal 25%; but when the anchor was 65%, the median estimate was assimilated upward toward 65% to equal 45%.

Assimilation effects like these are typically mathematically modeled using Anderson's (1965; 1981) integration model. A mathematical formalization like the

integration model formalization was alluded to in at least one anchoring effect paper (see Jacowitz & Kahneman, 's, 1995, discussion of priming models of anchoring effects). In addition, this mathematical formalization has been used to model assimilation effects in phenomena as diverse as impression formation (the domain that originally inspired Anderson's model, see Urada, Stenstrom, & Miller, 2007, for a recent application), physical attractiveness (e.g., Wedell, Parducci, & Geiselman, 1987), product evaluation (e.g., Miyazaki, Grewal, & Goodstein, 2005; Troutman & Shanteau, 1976), risk assessment (e.g., Hampson, Andrews, Barckley, Lee, & Lichtenstein, 2003), and the best timing for lesbian and gay politicians to come out of the closet (Golebiowska, 2003)¹.

The Proposed Mathematical Model

Anderson's (1965; 1981) integration model would model the assimilation observed in anchoring effects as a weighted average of the anchor value (A) and the unbiased estimate a participant would have made had she or he never seen the anchor (U: U for Unbiased; see below for how this quantity can be empirically measured):

$$EST = wA + (1-w)U \quad (1)$$

where EST represents a participant's estimate (i.e., the dependent measure in anchoring estimation tasks) and w is the weight bound between 0 and 1 of the anchor value (A) relative to the unbiased estimate (U). A weight of 0 would represent a case in which estimates were not affected at all by exposure to the anchor. In such a case, unbiased estimates (U) would be equal to participants' estimates (EST) so that $EST = U$. A weight of 1 would represent a case in which all participants simply respond with the anchor value. Weights between these two extremes represent estimates that are assimilated toward the anchor value, but are not equal to it.

The key problem in using Anderson's (1965; 1981) integration model to model anchoring effects is that it requires the modeler to know what participants' unbiased estimates (U) would have been had they never seen the anchor. Measuring these unbiased estimates is made particularly difficult, because it is not possible to ask participants to make a numerical estimate twice (once before and once after being exposed to the anchor value) as

their first numerical estimate will bias their second. To solve this problem, the methodology proposed here would have participants make a non-numerical estimate before being exposed to the anchor and then make a numerical estimate afterwards. The mapping between non-numerical estimates and numerical estimates can then be established by running a control condition in which participants make both types of estimates without being exposed to the anchor and calculating a regression line between the two types of estimates. The unbiased estimates (U) of the participants in the experimental condition can then be calculated using the non-numerical estimates that these participants make and the regression line.

Figure 1. Graphic estimate of the height of the Sears Tower. Participants placed a tick mark between the horizontal line representing the height of the Empire State Building and the horizontal line representing the height of the Petronas Towers to represent how tall they believed the Sears Tower to be.

In the data modeled below, for example, the task was to estimate the height of the Sears Tower (a Chicago landmark and one of the world's tallest buildings; since the time during which these data were collected, this building has been renamed the Willis Tower). Participants made two estimates: a non-numerical estimate and a numerical estimate. The non-numerical estimate was made on the graphic presented in Figure 1. Participants were told that the Empire State Building was the tallest building in the world

until the Sears' Tower was built and that the Sears' Tower was the tallest building in the world until the Petronas Towers in Kuala Lumpur, Malaysia were built (taller buildings yet have been built since the Petronas Towers were built). Participants made a tick mark between the two horizontal lines in Figure 1 to denote how tall they believed the Sears Tower to be relative to the Empire State Building and the Petronas Towers. The distance between the bottom line representing the height of the Empire State Building and each participant's tick mark was then measured in millimeters (mm).

The numerical estimate was the number of feet tall that participants estimated the Sears Tower to be. Participants in the control condition made the non-numerical estimate and then the numerical estimate without being exposed to the anchor. Participants in the experimental condition made the non-numerical estimate before they made a judgment regarding whether the Sears Tower was taller or shorter than the anchor value of 1,367 feet and then made the numerical estimate. A regression line was calculated between the control participants' non-numerical and numerical estimates. This regression line was then used to calculate the experimental participants' unbiased estimates (U) from their non-numerical estimates.

Figure 2. Anchoring effect that would be characterized as an assimilation effect. The black line represents the predicted pattern of estimates, if estimates were not affected by the anchor. The gray line represents the predicted pattern of estimates, if an assimilation effect were observed. Notice that the gray line represents a weighted average of the black line (estimates unbiased by the anchor) and the anchor value (See Equation 1).

A pattern of biases that would fit Anderson's (1965; 1981) integration model definition of an assimilation effect as presented in Equation 1 is demonstrated in Figure 2. The x-axis represents unbiased estimates (U) and the y-axis represents participants' estimates in anchoring estimation tasks (EST). Do not confuse this figure with the similar-looking figures used by Chapman and Johnson (1994). In Chapman and Johnson's figures, the x-axis represented

alternative anchor values. In Figure 2, the x-axis represents unbiased estimates and the location labeled “Anchor” represents a situation wherein a participant’s unbiased estimate just happened to be equal to the anchor value. The black line in Figure 2 represents what the pattern of estimates would look like, if the anchor did not bias estimates (i.e., the case in which $w = 0$ and $EST = U$). The gray line represents a pattern of biased estimation that would be characterized as an assimilation effect (any linear slope between the slope of the black line and horizontal—that is, where w in Equation 1 takes a value greater than zero and less than one—would be classified as an assimilation effect).

Notice that regardless of the values of the unbiased estimates (U), Equation 1 predicts that they will be biased toward the anchor value by the same proportion. For example, all values might be biased 20% toward the anchor. Sometimes the term “assimilation effect” has been used roughly to refer to any bias towards a standard regardless of the extent of the bias and whether the bias toward the standard is uniform (e.g., Schwarz & Bless, 1992). While using the term in this way often provides a useful way to quickly classify results (i.e., as either “assimilation,” bias toward or “contrast,” bias away from a standard), Anderson’s (1965; 1981) definition is more precise in that it captures the degree of bias toward the anchor across the entire range of unbiased estimates and provides a starting point from which to model anchoring effects. If it turns out that not all estimates are biased toward the anchor by the same proportion (e.g., unbiased estimates close to the anchor might be biased towards the anchor by a smaller proportion than unbiased estimates that are farther away from the anchor or vice versa), then the methodology proposed here can also be used to fit alternative equations—other than the integration theory equation—to anchoring effect data.

We used this methodology and collected anchoring effect data to which Anderson’s (1965; 1981) integration model could be fit.

Anchoring Effect Data

The purpose of the experiment reported here was to use the methodology proposed above to collect data to which mathematical models—Anderson’s (1965; 1981) integration model, in particular—could be fit. There was an experimental group of participants and a control group. The experimental group made a non-numerical estimate of the height of the Sears’ Tower, then compared its height to the anchor value of 1,367 feet, and finally made a numerical estimate of the height of the Sears’ Tower in feet. The control group made a non-numerical estimate and then a numerical estimate without ever being exposed to the anchor.

Method

Participants. One hundred sixty passengers on the Chicago elevated train system participated voluntarily (80 in the control condition and 80 in the experimental condition).

Materials and Procedure. We told our participants that the Empire State Building was the tallest building in the world until the Sears Tower was built and that the Sears Tower was the tallest building in the world until the Petronas Towers were built. To measure unbiased estimates, we first asked participants to estimate the height of the Sears Tower graphically by showing them in-scale silhouettes of the Empire State Building and the Petronas Towers as shown in Figure 1. Horizontal lines crossed the page to represent the height of each skyscraper. Participants placed a tick mark between the lines to represent their estimates of the height of the Sears Tower. After estimating the height of the Sears Tower graphically, participants in the control condition simply estimated the height of the Sears Tower in feet (numerical estimate). Participants in the experimental condition judged the height of the Sears Tower to be “more” than or “less” than the anchor value of 1,367 feet before estimating the height of the Sears Tower in feet (numerical estimate).

Results

The results are presented in Figure 3. As noted in the discussion of Figure 2 above, be careful not to confuse these figures with the similar-looking figures used by Chapman and Johnson (1994). The x-axis here represents unbiased estimates as measured using the graphic presented in Figure 1; and the y-axis represents participants’ numerical estimates in feet. We first investigated whether an anchoring effect was observed by performing a t-test on the absolute difference between participants’ numerical estimates in feet and the anchor value of 1,367 feet. The anchoring effect was highly reliable, $t(158)=4.72$, $p<.01$. Estimates were significantly closer to the anchor value in the experimental condition ($M=128.30$ feet away from 1,367 feet, $SD=127.93$) than in the control condition ($M=479.90$ feet away from 1,367 feet, $SD=654.42$).

Fitting the Model

Equation 1 was fit to the results of this experiment. The criterion variable, EST , represented each participant’s estimate. To use Equations 1 to predict EST , one must somehow measure the estimates participants would have made had they never seen the anchor value. That is, one must measure participants’ unbiased estimates, Parameter U . To do so, we used the results from the control group to regress their non-numerical estimates (as collected using the graphic presented in Figure 1 and measured on mm from the bottom horizontal line representing the height of the Empire State Building) on their numerical estimates. We then used this regression equation along with each experimental participant’s non-numerical estimate to predict what their unbiased numerical estimates, U , would have been had they never seen the anchor. The regression line predicts U as: $U=766.12+(50.93*\text{the distance in mm between the bottom line in Figure 1 representing the height of the Empire State Building and each participant’s tick mark})$. With EST equal to each experimental participant’s estimate and U equal to the value predicted by the regression equation, assimilation effects toward the anchor were modeled using Equation 1.

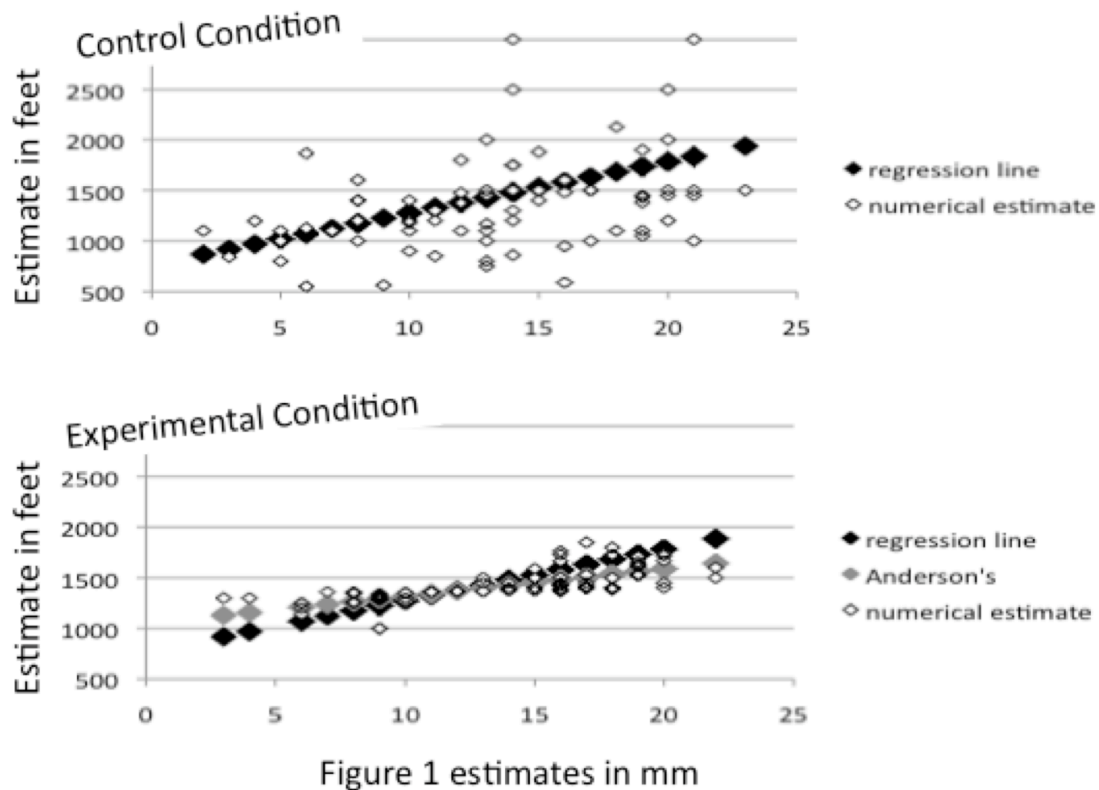

Figure 3. Results of the anchoring effect experiment reported here including the regression line and Anderson's (1965;1981) integration model fits. The x-axis represents participants' unbiased estimates of the height of the Sears/Willis Tower on the graphic presented in Figure 1 and the y-axis represents participants' numerical estimates of the height in feet. The white diamonds represent particular participants' estimates; the black diamonds represent the regression line calculated on the control participants' estimates; and the gray diamonds represent the best fit from Anderson's integration model.

Parameter A, representing the anchor value, took a value of 1,367 feet and the best-fitting value for Parameter w was calculated using a root mean squared error (RMSE) criterion. The best-fitting value for Parameter w was 0.47; and the RMSE was 116.93. A paired sample t-test on the squared errors of the values predicted by Anderson's integration model versus the squared errors of the values predicted by the regression equation found that Anderson's integration model provided a better fit, $t(79)=3.81$, $p<.01$.

Discussion

A method of mathematically modeling anchoring effects was proposed. This method calculated unbiased estimates (the estimates participants would have made had they never seen the anchor value) by having participants make a non-numerical estimate before being exposed to the anchor value and a numerical estimate afterwards. The mapping between non-numerical estimates and numerical estimates was calculated by asking a control group of participants to make both types of estimates without ever being exposed to the anchor and calculated a regression line between the two types of estimates. The regression line along with the non-

numerical estimates of the experimental participants allowed us to estimate what the experimental participants' estimates would have been had they never been exposed to the anchor value. Anderson's (1965; 1981) integration model (Equation 1) was then fit to these data where U represented each experimental participants' unbiased estimate as calculated by the regression line, EST represented each participants' numerical estimate, and A represented the anchor value of 1,367 feet. The best fitting value for parameter w using a RMSE criterion was 0.47.

Future research should fit other types of equations to anchoring effect data collected using this method. Doing so might prove useful for further refining theoretical models of anchoring effects. For example, if the anchor value is outside of the range of acceptable estimates, then Tversky and Kahneman's (1974) account of anchoring effects—under which anchors provide a starting point for participants' search for an appropriate estimate—would not produce a pattern of results that should be modeled using Anderson's integration model. Instead of predicting that all unbiased estimates would be biased toward the anchor by the same proportion, Tversky and Kahneman's (1974)

account would predict an approximately horizontal estimation function. It would predict a horizontal estimation function, because all participants would start their search for an appropriate value at the anchor value which is outside of the range of acceptable estimates, and adjust from there, stopping at the first acceptable value. They would do so regardless of what their unbiased estimates would have been had they never been exposed to the anchor value. One qualification on this prediction of the anchoring and adjustment model of anchoring effects would be if the range of values that participants thought acceptable correlated with their unbiased estimates, but this question could be addressed in future research as well (by having control participants identify the range of values they consider acceptable) and the issue would not have been addressable without the methodology proposed here.

By contrast, priming models of anchoring effects (Wilson, et al., 1996; Wong & Kwong, 2000) would predict estimation functions that would follow Anderson's integration model pattern (see Jacowitz & Kahneman, 's, 1995, discussion of priming models of anchoring effects). Exposure to the anchor value would prime that value and then estimates would be a weighted average between the primed values and the unbiased estimates participants would have made had they never been exposed to the anchor.

The pattern of bias predicted by Mussweiler and Strack's (1999; see also Strack & Mussweiler, 1997) selective accessibility model is less clear. The selective accessibility model assumes that when people compare the unknown, to-be-estimated value to the anchor value, they test whether the unknown, to-be-estimated value might be the same as the anchor value by searching for semantic information that would confirm that the to-be-estimated value is equal to the anchor value. Confirmation biases almost always produce a situation wherein people are able to find semantic information about the to-be-estimated value suggesting that it is equal to the anchor value. If this account of anchoring effects is correct, then the degree of bias toward the anchor will depend upon the amount of confirmatory information they are able to recall. The ability to find such confirmatory evidence may vary as a function of people's unbiased estimates. People whose estimates would have otherwise suggested a value close to the anchor based upon their unbiased semantic knowledge of the to-be-estimated value may be more likely to find confirmatory evidence than people whose unbiased estimates would have otherwise been farther away. The proportion of bias towards the anchor may then be greater for unbiased estimates that are relatively close to the anchor than for unbiased estimates that are farther away from the anchor. Furthermore, future work might investigate the role of selective accessibility mechanisms in anchoring effects by using the methodology proposed here to investigate anchoring effects when participants have a great deal of semantic knowledge about the to-be-estimated value and when they do not.

The methodology proposed here (perhaps using a rating scale to measure unbiased estimates, rather than the measure presented in Figure 1) may also be useful for studying practical applications of anchoring effects in situations such as negotiations (e.g., Chapman & Bornstein, 1996; Galinsky

& Mussweiler, 2001), auctions (Ku, Galinsky, & Murnighan, 2006), and pricing (Northcraft & Neale, 1987). For example, starting negotiations over the selling price of a home at a high initial asking price may have different effects depending upon what the potential buyer's unbiased estimate of a reasonable price for the house would have been had she or he never heard the asking price. It is not clear *a priori* whether all buyers' bids are biased toward the initial asking price by the same proportion. It might turn out that closer unbiased estimates are biased toward the initial asking price by a smaller proportion; or it might turn out that they are biased toward the initial asking price by a greater proportion. If it turns out that closer unbiased estimates are biased toward the initial asking price by a greater proportion, then it may not be the case that larger initial asking prices always produce the highest selling prices even if on average they do so. It may turn out that this phenomenon is mostly due to people who's unbiased estimates would have been relatively high before hand and the bias just makes their estimates of an appropriate bid higher yet. If so, then lower initial asking prices might be more effective in producing high selling prices among the segment of consumers whose unbiased estimates of an appropriate price were not quite as high at the start. If so, then the methodology proposed here might be useful in setting optimal initial asking prices for the entire range of potential consumers.

Jaak Panksepp, Distinguished Research Professor Emeritus of Psychology, Bowling Green State University. Head, Affective Neuroscience Research, Falk Center for Molecular Therapeutics, Northwestern University. In addition to 300+ scientific articles, I have co-edited the multivolume Handbook of the Hypothalamus and of Emotions and Psychopathology, a series in Advances in Biological Psychiatry and most recently a Textbook of Biological Psychiatry (Wiley, 2004), My other textbook, Affective Neuroscience: The Foundations of Human and Animal Emotions (Oxford, 1998), has helped inaugurate a new field of inquiry which attempts to probe the affective infrastructure of the mammalian brain. Our working assumption is that all of consciousness was built on affective value systems during the long course of brain evolution

Speakers

Rami Gabriel, Ph.D in Cognitive and Perceptual Sciences from University of California, Santa Barbara. Dissertation concerned non-conscious affective processes in a Prosopagnosic patient. Member of Columbia College Chicago School of Liberal Arts and Sciences Research Group in Mind, Science, and Culture.

Title of talk: Modularity in Cognitive ψ and Affective Neuroscience.

My talk explores the psychological module in the context of findings from affective neuroscience. I contrast, in terms of practicality and veridicality, cognitive science's formulation of the cognitive module with Panksepp's notion of basic biological behavioral systems. The deeper theme of my presentation is the question of human nature and the processes of the human animal we need to specify towards positing a biologically-based codification of the cognitive processes that constitute human nature.

Stephen T. Asma, Ph.D in Philosophy of Science, is author of several books that seek to bridge the sciences and humanities. He is Professor of Philosophy at Columbia College

Chicago, and member of the Liberal Arts and Sciences Research Group in Mind, Science, and Culture.

Title: Affective Neuroscience and Its Implications for the Philosophy of Self.

The mind/body problem continues to plague philosophy. The nature of Self awareness and the origin and persistence of personal identity still loom large in contemporary philosophy of mind. Many philosophers have been wooed by the computational approach to consciousness and they attempt to generate the Self amidst the phenomenon of neo-cortical information processing. Affective neuroscience offers another pathway to understanding the evolution and nature of Self. This talk will explore how affective neuroscience acts as a positive game-changer in the philosophical pursuit of Self. In particular, I will focus on closing the gap between the phenomenology of psychological consolidation and affective neurodynamic processes.

Glennon Curran, May 2011 Candidate for Juris Doctor at The John Marshall Law School, Chicago, Illinois. Executive Board Member of The John Marshall Law School Center for Trial Advocacy and Dispute Resolution. Member of Columbia College Chicago School of Liberal Arts and Sciences Research Group in Mind, Science, and Culture.

Title of Talk: Affective Neuroscience and Law

My talk explores the application of Affective Neuroscience to the law. Jaak Panksepp's exegesis of the triune brain complicates extant applications of cognitive neuroscience to the law. I contrast the neocortical causal explanations of the mental culpability of criminal defendants made in Cognitive Neuroscience with sub-cortical affective systems explanations raised in Affective Neuroscience. I argue the sub-cortical foundations of human behavior must be considered in any attempt to inform law with neuroscience.

Response Choice When Telling Lies

Emma Williams

School of Psychology, Cardiff University

Lewis Bott

School of Psychology, Cardiff University

Michael Lewis

School of Psychology, Cardiff University

John Patrick

School of Psychology, Cardiff University

Abstract: It is commonly believed that telling a lie is more difficult than telling the truth. However, the precise reason for this difficulty remains uncertain. The Activation-Decision-Construction Model (ADCM; Walczyk, Roper, Seemann & Humphrey, 2003) suggests that telling a lie will take longer than telling the truth due to the additional processes involved, such as suppression of the truth. Experimental work investigated the lie construction component of the model by manipulating the number of plausible lie responses available. Participants lied and told the truth regarding the colour of a square presented on a computer screen. Results support the general claims of the ADCM, but suggest that longer response times when individuals lie to questions with more than one possible lie response relate to a fixed cost choice between multiple response possibilities. This contributes to current understanding of which situations may enhance processing differences between telling a lie and telling the truth.

Does Practice Narrow the Radius of Spatial Interference in Mental Images?

Don Lyon

L3 Communications

Abstract: When people attempt to generate a mental image of a complex, verbally-described path, crowded regions of the path suffer from spatial interference (Lyon, Gunzelmann & Gluck, *Cognitive Psychology*, 57, 2008). A path is presented as a sequence of one-unit segments within a 7x7 grid, analogous to city blocks (e.g. 'Up 1 [Block]'; 'Right 1'; 'Down 1', etc.). Participants must decide whether each new segment intersects with a prior part of the path. Initially, prior segments of a path within 2 grid spaces of the current path segment produced spatial interference. Although there were substantial individual differences, for most participants interference radius was reduced to one grid space with under 10 hours of practice. One possible explanation for this reduction is that, with practice, people can learn to attend selectively to increasingly smaller areas within a vision-like representation of the mental image, in the absence of any actual visual stimulus.

A Sense of Order: Numerical ordering ability predicts complex mental arithmetic performance

Ian Lyons

University of Chicago

Sian Beilock

University of Chicago

Abstract: What are the key cognitive factors that characterize the potential difference between symbolic and non-symbolic representations of numerical magnitude, and can individual variability in such factors be used to predict differences in more complex mathematical processes? We suggest that the availability of information about relative numerical order is a critical factor that distinguishes symbolic from non-symbolic numbers. In the current experiment, we provide evidence that individual variability in symbolic numerical ordering ability strongly predicts performance on a series of complex mental arithmetic tasks even when controlling for a wide array of competing factors, including individuals' precision in non-symbolic magnitude representations. Moreover, symbolic numerical ordering ability is shown to fully mediate the previously reported relation between non-symbolic magnitude processing and more complex mathematical skills. These results have important implications for designing math-education techniques and identifying reliable math-performance markers.

Imaginary affordances shape children's preference judgments

Tania Henetz

Stanford University

Daniel Casasanto

Max Planck Institute for Psycholinguistics, Neurobiology of Language Group, Nijmegen, NL

Abstract: Motor fluency influences preference judgments: people tend to like things they can manipulate easily. Yet, links between motor fluency and preference extend beyond the domain of concrete objects that afford physical manipulation. People implicitly associate abstract ideas like goodness and intelligence with locations in space that ordinarily afford fluent actions. How do these abstract associations develop? Here we tested whether children's preference judgments are influenced by implicit affordances of imaginary objects. Children imagined helping a cartoon character store toys in a bookcase, drawn next to the character. They tended to assign toys the characters liked to locations on the shelves that would afford fluent actions and toys they didn't like to locations that would afford less fluent actions. Crucially, the 'fluent' location was determined by implicit constraints on the character's actions, not by the child's own action affordances. Imaginary affordances may help link concrete motor actions with abstract preference judgments.

Testing fMRI predictions of a Cognitive Model of the Problem State Multitasking Bottleneck

Jelmer Borst

University of Groningen Carnegie Mellon University

Niels Taatgen

University of Groningen Carnegie Mellon University

Hedderik Van Rijn

University of Groningen

Andrea Stocco

Carnegie Mellon University

Abstract: It has been shown that people can only maintain one intermediate mental representation, or 'problem state', concurrently. When multiple problem states have to be maintained, performance decreases sharply, an effect referred to as the problem state bottleneck. We investigate this bottleneck using a triple-task, in which participants have to solve subtraction problems, enter text, and perform a listening task concurrently. The triple-task confirmed the existence of a problem state bottleneck. To explain the behavioral results in detail, a cognitive model was developed using ACT-R (Anderson, 2007) and the threaded cognition theory (Salvucci & Taatgen, 2008). The model showed a close fit to the empirical data. It was subsequently used to generate fMRI predictions for five brain areas. These predictions were tested in an experiment, showing a good correspondence between model predictions and fMRI data, indicating that the problem state bottleneck is probably located in the intraparietal sulcus.

Grounded Congruency Effects Between Vertical Meaning and Vertical Responding: Not Replicated

Lauren McDonough
Emory University

Christine Wilson-Mendenhall
Emory University

Lawrence Barsalou
Emory University

Abstract: According to theories of grounded cognition, words whose semantics are associated with a salient vertical position (e.g., CEILING vs. CARPET) should activate simulations of these positions in space. When responses are analogously made in the vertical dimension, grounded congruency effects should result (e.g., processing CEILING should be faster for an UP vs. DOWN response). Previous research obtained grounded congruency effects when participants used ink color (RED vs. BLUE) as a cue for response direction (Casasanto, 2008). Typically researchers assume that these effects are automatic, but they could possibly be strategic. Two experiments attempted to assess this issue with 6 groups of 24 participants each, but failed to replicate the original grounded congruency effect, leading us to question its reliability when ink color is used as a cue. We further discovered a motor facilitation effect for upward as opposed to downward responses not reported previously in this paradigm.

MIReR: Media Integration Reflection Resource

Andreea Danielescu

Arizona State University

Ellen Campana

Arizona State University

Abstract: Designers of experiential media systems rely on intuition and experience to create systems. This trial and error process takes time to learn, and it is possible to exceed a user's cognitive load in multimodal environments. This offers an opportunity to explore perception and cognition. Behavioral experiments, the standard for psychological inquiry, are time consuming and focus on one variable to achieve accurate results. Instead, MIReR provides a dynamic, holistic way of exploring data collected from user experiences. A unified representational framework makes this possible – designers provide a concept map that describes the intended meaning behind the sounds and visuals, and their relationship. This map is analyzed by MIReR's cognitive architecture and compared to user experience data to produce an estimate of the user's cognitive load. As the designer explores different possibilities, MIReR tracks changes and effects on users, creating an environment that produces new insights into perception and cognition.

Social Influences on the, um, Use of, uh, Fillers

Esther Walker

University of British Columbia

Evan Risko

University of British Columbia

Alan Kingstone

University of British Columbia

Abstract: Language, at its core, is a social act. The present investigation sought to examine the influence of interpersonal context on filler use ("um", "uh") while answering factual questions. Experiments 1 and 2 investigated differences in computer versus human interaction. As predicted, more fillers were uttered when interacting with a human than with a computer. Experiment 3 sought to examine a self-presentational view of filler use, whereby the mere presence of another human should increase one's use of fillers. Consistent with a self-presentational account, mere presence of the experimenter elicited more fillers than when the experimenter was absent. A cross experimental analysis revealed that while mere presence increases filler production, the need for interpersonal coordination increases filler use above and beyond mere presence. These results are consistent with at least two views of filler function: (1) fillers are used to save face and (2) fillers are used to coordinate interpersonal interactions.

Probability estimation by mice in an interval timing task

Aaron Kheifets

Rutgers University Center for Cognitive Science: RUCCS

C. Randy Gallistel

Rutgers University Center for Cognitive Science: RUCCS

Abstract: Keeping track of and detecting changes in the probability of events is a central problem for animals. We presented mice with an interval timing task: with probability p , mice were reinforced for staying at the first hopper until time t . With complementary probability $1-p$ they were reinforced for arriving at the second hopper before $t+k$. Because no animals are perfect timers, this task was difficult due to small k . Depending on p , the optimal switch point changed: if long trials were more likely, switching too late became more costly than switching too early, so the optimal switch time occurred later. Subjects showed highly significant ($p < 0.005$) differences in their mean switch times when p was manipulated. Moreover, subjects were able to update their frequency estimates when the underlying probabilities of trial types changed and their estimates converged on accurate values quickly in comparison to plausible Bayesian optimal models.

The Specificity of Non-Arbitrary Sound-to-Meaning Correspondences in Spoken Language

Christina Y. Tzeng

Emory University

Lynne C. Nygaard

Emory University

Laura L. Namy

Emory University

Abstract: Sound symbolism, or non-arbitrary correspondences between the sound of a word and its meaning, is an inherent property of natural language. Although previous research suggests that listeners are sensitive to sound-to-meaning correspondences, little is known about the specificity of these mappings. The present study investigated whether sound symbolic properties correspond to specific meanings, or whether these properties aid mappings to other semantic dimensions as well. English-speaking adults heard sound symbolic foreign translations of four adjective pairs (big-small, pointy-round, fast-slow, still-moving), and for each foreign word, chose which of two English antonyms (matched or mismatched with word dimension) was its correct translation. Participants reliably matched foreign words to their correct meanings, as well as to related semantic dimensions, suggesting not only that listeners utilize sound-to-meaning correspondences to infer the meanings of unfamiliar words, but also that sound-symbolic properties facilitate word-to-meaning mappings within a range of associated and co-varying semantic dimensions.

Pattern Recognition Principle Theoretical Model of Mind-Brain Functioning

Gilberto de Paiva

Abstract: The Computational Theory of Mind and the Connectionist Neural Model are actually the dominant cognitive models in the scientific community. But there is still a discussion about their compatibility as the basis of Cognitive Science. A more fundamental explanation of this two leading cognitive mechanisms in physical basis can give a better explanation of the mind and brain phenomena.

I propose the concepts of PATTERN RECOGNITION-PROCESSING-LEARNING as NECESSARY AND SUFFICIENT PRINCIPLE to build a solid foundation of cognitive science. This encloses a general body-mind, physical, psychological, neural, functional and computational reductionist explanation of the mind cognitive phenomena.

Supporting arguments are: 1- Pattern recognition is a necessary principle for cognitive science. It is a key process in many different scientific areas, but no cognitive science model takes it formally for a general brain-mind theory. 2- The equivalence of the physical-neural-computational mechanisms of pattern recognition as the basis of the cognitive phenomena in performing all cognitive functions (sensory, memory, learning, processing, logical, feeling, emotions, thought, consciousness, etc) , which are here demonstrated. 3- I also propose some key biological cognitive processes and strategies strictly related to pattern recognition processing. 4- A definitional-explicative modeling building theory is also shown giving simple, understandable and unambiguous definitions and scientific explanation of most key cognitive concepts like thinking, self and consciousness. Such a theory is of fundamental importance because those type of cognitive concepts lacks even a reasonable definition. With a scientific-objective definitions we can evaluate, compare and estimate its consistency and also propose experimental and empirical experiments. As an example I suggest one preliminary definition of self-consciousness as: "the recognition by the pattern recognition system of the patterns of its own activity". 5- A mathematical-logical formalism study of cognitive pattern recognition is here proposed as theoretical basis. Here a general formal definition of pattern recognition is proposed in the cognitive science scope. 6- With this theoretical formulation we are able to include other cognitive properties to any basic definition as far as needed, demonstrating it as a solid and promising theory.

As any candidate as a complete theory of cognitive science, this model allow us to reinterpret all branches of human reasoning, including the philosophy and foundations of science and the human understanding of the universe. With the promising applied pattern recognition technology already in development, this model could help to give some directions to artificial intelligence and also neurobiology and psychology-sociology research.

Individual Differences in Explaining Noisy Data

Daniel R. Little

Indiana University

Richard M. Shiffrin

Indiana University

Abstract: In science, we design our inference approaches to trade off fit to observed data (models are good that fit well) and complexity (models or explanations that fit or explain everything are bad). Here, we examine how observers balance fit and complexity by asking observers to estimate causal models for noisy data. Specifically, participants are shown a number of scatterplots that vary in the number of data points shown, the noise added to the true function and the complexity of the true function. For each set of noisy data points, participants estimate a function which best captures their guess at the causal explanation between the input and the output. A generative psychological model combining Bayesian model selection and Gaussian process regression is used to examine individual differences in biases toward simple explanations. Our results indicate that some participants prefer simple polynomial, rule-based explanations and others prefer distance-based, similarity explanations.

Making a good impression (formation model): a more complete account of processing

Tei Laine

Institute of High Performance Computing

Swati Gupta

Institute of High Performance Computing

Brian M. Monroe

Institute of High Performance Computing

Abstract: First impression formation is the process by which people make assumptions, regardless of objective accuracy, about someone they meet for the first time by integrating information including the person's appearance, verbal and non-verbal cues, and facts she might reveal about herself.

We propose a model of first impression formation that integrates this kind of information into a coherent representation taking into account the 1) potentially asymmetric nature of inferences people make from stereotypes, traits, and behaviors, 2) prior probabilities of inferred characteristics, 3) cognitive capacity limitations in processing of incoming information, and 4) the influence of positive and negative affect in the impression.

We think that our model not only compares favorably with Kunda & Thagard (1996) parallel constraint satisfaction model, but also accounts for additional phenomena such as asymmetrical inferences and affective coherence.

The representation of idiom words in the mental lexicon

Simone Sprenger

University of Groningen

Hedderik van Rijn

University of Groningen

Abstract: The way in which idioms are processed and the nature of their underlying representations are subject to an ongoing debate. Most processing models agree that idioms are specific combinations of ordinary words. However, models differ with respect to the exact role that these words are allowed to play.

In the present study we tested the hypothesis that the relations between idiom words are specified on a lexical processing level. Specifically, we tested whether the constituent words of an idiom activate each other in the absence of an idiomatic (phrasal) context. In two lexical decision experiments, we found that this is indeed the case. However, the effect is modulated by the type of target word that precedes the idiomatic targets. Targets that are literally related to the first idiom target prevent activation of the second idiom target.

The results support the superlemma model of idiom processing (Sprenger, Levelt & Kempen, 2006).

Assessing the Effectiveness of Wayfinding Directions

Alycia Hund

Illinois State University

Amanda Padgitt

Illinois State University

Abstract: Our goal was to assess people's responses to wayfinding directions. Ninety college students rated the effectiveness of route descriptions through the basement of a university building. They also provide open-ended responses regarding wayfinding preferences and completed wayfinding anxiety, wayfinding strategy, and environmental familiarity self-report measures and a sense of direction exercise. The primary goal was to specify the descriptive features contained in effective and ineffective wayfinding descriptions. The best-rated route descriptions included more cardinal features, landmarks, left-right, distance, number, straight, and miscellaneous information than did the worst-rated route descriptions. Moreover, positive mentions of landmarks and negative mentions of cardinal directions were very frequent. As expected, women reported significantly higher spatial anxiety than did men. Men preferred orientation strategies more than did women, whereas women preferred route strategies more than did men. Women also reported poorer sense of direction and made larger sense of direction errors than did men.

How Agent Placement Can Influence Perceived Boss/Co-worker Agreement in a Simulated Work Environment

Justin L. Matthews

University of California, Merced

Teenie Matlock

University of California, Merced

Abstract: Interpersonal distance, the physical distance between people while they interact, is known to influence attitudes and other social dynamics. For example, merely sitting closer to a person who is presenting information can increase the persuasive power of that speaker. In the current work, we investigate how interpersonal distance will influence perceived agreement among employees in an office setting. Our participants read a passage that asked them to imagine working for an advertising firm and being in a meeting about employee layoffs with a boss. After looking at a picture of an employee seating arrangement that was close, medium, or far from a boss during the meeting, participants were asked to estimate how far the chairs were from the boss and to judge how much agreement they felt during the meeting. On average, participants indicated that they felt less agreement with bosses when interpersonal distance was high (versus medium or low). The results, which revealed that increased physical distance is associated with greater attitude "distance", have implications for the design and use of applications for virtual meetings and more generally, social interactions in virtual environments.

The structure of event representations: behavioral, imaging, and computational investigations

Anna Schapiro

Princeton University

Timothy Rogers

University of Wisconsin-Madison

Matthew Botvinick

Princeton University

Abstract: Event segmentation is often thought to rely on the identification of points in a sequence where there is relative uncertainty about what will happen next. We exposed participants to sequences of stimuli that had temporal structure but no variability in predictive uncertainty: each stimulus could be followed by four others with equal probability. We found reliable parsing between groups of stimuli that were preceded and followed by overlapping sets of items, suggesting that people are sensitive to temporal statistics beyond predictive uncertainty. We hypothesized that this reflects learning of temporal category structure, with items that occur in overlapping temporal contexts represented as belonging to the same category. Supporting this idea we found that, following exposure to the same structured sequence, participants sorted items based on their temporal contexts. To elucidate the mechanisms and representations supporting this behavior we consider alternative computational models of temporal structure learning and present preliminary fMRI results.

Pair Analysis and Joint Action Theory: A Research Protocol to Study Cognition and Interaction in Visual Analytics

Richard Arias Hernández

Simon Fraser University, School of Interactive Arts and Technology

Linda T. Kaastra

University of British Columbia, Media and Graphics Interdisciplinary Centre

Brian D. Fisher

Simon Fraser University, School of Interactive Arts and Technology

Abstract: Visual analytics, the "science of analytical reasoning with interactive visual interfaces," calls for the development of new models of human cognition in analytic interaction with information technology. While foundational work brings traditional cognitive science models to address interaction with visualization environments, research protocols to empirically test these models in "the wild" are lacking. We combine a research protocol called "Pair Analysis" with H.H. Clark's Joint Action Theory as a theory-methods package for studying cognition and interaction in visual analytic environments. Pair Analysis, an observed analytic interaction by a subject matter expert and a visual-analytic tools expert, provides a unique empirical window into the cognitive process of analytical reasoning and the social processes of interaction. We use JAT's operational concepts to characterize analytic dyads' thought processes and joint use of visualization technology. Our main hypothesis is that sustaining rhythmic interactions in Pair Analysis is indicative of sustaining cognitive flow.

The Importance of Visual Modeling in Children's Understanding of Physical Science

Nancy L Stein

University of Chicago (U of C)

Marc W. Hernandez

NORC, UYniversity of Chicago

Abstract: How do we teach children about the physical universe, given that much of what is to be learned is invisible? How does visual dynamic modeling facilitate the process of physical science understanding? What are the constraints on dynamic visual modeling? We carried out two studies on 4th and 7th grade children, where the presence or absence of visual models and dynamic visual models were varied. Fourth grade students were as good as 7th grade students in learning all parts of the module sequence. Children receiving dynamic visual graphics outperformed children who saw only static visual graphics, and both of these groups outperformed children who received only the oral/written part of the text. The presence of graphics, however, was not enough to ensure the learning of measurement concepts. Strategies that breakdown parallel physical processes and temporalize them, as well as embodiment strategies are also necessary.

Reversing the side-effect effect: the 'Rational Scientist' explanation

Kevin Uttich

University of California-Berkeley

Tania Lombrozo

University of California-Berkeley

Abstract: Theory of mind, our intuitive understanding of the mind, is often conceptualized as analogous to a scientific theory with the function of predicting and explaining behavior. However, the so-called "side-effect effect" illustrates that moral considerations influence theory of mind judgments, and has been taken as evidence that theory of mind is fundamentally evaluative. We present new evidence for an alternative, the "rational scientist" view, which holds that moral evaluations inform ToM judgments, but that this relationship arises because behavior that conforms to norms (moral or otherwise) is less informative about underlying mental states than is behavior that violates norms. In two new experiments we demonstrate that different norms (moral or conventional) lead to different intentional descriptions of the same actions, and that the effect can be eliminated when norms are reversed. This view preserves the traditional understanding of ToM, but also suggests the importance of normative considerations in social cognition.

MHP/RT: Model Human Processor with Real Time Constraints

Makoto Toyota

T-method

Muneo Kitajima

National Institute of Advanced Industrial Science and Technology

Abstract: We propose "Model Human Processor with Real Time Constraints" as a simulation model of human behavior selection. It stems on the successful simulation model of human information processing, Model Human Processor (Card, Moran, and Newell, 1983), and extends it by incorporating three theories, Maximum Satisfaction Architecture (MSA, presented at CogSci2007), Structured Meme Theory (SMT, presented at CogSci2008), and Brain Information Hydrodynamics (BIH, presented at CogSci2008). MSA, SMT and BIH deal with coordination of behavioral goals, utilization of long-term memory that works as an autonomous system, and a mechanism for synchronizing individual with environment, respectively. MHP/RT works as follows: 1) inputs information from environment and individual, 2) MHP/RT builds a cognitive frame in working memory, 3) resonates it with autonomous long-term memory, 4) maps the resonance on consciousness to form reduced representation of the input information, 5) predicts future cognitive frames to coordinate input and working memory.

CCE: Cognitive Chrono-Ethnography

Muneo Kitajima

National Institute of Advanced Industrial Science and Technology

Makoto Toyota

T-method

Abstract: We, human beings, select next behaviors that should maximize our satisfaction by making use of meme that stores our past experiences and by processing input from environment and individual by appropriately allocating available cognitive resources. The underlying processes are simulated by Model Human Processor with Real Time Constraints, MHP/RT (to be presented at CogSci2010). On the basis of MHP/RT, this paper proposes a new study method for understanding human behavior selections in daily life, Cognitive Chrono-Ethnography, CCE. When a study field is specified, CCE defines critical parameters by conducting qualitative MHP/RT simulations, then designs ethnographical field observations and recordings of elite monitors' behaviors in the space defied by the critical parameters. Structured interviews follow in order to obtain the descriptions of the participants' history of behavioral development. By analyzing the results of interviews, models of present behavior selections and chronological changes will be built.

<http://staff.aist.go.jp/kitajima.muneo/organic-self-consistent-field-theory/index.html>

On the diversity of folk morality: Measuring classical positions in moral philosophy

Stephanie Müller

University of Granada, Spain

Bernd-Christian Otto

University of Heidelberg, Germany

Edward Cokely

Max Planck Institute for Human Development

Abstract: Moral psychology often oversimplifies moral philosophical debates into either deontological or consequentialist theories. The current research attempted to document greater variation in the extent to which participants used one of six core concepts to justify actions (i.e., appeals to religion, intuition, or one of four classical philosophical positions associated with Bentham, Hobbes, Kant, or Schopenhauer). Two hundred and fifty student participants (121 males) from the University of Granada were asked why a specific action would be "morally" correct or incorrect, which of the six concepts would be most adequate to justify the action, and whether they would behave similarly. Results indicated that participants agreed on a variety of diverse moral positions and that moral justification changed depending on context. The present research contributes to a growing body of work suggesting that different people apply different moral concepts to different life situations.

Linguistic Control in Monolingual and Bilingual Language Learners

James Bartolotti

Northwestern University

Viorica Marian

Northwestern University

Abstract: One of the difficulties in learning a new language is controlling competition from the language(s) already known. This interference resembles between-language competition in bilinguals, whose languages are both activated in parallel (Marian & Spivey, 2003). To test whether bilingualism confers an advantage in controlling competition during language learning, we compared monolinguals' and bilinguals' ability to manage interference from English while using a newly-learned language. Participants were taught an artificial vocabulary, then their eye-movements and mouse-movements were tracked in a visual world paradigm to assess activation of English competitors while processing the new language. We found that monolinguals, but not bilinguals, looked at interlingual competitors more than at controls, indicating greater interference from English. Similarly, monolinguals, but not bilinguals, demonstrated increased attraction to competitors compared to controls in mouse-movement trajectories. Results suggest that bilingual experience promotes efficient management of native language activation, with implications for linguistic control during language acquisition.

Intent discerning agent for more intuitive visualizations

Tera Marie Green

School of Interactive Arts and Technology (SIAT) Simon Fraser University

Steve DiPaola

School of Interactive Arts and Technology (SIAT) Simon Fraser University

Abstract: Today's visual interfaces are capable of representing large, semantically-complex datasets; user interaction of subsets is used to maximize display space. However, what data to provide and in what context requires decisions that are computationally and graphically expensive. We have built an autonomous, rule-based intelligent agent, which sits underneath a visualization, observes user behavior, determines user intent, and, based on what was learned, predicts future interest. The agent observes user manipulation and gathers interaction information continuously. For the purposes of demonstration, the agent sits underneath a shallow visualized hierarchical graph. The agent makes a determination about user intent through simple computations on its gathered interaction information and passes its decisions back to the visualization, which displays them to the user via ambient overlay. Future work will enable the agent to direct the interface as to which data to display and in which context to display it, enabling more intuitive human-computer collaboration.

A Difference in Working Memory Capacity among Chinese Speakers Using Different Computer Word Typing Methods

Jenn-Yeu Chen

National Cheng Kung University

Cheng-Yi Li

National Cheng Kung University

Abstract: Chen & Chuang (2008, CogSci) showed that Chinese speakers using phonology-based and orthography-based computer word typing methods (zhuyin vs. cangjie) displayed differential sensitivity in processing the phonological and the orthographic information of Chinese characters. The present study examined whether the zhuyin and the cangjie users might differ in their working memory (WM) capacities. Five verbal WM tasks and five visuospatial WM tasks were administered to 24 zhuyin and 23 cangjie users, whose typing speeds were comparable (53.7 and 53.2 characters per minute). Results show that the zhuyin users scored higher on the verbal WM tasks than the cangjie users, but the two groups performed similarly on the visuospatial WM tasks. The results suggest that general cognitive abilities like the WM capacity are related to the use of a technological artifact, consistent with the 'extended-mind' view of cognition proposed by Clark and Chalmers (1998).

Cognitive Arithmetic revisited: Effects of equation presentation format

Michael C. W. Yip

The Hong Kong Institute of Education

Abstract: The present study examined the cognitive processing of basic arithmetic. Thirty university students participated in a simple calculation verification experiment. In the experiment, a series of simple addition problems were randomly presented to each participant in one of the twelve experimental conditions ($3 + 4 = 8$) or ($8 = 3 + 4$) or ($?O + ?l = "$) or ($" = ?O + ?l$) or ($?O + 4 = "$) or ($8 = ?O + ?l$) or ($12 = ?O + j\tilde{a}$) or ($8 + 7 = 13$). Participants were asked to verify whether the equation is correct or not by pressing a key as quickly and accurately as possible. The general pattern of results revealed that both the variables of equation presentation format and the numerical surface form influences the equation verification time but this was not the case for the variable of problem size.

The Capacity to Discover: Working Memory and the Ability to Use Self-Explanation to Discover Early Algebra Concepts

Marci DeCaro

Vanderbilt University

Bethany Rittle-Johnson

Vanderbilt University

Abstract: Prompting learners to generate explanations (self-explanation) can facilitate knowledge discovery and integration (Atkinson et al., 2000; Siegler, 2002) but does not always (Matthews & Rittle-Johnson, 2009). We examined whether greater capacity to retrieve problem-relevant information from memory (higher working-memory capacity) would enhance procedure discovery using self-explanation. Students ($N=104$; 2nd-4th graders) were instructed about math equivalence either before or after solving problems involving operations on both sides of the equal sign (e.g., $3+7+8=3+_$). During problem-solving, some students self-explained answers, and some completed additional practice instead. Problem-solving accuracy was no different across the four conditions at posttest or retention. However, working-memory capacity moderated the effect of condition on retention. Self-explanation did not improve learning if instruction occurred first. However, when students solved problems before instruction, self-explanation benefited those students who were higher in working-memory capacity. Individual differences in learners' cognitive capacities may influence when self-explanation is beneficial as a discovery tool.

Number, Language, and Object Individuation

Lisa Cantrell

Indiana University

Linda B. Smith

Indiana University

Abstract: Recent research has suggested that the number of objects in a set affects the kinds of properties people attend to when speaking and categorizing (Barner & McKeown, 2005; Cantrell & Smith, 2009; Newstead & Coventry 2001). Here we asked whether number also affects the count-mass syntax that speakers use for common objects. Children ages 3-5 years were asked to look at pictures of common items (e.g., chairs, paper, soap) and label them. The images varied in number; children saw objects in sets of 2, 6 or 25. Results showed an effect of number on the kind of language children used. As the number of items increased, children became less likely to use individuating syntax, suggesting that objects in larger sets were seen less as individual entities and more as portions of a continuous mass. These results have theoretical implications for current ideas in number and object representation.

The Cognitive and Motor Performance of Children with Functional Articulation Disorders

Rong-Ju Cherng

National Cheng Kung University

Abstract: Thirty children with functional articulation disorders (FAD) at the age of 4 to 8 years and age- and gender-matched typically-developing (TD) children were recruited to examine and compare their cognitive and motor performance. The Chinese versions of Peabody Picture Vocabulary Test and The Chinese versions of the Test of Non-verbal Intelligence-3rd edition were used for cognitive assessment and Bruininks-Oseretsky Test of Motor Proficiency, 2nd edition (BOT-2) and Movement Assessment Battery for Children (M-ABC) were used for motor assessment in the study. The results showed that children with FDA had significantly lower cognitive performance than TD children although their scores were all within the normal range. Children with FAD did not differ from TD children in the overall motor performance in either motor test. However, children with FAD showed worse performance than TD children in fine motor precision subtest. The performance of fine motor precision subtest was correlated with cognitive performance.

I let the music speak: a model of music perception that predicts speech segmentation

Geraint Wiggins

Goldsmiths, University of London

Abstract: To study the relationship between language and music, we apply a successful model of music perception to segmentation of phoneme streams into syllables.

Our model is a complex mixed-order multiple-feature n-gram model, with advanced back-off and smoothing capabilities. It has a long-term component, learned by unsupervised mere exposure, and a short-term component, exposed to the current stimulus; entropic weighting biases predictions between components. It was invented to simulate implicit learning of melodic pitch expectation, but it also predicts melodic segmentation, subjective expectation strength, associated neurophysiological activity, and aspects of expert musicologists' judgements. It is unusual as a Markov model in being multidimensional: it is capable of modeling sequences of objects with multiple features, using those features independently or together, and combining resulting multiple predictions in a principled way.

Here, we model phoneme/stress sequences from the TIMIT speech resource metadata, using 2,342 phoneme sequences from US English, containing 21,427 syllables and 82,611 separate phoneme occurrences. We predict syllable boundaries by rise-picking in the resulting sequence of information-content values. The model predicts given segmentation with $\kappa=0.48$, precision is .71, recall is .63, $F1=.67$, correct, using phoneme and stress only, over this surprisingly small learning corpus.

The results suggest that our model may be a cross-modal model of perceptual sequence learning.

Peer Reviewing in Undergraduate Psychology Students

Joanna Salapska-Gelleri

Florida Gulf Coast University

Abstract: Students peer reviewed each others' grant proposals in an undergraduate psychology course. Unlike traditional in-class peer reviews, these were completed online and discussed during a class period. The review occurred multiple times throughout the year. Students had a chance to correct their papers and then resubmit for a second peer-review. As compared to students who either did not have the benefit of a peer review, only a single faculty grade, and ones who only received a one-time review, those students whose papers were reviewed multiple times received significantly higher marks on their final papers as judged by an outside reviewer. The benefit of peer-reviewing has been experimentally demonstrated in the past (Dunn,1996; Topping, 1998) but faculty have been reluctant to use this pedagogical tool due to time constraints. The current demonstration utilized a hybrid setting where students completed the reviews online and delivered the results in a brief in-class activity.

Training University Students on the Balance Scale Problem

Thomas Scaife

The Ohio State University

Andrew Heckler

The Ohio State University

Abstract: The cognitive development relating to solving balance scale problems has been studied in great detail, though effective training methods have not. In this study, students enrolled in a university-level introductory physics course were trained with examples from one of four conditions: when only one quantity (either weight or lever arm length) was different on each side of the balance, or when both weight and length were different, but the correct response corresponded to the side with either the greater length or greater weight. We found that when training involved the variation of only one quantity, participants were able to transfer learning to other configurations of weight and lever arm length. However, when training involved the variation of both quantities, participants were only able to answer correctly questions similar to those with which they were trained. These participants were unable to transfer learning to other configurations.

Verb tense and aspect in scene descriptions in a humanoid robot

Carol J. Madden

Stem Cell and Brain Research Institute, Lyon France

Stéphane Lallée

Stem Cell and Brain Research Institute, Lyon France

Peter Ford Dominey

Stem Cell and Brain Research Institute, Lyon France

Abstract: The present research implements a more human-like system of language in a humanoid robot model through improved use of grammatical constructions in described events. The present demonstrations show how the iCub humanoid robot is taught to recognize and use verb tense and aspect more appropriately. While hearing spoken verbal descriptions and watching visual displays of simple events involving objects moving on a table, the iCub robot begins to link the correct grammatical constructions with the appropriate information from its visual inputs and perceptual primitives. Thus, when it views a scene, the iCub robot is more likely to use the correct linguistic constructions to accurately describe it. In this way, past events are accurately described in the past tense, whereas ongoing events are described in the present progressive. Experimental evidence shows increased accuracy of scene descriptions for the iCub humanoid robot after learning phases involving live human-robot interactions. Supported by FP7 CHRIS & Organic, and ANR Comprendre and Amorce.

The importance of being present: The effect of a real or videotaped person on visual attention

Kaitlin Laidlaw

University of British Columbia

Tom Foulsham

University of British Columbia

Gustav Kuhn

Brunel University

Alan Kingstone

University of British Columbia

Abstract: How does visual attention operate in social contexts? Most research exploring this question has used picture or video paradigms that contain social stimuli but do not provide any opportunity for social interaction with the participant. In our study, we monitored participants' eye movements as they sat in a waiting room. Participants waited while either a confederate quietly completed a questionnaire, or while a video of the same confederate filling out the questionnaire was displayed on a nearby computer. Participants' fixation patterns of real vs. videotaped confederates indicated that participants actively avoided looking at the real person, while they looked more and for longer at the videotaped confederate. These results demonstrate the importance of social presence on visual attention and suggest that video- or picture-based studies of social attention are measuring performance and drawing conclusions that do not accurately reflect the real effect of social presence on visual attention.

Exploring Phonological Levenshtein Distance Effects in Auditory Lexical Decision

Lidia Suárez

National University of Singapore

Seok Hui Tan

National University of Singapore

Melvin J. Yap

National University of Singapore

Winston D. Goh

National University of Singapore

Abstract: Phonological similarity among spoken words is traditionally indexed by neighbourhood density (i.e., the number of words differing by a single phoneme from the target). However, density is of limited utility for long words, which have few or no neighbours. In this study, we explored the effects of phonological similarity and word-frequency on auditory lexical decision performance, using multisyllabic words with no neighbours and a new similarity metric called phonological Levenshtein distance (PLD20), which reflects the mean number of substitution, insertion, or deletion operations required to transform a word into 20 of its closest Levenshtein neighbours. Inhibitory effects of PLD20 were observed, where words with closer neighbours were recognised slower; importantly, these effects were present for only low-frequency words, replicating previous findings with other neighbourhood measures. The properties of PLD20 make it a promising new measure for quantifying the phonological distinctiveness of multisyllabic words in spoken word recognition research.

How is children's exploratory play influenced by evidence conflicting with their theory?

Tessa J. P. van Schijndel

Developmental Psychology University of Amsterdam

Maartje E. J. Raijmakers

Developmental Psychology University of Amsterdam

Abstract: Bonawitz, Lim, and Schulz (2007) demonstrated that children's exploratory play is affected by the interaction of their naïve theories and the evidence they observe. 6- and 7-year-olds were more likely to play with a balance toy when they observed evidence inconsistent with their balancing theory than when they observed evidence consistent with their balancing theory. The present study was set up to investigate how children's exploratory play is influenced by evidence that conflicts with their theory. Do children who observe inconsistent evidence play more systematically and make more informative comparisons than children who observe consistent evidence? 4- to 6-year-olds' naïve theories on shadow size were assessed with the shadow task (Siegler, 1981). 52 children with one specific naïve theory were selected and shown evidence consistent or inconsistent with their theory. Preliminary results show that the inconsistent group made more informative comparisons during free exploratory play than the consistent group.

Causal reasoning in decision making: A test of causal model theory of choice

Motoyuki Saito

Kwansei Gakuin University

Tsuneo Shimazaki

Kwansei Gakuin University

Abstract: Hagmayer & Sloman (2009) proposed causal model theory of choice based on causal Bayesian networks in order to provide comprehensive explanation for causal reasoning and decision making. The purpose of this study is to test predictions made by their theory. It considers that a deliberately chosen action is an intervention and that inferences based on choice are derived from structure of causal models in disregard of parameters of them (i.e., base rate, causal strength). In Experiment 1, we manipulated base rate and asked participants to infer probabilities conditional on deliberately chosen actions, interventions, and observations within common cause model. The estimates based on choices resembled that based on interventions and didn't reflect the differences in base rate. In Experiment 2, in which causal strength was manipulated within participants, the results revealed that participants neglected common cause. The differences in experimental situations between causal reasoning and decision making are discussed.

Gaze movement and language production when talking about events in live-recorded video clips

Monique Flecken

University of Heidelberg

Christiane von Stutterheim

University of Heidelberg

Mary Carroll

University of Heidelberg

Abstract: The paper deals with the interrelation between patterns in gaze movement when watching dynamic video clips and what is mentioned at what point when talking about events. This interrelation was investigated with respect to dynamic, live-recorded videoclips depicting everyday situations. Speakers of three languages were asked to view the clips and tell what is happening. Attention distribution to different aspects of the clips (causative actions) were measured in 2 identified areas of interest: the area where the agent is located and the area in which the entity acted upon is located. Contrary to studies on the production of single words or clauses relating to pictures (eg. Meyer & Dobel 2003), gaze movement to the areas of interest and the time at which they are mentioned are not directly linked, given real time presentations. Factors that drive patterns of attention and mention over time cross-linguistically will be presented.

Fluency and cognitive control in judgment: Influences of memory and elaborative encoding

Paula Parpart

Max Planck Institute for Human Development

Edward T. Cokely

Max Planck Institute for Human Development

Abstract: Recent research has documented some surprising relations between cognitive control and fluency use in consumer judgments. Theoretically, the observed link is explained by differences in elaborative heuristic search: More elaborate encoding leads to more vivid memory representations, which changes the ease of cognitive processing along with one's subjective basis for judgment. The current research presents new evidence in a stock profit estimation task, documenting a relationship between better memory and the use of fluency. Specifically, participants were provided with fictional company names that varied in their ease of pronunciation, and were asked to judge past company profits. Participants with a higher reliance on the company name pronunciation for their judgments were found to later have higher recall and recognition of company names. Results are consistent with an elaborative heuristic search account of the unusual relationship between heuristics and cognitive control. Implications for dual process theories are discussed.

Bridging the Implementation Gap: From Sensorimotor Experience to Abstract Conceptual Knowledge

Anna Koop

University of Alberta

Leah Hackman

University of Alberta

Rich Sutton

University of Alberta

Abstract: We develop a sensorimotor perspective on conceptual knowledge, paying particular attention to the imperatives of an artificial system. Motivated by the gap between low-level sensorimotor experience and human-level conceptual knowledge, we contrast experiential knowledge with the classical notion of concepts. We discuss three ways in which experience and classical concepts differ: experience is dynamic rather than static, subjective rather than objective, and composed of minutiae rather than compact abstractions. We present a mechanism for abstracting from experience and show how it might recover some of the benefits of concepts while addressing some of the difficulties of classical theory. Finally, we implement a simple example which illustrates first steps towards bridging the gap between sensorimotor experience and high-level concepts.

An examination of learner control during web-based instruction

Jessica Federman

Cornell University

Ryan Morris

Cornell University

Lisa Dragoni

Cornell University

Abstract: We investigated the efficacy of an asynchronous computer-based educational learning platform called VideoNote. Key features of the technology include: video streamed content, searchable, detailed, time-linked text notes of learning topics that are hierarchically ordered, detailed analytics that timestamp and track which topics within the video students are viewing, and a mechanism for students to rate and mark the difficulty of certain topics to ease subsequent review. Students used the tool as a supplement to course lecture and for distance learning. Using a randomly assigned, between subject sample (N=77), students who used Video Note improved their exam grades by 9.5

The Linguistic Distribution of Relational Categories

Micah Goldwater

Northwestern University

Jon Willits

University of Wisconsin

Abstract: Behavioral research has distinguished relational categories (e.g., barrier), which are defined by relations among entities, from feature-based categories (e.g., vegetable), which are defined by sets of descriptive features intrinsic to entities (e.g., Gentner & Kurtz, 2005; Rein, Goldwater, & Markman 2010). Corpora research has demonstrated that category structure is reflected in their distribution in natural language texts (e.g., Willits, 2009). The current project connects these two lines of research by examining the distributions of both kinds of categories. Findings include: Feature-based categories' distributions are more similar to each other than relational categories' are to each other. Relational categories appear in more diverse contexts than feature-based; however relational categories are "anchored" by a single frequent collocate to a greater degree than are feature-based categories. We discuss relations between corpus measures and behavioral ratings and consider theoretical implications for category representation.

Multisensory stimuli improve numerical matching abilities of preschool children

Kerry Jordan

Utah State University

Joseph Baker

Utah State University

K.S. Rodzon

Utah State University

Abstract: We previously showed that giving young infants synchronous, multisensory information about number increases the precision of their numerical discriminations. Does intersensory redundancy also facilitate numerical learning in older children? Twenty-four preschool children (3-5 years) played a number matching game on a touch-screen computer. On each trial, children counted a sample numerosity whose elements were presented serially. On some trials, the sample was visual, on some auditory, while on still others audiovisual. Children were then presented with two choices and asked to touch the numerically matching array. Data support the idea that intersensory redundancy improves children's numerical estimations. Multisensory information may be more salient than unimodal information, which could better recruit attention and result in more precise learning and remembering than when such information is presented to only one modality. Results should spur future research into whether such multisensory facilitation can be harnessed for educational benefit in the early mathematics classroom.

Wayfinding Tasks and Heuristics

Simon J. Buechner

Center fo Cognitive Science

Christoph Hölscher

Center fo Cognitive Science

Abstract: Wayfinding is the process of determining and following a route between an origin and a destination (Golledge, 1999). Research on wayfinding has been conducted by means of a variety of tasks making it difficult to compare research results among each other. Wiener, Buechner & Hölscher (2009) proposed a taxonomy of wayfinding tasks that classifies the tasks with respect to external constraints and the type of knowledge that is required to solve the task. Besides these two factors, heuristics play an important role for wayfinding. A number of heuristics for wayfinding tasks are documented in the literature, including but not limited to work by the authors. We will first present the taxonomy and then relate observed heuristics to the tasks. The relationship of tasks and heuristics will then be discussed with respect to superordinate concepts.

Auditory distraction during semantic processing: Data and a model

Philip Beaman

University of Reading

John Marsh

Cardiff University

Dylan Jones

Cardiff University, University of Western Australia

Abstract: An experiment is reported demonstrating how free recall of visually-presented, categorically-related lists of words is disturbed by the presence of auditory distracters which subjects were instructed to ignore. Data show that auditory distracters from the same category as the to-be-recalled items produce the most disturbance to recall and result in the most intrusion errors. Additionally, the points at which these intrusion errors occur differ dependent upon whether recall is written or spoken. A variant of the SIMPLE (Scale Invariant Memory and Perceptual Learning) model (Brown, Neath & Chater, 2007) is fit to these data and the modifications necessary to achieve this fit are discussed. It is concluded that intrusion errors are not random but are dependent upon a weighted combination of the semantic and temporal overlap between the to-be-recalled and to-be-ignored material in semantic processing tasks and free recall

How to Foster the Integration of Text and Diagrams: An Eye Tracking Study on the Use of Signals in Multimedia Learning

Katharina Scheiter

Knowledge Media Research Center

Alexander Eitel

Knowledge Media Research Center

Abstract: Learners studying text and diagrams (multimedia) often fail to integrate information from both sources. Hence, signals that make explicit the relation between both representations should improve understanding. The current study investigated which changes in information processing can explain improvements in comprehension due to signals. In an eye tracking study 35 students learned about the functioning of the heart. In a no-signals condition, a text and diagram were presented unaltered. In the signals-condition, correspondences between the representations were highlighted by means of labels, color coding, and deixis. Signals improved understanding of text-diagram correspondences and guided attention towards diagrams. Moreover, diagrams were fixated earlier in the signals-condition. A mediation analysis showed that these changes in visual attention completely explained the effect of signals on comprehension. Hence, signals improve learning from text and diagrams by fostering learners' early reference to diagrams and by increasing the amount of attention devoted to them.

Cognitive Modeling Repository

Jay Myung
Ohio State University

Mark Pitt
Ohio State University

Abstract: Quantitative modeling has contributed substantially to the advancement of the cognitive sciences. Papers introducing and testing cognitive models regularly appear in the top journals. The growth and success of cognitive modeling demonstrate why modeling itself should be a primary quantitative method in the researcher's toolbox. Yet this method of scientific investigation remains under-utilized by the research community at large, in part because of the hassles in obtaining data sets to model and the difficulties in implementing models. The goal of this project is to assist scientists in their cognitive modeling efforts by creating an online repository containing data sets that can be modeled and the cognitive models themselves. The current state of the project and future plans will be presented. Funded by the Mathematical Modeling of Cognition and Decision of the Air Force Office of Scientific Research.

The hindsight bias in temporal predictions of animated automobile accidents

Dustin Calvillo

California State University San Marcos

Dayna Gomes

California State University, Los Angeles

Abstract: The hindsight bias occurs when people judge the outcome of an event as more predictable than it actually was before it occurred. The current experiment examined the hindsight bias in animations of automobile accidents. Participants viewed eight animations in one of two conditions. Those in the foresight condition were told that some animations contained accidents and were instructed to stop the animation when they were certain that an accident would occur. Those in the hindsight condition were told that all animations contained accidents and viewed each animation twice. They viewed the entire animation first. On the second viewing, they stopped the animation when they thought a naïve viewer would be certain an accident would occur. Those in the hindsight condition stopped the animations closer to when the accident actually occurred than those in the foresight condition, demonstrating a hindsight bias.

Strategies for multitasking: An fMRI study of individual differences in multitasking ability

Winston Jones

Mississippi State University

Jarrold Moss

Mississippi State University

Stephanie Doane

Mississippi State University

Abstract: Multitasking is the ability to interleave tasks that vary in duration and the demands placed on cognitive resources. The Abstract Decision Making (ADM) task correlates with performance in real-world multitasking environments (Joslyn & Hunt, 1998). This study uses the ADM to measure multitasking ability. Our hypothesis is that use of consistent and effective task strategies can partially explain individual differences in multitasking ability. This hypothesis was investigated using behavioral and fMRI measures. The behavioral results show a correlation between strategy consistency and individual differences in ADM performance and support the strategy hypothesis. The fMRI results suggest that executive control areas of the brain are involved in task performance, but that activation in these areas alone does not explain differences in ADM performance. However, activation in other areas, including temporo-parietal regions, is correlated with individual differences in performance.

Facilitation in Second Language Word Meaning Evaluation from Masked Primes

Robert Zheng
University of Utah

Fernando Rubio
University of Utah

Dan Woltz
University of Utah

Abstract: An experiment with 90 students learning Spanish as a second language was conducted to investigate 1) the ability of cross-language primes to facilitate semantic decisions which required L2 meaning retrieval of recently learned words, and 2) the relationship between prime facilitation and prime awareness. The priming task consisted of a Spanish word presented in the upper third of the computer display, followed by two pictures in the lower left and right corners of the display. Our results indicated facilitation in vocabulary response time was substantial at both 67 and 83 ms prime exposure duration. There was no dependable facilitation at 50 ms exposure. It was concluded that automatic prime effects, independent of strategic processing of primes, might offer an important tool for reducing the working memory load inherent in initial L2 acquisition which could allow greater opportunity for the acquisition of semantic and structural elements of the new language.

Physical design tools support and hinder innovative engineering design

Jooyoung Jang

LRDC (Learning Research and Development Center), University OF Pittsburgh

Christian Schunn

LRDC (Learning Research and Development Center), University of Pittsburgh

Abstract: Engineers use various physical tools (e.g., computers, smartboards, notes, and prototypes) to support their design work. To understand cognitive processes underlying the innovative design process and to reveal the characteristics of innovation-supporting environments, we examined the pattern of tool use in 43 interdisciplinary engineering design teams enrolled in a full-semester Product Realization course. Teams worked all semester on a single project, with each team being assigned a different industry-sponsored project. Group meetings were video-recorded. Team success was measured in terms of meeting client requirements, and groups were divided into high, medium, and low success. Low success groups (relative to high and medium) used smartboards and prototypes less often and paper notes relatively more often. The results suggest that more successful groups focused on group discussion, supported by large sharable screen, and transitional thinking from abstract ideas to concrete products.

Seductive Images and Metacomprehension of Science Texts

Allison Jaeger

University of Illinois at Chicago

Jennifer Wiley

University of Illinois at Chicago

Abstract: Although the intention behind including illustrations alongside expository text is generally to increase student motivation, interest, or understanding, images do not always have beneficial effects. Generally, students tend to have poor comprehension when learning from expository science texts. Further, they also tend to have poor metacomprehension accuracy, meaning they are not able to differentiate what they have understood well, from what they have understood poorly. In the current study, the inclusion of either conceptual or seductive images actually increased comprehension as compared to a no-image condition. The inclusion of images also tended to increase readers' interest in the texts. However, including seductive images decreased metacomprehension accuracy compared to the no-image condition. This suggests that seductive images may provide readers with a false sense of fluency or understanding which could potentially undermine effective self-regulation and studying behaviors.

Emotion and association-memory

Christopher Madan

University of Alberta

Christine Lau

University of Alberta

Jeremy Caplan

University of Alberta

Esther Fujiwara

University of Alberta

Abstract: Emotional items are remembered better than neutral items. It is unclear how this extends to memory for associations involving emotional items. We manipulated the pairings of emotional and neutral words and direction of cued-recall probes. Pairs were pure (EMOTIONAL-EMOTIONAL, NEUTRAL-NEUTRAL) or mixed (EMOTIONAL-NEUTRAL, NEUTRAL-EMOTIONAL). We asked whether emotion would enhance association-memory, independently of its effects on item-memory (e.g., target retrievability). We fit the data with a probabilistic model to obtain estimates of how emotion influenced cued recall depending on emotionality of the target or probe (item-memory effects), or relationship between constituents (association-memory effect). In a follow-up we replaced emotional words with taboo words to exaggerate the manipulation. Findings suggest that mildly emotional words reduced memory for the associations whereas taboo words neither impaired nor enhanced memory for the associations. Consistent with other recent findings, our results suggest that emotional enhancement of memory effects do not extend to relational memory.

The Effects of Alcohol Use on Creative Problem Solving

Andrew Jarosz

University of Illinois at Chicago

Gregory Colflesh

Georgia Tech

Jennifer Wiley

University of Illinois at Chicago

Abstract: Though creativity is highly valued in many disciplines, ranging from the fine arts to the natural sciences, little is known concerning its underlying causes and mechanisms. In particular, the problem solving literature has long sought an explanation for the processes underlying creative problem solving. The present study tested the commonly held notion that alcohol use increases an individual's creativity, using a problem solving paradigm. Participants completed the Remote Associates Task (RAT), while either sober or intoxicated to a blood alcohol content of approximately .07. It was found that intoxicated individuals outperformed their sober counterparts. These results are interpreted as evidence that alcohol use leads to a diffuse attentional state, which in turn can benefit creative problem solving.

Tapping into Student Knowledge about Science Systems

Jodi Davenport

WestEd

Edys Quellmalz

WestEd

Mike Timms

WestEd

Abstract: What do students know about science? If students have a deep understanding of a science system they should understand core concepts and be able to use their knowledge to make inferences and carryout scientific investigations. Thus, the challenge of science assessment is to develop tasks that not only tap into declarative and procedural knowledge, but also schematic and strategic knowledge that allow students to demonstrate the ability to reason through complex systems and use existing knowledge to generate new understandings.

The current study investigates the range of knowledge and skills addressed by existing middle school science assessments administered at state, national and international levels. We conducted an analysis of released and sample items related to ecosystems and chemistry from more than 30 exams. We will present the results of our analysis and a framework that characterizes the types of knowledge likely to be elicited by different types of assessment items.

Preschoolers writing of multidigit numbers: From an additive to multiplicative representational system?

Sandra Street

Indiana University

Richard Prather

Indiana University

Cody Stitzel

Indiana University

Linda Smith

Indiana University

Kelly Mix

Michigan State University

Abstract: Possible systems for representing multi-digit numbers include additive systems (such as roman numerals) in which unique symbols that represent different amounts are written in strings and multiplicative systems in which the same digit represents different multiples of different set sizes depending on place, as in the base-10 place value system. Multiplicative systems such as this depend on place holders (zero). Preschool children (4 to 6 years of age) prior to any explicit training with multi-digit representations were asked to write 2 and 3 digit numbers. Children's responses were collected and coded for a variety of features. Young children on their own seem to develop an additive idea about how to represent multidigit numbers, that preserves left to right place value, and uses 0 to represent group size (e.g., two hundred twenty seven = 20027 or 200207).

Knowledge about the role of illustrations on motivation for reading

Hideaki Shimada

Shinshu University

Abstract: Suppose that you grab an instructional manual, you may glance over some of the pages to determine whether it looks interesting enough to read carefully. Our past study demonstrated that illustrations enhance readers' motivation in the first few seconds in text comprehension. This study examined the knowledge about the role of illustrations and the relationships to the motivation effect. In the first phase of this experiment, participants were required to glance over a page of a disaster prevention manual for two seconds and to answer questions as to motivation, such as "Did the page motivate you to read?" In the next phase, they were required to evaluate a subjective amount of information and comprehension efficiency for each page. Results showed that illustrations didn't increase the subjective amount of information but subjective efficiency, which enhanced motivation to read.

Effects of Self-Explanation and Prompts Depend on the Students' Need for Cognition

Kyung Soo Do

Sungkyunkwan University

Hyo-hee Lee

Sungkyunkwan University

Hanna Kim

Sungkyunkwan University

Abstract: Determining what to explain and generating explanations have to be satisfied to do successful self-explanations. Providing prompts helps the first part, and students' having high Need for Cognition can help the whole process. Seventy four adult vocational school students participated in a three factors (ie., self-explanation, prompt, Need for cognition) between subjects experiment. The results were different depending on the tasks and the students' level of Need for Cognition. In memory tests, asking to do self-explanations or giving prompts helps students of low levels of Need for Cognition. However, asking to do self-explanations or giving prompts was not effective to students of high level of Need for Cognition. In tests measuring understanding, the main effect of Need for Cognition was significant, and three factors interaction effects was marginally significant. Giving prompts helped students of high Need for Cognition understand better. The results were interpreted in terms of cognitive load.

Engineering Models of Human Behavior

Spyridon Revithis

University of New South Wales

Abstract: The level at which a computational cognitive model provides explanations of phenomena is often unclear, especially when there is no sufficient distinction between behavior and cognition. It has been shown that human behavior is amenable to SOM modeling aiming at compressed classification and prediction. Reducible to an engineering level this modeling approach offers no associations to biologically plausible cognitive mechanisms if there is no explicated claim of correspondence between the mechanisms used and the biological mechanisms that drive behavior. At the statistical level no claim of biological plausibility is always a prerequisite for the validity of the model.

Case studies of behavioral SOM models, conducted by the author, demonstrate and support the proposition that engineering models are not by default brain cognitive models or causal models of human behavior until appropriate associations have been established; prior to the latter, SOM models merely suggest algorithmic engineering solutions to challenging statistical problems.

Attention for Action: Attentional Modulation by the Hands

Holger Schultheis

Universität Bremen

Laura Carlson

University of Notre Dame

Richard Abrams

Washington University

Abstract: Actions by the hands may be represented with respect to a spatial reference frame that is centered on the hands, thereby organizing the surrounding space into regions and possibly influencing the allocation of attention to these regions. Indeed, it is more difficult to disengage visual attention from a visual search display when responses are made by hands that are grasping the display screen than by hands that are on the lap. In the current study we assess whether the attentional modulation is due to proximity to the screen or orientation of the hands. Specifically, we contrast conditions that dissociate proximity (hands near or far from the screen) and orientation (hands spanning the display with responses toward the stimuli, hands spanning the display with responses orthogonal to the stimuli, and hands near to but not spanning the display). The results indicate that both proximity and orientation influence the allocation of attention.

The effect of conventionality and aptness on suppression of metaphor-irrelevant meaning

Tomohiro Taira

Kyoto University

Takashi Kusumi

Kyoto University

Abstract: Metaphor comprehension needs a categorization process. The categorization process includes two different functions to the vehicle of metaphor: one is the activation of metaphor-relevant meaning, and the other is the suppression of metaphor-irrelevant meaning. Some previous studies showed that the conventionality of the vehicle and the aptness of the metaphor affect whether the categorization process happens. But they did not clarify whether these factors affect the activation and the suppression. In this point, our past study showed the evidence of the effect of the conventionality and the aptness on the activation of metaphor-relevant meaning. And in this study, we investigated the effect of these factors on the suppression of metaphor-irrelevant meaning. One experiment that consisted of a metaphor-priming task and a meaningfulness decision task showed that after metaphor comprehension, the vehicle suppress the metaphor-irrelevant meaning regardless both of the conventionality of the vehicle and the aptness of the metaphor.

A Categorization of Face Recognition Deficits in Congenital Prosopagnosia

Rainer Stollhoff

Max Planck Institute for Mathematics in the Sciences, Leipzig, Germany

Jürgen Jost

Max Planck Institute for Mathematics in the Sciences, Leipzig, Germany Santa Fe Institute,
Santa Fe, NM, USA

Ingo Kennerknecht

Institute of Human Genetics, Westfälische Wilhelms-Universität, Münster, Germany

Abstract: Congenital prosopagnosia refers to a lifelong impairment in face identification that is present from birth. In contrast to acquired prosopagnosia, where the deficit is due to brain damage, people with congenital prosopagnosia never evolve a functional face recognition system in the first place but develop compensatory processing strategies to overcome their deficit. In order to assess both deficit and compensatory processing in congenital prosopagnosia, we conducted a series of experiments with a large group of 15 prosopagnosic participants. The tests administered covered different aspects of face and object recognition: Identification under unlimited and restricted viewing times, the influence of rotation in depth, recall of target stimuli after one year, and recognition of famous faces. Based on the test results, we propose a categorization of congenital prosopagnosia along the lines of an apperceptive, associative or amnesic deficit and discuss this categorization scheme with respect to potential neuroanatomical differences underlying the deficit.

Focusing on the Intermediate Event Makes the Chain Structure More Learnable

Kyung Soo Do

Sungkyunkwan Univ.

JaeHyuk Choi

Sungkyunkwan Univ.

Abstract: The chain structure has not been easily inferred when three events are causally related like a chain (A causes B, and B in turn causes C). We hypothesized that focusing on the intermediate event make the chain structure more learnable, if the causal structure is locally computed (Fernbach & Sloman, 2009). In Experiment 1, focusing is manipulated by informing which event is important. Participants who were informed that the intermediate event (B) is important inferred the chain structure (61

Effects of Physical Structure and Creators' Intentions on Judgments of Function

Kyung Soo Do

Sungkyunkwan University

Kyuhee Kim

Sungkyunkwan University

Abstract: Affordances from physical structure and creator's intentions have been regarded as the determinants of an object's perceived function. Two experiments were conducted to explore the conditions when creator's intentions affected judgments of function. Participants rated the plausibility of the two possible functions after an outline drawing of an object and verbal description of creator's intentions were presented to them. When one of the two functions was easily derived from the drawing (Experiment 1), the function was judged more plausible regardless of creators' intention. However, the difference between the plausibility ratings of the two functions got smaller when intention did not match the dominant function. When the two functions were equally likely from the drawing (Experiment 2), creators' intentions affected the perceived function of an object. The results of two experiments suggested that creators' intentions affect the judgment of function only when affordances are not strong.

A Computation Model synthesizing the Rule based and Experience based Cognitive Processes of Chinese Characters

Sau-chin Chen

Tzu Chi University

Jon-Fan Hu

National Cheng Kung University

Ping Li

Pennsylvania State University

Abstract: A new model organizing two self-organizing maps (SOM) is presented here for synthesizing the rule based and experience based cognitive activities in support of processing the sounds and forms of Chinese characters. One SOM is constructed to form the phonological representations generated from the Chinese PatPho (Zhao & Li, 2009); and another SOM is aimed to produce the orthographic representations according to the Chinese character coding system (Chen, Zhao, & Li, 2009). The two SOMs are connected by an associative learning algorithm in shaping the mapping between the phonological and form patterns. The mappings belong to the phonetic radical and characters with this radical are suggested to construct the Chinese phonetic-and-sound relations. This presentation summarizes the tests on a specific group of characters representing the typical phonetic-and-sound relations. Insights of this model would reveal if these mappings are the origins of the rule based and experience based cognitive activities respectively.

Virtual Brainstorming: Avatar Visibility and Group Size

Thomas Ward

University of Alabama

Matthew Guerdat

University of Alabama

Beverly Roskos-Ewoldsen

University of Alabama

Abstract: Dyads and triads of college students brainstormed via computer based text chat rather than face-to-face. In one condition, participants were represented as 3D avatars in a virtual space. In another, no avatars were visible. It was hypothesized that triads would outperform dyads due to facilitation from a third perspective, and that having avatars visible would increase participants' sense of presence and task involvement, resulting in better performance. Participants were given standard brainstorming instructions that emphasized withholding criticism, generating unusual ideas, generating as many ideas as possible, and piggybacking on others' ideas. The task was to generate ideas as for how to improve the university. Participants were surveyed after the problem solving task regarding their sense of presence and task involvement. Triads outperformed dyads but there was no facilitation of presence or idea generation from having visible avatar representations. Implications for the believability of virtual environments are discussed.

Semantic richness modulates early word processing within left-lateralized visual brain areas and enhances repetition priming

Milena Rabovsky

Humboldt University at Berlin

Werner Sommer

Humboldt University at Berlin

Rasha Abdel Rahman

Humboldt University at Berlin

Abstract: Repetition priming has been shown to be modulated by prior knowledge about structural regularities (Stark & McClelland, 2000). Here, we examined influences of higher-level semantic knowledge, more specifically the richness of semantic representations, on repetition priming. The EEG was recorded while twenty-four participants performed a visual lexical decision task on 160 words and 160 pseudowords. Within the word stimuli, we orthogonally manipulated two measures of semantic richness, namely the number of semantic features (McRae et al., 2005) and free associations (Nelson et al., 2004); the whole stimulus set was presented twice. The number of semantic features modulated the amplitude of the posterior N2 component over left occipito-temporal areas. This effect arose only about 30 ms after the onset of lexicality effects on left-lateralized N170 amplitudes, presumably reflecting visual word form processing within the fusiform gyrus. Thus, word form and meaning are accessed in rapid succession within left-lateralized visual brain regions. Repetition priming was consistently enhanced for words with many semantic features in both performance and ERP data, suggesting a role for feature-based semantic richness in word repetition priming.

The role of stimulus familiarity in non-linguistic sequence learning

Jennifer A. Sturm

Northumbria University

Kenny Smith

Northumbria University

Abstract: Recent experiments suggest that the mechanisms employed in language learning are also involved in sequential learning of non-linguistic stimuli and are therefore domain-general. However, the non-linguistic materials typically used in these experiments (e.g. Kirkham, Slemmer & Johnson, 2002) do not adequately replicate the internal complexity of words in language. Furthermore, stimulus familiarity appears to play a crucial role (Saffran, 2007). We explore both factors, investigating the acquisition of non-adjacencies (ubiquitous in language) in non-linguistic sequences. Crucially, the black and white matrix patterns we use are orthographically matched with an artificial language, replicating the componential re-use of elements in language or speech (Sturm & Smith, 2009). Prior to the sequence learning experiment, participants were familiarized with individual patterns. The results show that although participants became familiarized with the patterns, they were unable to identify the grammar underlying sequences of those patterns. These findings allude to an important role of domain-specific expectations.

The Development of Numeracy: Fingers Count!

Marcie Penner-Wilger

Sheri-Lynn Skwarchuk

University of Winnipeg

Deepthi Kamawar

Carleton University

Jeffrey Bisanz

University of Alberta

Abstract: Butterworth (1999) proposed that three component abilities support the development of numeracy: subitizing, finger gnosis, and finger agility. We assessed these abilities in children in Grade 1 ($N = 144$) and followed them to Grade 2 ($n = 102$). In Grade 1, subitizing and finger gnosis were related to children's number system knowledge and all three component abilities were related to calculation skill. Using cluster analysis, we identified three groups of children based on skill profiles across subitizing, finger gnosis, and finger tapping. One group had strong subitizing, finger gnosis and finger agility – they also had good numeracy performance both concurrently in Grade 1 and longitudinally in Grade 2. Two other groups both performed worse than the highly-skilled group on numeracy measures in Grade 1 and Grade 2; these two less-skilled groups showed strikingly different patterns of performance on number comparison, a task designed to assess the representation of number.

Location, Location, Location: Environmental constraints on interpreting spatial terms

Kevin Mickey

University of Notre Dame

Laura Carlson

University of Notre Dame

Scott Freunds Schuh

University of Minnesota, Duluth

Abstract: The environment can constrain the way we think and act within it. Such an influence has been largely ignored within the domain of spatial language, which has largely focused on objects and their identities, independently of the environments in which they occur. To investigate whether the environment also has an influence, we instructed participants to place a located object either near or far from a reference object within survey perspectives of manipulated 3D environments. When a geographical feature in that environment was present and had meaningful semantic content, it systematically altered the distance, direction and orientation of the placements, with these alterations well beyond the range expected based on a geometric definition of the spatial term. This environmental influence is consistent with a situated view of cognition.

Goals and the Perception of Distance and Time in Virtual Spaces

Angie Johnson

University of Northumbria at Newcastle

Kenny Coventry

University of Northumbria at Newcastle

Emine Mine Thompson

University of Northumbria at Newcastle

Abstract: Individuals rarely walk in an environment without a purpose. However, the influence of goals on the development of 'cognitive maps' has largely been ignored. The results of two experiments are reported that investigated the role of both goals and environmental structures on memory for distance and time in Virtual Reality (VR) environments. Experiments 1 and 2 compared the effect of goals varying in urgency and desirability, on memory for distance and time in VR environments with (Experiment 1) and without turns (Experiment 2). Striking effects of goals were found for memory for distance and time in both environments. Experiment 3 examined the origins of these goals effects through the use of physiological measurement and mood scales. Results show that goals influence distance estimation as a function of the degree of urgency experienced in situ, and not as a function of overall mood state or arousal they induce.

Artificial Cognitive Systems for Human-like Situation Awareness Ability

Soo-Young Lee
KAIST

Abstract: The Artificial Cognitive Systems (ACS) will be investigated for human-like functions such as vision, auditory, inference, and behavior. Especially, computational models and artificial HW/SW systems will be devised for Proactive Knowledge Development (PKD) and Self-Identity (SI). The PKD model provides bilateral interactions between robot and unknown environment (people, other robots, cyberspace). For the situation awareness in unknown environment it is required to receive audio-visual signals and to accumulate knowledge. If the knowledge is not enough, the PKD should improve by itself through internet and others. For human-oriented decision making it is also required for the robot to have self-identify and emotion. Finally, the developed models and system will be mounted on a robot for the human-robot co-existing society. Based on the computational models of PKD and SI, we would like to build functional modules for Knowledge Representation, Knowledge Accumulation, Situation Awareness, Decision Making, and Human Behavior.

Comprehension and a Complex Task: A construction-integration study of individual performance in a non-routine task situation

Paul Ladny

Mississippi State University

Jordan McGuire

Mississippi State University

Randy J. Brou

Navy Personnel Research, Studies, and Technology

Stephanie M. Doane

Mississippi State University

Abstract: Comprehension is the ability to relate background knowledge to incoming information to build a "situation model" (Kintsch, 1998). The ConstructionIntegration (C/I) architecture of comprehension has been shown to predict individual performance on complex but routine tasks (e.g., Doane & Sohn, 2000). This study tests the ability of the architecture to explain and predict nonroutine (unexpected) instrument flight performance in aviation piloting. The behavioral results indicate significant differences in individual pilot ability to detect and recover from unexpected instrument failures as a function of piloting expertise. However, expertise is not the sole predictor of performance. The computational experiments indicate that the C/I architecture explains and predicts a significant amount of individual pilot performance. Overall the findings suggest that comprehensionbased processes play a significant role in understanding human performance in unexpected situations.

Competitive Routes to Belief and Their Impact on Future Learning

Carlos R. Salas

University of Illinois at Chicago

Thomas D. Griffin

University of Illinois at Chicago

Abstract: Models of belief formation and conceptual change have begun to allow for affective preferences and motives to supplement normative processes, such as reasoning and coherence evaluation (Kunda, 1990; Thagard, 2006). Griffin (2008) goes a step further in arguing that affect can be a separate competitive route to belief formation that could prevent these normative processes from taking place. One implication is that affect-based beliefs will lack the conceptual coherence presumably produced by engaging in reasoning and coherence evaluation processes. Borrowing from the expertise literature (e.g., Ericsson & Kintsch, 1995), this reduced conceptual coherence should hinder one's ability to represent new domain-related information. We present a study showing that a person's route to belief (evidence or emotion based) predicts their comprehension of belief-relevant information, even after controlling for several general and domain-specific individual differences in knowledge, skills, dispositions, motivation, and task engagement.

Unique and Additive Effects of Self-Explaining and Contrasting Cases on Learning Fraction Division

Shanta Hattikudur

University of Wisconsin - Madison

Pooja G. Sidney

University of Wisconsin - Madison

Martha W. Alibali

University of Wisconsin - Madison

Abstract: Studies show that both contrasting cases and self-explanation are useful in promoting procedural and conceptual knowledge when learning from worked examples. It is not clear whether these instructional tools draw on similar problem-solving skills or provide unique support for learning. The purpose of this study is to assess whether self-explanation and contrasting cases are more effective when combined than when applied separately. To the extent that these processes can be manipulated separately, we hypothesize that the effects of both instructional techniques are unique, and together will lead to greater knowledge gains.

Participants completed a pretest, assessing their ability to divide fractions, before engaging in a problem study session and procedural lesson about fraction division. Participants then completed the posttest, which included procedural and conceptual transfer measures. Pilot data suggest that there are differences between the benefits of self-explanation and contrasting cases on procedural and conceptual learning.

When dog is more wolf than bone: Computational and electrophysiological evidence for featural organization of semantic memory

Sarah Laszlo

Carnegie Mellon University

Blair Armstrong

Carnegie Mellon University

Joseph MacInnes

Oculus Info. Inc.

David Plaut

Carnegie Mellon University

Kara Federmeier

University of Illinois, Urbana-Champaign

Abstract: Semantic space algorithms account for human performance in semantic tasks via knowledge representations derived from the analysis of large text corpora. The N400 Event-Related Potential (ERP) component is thought to reflect automatic access of the same lexical-semantic information. We trained LSA (Landauer & Dumais, 1997) and HAL (Lund & Burgess, 1997) on a random selection of Wikipedia articles and compared the algorithms' performance at predicting the similarity between N400 waveforms elicited during reading. HAL was best at explaining the ERP data, suggesting that its representations—thought to be more semantic-featural than lexical-associative in nature—are most similar to those automatically accessed during N400 processing. These results are consistent with findings that, although the N400 is sensitive to lexical relationships, it seems to represent access of information arranged primarily by semantic features. Preliminary evaluations of other algorithms (e.g., COALS, Rohde, Gonnerman & Plaut, submitted) further support this conclusion.

Hindsight bias in judgments of others' performance on inattentional blindness tasks

Alan Penalzoa

California State University San Marcos

Dustin P. Calvillo

California State University San Marcos

Richard Brooks

California State University San Marcos

Dayna M. Gomes

California State University, Los Angeles

Abstract: The hindsight bias occurs when people judge the outcome of an event as more predictable after the event has already happened. Participants ($N = 45$) completed two inattentional blindness tasks, in which an unexpected object appeared while participants performed a primary task. Participants were asked if they noticed the unexpected object. They were then shown the unexpected object and asked how many people (out of 100) they thought would be able to see it. For both tasks, those who saw the objects (Task 1: $n = 5$; Task 2: $n = 19$) judged that more people would see it (overall: $M = 39.8$, $SD = 23.0$) than those who did not (overall: $M = 17.1$, $SD = 14.6$). This finding is consistent with a hindsight bias: those who experienced seeing the object thought that others would see it, while those who did not, thought others would not.

A decision science blind to decision procedures would be "unfair": The effect of decision process on decision-outcome satisfaction and subsequent choice in a performance environment

Daniel DeCaro

Miami University (MU)

Joseph Johnson

Mimia Univeristy (MU)

Abstract: Contemporary models of decision making assume individuals evaluate options solely in terms of their expected outcomes. However, recent research indicates that in institutional settings decision makers are also concerned with the procedural fairness of the decision process that generates those outcomes, such as whether decision makers were granted democratic inclusion in the decision-making process itself. We provide a much-needed quantification of the value decision makers place on inclusive decision procedures, showing (a) the pattern by which decision procedures alter individuals' perceptions of otherwise identical outcomes, spanning losses and gains of differing quantity and quality (e.g., failure/success) and (b) that decision makers' felt freedom and feeling of being treated respectfully mediate the effect of decision process on the perception of outcomes. We show that individuals prefer lesser economic returns in order to receive higher utility from the decision process, and we discuss the implications of this finding for decision science.

A Functional, Hormonal, and Computational Study of Sex Differences in Working Memory

Brandon Abbs

Harvard Medical School Brigham and Women's Hospital Connor's Center for Women's Health
and Gender Biology MGH-MIT Athinoula Martinos Center for Biomedical Imaging

Jill Goldstein

Harvard Medical School Brigham and Women's Hospital Connor's Center for Women's Health
and Gender Biology MGH-MIT Athinoula Martinos Center for Biomedical Imaging

Abstract: Studies show sex differences in working memory (WM) measured by using functional magnetic resonance imaging (fMRI). Effects have been associated with hormonal regulation of prefrontal (PFC) and parietal (PAR) cortices, regions implicated in WM function. Determining the pathophysiology of these sex differences has implications for understanding individual differences in WM. Using fMRI, we assessed WM using an N-back task and acquired hormonal status in 13 males and 13 females. Findings demonstrated sex differences in brain activity and connectivity between PAR and PFC, which were associated with female hormonal status. We suggest that hormones may regulate the 'gain' of neuronal activity in PFC and PAR, leading to less diffuse activation in women compared to men, the effect for which we propose a neural network model.

Now You See It, Now You Dont: Social Attention in a Magic Trick, Live and On Video

Robert Teszka

University of British Columbia

Evan Risko

University of British Columbia

Gustav Kuhn

Brunel

Alan Kingstone

University of British Columbia

Abstract: Research in social attention assumes that the way individuals attend to images of people accurately reflects how individuals attend to real live people. We examined whether this assumption is valid by studying how verbal cues affect where people look. In previous work using a live performance of a magic trick, verbal cues by the magician were shown to affect shifts in gaze. We extended this work by recording a similar trick in HD video and having observers watch the video while wearing an eye-tracker in order to investigate the effects of presentation medium (live vs. video) on social attention. While we discovered several key similarities across presentation mediums (e.g., verbal cues affected social attention), there were also some remarkable differences as well (e.g., the strength and frequency of the attention effect). The implication of these data for past and present theories of social attention, and future research approaches are discussed.

Declarative and procedural memory abilities as predictors of successful adult language learning

Katherine Brill

University of Illinois at Chicago

Mandy Faretta

University of Illinois at Chicago

Francis Wong

Northwestern University

Patrick Wong

Northwestern University

Kara Morgan-Short

University of Illinois at Chicago

Abstract: Evidence from two related but independent fields of research, second language acquisition (SLA) and cognitive neuroscience, suggests that some adult learners do reach high proficiency in an L2, as assessed by performance on language tasks. Not much is known about how or why certain adults attain high proficiency while others do not. Certain cognitive abilities, specifically procedural and declarative memory systems, may factor into language proficiency. This research aims to address this question by examining how individual differences interact with implicit language learning. Subjects completed a battery of cognitive tests including the Tower of London task, the Continuous Visual Monitoring Task and the Modern Language Aptitude Task, and learned an L2 under implicit training conditions. After practicing on comprehension and production tasks, subjects were given a grammaticality judgment task. A multiple regression was conducted to determine what cognitive abilities are unique predictors of L2 aptitude (as measured by the GJT).

A Bird's-Eye View of Numerical Discrimination in the Wild

Alexis Garland

Victoria University of Wellington

Jason Low

Victoria University of Wellington

K.C. Burns

Victoria University of Wellington

Abstract: Theory in numerical cognition has been in large part informed by evidence of numerical discrimination in humans and primates. Posited universal cognitive systems have, as a result, fundamentally been shaped by mammalian physiology and phylogeny, with findings largely supporting a ratio-based system. Explorations of large number discrimination with wild populations of any kind have, until now, been virtually unknown. Extant evidence on avian numerical capacity either focuses on large number discrimination in trained pigeons within a laboratory setting or object identification in terms of clutch size and brood parasitism in water fowl. Heretofore, no evidence has been uncovered to indicate the precise cognitive mechanisms that may be deployed in avian numerical choices of 'more' in a natural setting. Our study presents stark new evidence that redefines the capacities and limitations of number representation in the scatter-hoarding New Zealand robin (*Petroica australis*).

Distinguishing first-line defaults and second-line conceptualization in reasoning about humans, robots, and computers

Daniel Levin

Vanderbilt University

Megan Saylor

Vanderbilt University

Simon Lynn

Vanderbilt University

Abstract: We previously demonstrated that people distinguish between human and nonhuman intelligence by assuming that humans are more likely to engage in intentional goal-directed behaviors than computers or robots. In the present study, we tested whether participants who respond relatively quickly when making predictions about an entity are distinguish more or less between human and nonhuman agents. Participants responded to a series of five scenarios in which they chose between intentional and nonintentional actions for a human, a computer, and a robot. Those who chose quickly were more likely to distinguish human and nonhuman agents than participants who deliberated more over their responses. We suggest that the short-response time participants were employing a first-line default to distinguish between human intentionality and more mechanical nonhuman behavior, and that the slower, more deliberative participants engaged in deeper second-line reasoning that changed their predictions for the behavior of a human agent.

Cross-Modality Strategy Transfer: A behavioral study of strategic discrimination skill acquisition and transfer across auditory and visual modalities

Hao Bai

Mississippi State University

Paul Ladny

Mississippi State University

J. Gregory Trafton

Naval Research Laboratory

Randy J. Brou

Navy Personnel Research, Studies, and Technology

Stephanie M. Doane

Mississippi State University

Abstract: Discrimination is the ability to differentiate one object from another. Previous research suggests that with practice, individuals develop efficient discrimination strategies, and that strategies acquired in training transfer within a modality to novel stimuli (e.g., Haider & Frensch, 1999; Sohn, Doane, & Garrison, 2006). This study examines whether discrimination strategies transfer across presentation modalities. Subjects were trained to make difficult (similar) or easy (dissimilar) discriminations among visual or auditory objects during training. At transfer, subjects made difficult discriminations among stimuli presented in a different modality. Results suggest that the strategy acquired by subjects trained on difficult discriminations leads to superior performance at transfer compared to subjects trained on easy discriminations regardless of the modality of initial training and the modality switch at transfer. Cross-modal transfer was observed, and this suggests the role of a central mechanism in the acquisition and transfer of strategic skills.

”That’s what she said”: The effect of emotional prosody on the interpretation of intent.

Jennifer M. Roche

The University of Memphis

Rick Dale

The University of Memphis

Abstract: Nygaard and Lunders (2002) have shown that emotional prosody impacts the resolution of lexical ambiguity during spoken language, yet sentential meaning is often ignored (Snedeker, 2008). The integration of linguistic and non-linguistic cues to speech is vital for successful interpretation of intent. Experiment 1 evaluated the perception of sentential contexts with emotional prosody (e.g., irritation, disgust, neutral, compassion, sarcasm and innuendo). Results suggested that listeners have the ability to differentially categorize the intent behind statements, based on emotional prosody. Experiment 2 evaluated the online process of categorizing sentences with emotional prosody, via systematic curvatures in the arm using the Wii remote. Results of Experiment 2 suggest that a perceiver’s arm curvatures are reflective of the differentially interpreted categorized emotional information when the sentences remained stable. This supports the notion that emotional information plays a large role in the interpretation of sentential meaning, as it sharply influences the interpretation of intent.

Turn that frown upside down and to the left: Memory for faces is affected by their gravitational orientation

Nicolas Davidenko

Stanford University

Stephen Flusberg

Stanford University

Abstract: Recent research suggests the way our body is situated influences how we perceive our environment (Lopez et al., 2009), but it remains unclear whether our body's position influences how we process faces when retinal cues are kept constant (Troje, 2003; Lobmaier & Mast, 2007). In this study, participants completed an old/new face memory task in three different body positions (sitting upright, lying right, and lying left) and four different image orientations (upright, inverted, 90 degrees clockwise, and 90 degrees counterclockwise), allowing us to isolate the effects of retinal versus gravitational face orientation on recognition memory. We found a main effect of retinal face orientation, with higher d' to faces oriented upright versus inverted with respect to participants' retinas. Keeping retinal orientation constant, we also found an effect of gravitational orientation, with higher d' to faces orientated upright with respect to gravity, indicating a role of gravitational orientation in face processing.

Individual Differences in Successful Second Language Learning: The Roles of Working Memory and Intelligence

University of Illinois at Chicago

Abstract: Individual Differences in Successful Second Language Learning: The Roles of Working Memory and Intelligence

B. McCarthy, M. Faretta, F. Wong, P. Wong, & K. Morgan-Short

Poster Abstract

Learning a second language (L2) in adulthood is notoriously difficult. Some learners, however, seem to learn with ease. In order to understand the characteristics of successful learners, research has explored the role of individual differences. The current study examines the role of two individual cognitive abilities: working memory and intelligence. Participants complete a battery of cognitive tasks, including a listening span test and the Kaufman Brief Intelligence Test. They subsequently learn an artificial language, which is meaningful, productive and consistent with natural languages, over the course of four training sessions. Language proficiency is assessed within subjects at the end of the first and final session, and a multiple regression analysis is conducted to probe the contribution of working memory and intelligence to successful L2 development. Implications for theories of L2 learning and for L2 learners are discussed.

Individual differences in anticipatory eye-movements: Vocabulary size is associated with speed of noun-verb integration

Arielle Borovsky
UCSD

Jeffrey Elman
UCSD

Abstract: Humans can integrate information from a rapidly changing speech stream with astonishing speed. In this study, we measure the impact of vocabulary knowledge on the incremental integration of speech using language-mediated anticipatory eye-movements. Following Kamide, Altmann & Haywood (2003), Experiment 2, we examined the degree to which an upcoming sentential Theme is anticipated by a combination of information from an Agent and Verb (eg. "The pirate hides the treasure" vs. "The dog hides the bones"). Replicating prior results, combinatory effects of the Agent and Verb yielded anticipatory looks to the Theme. When participant's performance was split by receptive vocabulary score, differences in anticipatory eye movements were apparent. The group with higher vocabulary scores was faster to integrate Agent and Verb information to correctly look at the upcoming Theme. Together our findings suggest that prior language knowledge plays a pivotal role in even simple sentence processing tasks.

Reasoning through Mindful Actions: Effect of Instruction and Spatial Ability on Understanding Dynamic Systems

Margaret Chan

Teachers College, Columbia University

Abstract: The ability to understand systems is important for individuals engaged in various domains in science. Prior research has demonstrated direct-manipulation animation (DMA) effectively supports learners to understand dynamic systems. However, the role of learners' characteristics and scaffolding upon their performance remains unclear. The current study examines how instruction and spatial ability modulates learners' executive attention when they use DMAs to learn physical systems. To demonstrate comprehension and reasoning ability, participants were asked to explain and predict outcomes of "what-if" scenarios. Their eye-movements during their interaction with DMAs were recorded. Participants' eye-gaze patterns and learning performance revealed interactivity itself did not lead to understanding of these systems. Instead, the conjunction of attending to relevant information while actively manipulating the animation facilitated retention and reasoning. Spatial ability, however, was not significant in predicting performance. Overall, findings suggest learning with interactive animation involves cognizant interchange between bottom-up visuo-motor support and top-down cognitive control.

Are children irrational category learners? Evidence from a process model

Gavin Jenkins

University of Iowa

Jodi Smith

University of Iowa

John Spencer

University of Iowa

Larissa Samuelson

University of Iowa

Abstract: How do multiple labeling events influence children's understanding of objects that can be named at multiple levels of specificity ("Rover" or "dog")? To investigate, we replicated Xu & Tenenbaum (2007, *Psychological Review*, 114, 245-272), who found that children generalized more narrowly when three identical toys (e.g., plush Dalmatians) were labeled with a novel word compared to one toy labeled three times. Xu & Tenenbaum suggested the extra two referents provide statistical evidence that rationally supports a narrow hypothesis. In our "extra labeling" condition, however, children generalized broadly when each object was labeled ten times instead of once. This violates the predictions of a purely rational account and suggests situational, lower-level processes are critical to novel word generalization. A Dynamic Neural Field model is used to examine these processes, and further shows how process-oriented models can solve the problem of overlapping extensions.

Brain Response Over Time to Structured and Unstructured Musical Sequences

Kat Agres

Psychology Department, Cornell University

Hia Datta

Sackler Institute for Developmental Psychobiology, Weill Cornell Medical College

Jason Zevin

Sackler Institute for Developmental Psychobiology, Weill Cornell Medical College

Abstract: Research in speech and music shows that listeners model their auditory environment to form expectations about future input. Here we asked how the ability to predict upcoming musical tones based on both general implicit knowledge of musical structure and familiarity with a particular tune influence early portions of the auditory evoked response (AER). Using electroencephalography, we examined how predictability influenced brain responses to repeated tunes. The musical stimuli were simple, monophonic Irish folk tunes (Normal) and Random sequences in which the notes of each tune were presented in randomized order. Because the Random stimuli lacked musical structure, we hypothesized that listeners would be unsuccessful in learning or creating predictive models for these sequences. Differences were observed in early AER between the Normal and Random sequences. The results suggest that listeners successfully learn, remember and model the Normal sequences, but are unable to do this for Random sequences.

Seeing the world through a visual language: Visual world paradigm in British Sign Language

Robin L. Thompson
University College London

David P. Vinson
University College London

Neil Fox
University College London

Gabriella Vigliocco
University College London

Abstract: We used a visual world paradigm with British Sign Language (BSL) to test the methodology with a visually perceived language, and gain insight into the time course of BSL processing at the lexical level. Subjects were tracked while viewing four object pictures and a BSL video. One picture was (semantically or phonologically) related to the target sign, with target pictures present on some trials and absent on others.

Like previous spoken language studies, sign perceivers looked significantly more often towards related distracters than unrelated after the onset of the target sign, regardless of target picture presence. However, results indicate important differences in the time course of looks compared to speech, with gaze to pictures infrequent (due to attention to video) and earlier, often before actual sign onset. This last occurs because, unlike speech, the preparation phase (in which sign handshape and location are attained) is visible, allowing earlier cohort activation.

Insight into dynamics of speech perception in English and Japanese native speakers using a mouse-tracking paradigm

Hia Datta

Sackler Institute for Developmental Psychobiology, WCMC & The Graduate Center, CUNY

Ran Liu

Department of Psychology, Carnegie Mellon University & Sackler Institute for Developmental Psychobiology, WCMC

Jason Zevin

Sackler Institute for Developmental Psychobiology, WCMC

Abstract: In American English, the qualitative vowel contrasts /I/-/E/ and /E/-/ae/ are distinguished primarily by spectral and duration cues, respectively. Japanese uses duration cues for quantitative, but not qualitative contrasts. We measured arm movements with a mouse-tracking task while native English and Japanese speakers living in the United States distinguished spectral and duration contrasts in the word pairs "pin/pen" and "pen/pan." While both groups identified the words correctly, when distinguishing pan from pen, the English but not Japanese speakers' mouse-trajectories lean towards 'pen' earlier in the trial, when the information accumulated to that point is more consistent with the shorter of the two words. This suggests that while English speakers act rapidly on incoming acoustic information as it unfolds, Japanese speakers wait for more information before responding. These results may reflect Japanese speakers' expertise with duration cues from extensive experience with native quantity contrasts.

Concrete Models as Aids to Representational Translation of Molecular Diagrams

Andrew Stull

University of California, Santa Barbara

Hegarty Mary

University of California, Santa Barbara

Stieff Mike

University of Maryland, College Park

Dixon Bonnie

University of Maryland, College Park

Abstract: Chemists use many different types of diagrams to represent molecules and must develop skills to accurately translate between such diagrams. Translating between such diagrams can potentially involve the intermediate step of forming an internal 3-d representation of the molecule, so we hypothesized that performance would be enhanced when concrete models were used. Thirty students were provided with models as they translated one molecular diagram into a second and their spontaneous use of the models was recorded. Students' model use was coded for behaviors, such as moving, holding, reconfiguring, pointing to, or gesturing about the model. Results showed a great diversity in whether and how students used the models. Although performance on the representational translation task was generally poor, using the models was positively correlated with performance. We will also report the results of a follow-up study that compares student performance with and without models.

I spy with your eye: On the perception of others' gaze

Nicola Anderson

University of British Columbia

Craig Anderson

University of British Columbia

Evan Risko

University of British Columbia

Alan Kingstone

University of British Columbia

Abstract: Eye tracking can often be prohibitively expensive, proprietary and incredibly complex. We examined the accuracy of eye tracking using only a web camera. Participants were shown webcam recordings of a persons' eyes moving 1, 2, or 3 degrees of visual angle in one of 8 directions (North, NE, E, SE, etc) or no eye movement occurred at all. Observers judged whether an eye movement was made, and if so, its direction. Detection and direction judgments were significantly above chance across all three distances, with larger eye movements resulting in better performance. These data indicate that a webcam plus human observer system can be used to study human eye movements in a simple non-invasive manner. They also support theories of human social attention and evolution predicated on the assumption that humans have developed an especially fine ability to detect the eye movements of others and determine where those eyes are looking.

Beyond binary: One small step across the artificial-naturalistic divide in understanding human category learning

Kimery Levering

State University of New York: Binghamton

Kenneth Kurtz

State University of New York: Binghamton

Abstract: The foundational six types problem (Shepard, Hovland, & Jenkins, 1961) offers a limited view of human category learning due to minimal ecological validity. The SHJ types actually do address the explanatory constructs historically proposed to explain natural categories (rules, exemplars, family resemblance), but do so in an impoverished manner due to binary-valued dimensions. We studied the SHJ types using stimuli with four values on each dimension. The SHJ types become more like natural concepts with more robust intension (internal structure) and extension (category size). This allows for richer evaluation of the representations and processes underlying learner performance. Results depart from the traditional ease of learning order (I>II>III,IV,V>VI) since Type IV (family resemblance structure) shows higher accuracy than Type II early in learning. Transfer to novel items and typicality ratings reveal graded structure even in rule-described categories and show distinct signatures of the categorization basis used by each learner.

Dimension Word Knowledge and Flexible Attention Shifting

Rima Hanania

Indiana University

Thea Ionescu

Babe-Bolyai University, Cluj Napoca, Romania

Linda B. Smith

Indiana University

Abstract: One of the developing skills in executive functions is the flexible control of selective attention. Young children improve in this ability during the preschool years as measured by such tasks as the Dimension Change Card Sort (DCCS) which asks children to sort pictures, first by one dimension (e.g. color), and then by another (e.g. shape). Three-year-olds sort correctly by the first dimension, but do not sort correctly when the rule changes (i.e., they perseverate). By five, children switch flexibly between dimensions. This study asks about the relationship between perseveration in the DCCS and dimensional word knowledge which also improves during preschool years. Thirty children participated in a study which tests knowledge of feature terms (e.g., red, blue) and dimension terms (e.g. color, shape). Results indicate no difference in knowledge of feature terms for the two groups, but children who switch successfully in the DCCS were significantly better at dimension terms.

Lay Theories and Linguistic Framing in Teaching Children about Nutrition

Sarah Gripshover

Stanford University

Ellen Markman

Stanford University

Abstract: Research has shown that health interventions that build wisely upon existing conceptual knowledge can be effective in producing conceptual and behavioral change. Pre-school aged children have been found to understand the relationship between food and the body principally in terms of their lay mechanical theories. A conceptual intervention is designed to build upon this emerging understanding in order to teach nutritional balance and variety. Special attention is paid to the role of linguistic framing in building coherently upon children's existing mechanical knowledge. In particular, framing inert, inactive food as a causal agent in sentences such as milk gives you strong bones may be especially opaque given children's mechanical understanding of nutrition, compared with framing the body as the causal agent, e.g., your bones use milk to grow strong. Results indicate that children given a body-agentively—but not food-agentively—framed intervention achieved greater understanding of nutritional balance and variety.

The hindsight bias with dynamic stimuli and the propensity effect with static stimuli

Dayna Gomes

California State University, Los Angeles

Dustin Calvillo

California State University San Marcos

Abstract: A reversal of the hindsight bias, termed the propensity effect, has been found with dynamic stimuli when likelihood estimates of an event are lower among people with outcome knowledge than among those without outcome knowledge (Roese, Fessel, Summerville, Kruger, & Dilich, 2006). One hundred sixty-two participants were shown a vehicular accident depicted either by diagrams or by an animation. Some participants saw information leading up to the accident and were asked to predict the likelihood of an accident occurring. Others saw the accident and were instructed to disregard this outcome knowledge before providing a likelihood estimate. Results contradicted previous findings; the propensity effect occurred with diagrams and the hindsight bias occurred with the animation. Evidence for the propensity effect appears to depend on how stimuli are constructed and the point at which participants are asked to disregard outcome information. The present findings indicate that different presentation modes influence decision making.

Category Learning in Second Life: Effects of Learning Context on Mechanisms of Categorization

Joshua Sturm

Vassar College

Peter Nachbaur

Vassar College

Vassar College

Julianne Herts

Vassar College

Jan Andrews

Vassar College

Ken Livingston

Vassar College

Abstract: A major challenge in category learning research is designing novel stimuli that are functionally meaningful, then presenting them in an environment that is sufficiently controlled while remaining true to the dynamic nature of the real world. The interactive online environment Second Life represents an interesting methodological setting for such work, offering sophisticated stimulus design software, a powerful scripting language, and a fully editable physics engine. Two well-documented phenomena of category learning are "compression" (where objects classified together appear more similar) and "expansion" (where objects classified differently appear more different). Our studies using Second Life have thus far demonstrated its utility as a research tool by 1) successfully creating a compression effect "in world," 2) showing that this effect did not require verbal labels, and 3) revealing that a more interactive version of the task with much more complex and naturalistic stimuli produced learning without compression or expansion effects.

Deciding Whether or Not to Guess the Answer Predicts Subsequent Learning

Sean Kang
UCSD

Michael Mozer
University of Colorado

Harold Pashler
UCSD

Abstract: In a study on the effects of incorrect guessing on subsequently learning from feedback, we found confidence for wrong responses on an initial test was positively associated with correct final recall (higher confidence errors corrected better; Butterfield & Metcalfe, 2001). One explanation for this hypercorrection effect is that subjects are surprised by their error and thus pay more attention to the feedback (Fazio & Marsh, 2009). Inconsistent with this surprise hypothesis, however, was our finding that the decision to volunteer a low-confidence guess, even when the response was wrong, was associated with better subsequent learning of the correct answer than when a response/guess was withheld. We propose that the willingness to venture a guess, even when confidence is low, may reflect a higher state of learning, relative to choosing to omit a response. We present additional behavioral data and an error-correction neural network model in support of our alternative hypothesis.

Am I a Robot? How Verb Agency and Agent Description Influence Perspective-Taking in Visual Scenes

Michelle D. Greenwood
University of California, Merced

Teenie Matlock
University of California, Merced

Michael J. Spivey
University of California, Merced

Justin L. Matthews
University of California, Merced

Abstract: People often take an egocentric perspective when describing space. However, they occasionally take an alternative perspective. When and why? In a series of experiments that followed work on perspective, we explored this question. In one experiment, participants were given photographs of two objects on a table. Objectively, the scene could be described from either the perspective of the person viewing the picture or from the opposite perspective (i.e., facing the viewer). To test which viewpoint would be elicited, we asked participants to describe where an object was relative to another. In one experiment, a toy humanoid robot (facing the participant) was included in the scene to determine whether people would take its vantage point when referring to object locations, and how this inclination might vary according to changes in linguistic context. Results indicate that people can spontaneously take the perspective of an agent-like toy when describing object locations.

The role of conventional number knowledge in young children's nonverbal number matching: Is "two" special?

Mee-Kyoung Kwon
the University of Chicago

Yoonkyung Jeong
Catholic Universtiy

Susan Levine
the University of Chicago

Abstract: Two studies examined the role of conventional number knowledge on young children's nonverbal number matching (NVM). We hypothesized that acquiring two number words ("one" and "two") would facilitate children's performance on the NVM task by highlighting numerical comparisons rather than comparisons based on other variables. To test this hypothesis, two- and three-year-olds were given a NVM task that was either controlled for line-length/density (Experiment 1) or total surface area (Experiment 2). Conventional number knowledge was assessed using two tasks: Give-A-Number and How-Many. Results from Experiments 1 and 2 showed the advantage of knowing at least two number words: "Two-knowers" and above performed significantly better on NVM than one-knowers or non-counters. Performance of one-knowers and non-counters did not significantly differ, suggesting that children's performance on NVM is not significantly impacted by learning only one number word.

A sequence analysis of actions in complex system comprehension

Patrick Jeuniaux

Universite Laval

Daniel Lafond

DRDC-Valcartier

François Bernier

DRDC-Valcartier

Abstract: Complex systems have a broad network of relations for which human comprehension is severely limited and analysts often rely on the support of technological systems. In this study we investigated whether comprehension can be augmented by IMAGE – a set of interactive visualization, data exploration and knowledge representation tools – and explore behavioural signatures associated with the optimal use of IMAGE. The comprehension and use of IMAGE of 24 participants were examined in the context of a scenario involving military convoys evolving their strategy according to the reactions of a hostile and dynamic environment. Comprehension was measured by a score normalized in function of a randomly generated exploration of the system. A sequence analysis was performed to extract the pattern of IMAGE-user interaction. Our results reveal a great diversity across participants and that transitional probability of key IMAGE events is not related to augmented comprehension in a simple structured way.

A valid separation of location memory based on allocentric and egocentric reference frames

Jonna Nilsson

Northumbria University & Newcastle University

Kenny Coventry

Northumbria University

Nicol Ferrier

Newcastle University

Abstract: A valid separation of location memory based on allocentric and egocentric reference frames

Jonna Nilsson, Kenny Coventry, Nicol Ferrier

The existence of two separate spatial systems, one based on an egocentric viewpoint-dependent reference frame and one based on an allocentric viewpoint-independent reference frame, is now well accepted both at a conceptual and a neurological level (O'Keefe & Nadel, 1978; Lavenex & Lavenex, 2009; Zaehle et al, 2007). However, methodologies intended to separate and compare location memory based on distinct reference frames in humans vary widely and are often confounded. To allow for a more reliable separation of the egocentric and allocentric reference frames, a new location memory task was developed that eliminated these confounds. The results of a series of studies based on this task are reported and discussed. The results highlight the importance of controlling for the extraneous variables present in previous studies. It is evident that the investigation of location memory has a lot to gain from the valid separation of the allocentric and egocentric spatial systems.

The relationship between similarities computed by LSA and several types of association

Keisuke Inohara

Kyoto University

Takashi Kusumi

Kyoto University

Abstract: Latent Semantic Analysis (LSA) is a computational theory of meaning. Meanings of words are extracted from a large corpus of texts by a statistical method and represented as vectors in a semantic space. It is known that similarities of word-pairs computed by LSA can explain various language processing of human(e.g., Landauer and Dumais, 1997). To know features of LSA, we created four semantic spaces from Japanese corpses: news paper, novels, books (except for novels), and both of novels and books. The similarities of word pairs were compared with scores in different types of association tasks. Participants were asked to associate several concepts(e.g., subordinate categories, synonyms, or action concepts) with stimulus words. As a result, a correlation coefficient between the similarities and association scores of the action concept task is the highest. This finding is consistent with Hare et al.(2009), LSA and similar models reflect people's knowledge about daily events.

Reanalysis of Linda Problem

SangSuk Yoon

Pusan National University

MinGyung Choi

Pusan National University

HyunJung Shin

Pusan National University

Abstract: There has been many researches about conjunction fallacy, which people tend to evaluate conjunctive statement more probable than component statements. Conjunction Fallacy shows that people obviously violate probability rules, which is conjunctive state cannot be higher than component statement. However, we in our experiment, we tried to explain this fallacy by using conditional probability. If people used bayesian updating rule, then the fallacy cannot be the evidence of people's irrationality. In our result, people showed some pattern that they had used bayesian updating rules, but the result was not statistically significant.

A computational model for the acquisition of referring subjects in discourse

Jacolien van Rij

University of Groningen

Hedderik van Rijn

University of Groningen

Petra Hendriks

University of Groningen

Abstract: In this study, we investigate how children acquire adult-like performance on their use of referring subjects, by modeling experimental data within the cognitive architecture ACT-R. When choosing which type of referring expression to use, speakers have to take into account the linguistic discourse context as well as the way listeners will interpret the referring expression in that context. Children, however, tend to produce unrecoverable pronouns in particular contexts where adults would use a full noun phrase. This suggests that children are not yet able to take into account the listener's perspective. Based on simulations of our computational model, we argue that the adult use of referring subjects is crucially dependent on sufficient working memory capacity and speed of linguistic processing.

Word-Form Typicality and Its Influence on Grammatical Category Assignment

Thomas Farmer
Northumbria University

Padraic Monaghan
Lancaster University

Jennifer Misyak
Cornell University

Morten Christiansen
Cornell University

Abstract: Farmer et al. (2006) found that how typical a word's phonology is of other words in its lexical category influences the reading times of nouns and verbs in predictive contexts. When a preceding context generated a strong expectation for a noun, target noun-like nouns were read faster than verb-like nouns, along with a similar effect for verbs. Further, Dikker et al. (2010) found that the magnitude of the M100 response (sensitive to category-expectation violations) was modulated by phonological typicality: when a mismatch existed between whether context predicted a noun and the noun's degree of typicality, a heightened M100 response occurred in visual cortex. Here, using lexical decision and a self-paced reading, we examine whether these word-form effects occur in all cases where a noun or verb is possible, or whether they are more robust when expectations are strong, and thus visual word-form information may be enough to facilitate categorization.

Did you say "gross snails" or "gross nails?" The problem of segmenting co-occurrences of the same segment

Dahee Kim

OSU, Linguistics

Colin Widmer

OSU, Psychology

Christine Szostak

OSU, Psychology

Mark Pitt

OSU, Psychology

Abstract: To comprehend spoken language, listeners have to segment words from a continuous stream of speech. This task may be difficult when [s] repeats at a word boundary (e.g., gas station) because the two s's could blend together and form one long s-sound. Do talkers produce cues that signal the word boundary? If not, how do listeners segment the words correctly? We addressed these questions by having talkers produce two-word sequences that could be interpreted in three ways, depending on how the middle s-sound was heard (e.g. grow snails, gross snails and gross nails). Acoustic analyses of their productions examined whether there are cues indicating the presence of a word boundary. Listening experiments using the talkers' productions as stimuli were carried out to determine the extent to which signal-based and knowledge-based cues are used to resolve ambiguities. Implications of the results for models of spoken word recognition will be presented.

Expectations of common ground with a computer dialog agent

Donna Byron

Northeastern University

Joy Hanna

Oberlin College

William Hartmann

Ohio State University

Abstract: The time required to comprehend referring expressions is influenced by many contextual factors that establish expectations, including attributes of the referent and competitors, the discourse history, and the common ground between dialog partners. When human partners violate expectations by, for example, breaking a conceptual pact to maintain a referential perspective across mentions, listeners incur processing costs. But listeners don't have difficulty when other partners refer differently. We use this response pattern to examine whether subjects process discourse from computer agents the same way as from human partners, and what expectations they have of multiple agents. As computer dialog systems mature, we expect individual computers to be running multiple dialog agents playing diverse roles: information butlers, virtual salesmen, health coaches, etc. Knowing more about the expectations humans have of these dialog partners is a fundamental first step toward designing algorithms that can generate referring expressions that are easy to comprehend.

Interaction of bottom-up and top-down attentional influences on the processing of contingency information

Kelly Goedert

Seton Hall University

Brianna Eiter

Hofstra University

Abstract: How do individuals determine what information to attend to when making causal inferences on the basis of contingency information? Although much research has focused on the role of top-down attentional influences on this process (e.g., effects of prior beliefs and motivation), little work has addressed the role of bottom-up attentional influences, which may be driven by low-level perceptual and motor processes. In prior work, the current authors demonstrated a distinct bottom-up rightward bias in overt attention during contingency acquisition that was associated with subsequent causal judgments (Goedert & Eiter, 2008). Here we recorded eye movements of participants while they acquired information about two candidate causes whose spatial locations varied over the course of learning. We found that the bottom-up rightward bias in gaze direction persisted in spite of the varied spatial locations of the causes. Additionally, the bias interacted with top-down, knowledge-based contingency acquisition processes to influence participants' gaze patterns.

Influence on memory of the temporal schedule of repetitions over multiple days and its modulation by the retention interval

Emilie GERBIER

Université Lyon 2

Olivier KOENIG

Université Lyon 2

Abstract: We studied the influence on memory of three temporal schedules of repetitions of vocabulary pairs. Pairs were presented on Day 1, 7, and 13 in a Uniform schedule; on Day 1, 2, and 13 in an Expanding schedule; and on Day 1, 12, and 13 in a Contracting schedule, with schedule as a within-subject factor. Retention was tested with a cued-recall task performed on Day 15, 19 (Experiment 1), or 26 (Experiment 2). Cued recall did not differ as a function of the schedule on Day 15, whereas the Expanding schedule led to the best performance on Day 19 and 26. We interpreted this new finding of a modulation of the effect of schedule as a function of the retention interval within the frame of a model based on the study-phase retrieval theory that accounts for different forgetting curves for different schedules.

Matching Exact Posterior Probabilities in the Multinomial Interactive Activation Model

Pranav Khaitan

Stanford University

James L. McClelland

Stanford University

Abstract: Interactive activation models of context effects in perception ((McClelland & Rumelhart, 1981; McClelland & Elman, 1986) have been criticized for failing to combine stimulus and context information in a Bayes-optimal way, leading to a rejection of interactive approaches (Norris & McQueen, 2008). We show that interactive activation can compute correct Bayesian posterior probabilities. We present a variant of the interactive activation model that produces outputs exactly corresponding to the correct posterior probabilities of letters given specified letter feature and context information. In the new variant of the model, inhibition between units within pools is replaced by selection of a single unit to be active, using the softmax function to assign probabilities to candidate alternatives. The model is fully interactive, yet the probability of a letter unit being activated is both provably and demonstrably equal to the posterior probability given the presented feature and context information.

Threat and anxiety interactively impair task switching ability

Wolfgang Rauch

Goethe University Frankfurt IDeA - Center for Individual Development and Adaptive Education

Marie Lauer-Schmaltz

Goethe University Frankfurt

Abstract: Anxiety is associated with an attentional bias toward threat, yet the underlying mechanisms of this bias remain to be explored. Based on the assumption that anxiety selectively increases the strength of stimulus-driven attention to threat, we hypothesize that threatening stimuli and anxiety interactively impair the ability to re-allocate attention based on internal goals.

We tested this assumption in a task-switching experiment with N=29 participants. Compared to task repetition, task switching requires goal-directed attention in order to reconfigure the task set. Both emotionally neutral and threatening stimuli were presented, and dispositional anxiety was measured using the STAI questionnaire. Results showed an interaction of anxiety and emotional quality of pre-switch stimuli on switch cost, independent of the emotional quality of the currently presented stimulus: switch cost was larger for more anxious participants, but only when the task switch was preceded by a threatening stimulus.

Grammars for Funk Drumming: Symbolic and Motor-Spatial Aspects

Richard Ashley

Northwestern University

Abstract: Skilled musical performance requires a detailed knowledge of the grammatical patterns of a musical style, but also spatial and motoric skills in coordinating the abilities of the human body with the affordances of musical instruments. This study investigates these aspects of musical performance in the domain of popular music drumming, seeking to understand how drum patterns are constructed and produced by skilled players. It considers drum patterns from two perspectives: abstract grammaticality as revealed in frequency of sequences of drum sounds (via a probabilistic grammar), and also embodied and spatial cognition, as revealed in how patterns are produced by the player by motion sequences across the drumset. To investigate these issues, a combination of corpus analysis and experimental methods have been employed. Results to date indicate that production of drum patterns is based partly on articulatory constraints (ease of production), but also on a cognitive or acoustic attribute of contrastiveness.

About the Validity of Computer Models in Cognitive Science

Ricardo Sanz

Universidad Politecnica de Madrid

Carlos Hernández

Universidad Politecnica de Madrid

Jaime Gómez

Universidad Politecnica de Madrid

Guadalupe Sánchez

Universidad Politecnica de Madrid

Adolfo Hernando

Universidad Politecnica de Madrid

Abstract: Many cognitive models are evaluated by implementing an artificial system –a program, a robot– that performs the concrete task that the model is addressing. Success in task performance by the program is considered a proof of the adequacy of the cognitive model proposed. However, this is not a valid inference in general. The reason is that the transformation of the model from a textual or graphical form into a computer implementation is not transparent. This implies that phenomena and properties observed in the program cannot be predicated of the model. The reason for the lack of transparency is that models are not expressed using a rigorous language and that transformations into implementations aren't rigorous either. Hacks are introduced during the construction of the program –to make it work– and they are not taken back into the model, hence invalidating the model-implementation relation.

The roles of working memory capacity and spatial ability in first-time solution of the Tower of Hanoi

Patrick Cushen

University of Illinois at Chicago

Jennifer Wiley

University of Illinois at Chicago

Abstract: Decades of research have highlighted the important role of working memory capacity (WMC) in higher cognition and problem solving. Strangely, the relationship between WMC and the Tower of Hanoi task, a classic problem in Cognitive Psychology, has yet to be firmly established. Many studies have failed to find the suspected relationship and those that have identified a relationship have almost universally used spatial-modality measures of WMC. These results fail to differentiate between whether it was an individual's WMC or spatial ability that predicted performance. As such, the goal of the current research was to investigate the complex relationship between WMC, spatial ability, and the Tower of Hanoi. Results suggest different roles for WMC and spatial ability in the first-time solution of the Tower of Hanoi.

Causal Learning in Joint Activity: Comparing Collaborative, Active, and Passive Contexts

Andrew G. Young

University of Wisconsin - Madison

Martha W. Alibali

University of Wisconsin - Madison

Charles W. Kalish

University of Wisconsin - Madison

Abstract: Children's causal learning from intentional actions (i.e., interventions) can be dramatically affected by the psychological and social circumstances in which they are produced. A context fundamental to children's learning across many domains is joint activity; however little is known about children's causal learning with others. Collaborative settings with shared goals and action plans might facilitate children's learning from their own and a partner's coordinated actions (Sommerville & Hammond, 2007). Alternatively, children's own interventions may be more informative than those produced by a partner (Kushnir, Wellman, & Gelman, 2009). To address these issues, young children learned about simple causal systems via interventions performed: 1) by themselves, 2) by an experimenter, or 3) jointly with an experimenter. Children's subsequent causal knowledge, source-memory, and free play are compared across these collaborative contexts. Findings may provide guidance about structuring learning environments.

What makes for inspirational examples in design? The effects of example modality, distance, and familiarity.

Joel Chan

University of Pittsburgh

Katherine Fu

Carnegie-Mellon University

Christian Schunn

University of Pittsburgh

Kristin Wood

University of Texas-Austin

Jonathan Cagan

Carnegie-Mellon University

Kenneth Kotovsky

Carnegie-Mellon University

Abstract: An important question in the cognitive science of design concerns the influence of environmental input on ideation processes. Prior work has demonstrated that analogizing over examples in the environment is a double-edged sword: examples can help designers come up with innovative designs, but variations in key properties can result in negative design outcomes (e.g., fixation). We investigated the influence of variations in presentation modality, analogical distance, and familiarity of provided design examples on ideation processes. Engineering students generated solution concepts for an engineering design problem with or without provided design examples (analogy groups vs. control group). Examples in the analogy groups were fully crossed by modality (pictures vs. text), distance (near vs. far), and familiarity (familiar vs. unfamiliar). Results indicate that designers' familiarity with examples influence whether they suppress or promote innovation, regardless of modality or analogical distance.

False Recognition in the DRM-Paradigm reflects False Encoding

Tamella M. Pettitt

Birkbeck College, University of London

Eddy J. Davelaar

Birkbeck College, University of London

Abstract: A thorny question is whether the high rate of false memories in the Deese/Roediger-McDermott (DRM) paradigm is due to encoding or retrieval processes. Previous work suggests a locus at encoding using the free recall task. Here we use a recognition task in which false memories have typically been associated with intrusions due to high levels of featural overlap between the test probe and the stored memories. We used the REM model to assess the expectations from a retrieval account and from an encoding account of false memories. These simulations show that (probabilistic) false encoding leads to exceptionally large standard deviations in memory strength that are shown in ROC curves. We tested and verified these predictions in an experiment using a divided attention paradigm. These findings suggest that high false alarm rate in a DRM-paradigm might not be as useful as a proxy for everyday false memories as previously supposed.

Monday is before Tuesday in speech, but left of Tuesday in gesture.

Daniel Casasanto

Max Planck Institute for Psycholinguistics, Donders Institute for Brain, Cognition and Behaviour

Kyle Jasmin

Max Planck Institute for Psycholinguistics

Abstract: Do English speakers gesture about time the same way they talk about it? In spoken English, time appears to flow along the sagittal (front/back) axis: we look forward to the future and back on the past. Yet, when English speakers produce spontaneous gestures they often use the lateral axis, gesturing leftward for earlier times and rightward for later times, consistent with the flow of time on calendars and graphs.

Here we show that speakers spatialize time on the lateral axis overwhelmingly more often than on the sagittal axis in spontaneous co-speech gestures. This is true despite the prevalence of spoken front/back metaphors and complete absence of left/right metaphors for time in spoken language. Interestingly, front-back gestures, though rare, were more common during deictic language, consistent with predictions based on signed languages. We propose possible pragmatic, kinematic, and mnemonic motivations for this dissociation between spatio-temporal metaphors in speech and gesture.

Enhanced visuo-spatial learning and memory effects in time-space synesthesia

Ursina Teuscher

University of California, San Diego

David Brang

University of California, San Diego

Vilayanur S. Ramachandran

University of California, San Diego

Seana Coulson

University of California, San Diego

Abstract: Time-space synesthetes report that they consistently experience time events, such as the months of the year, as having a specific spatial layout. Two studies compared 11 synesthetes' and 41 non-synesthetic controls' ability to memorize novel spatial calendars. Both studies revealed better memory performance (quicker reaction times and higher consistency) in synesthetes than controls, even if the memorized calendar was specifically designed to conflict with synesthetes' own involuntarily experienced calendar. Furthermore, an additional group of controls' performance was better for counterclockwise than clockwise calendars, perhaps due to less interference with conventional mappings. These findings suggest that time-space synesthetes' enhanced visuo-spatial memory abilities may underlie the emergence of time-space synesthesia, as people with a greater capacity to learn mappings between spatial forms and temporal sequences might be more likely to think of months of the year in terms of idiosyncratic shapes, while others might be more reliant on culturally established mapping schemes.

Analyzing Discourse Functions in Student Research Reports to Assess Gains Due To Research Experiences

Roman Taraban

Texas Tech University

Brianna Bennett

Texas Tech University

Xiaofang Zeng

Texas Tech University

Abstract: Two case studies are presented that concern the assessment of scientific discourse in undergraduates' research papers. An assessment methodology was developed capable of tracking and evaluating the level and kinds of changes that result from students' participation in laboratory experiences. An upper-level performance limit was established by analyzing journal articles written by the students' faculty mentors. Students were compared to mentors in terms of the frequency of use of higher-level (e.g., stating a hypothesis) and lower-level discourse functions (e.g., stating background information), as well as with respect to the syntactic complexity of their respective sentence constructions. In self-reports of research knowledge and skills, students express gains that are not evident in their papers, suggesting that the written form poses specific challenges. We consider prospects for automating the assessment of students' research papers by using electronic means to assist in the identification and enumeration of the types and frequencies of discourse functions in these papers.

Embodying attentional states: The role of posture in task performance

Joseph Chisholm

University of British Columbia

Evan Risko

University of British Columbia

Alan Kingstone

University of British Columbia

Abstract: When participating in either an engaging or unengaging task, individuals appear to adopt consistent postures that may reflect a focused or unfocused attentional state. Posture is known to communicate certain affective states; however, it is of interest whether posture may elicit an attentional state that can influence performance on a task. To address this question, participants were first instructed to sit focused or unfocused while conducting a word recall and visual search task. Results showed a benefit of being in a focused posture in the visual search task as well as consistent postures adopted within groups. However, when participants were given instructions on how to sit, without explicit mention of focused or unfocused postures, no performance differences were observed. These results suggest that posture alone may not be enough to elicit particular attentional states, at least not in the tasks we used. Implications and future directions will be discussed.

Similarity avoidance in processing consonants: apparent exceptions from Polynesian languages

John Alderete

Simon Fraser University

Abstract: In languages as diverse as English, Arabic, and Russian, the cooccurrence frequency of two consonants can be predicted from a gradient measure of the similarity of the phonological make-up of the two consonants. An argument for the role of phonological similarity in these languages is that it tends to be the case that sound classes with more members have weaker cooccurrence restrictions than classes with fewer members. More members require more contrasts, which reduces similarity. In Arabic, there are weaker restrictions on coronals (n=11) than labials (n=4) because coronals exhibit more contrasts. However, there are a number of well-documented Polynesian languages (Maori, Hawaiian, Tongan) where the reverse is true: there are more labial consonants than coronals, but there are stronger cooccurrence restrictions on labials than coronals. This project investigates the lexical statistics of these languages and proposes a revised characterization of similarity avoidance that has greater cross-linguistic coverage.

Cross-Situational Word Learning in Bilinguals

Viridiana Benitez

Indiana University

Linda B. Smith

Indiana University

Abstract: Recent research indicates that fluency in more than one language has consequences for fundamental aspects of the cognitive system beyond that of speaking two languages. Specifically, a now growing body of research shows speakers of two languages can allocate their attention more efficiently than speakers of one language in nonlinguistic tasks (e.g., Bialystok, Klein, Craik, & Viswanathan, 2004). In addition, bilingualism has also been shown to promote abilities in the linguistic domain, such as the ability to learn novel words better than monolinguals (Kaushanskaya and Marian, 2009). In the present study, we investigated how the efficiency of attentional allocation and the ability to learn novel words may interact and affect performance in Yu and Smith's (2007) cross-situational word learning paradigm. Monolingual and bilingual adults' learning of 18 novel words using this paradigm were examined, and results help to better understand the effects of bilingualism on cognition.

Metacognition and Writing: How an Academically Gifted Adolescent Organizes and Controls the Writing Process

Delayne Connor
Bridgewater State College

Abstract: This single subject study concerns a 14 year-old academically gifted student's use of metacognition when producing written discourse in response to a writing prompt. Ethnographic procedures were used to collect and analyze data. The participant engaged in a think-aloud procedure as he composed an expository paper, and his transcribed verbalizations were then analyzed for metacognitive strategy use. The strategies were organized into a taxonomy by means of Spradley's domain and taxonomic analysis.

Results indicated that the participant advanced the writing process by employing five major types or domains of strategies. They are: (a) planning discourse/thinking, (b) evaluating discourse/thinking, (c) recognizing difficulty with discourse/thinking, (d) responding to difficulty with discourse/thinking, and (e) repairing discourse/thinking. The participant employed over 80 individual strategies within these five domains as he wrote a well organized and cohesive composition at one of Britton et al.'s higher abstractive levels of discourse.

Immediate Introduction to Multiple Procedures Supports Procedural Flexibility in Equation Solving

Kelley Durkin

Vanderbilt University

Harvard University

Abstract: Knowing multiple procedures and using them adaptively is important for problem-solving. We examined how different methods for developing procedural flexibility affected novices learning equation solving. Students ($N = 198$) were assigned to one of three conditions that differed in whether multiple procedures were introduced immediately or after practice with one procedure (no delay vs. delay) and in whether comparison of examples was supported. Students in the no delay condition had greater procedural flexibility and accuracy than students in either delay condition, regardless of whether they compared examples. Differences in students' explanations during the intervention suggest reasons for the benefits of immediate introduction to multiple procedures. Students in the no delay condition more frequently compared and evaluated efficiency of procedures than students in delay conditions. They also more frequently used efficient procedures during the intervention. Immediate introduction to multiple procedures supports attention to and adaption of efficient procedures, which benefits flexibility.

Promoting Cross-Disciplinary Communication in Nanotechnology

Sarah Kriz

University of Washington

Karen Cheng

University of Washington

Marco Rolandi

University of Washington

Yeechi Chen

University of Washington

Abstract: Nanotechnology is a quickly growing field comprised of researchers from many disciplines who investigate nanoscale materials and phenomena. Because many well-established disciplines merge together to form the field of nanotechnology, a crucial aspect of nanotechnology education is promoting cross-disciplinary thinking and collaboration. We present a model that proposes a novel approach to multidisciplinary learning in nanotechnology. While existing educational solutions attempt to expose students to content from all of the nanotechnology disciplines, we focus on the development of visual communication skills as a means to promoting cross-disciplinary thinking and communication. We have developed a graduate course that combines the instruction of visual communication design principles with a studio component that allows students to create science graphics and reflect on how design choices relate to disciplinary goals and cross-disciplinary communication. We discuss the benefit of this course in the larger nanotechnology educational curriculum.

Nouns are more stable than Verbs: Patterns of semantic change in 19th century English

Eyal Sagi

Northwestern University

Abstract: It has been hypothesized in the literature that nouns are acquired earlier than verbs because they are more concrete and involve fewer relations. This hypothesis also predicts that the meaning of nouns should be more stable over time and across speakers. In this paper I use Latent Semantic Analysis of a 19th century literary corpus containing works from British and American authors to test this prediction.

I examined the variability in the vector representations of frequently used nouns and verbs based on the culture of the author and the time period. The results show the nouns vary less than verbs between the two cultures and across time. Moreover, these differences still exist when the concreteness of the words is taken into account. These results are consistent with the hypothesis that the relational nature of verbs contributes to their difficulty and variability beyond its effect on the verb's concreteness.

Context in distributed situated cognition

Hedda Rahel Schmidtke

Karlsruhe Institute of Technology (KIT)

Michael Beigl

Karlsruhe Institute of Technology (KIT)

Abstract: Ambient Intelligence (AmI) can be understood as a research effort towards physical environments that can use artificial intelligence techniques, in order to serve people in an intelligent, pro-active manner. AmI environments provide a unique, novel platform for studying and applying concepts of situated cognition and self-organization. In particular, we find that representations of context are crucial for AmI systems to perform these tasks. We follow the idea that the notion of context plays a central role with respect to economy, evolution, and architecture of cognitive systems. In particular, context can be understood to bridge the gap between the sensory stream and goal-directed reasoning. We present a logical language in which contexts, and not objects, properties, or propositions, are the primary entities. We show that, from this logical formalism, a corresponding symbolic-connectionist hybrid model of distributed, situated cognition can be derived.

Exploring Active Learning in a Bayesian Framework

Stephen Denton

Indiana University, Bloomington

John Kruschke

Indiana University, Bloomington

Abstract: Bayesian approaches provide a framework for models of active learning—learning in which stimuli are actively probed to disambiguate potential beliefs regarding outcomes. Within a Bayesian framework, uncertainty across beliefs is inherently represented and expected uncertainty reductions for candidate stimuli can be evaluated. Bayesian active learning models offer the prediction that an active learner would select the stimuli for which the expected uncertainty across all hypotheses is minimized. This research contrasts four possible hypothesis spaces for active learning consisting of two simple cue-combination models and two possible priors. An automated search of associative learning structures for which the models make maximally different predictions was performed. Participants were tested on these same structures in an allergy diagnosis context and were asked which cues they would find the most informative to learn about; i.e., their active learning preferences were assessed. Model and prior combinations that best mimic human active learning are discussed.

Linguistic Mediation of Visual Search: The effects of relative timing of speech and display

Eric Chiu

University of California, Merced (UCM)

Michael Spivey

University of California, Merced (UCM)

Abstract: Recent studies have shown that instead of a dichotomy between parallel and serial search strategies, in many instances we see a combination of both search strategies utilized. Consequently, computational models and theoretical accounts of visual search processing have evolved from traditional parallel or serial descriptions to labels of "efficient" and "inefficient." In the first experiment, we replicate previous findings regarding incremental spoken language comprehension on visual search processing utilizing a between subjects design. Next, a series of four experiments further explore the subtle timing of the influence of real-time language processing on visual search. The results provide further evidence toward understanding linguistically mediated influences on real-time visual search processing and support an interactive processing account of visual search and language comprehension.

Belief bias in judgments of sample-size adequacy

Richard Anderson

Bowling Green State University

Leisha Colyn

Bowling Green State University

Beth Hartzler

Bowling Green State University

Abstract: Previous research on syllogistic logical reasoning indicates that people are more likely to judge an argument as valid when they believe the argument's conclusion to be true. The present research assessed whether belief bias would also occur in intuitive statistical judgment. There were two versions of a judgment scenario (varying between subjects). Version A described an observer who, based on 100 observations, draws the conclusion that most Americans are left-handed. Version B was like A except the conclusion was that most Americans are right-handed. Participants' task was to assess the degree to which 100 is a sufficiently large sample to support a confident conclusion (i.e., that Americans tend to be left-handed, or that Americans tend to be right-handed). Participants judged the sample size to be more adequate when the argument conclusion was presumably believed (i.e., that "most Americans are right-handed") than when the conclusion was "most Americans are left-handed."

Must analysis of meaning follow analysis of form? A time course analysis

Laurie Beth Feldman

The University at Albany, SUNY & Haskins Labs

Fermín Moscoso del Prado Martín

CNRS & Université de Provence, France

Patrick A O'Connor

The University at Albany, SUNY & Haskins Labs

Abstract: Many models of word recognition assume that processing proceeds sequentially from analysis of form to analysis of meaning. In the context of morphological processing, some interpret the apparent absence of differences in recognition latencies to targets (RAT) in form and semantically similar (ratty-RAT) and in form similar and semantically dissimilar (ratify-RAT) prime contexts as consistent with this claim. We examined the time course over which degree of semantic similarity between morphologically related pairs influences recognition in the forward masked priming variant of the lexical decision paradigm. Across a range of SOAs., latencies were significantly faster after semantically similar than dissimilar primes, Results limit the scope of form-then-semantics models of recognition and demonstrate that semantic context influences even the very early stages of recognition.

Learning Cross-Modal Contingencies through Attentional Cues

Daniel Yurovsky

Indiana University

Rachel Wu

Birkbeck, University of London

Natasha Kirkham

Birkbeck, University of London

Chen Yu

Indiana University

Abstract: Infants must develop attentional mechanisms that support extraction of relevant information from a cluttered world. Though both social and non-social cues shift infants' attention, Wu and Kirkham (accepted) showed they produce qualitatively different learning effects in 4 and 8-month-old infants. While both types of cues led infants to attend preferentially to the relevant locations during training, cross-modal contingencies were learned only by older infants exposed to social cues. In this work, we analyzed the eye movement of these infants to shed light on the underlying attentional processes elicited by these cues. Using a dual-process model to link learning to looking (Yurovsky, Hidaka, Yu, & Smith, Cogsci Conference 2010), we characterized each infant's underlying learning function and used these functions to predict individual test results. We can thus understand the impact of social and non-social cues by examining how cue-elicited differences in exploratory behavior cascade into differences in learning.

The Effects of Alcohol on Working Memory and Change Detection

Gregory Colflesh

Georgia Institute of Technology

Andrew Jarosz

University of Illinois at Chicago

Jennifer Wiley

University of Illinois at Chicago

Abstract: The prevailing account of how alcohol affects attention suggests that intoxication reduces attentional focus and capacity. To better understand presumed cognitive consequences of intoxication, the present study tested the effects of moderate intoxication (.07 BAC) on both change blindness and complex span tasks. Change blindness tasks require finding a small change across alternating versions of a scene. Complex span tasks consist of interleaved processing and storage components. As expected, intoxication significantly decreased performance on the complex span tasks. But, surprisingly, it improved performance on the change blindness task. The results are interpreted as evidence that intoxication decreases attentional control, and causes a more diffuse attentional state. This can harm performance on some tasks where attentional control or focus are required, but may actually facilitate performance on other tasks.

Effects of the Exploration Perspective on Pointing Accuracy

Julia Frankenstein

University of Freiburg

Manuel Vidal

College de France, Paris

Michael Rouillé

IRISA / INRIA Rennes

Stéphane Donikian

IRISA / INRIA Rennes

Mohamed Zaoui

College de France, Paris

Alain Berthoz

College de France, Paris

Abstract: Abstract: We examined the influence of the perspective during exploration on the ability of subjects to point correctly to memorized targets in a virtual 3D environment. This environment consisted of a two-storied factory building with 32 machines on the ground floor. Four machines were marked as targets. Eight trials were conducted in each of the four different perspectives: map view from above, four different views from the corners, perceiving the environment as a person walking through it, and following an avatar through the environment. Subsequently, participants were asked to point to the four targets from the upper floor.

We expected the best performance in the map view as all information is given in a single reference frame and a rotation suffices for pointing. Surprisingly, eleven of the nineteen participants performed best in conditions different from the most straightforward. This finding indicates that different memorization strategies were used by different persons.

The Effect of Processing Type on Re-Categorization

David G. Cosejo

University of Illinois at Chicago

Stellan Ohlsson

University of Illinois at Chicago

Abstract: The effect of processing type on the process of overriding prior experience and learning – restructuring – was examined within a categorization paradigm. Participants were trained to categorize either explicitly, implicitly or received no training. Explicit training encouraged participants to use hypothesis-testing while implicit training encouraged categorizing via intuition or "gut instinct." Participants then worked on a modified categorization task in which they learned an initial "misconception" category and later had to restructure their representation to learn a target category. Participants were able to successfully learn the misconception and restructure to the target. Data suggest that increased category complexity results in a longer learning period that leads to the generation of a category representation that is more accessible and more readily restructured. The complexity effect is driven by similar performance across the different training types. The experimental and real-world implications for the interplay between stimuli complexity and processing type are addressed.

Fractioning Factors that Influence Phonological Word Form Learning

Libo Zhao

Department of Psychology, University of Iowa

Prahlad Gupta

Department of Psychology, University of Iowa

Abstract: Although learning of phonological word forms is important for mastering a language, little is known about the factors influencing it. We addressed this question by comparing phonological word form learning in two situations: learning novel word forms as the labels for referents (deliberate word learning); and learning novel word forms through incidental exposures to the word forms alone, without any referents (incidental word form learning). Phonological word form learning as measured by stem completion ability was found to be better in the former than in the latter situation (Experiment 1). Experiment 2 found that deliberate memorization of word forms, even without any referents, also yielded better stem completion ability than purely incidental learning. These results suggest that incidental word form learning may not yield full mastery of word forms, and that deliberate learning may be a necessary component for such mastery.

Large differences in the distribution of instances of common object-based categories in early childhood

Alfredo F. Pereira

Indiana University Bloomington

Karin H. James

Indiana University Bloomington

Susan S. SJones

Indiana University Bloomington

Linda B. Smith

Indiana University Bloomington

Abstract: Few studies have documented the examples of common early-learned object-based categories children actually encounter. This study asked parents ($N = 10$) to record, using a digital camera, the concrete instances their children saw ($M = 16$ mo). For five days, if an object was labeled with one of the nouns inside a pre-determined list of eight nouns, parents were to take a photo—our final dataset consisted of 700 photos. We coded the contents of each photo as: 3D real object, 3D realistic toy, 3D simple shape toy, 2D realistic object, and 2D simple shape.

Our results show large differences between categories in terms of type of exemplars: mostly composed of 3D real objects, with a mixture of 3D and 2D variability, or only experienced as 2D images.

These results are relevant to theories of visual object categorization—e.g. in understanding viewpoint invariance, or perception of abstract structural shape.

Phonetic symbolism for size and shape

Patrick Thompson

University of Warwick

Zachary Estes

University of Warwick

Abstract: Many previous studies of phonetic symbolism, wherein the sounds of a word convey the referent's attributes, have confounded multiple attributes such as size and shape. In the current study, participants viewed novel objects of varying size and shape and were asked to rate the appropriateness of a spoken non-word as a name for the object. Size and shape interacted (e.g., higher ratings were given for names with front vowels like /i/ when the object was small and spiky), and both spiky and round objects were phonetically marked. However, participants tended to use phonemes to mark size only when the object is large. This suggests that marking via phonemes should not be assumed to simultaneously mark all physical properties of the object (i.e., both size and shape). Consequently, phonetic symbolism of physical properties may not correlate as neatly with gesture as has previously been thought.

Using Embodied Cognition in the Instruction of Abstract Programming Concepts

Cameron L. Fadjó

Teachers College, Columbia University

John B. Black

Teachers College, Columbia University

JeeHye Hong

Teachers College, Columbia University

Chun-Hao Chang

Teachers College, Columbia University

Abstract: We present two models, physical and imaginary, for implementing embodied cognition during the instruction of abstract programming concepts. We examine previous studies using embodiment in the instruction of reading (Glenberg et al., 2004), mathematics (Goldstone & Landy, 2010), and science (Chan & Black, 2006a, 2006b) as a foundation for proposing an embodied instruction of programming. We discuss the embodied instruction of abstract symbols in mathematics and suggest that the nature of programming a video game (Fadjó et al., 2009a, 2009b) provides adequate grounding (Barsalou, 2008) for the instruction of abstract conditional statements. We suggest that an embodied form of instruction integrates the actions prevalent in two-dimensional video games with the instruction of abstract programming concepts. We discuss our findings on using Instructional Embodiment (Fadjó et al., 2009a) to improve novice programmer's tracing and conditional logic thinking skills.

Decision-Making in Older Adults: Sometimes Older is Wiser

Darrell Worthy

University of Texas at Austin

W. Todd Maddox

University of Texas at Austin

Abstract: We examined the performance of younger and older adults in a dynamic decision making task that required exploring long-term increasing options that had worse short term gains, but that eventually yielded higher rewards. Results indicate that older adults are more willing to sample the long-term increasing option earlier in the task than the Younger adults. We employed a model-based approach that modified a simple reinforcement learning model to allow for biases to 'stay' or 'switch' following a response (e.g. Otto et al., in press). Using this approach we were able to characterize exploration of alternative options or exploitation of the best option as 'targeted' or 'untargeted' responding. We found that Older adults were best fit by the targeted exploration model. This suggests that while Younger adults tend to repeatedly select short-term advantageous options, Older adults engage in greater exploration of the decision space, and this leads to better performance.

Coordination dynamics in speech and lexical semantics

Christopher Kello

University of California, Merced

Theo Rhodes

University of California, Merced

Geoff Hollis

University of Cincinnati

Bryan Kerster

University of California, Merced

Abstract: Variations in individual human behavior are intrinsically long-range correlated (i.e. $1/f$ noise). These correlations may reflect interdependence (i.e. coordination) among components at various scales of structure and dynamics (e.g., neurons, cortical columns, brain areas, brain-body interactions). Two experiments tested whether long-range correlations emerge when two people interact. In experiment 1, perceptual-motor coordination was invoked by instructing participant pairs to coordinate uttering the word "mom" in alternation with key taps. In experiment 2, semantic coordination was invoked by alternating free word associations (e.g. one says "cat", the other says "dog", first says "collar", second says "shirt", and so on). Fluctuations in series of mom-tap intervals were long-range correlated. Long-range correlations were also found in semantics fluctuations of free word associations, the latter being weaker and derived from lexical co-occurrence statistics. Results indicate that common principles of coordination apply across individual and dyadic scales of perceptual-motor and cognitive performances.

Knowing who knows what best: Preschoolers selectively use others' past accuracy in causal learning

Chris Vredenburgh

Cornell University

Lauren Schneider

Cornell University

Andy Hsia

Cornell University

Tamar Kushnir

Cornell University

Abstract: Knowing who knows what best: Preschoolers selectively use others' past accuracy in causal learning

Authors: Christopher Vredenburgh, Lauren Schneider, Andy Hsia, and Tamar Kushnir

Preschoolers use a person's past accuracy labeling common objects as a cue to their "trustworthiness" when learning new words. These studies investigate how children use past accuracy to differentially trust people for causal learning. Across two studies, we found that children (Mean age = 4 years, 3 months; SD = 4 months) would differentially trust an accurate (versus inaccurate or ignorant) labeler for learning a novel causal function but not for learning a novel causal mechanism. However, when an accurate labeler was pitted against a causal expert, children trusted the expert with both causal mechanism and causal function. These studies demonstrate that children show selective trust of accurate labelers depending on the availability of sources with causal expertise. Thus, children are sensitive to domains of knowledge and can use them to request information from the most appropriate source.

The effects of perspective on understanding of projective spatial terms

Takatsugu Kojima

Kyoto University

Abstract: We use projective spatial terms to indicate a location and a direction in communications about both real space and three-dimensional computer graphics (3DCG) space. However, it is often possible to also use an overhead perspective or the perspective of a communication partner, especially in a communication system using 3DCG space, in addition to our own first-person view. This study focused on the effects of these three perspectives on understanding projective spatial terms in a 3DCG system. In this experiment, we used four projective spatial terms (front, back, left, and right) and 3DCG stimuli based on three views (a participant's first-person view, an overhead view, and a communication partner's view). We investigated how the three views influenced understanding of the spatial terms. The results show that an overhead view had little effect on understanding of the spatial terms and that the communication partner's view had considerable effect on such understanding.

Inferring Object Structure from Human Action at 9 Months

Stephen Killingsworth

Peabody College, Vanderbilt University

John Jacobson

Peabody College, Vanderbilt University

Megan Saylor

Peabody College, Vanderbilt University

Abstract: This study investigates whether 9-month-olds use action information to make predictions about the hidden structure of an object. Two groups saw an actor repeatedly raise and lower a box. In one group, the box was moved with a hidden handle. In the other group, a box with no handle was grasped along the hidden back face and repeatedly raised and lowered. Following this familiarization, the box was rotated 90 degrees either to reveal a structure consistent or to reveal a structure inconsistent with that suggested by the initial action. Patterns of looking between familiarization and test trials differed for the two familiarization groups, suggesting that 9-month-old infants can infer certain details of an object's structure from human action.

Social Indexing: How the People Around Us Aid Cognition

Chris N.H. Street

University College London (UCL)

Daniel. C Richardson

University College London (UCL)

Abstract: We hypothesise the existence of a specific attentional mechanism, social indexing, that directs gaze towards people in our environment who are relevant to moment by moment cognitive processing. Whilst Festinger (1954) proposed that individuals will depend upon and conform to similar others in times of uncertainty, the social indexing hypothesis posits that individuals will actively seek out information from those we perceive to be able to provide socially relevant information. Such an attentional mechanism would allow cognition to be situated in both the physical and social world (Hutchins, 1995). In an early demonstration, Crosby, Monin and Richardson (2008) showed that gaze is directed towards the target of potentially offensive remarks when they might provide an informative response. We discuss whether these results extend to both positive and negative remarks, and whether participants' confidence in their ability to interpret social situations will result in more or less social indexing behaviour.

Impact of Diverse Abilities on Learning to Write through Peer-Review

Melissa Patchan

University of Pittsburgh

Christian Schunn

University of Pittsburgh

Abstract: Theoretically, there are advantages to working with students of the same ability and different ability (Lou et al., 1996). In order to determine how students' ability affects the peer-review process, students' writing ability (e.g., high-ability versus low-ability) was first determined. Then students' were randomly assigned to review either four high-ability peers' papers or four low-ability peer's papers. In return, they received feedback from either four high-ability peers or four low-ability peers. The quality of students' second draft of their first paper and the quality of the first draft of a second paper were analyzed to determine whether students' learning was affected by the feedback they provided to high-ability versus low-ability students and by the feedback they received from high-ability versus low-ability students. In addition, several mediators (e.g., motivation, amount and type of feedback) were examined to explain the learning differences.

Look who's talking (and follow the leader)! Eye movements in a social interaction reveal effects of speaking and social status

Tom Foulsham

University of British Columbia (UBC)

Joey Cheng

University of British Columbia (UBC)

Jessica Tracy

University of British Columbia (UBC)

Joseph Henrich

University of British Columbia (UBC)

Alan Kingstone

University of British Columbia (UBC)

Abstract: Human visual attention tends to operate in an environment that is complex, dynamic and social. However, experimental investigations of where people direct their attention often neglect these factors. In our research, we recorded people making decisions in groups of 3 and then showed video clips of these situations to new participants while monitoring their eye movements. This provided a rich record of how people distributed their gaze on a moment-by-moment basis. Observers tended to look at the person who was talking at any one time, and they fixated this person slightly before they started to speak. Higher-level social attributions also had an effect: people who were rated as having high social status were gazed at more often, over and above the effects of speaking. These effects show that the gaze system is extremely sensitive to the complexities and dynamics of the current social context.

Using analogical learning in science curricula to improve conceptual understanding

J. Elizabeth Richey

Learning Research and Development Center, University of Pittsburgh

Alicia Chang

Learning Research and Development Center, University of Pittsburgh

Timothy J. Nokes

Learning Research and Development Center, University of Pittsburgh

Christian D. Schunn

Learning Research and Development Center, University of Pittsburgh

Abstract: The goal of the 21st Century Center for Research and Development in Cognition and Science Instruction (CaSE) is to improve middle school students' science learning by systematically applying cognitive science principles in the revision of instructional materials and teacher professional development. In this presentation we focus on the application of analogical learning principles to two popular middle school science curricula. Analogical learning through comparison is a powerful activity for facilitating the acquisition of critical features and concepts underlying concrete examples and preparing students for future learning. We instantiated these principles by creating "contrasting cases" to introduce abstract science concepts in conceptually driven lessons that could easily be inserted into existing curricula. We assessed the effectiveness of this intervention with tests targeting both the concepts that were covered in the cases as well as transfer concepts taught later in the curriculum. We will present preliminary data from pilot teachers.

Modeling age of exposure in L2 learning of vowel categories

Meghan Clayards

McGill University

Joseph Toscano

University of Iowa

Abstract: Age of exposure is known to be an important indicator of second language proficiency. Native-like phonological proficiency is attained only by learners exposed at the earliest ages. This paper examines one account of age-of-exposure effects. Two computational models (a mixture of Gaussians and a neural network) were trained without supervision on F1 and F2 tokens based on production data from two different vowel systems (Quichua and Spanish; Guion, 2003). Both models learn the individual phonological systems when trained on monolingual distributions. When exposed to bilingual data, both models also achieve varying degrees of success depending on when the second language (Spanish) is introduced in training, paralleling data from bilingual speakers with different ages of acquisition (Guion, 2003). This demonstrates that learners may be restricted in learning a second language not because of a biological critical period, but by the commitments that the system has already made to the first language.

Mental models of virology in experts and novices

Benjamin Jee

Northwestern University

David Uttal

Northwestern University

Caroline Crouch

Northwestern University

Amy Spiegel

University of Nebraska-Lincoln

Judy Diamond

University of Nebraska-Lincoln

Abstract: Viruses are invisible and their effects, though often experienced, arise through mechanisms that may be poorly understood by many people. The present work examined what people with different levels of virology expertise think and believe about viruses. We conducted detailed, semi-structured interviews about virus infection, replication, transmission, and other topics with a group of middle-school students, science teachers, and expert virologists. Participants' responses were coded for content and used to establish their mental models for several key topics (cf. Hmelo-Silver & Pfeffer, 2004). Analyses revealed that the experts' mental models were greatest in depth and breadth. Many of the students—and several teachers—possessed scientific inaccuracies and inconsistencies in their mental models. By capitalizing on experts' knowledge organizations and by targeting common misconceptions about viruses found in students and teachers, it will be possible to develop materials and tools for increasing people's understanding of viruses and the microbiological world.

Facilitating Educator Evaluation of Online Instructional Materials: Does Conceptual Browsing Impact Cognitive Processing?

Kirsten Butcher

University of Utah

Robert Zheng

University of Utah

Anne Cook

University of Utah

Lisa Ferrara

University of Utah

Sarah Davies

University of Utah

Ashley Crockett Mazal

University of Utah

Aaron Dewald

University of Utah

Abstract: A key challenge for beginning educators is finding high-quality online materials that will support deep learning in their classrooms. Identifying and evaluating effective digital resources requires careful attention to the match between domain learning goals and the conceptual information contained in resources, but preservice teachers often lack strong prior knowledge that would facilitate such processing. Conceptual browsing interfaces may support deeper cognitive processing by providing a visual representation of the conceptual relationships between domain ideas and by providing a direct retrieval mechanism to find specific online resources related to key domain ideas. Using a combined think-aloud and eye-tracking study, we are examining the effects of conceptual browsing vs. keyword searching on the cognitive processes of preservice teachers performing educational tasks. In this poster, we summarize preliminary results and discuss how keyword search vs. conceptual browsing interfaces can impact the depth with which beginning educators process online information.

Are Hindu-Arabic Numerals Concrete or Abstract Symbols?

Percival Matthews

Vanderbilt University

Abstract: Much recent experimental work has investigated the comparative merits of concrete versus abstract instantiations of to-be-learned concepts for promoting learning and transfer in complex domains. A critical question, however, is what exactly counts as a concrete instantiation. Using a design similar to that of Sloutsky, Kaminski, & Heckler (2005), the current experiments provide findings that suggest that Arabic numerals have effects that parallel those of perceptually concrete instantiations when used to illustrate the domain of modular arithmetic. Specifically, numerals can be used to speed initial learning within the domain, but impede transfer relative to more abstract instantiations of the same underlying content. Moreover, these effects can be moderated by subtle warm-up tasks that affect the degree to which these numerals activate prior arithmetic schemas. These results suggest that the current conception of "concrete" should be expanded to include representations typically thought to lie outside of the realm of concrete.

Order Effects in Categorization: Identifying "the Nuts" in Poker

Brian D. Gane

Georgia Institute of Technology

Richard Catrambone

Georgia Institute of Technology

Abstract: Research in concept learning indicates that the order of example instances affects acquisition of conceptual structures. There is less research, however, regarding how example order affects categorization skill. Might the order of training examples affect categorization even after the concepts have been learned? Participants were trained to categorize sets of playing cards into the best possible poker hand. Training followed either a blocked (the best hand remained the same for contiguous trials) or a mixed order (the best hand did not repeat more than twice in a row). Preliminary results suggest that example order affects categorization reaction time (RT) during acquisition training: the blocked order reduced RT. This trend reversed, however, during transfer trials: the mixed group had lower RT. These findings suggest that example order plays a role in developing categorization skill. We offer a preliminary explanation regarding how participants' strategy develops based on the order of training examples.

Semantics in the wild: Context-sensitive inferences about mammals

Jeremy Glick
Stanford University

James McClelland
Stanford University

Abstract: Several accounts of semantic representation have relied on a contextually insensitive similarity space, including recent structured probabilistic approaches (Kemp & Tenenbaum, 2009). However, evidence for these models relies on participants' inferences about a particular kind of property, namely, biological properties. We show that the training set used to extract a single tree structure by Kemp and Tenenbaum (2009) in fact contains additional structure in the relations between properties of different types. Moreover, participants who are asked to make inferences about different kinds of properties (biology, diet, habitat) show generalization differences that reflect this additional structure. We suggest that models of semantic representation must be able to dynamically adjust their representations in a context-sensitive manner, and we will present simulation results using a model that can do so.

Judgements of relative order: Mechanisms underlying subspan versus supraspan lists

Yang Liu

University of Alberta

Michelle Chan

University of Alberta

Jeremy Caplan

University of Alberta

Abstract: Judging the relative order of materials is a core function of human memory. In short, subspan consonant lists with immediate judgments of relative recency (JOR), instruction wording ("which item was presented earlier?" versus "which item was presented later?") could flip around memory search direction (Chan et al., 2009). We wondered whether instruction wording could have an analogous influence on the JOR judgement in supraspan lists. However, supraspan lists typically show a very different behavioural pattern - distance effects (e.g., Yntema & Trask, 1963). Our participants performed JOR judgements on "short" (LL=8) supraspan noun lists. We evaluate whether it is possible to reconcile the subspan and supraspan data by assuming that the judgement in both sub- and supra-span regimes are influenced by the same factors, positional discriminability and attentional bias across serial positions, and that speed-accuracy tradeoffs combined with ceiling in subspan lists account for the observed qualitative differences in behaviour.

Verb-body part associations across users of English, Telugu, and Hindi

Raju Bapi

Centre for Neural and Cognitive Sciences, University of Hyderabad

Jigar Patel

Centre for Neural and Cognitive Sciences, University of Hyderabad

Viswanath Naidu

Language Technologies Research Centre, IIIT, Hyderabad

Sireesha Jala

Vasanta Duggirala

Dept of Linguistics, Osmania University, Hyderabad

Suvarna Alladi

Memory Clinic, Dept of Neurology, Nizams Institute of Medical Sciences, Hyderabad

Abstract: Verb-body part association data were obtained from 36 adults using English (a second language), and Telugu and Hindi (as first languages). A set of 100 action verbs in English (same as those used in Maouene et al, 2008) and their equivalents in Telugu and Hindi served as target stimuli. Three groups of young adults (12 per language) provided written responses to action verbs printed in each language. There was greater agreement for verbs involving actions of hand, mouth and leg compared to the other body parts across all three languages. However, there were some language specific findings with respect to number of unique body parts specified, and the number of body parts required to cover 80

Reasoning in pedagogical versus deceptive situations

Russell Warner

University of Louisville

Todd Stoess

University of Louisville

Patrick Shafto

University of Louisville

Abstract: The majority of human learning occurs in social situations. In such situations, people may be cooperating or competing, and these different intentions may affect what kinds of information people exchange. Recently, Shafto and Goodman (2008) formalized a Bayesian model of reasoning in pedagogical situations – situations in which a knowledgeable teacher cooperates with a learner. This and other research suggests that individuals understand what information is more helpful and can use the knowledge of a person’s intent to facilitate learning. We extend this model to apply to both the pedagogical and deceptive situations. We present a new experiment comparing reasoning in pedagogical and deceptive games. In the experiment, participants play the role of teacher/deceiver or learner/reasoner in a series of games. The results show that people converge to strategies predicted by the model, that people’s behavior differs in pedagogical and deceptive conditions, and an analysis of individual games reveals interesting dynamics. We discuss the implications for models of learning in social situations.

Interactions Between the Fast and Slow Mental Processes

William Kennedy

George Mason University

Magdalena Bugajska

Naval Research Laboratory

Abstract: Our actions seem to be controlled by two separate types of mental processes: one fast, automatic, and unconscious and one slow, deliberate, and conscious. With the attention in the literature focused on the characteristics of the two processes and whether to include emotions, we do not find any discussion of how they interact. We present evidence that the slower process is not able to perceive the operation of faster process, but it can perceive the environmental stimulus common to both processes and the response of the faster process. It can then generate its own more deliberate response, possibly contrary to the faster process's response. We also provide evidence that the slower process is sometimes able to inhibit the fast process's response, but with effort. We present common experiences as well as cognitive theory and neurological studies in support of our description theory of the interactions of the two processes.

Word Length Effects and the Serial vs. Parallel Debate in Connectionist Models of Reading Aloud

Alan H. Kawamoto

UC Santa Cruz

Abstract: In reading aloud, naming latency (i.e., reaction time) increases linearly as the number of written symbols in a word increases (e.g., Rastle, Havelka, Wydell, Coltheart, & Besner, 2009). Advocates of dual-route models have argued that these effects can be accounted for by connectionist models that have a serial processing component, but not by models that are completely parallel when a single fixation is assumed. However, this conclusion is valid only for the specific assumptions made in parallel models implemented to date, and is not valid more generally. As Townsend and colleagues (Snodgrass & Townsend, 1980; Townsend, 1972) have argued, parallel models can mimic linearly increasing RTs as the number of items to be processed increases if stochastic processing times, limited processing capacity (i.e., attention), and a self-terminating stopping rule (i.e., the criterion to initiate articulation corresponding to the segment) are considered.

Differential effects of dopamine dysfunction on context usage in people with autism and schizophrenia: A computational exploration

Trent Kriete

University of California, Merced

David C. Noelle

University of California, Merced

Abstract: The ability to utilize contextual information in a flexible manner is vital for the successful navigation of our lives. People with autism demonstrate serious problems on tasks requiring the integration of contextual information across experiences. One such task is the determination of the proper meaning of an ambiguous word in a sentence. Homographs are words with one spelling, but different meanings, such as "bow" and "tear". People with autism appear unable to utilize sentential context in order to determine the correct meaning of a homograph. Instead, they rely on the statistically most frequent meaning. We present a neurocomputational model that suggests that these difficulties arise from a deficit in the flexible updating of attentional control, driven by dysfunctional interactions between the prefrontal cortex and the midbrain dopamine system. This work is compared to a previous computational account of the effects of abnormal dopamine levels on context processing difficulties in schizophrenia.

Can Statistics Change our Minds? The Role of Causal Explanation in Accommodation of Base Rate Statistics

Edward Munnich

Sierra Walton

University of San Francisco

Abstract: Can statistics change our minds? Base rate statistics are taken into account when they are causally relevant (e.g., Tversky & Kahneman, 1980). However, evidence is mixed on whether causally-relevant statistics can drive revision of existing beliefs: Hagmayer and Sloman (2009) found that those providing direct causal explanations for statistical patterns were more likely to recommend action than those providing incidental explanations. By contrast, Hewstone et al. (1988) found that the causal relevance of statistics only affected assignment of guilt when consistent with one's prejudices. To examine the extent to which beliefs can be revised due to statistics, we asked participants about statistics before and after feedback. Specifically, participants estimated quantities (e.g., U.S. traffic fatalities), provided explanations for trends in those statistics, and indicated what action they would take. We then provided actual statistics, and either a direct or incidental causal explanation for trends—and observed changes in actions participants would take.

Handedness and Hand Used Differentially Affect Object Facing

Jyotsna Vaid

Rebecca Rhodes

University of Michigan, Ann Arbor

Sumeyra Tosun

Texas A&M University, College Station

Abstract: When producing line drawings of common objects with an intrinsic front, directional biases are observed in starting location, stroke direction, and figure orientation. Previous studies of drawing directionality have predominantly examined right handers and/or have considered dominant hand drawing performance only. By contrast, the present study compared drawing directionality of right vs. left handers drawing objects with their dominant and non-dominant hands. Object facing direction was found to differ significantly as a function of handedness and hand used. Whereas right handers' orientation preference was generally unaffected by hand used to draw, left handers tended to show a stronger right-facing bias when drawing with their left hand than when drawing with their right hand. The latter finding is consistent with a biomechanical account in terms of hand movement asymmetries. Additional accounts of drawing asymmetries are addressed and their implications explored for current views on the relationship between perception, cognition, and action.

Experience word learning predicts children's ability to generalize novel labels

Emily Thom

University of California, Los Angeles (UCLA)

Catherine Sandhofer

University of California, Los Angeles

Abstract: Recent research has suggested that rapid word learning develops within specific categorical domains as the result of previous within the domain (Thom & Sandhofer, 2009). The current studies further examined the relationship between children's previous experience learning words within a category and their ability to extend additional words within the category. In Study 1, children's extension of novel labels was compared across three common categories in relation to their existing vocabulary size within that category. In Study 2, children were trained in a greater or fewer number of category exemplars in two common categories, then tested in their ability to generalize new labels within each of these categories. Preliminary results indicate that greater experience learning words within a category predicts better extension within that category, but not in other categories, suggesting the development of rapid word learning is domain-specific, and occurs as the result of experience learning words within each category.

A Biologically Plausible Account of the Computational Utility of Consciousness

William B. St. Clair

University of California Merced

David C. Noelle

University of California Merced

Abstract: According to Mathis and Mozer (1996), visual awareness requires internal representations to be stable over time. They demonstrated that attractor dynamics in a hand-wired, abstract, connectionist model could both produce this stability and also explain behavioral differences between conditions of subliminal and supraliminal stimulus presentation. One such demonstration involved a lexical decision study by Marcel (1980), in which conscious perception of an ambiguous prime word, disambiguated by previous context, sped lexical decision of a subsequent target word only when the target was related to the context-cued meaning of the prime. In contrast, subliminal presentation of the prime produced facilitation for targets related to either meaning of the prime. Here, we show that the attractor dynamics needed to explain this effect naturally arise from the balance of excitatory and inhibitory connections in cortex, as modeled in the biologically constrained Leabra framework, providing some neuroscientific support for this account of visual awareness.

Perceiving the Other during Joint Action

Jerome Scott Jordan

Justin Durtschi

Illinois State University

J. Cooper Cutting

Illinois State University

Abstract: The perceived vanishing point of a moving stimulus is displaced beyond the actual vanishing point. This forward displacement (FD) decreases with implied friction (i.e., the stimulus appears to move across a surface). The effect reverses when participants control stimulus movements (via right- and left-key presses) versus observe them. This reversal is consistent with economy-of-action (EOA) effects in which variables such as perceived pitch are influenced by the energy-demands implied by a stimulus (e.g., a steeper hill). The present poster presents experiments that reveal EOA effects when two participants control stimulus movements together, each having access to one of two control buttons. Specifically, FD increases across implied friction, regardless who controls the stimulus when it vanishes. Since participants are basically observers as the other participant controls the stimulus, the increase of FD during such observation indicates participants perceive the other-controlled stimulus movements in terms implied effort (i.e., EOA).

A Model of Cognitive Rehabilitation: Recovering with Constraints

Shin-ichi Asakawa

Tokyo Woman's Christian University

Yoshihiro Itaguchi

Waseda University

Abstract: Neural network modeling offers a useful computational framework for exploring the nature of normal and impaired cognitive processes. Among such modelings, Hinton and Shallice (1991) and Plaut (1996) lesioned recurrent neural networks and investigated the degree of recovery through retraining. However, many ways of brain damages has remained to be unresolved. The current works propose the method of constraints in which brain damages might occur. In order to understand the nature and variability of recovery in patients, we examined both simple three layerd perceptrons and attractor networks with lesions in various parts of networks, and observed recovery processes in retraining. The findings in this study revealed conditions to recover from brain damages and suggests good and proper ways of therapy in which therapists have to select training words to maximize generalization.

Restructuring representations in analogy making by children: the role of cognitive flexibility

Jean-Pierre Thibaut

LEAD

Robert French

LEAD

Yannick Gerard

LEAD

Abstract: In classical A:B::C:D analogies, it is often assumed that participants first find a relation between A and B, which is then transferred to C and D. By contrast, we hypothesized that the first interpretation of A-B must sometimes be later revised, given the nature of C and the D available in the solution set. We hypothesized that young children (5-6 year-olds) would encounter difficulties when restructuring is necessary because restructuring requires cognitive flexibility which is less developed in young children. In an A:B::C:D task, we compared analogies requiring restructuring with analogies that did not. We also compared analogies based on weakly semantically associated pairs (e.g., child-bed) with analogies based on strongly semantically associated pairs (e.g., dog-bone). Results revealed an interaction in which the difference between restructuring and no restructuring was significant only for analogies based on weak semantic associations. They were discussed in terms of executive functions.

White- and Grey-Matter Damage Differentially Impair Learning and Generalization in a Computational Model of the Raven Matrices Task

Abstract

Many preterm neonates have white-matter damage (WMD, damaged connections between neurons) and grey matter-damage (GMD, dead neurons). These children are known to have lower IQs than their full-term peers, yet the mechanisms underlying this association are poorly understood. We designed a developmental connectionist model of the Raven Matrices IQ task in which (1) all neurons had intact output, simulating normal development, or (2) half the neurons had noisy output, simulating noisy transmission or WMD, or (3) half the neurons had no output, simulating cell death or GMD. We found that damage increased task error. Further, WMD was worse than GMD overall, yet GMD was at once worse for generalization problems not given in training and better for training problems. Our model is the first to simulate an effect of perinatal brain damage on a cognitive task, and predicts that different types of brain damage may lead to different cognitive impairments.

Keywords: White-matter damage; cortical damage; preterm birth; Raven Matrices; IQ; connectionism; learning.

Background

In 2007, 12.7% of all births in the United States were preterm, an increase of over 2% since 1990 (Heron et al., 2009). This increase inevitably exacerbates family distress and healthcare costs, as children born preterm present many cognitive and developmental impairments compared to their full-term peers, including lower IQ scores (Bhutta, Cleves, Casey, Cradock, & Anand, 2002). The severity of preterm children's cognitive deficits appears to be correlated with brain abnormalities, e.g., reduced volume in specific brain regions (Peterson et al., 2000), which may result from abnormal development following perinatal brain damage (Robinson, 2005). Indeed, preterm neonates have immature brains that are likely to suffer damage from prematurity-associated adverse exposures before and after birth.

Perinatal brain damage can occur in either of the two major macroscopically distinct areas of the brain, the white (Dyet et al., 2006) and grey matter (Burd et al., 2009). White matter is made up of myelinated axons connecting neuronal regions and is the matter principally damaged in

preterm brains (Leviton & Paneth, 1990). By contrast, grey matter consists of neuronal cell bodies and its damage is usually more constrained in the preterm brain (Billiards, Pierson, Haynes, Folkerth, & Kinney, 2006). Although the association between cognitive impairments and brain damage is well known in the pediatric community, not much is known about either the general mechanisms underlying the association (Counsell et al., 2008), or more specifically, about how damage to white or grey matter may potentially affect cognitive function differentially. Although a previous computational model indicated that white-matter damage may be worse than grey-matter damage for synaptic recovery (Follett, Roth, Follett, & Dammann, 2009), that model did not implement any cognitive task and thus did not inform us about the effect of damage on cognition.

In order to explore how white- and grey-matter damage may affect cognitive ability, we designed a computational developmental model of a popular IQ task, the Raven Matrices, and incorporated white- and grey-matter damage in the model to assess their effects on task performance.

Computational Developmental Algorithm

Sibling-Descendent Cascade-Correlation (SDCC, Baluja & Fahlman, 1994) is a supervised-learning, artificial-neural-network algorithm which benefits from fast and powerful learning and implements some psychologically- and neurologically-plausible mechanisms (Shultz, 2006; Shultz, Mysore, & Quartz, 2007). Its developmental or constructive aspect comes from the fact that networks initially have only input and output units (fully interconnected with random weights), but develop by recruiting hidden units, as required to reduce error in training.

Training includes output and input phases. Networks are first given training patterns (input and target patterns), and training enters the output phase, in which the algorithm reduces output error, the discrepancy between output activation (initially random) and the target patterns. If the algorithm cannot bring error lower than the Score Threshold (ST) parameter, left at its default value of .4 for all training patterns, training switches to the input phase. In the input

phase, the network selects the one hidden unit, out of a pool of 8 randomly-initialized candidate recruits, that correlates most with output error. This selected unit is integrated into the network and training switches back to output phase. Training usually stops as soon as error for each training pattern drops below the ST. However, in order to have consistent amount of training across all types of networks, we imposed here a training limit of 14 hidden units and 2500 epochs, based on the average training cost of an independent, undamaged sample of 100 networks.

At the end of training, networks are tested by freezing connection weights (so that networks do not learn during testing), and measuring output error on testing patterns.

Raven Matrices task

The Raven Matrices task consists of a series of problems, in which subjects have to study a 3-by-3 matrix, and chose amongst 8 alternatives the figure that best fits the empty spot in the matrix (Figure 1).

Figure 1. An example Raven problem. Copyright © 1990 by the American Psychological Association. Reproduced with permission from Carpenter, Just, and Shell (1990). The use of APA information does not imply endorsement by APA.

There are four rules (Carpenter et al., 1990) for predicting the missing figure. In the constant-in-a row rule, a figure feature is constant across rows. For example, the narrow rectangle in Figure 1 is always vertical in the first row, horizontal in the second, and diagonal in the third. In the distribution-of-three rule, a feature is distributed amongst the figures in a row, e.g., the narrow rectangle is either black, striped, or transparent in each column in Figure 1. If one of the three features is absent, the distribution-of-two-values rule, sometimes considered as a separate rule, can also cover a distribution-of-two-values rule. In the quantitative-pairwise-progression rule, figure attributes (such as small squares in a grid) increment or decrement between adjacent columns. In the addition and subtraction rules, a figure

feature from column 1 is added to or subtracted from a figure in column 2 to produce a third figure in column 3.

Methods

We used SDCC to train and test undamaged networks on the Raven Matrices task. We next incorporated damage in two different groups of networks by either randomizing (white-matter damage) or blocking (grey-matter damage) the output activation of approximately half the networks' neurons.

Undamaged Training and Testing

A first group of 100 undamaged networks were trained and tested on Raven task problems that each implemented one of the four rules identified by Carpenter and colleagues (1990). Performance was evaluated on problems that networks knew about, and on novel problems, a technique somewhat similar to some psychological studies using the Raven task (e.g., Skuy et al., 2002).

Networks had eight inputs corresponding to the eight figures constituting a Raven problem, and one output corresponding to the missing ninth figure. Inputs and outputs used linear activation functions to cover the range of possible input and output values (see below). In order to compare network performance on known and novel data, two datasets of equal size were constructed: the training and generalization sets. Figure 2 illustrates an example Raven problem coded for training and generalization patterns.

Figure 2. A Raven problem represented in figures and as a training pattern, and its derived generalization pattern.

The left-most panel of Figure 2 shows the example figures, and the middle panel shows how the figures may be coded as a training pattern. For each training pattern, selected features were coded by integers (chosen at random between 1 and 4 from a uniform distribution) that represented the figure feature relevant to the problem rule. Each training pattern implemented one of the 4 rules identified by Carpenter and colleagues, (1990). For instance, in this constant-in-a-row example problem, 1.0 represents a vertical bar, 4.0 an horizontal one, and 2.0 a diagonal one.

The right panel shows a generalization pattern, obtained by subtracting .5 from every value of the example training pattern. Following previous practice (Dandurand, Berthiaume, & Shultz, 2007), generalization patterns were all obtained using this calculation (although in feature-addition and -subtraction problems, .5 was only subtracted

from numbers in the first two columns, because the third value depended on the first two). Other types of problems were coded similarly. Distribution-of-three problems had one of three numbers appear in each column. Quantitative-pairwise-progression problems were represented by an increment or decrement of numbers across adjacent columns. Addition and subtraction problems had a number from the second column added to or subtracted from the number the first column, to produce the third column number (in subtraction problems, the first column value was always bigger than in the second column, to ensure positive values in the third column). The range of input and output values was [.5, 8.0], where [5.0, 8.0] were only present when due to the addition of other features, i.e., [1.0, 4.0] for the training set and [.5, 3.5] for the generalization set.

Training and generalization sets each included 20 examples of each of the 5 types of Raven problems (feature-addition and-subtraction were considered 2 different types), for a total of 100 problems. Each dataset was created by sampling randomly, with possible repetitions of rows and problems, through the possible permutations of the 4 feature values, so that no network had identical training or testing. In test, after training, we calculated mean squared output error for both training and generalization datasets.

Damaged Training and Testing on the Raven task

Two other groups of 100 networks were trained and tested as described above, except that they were damaged by either randomly reducing (white-matter damage) or blocking (grey-matter damage) the output activation of some of their neurons. Damaged neurons were selected randomly for each network, and half of the input neurons and half of the candidate hidden neurons were damaged. There is nothing special about impairing half the neurons, we selected that proportion as a starting point for our experiments. Networks were free to recruit or not recruit impaired hidden neurons, so as to simulate more naturally perinatal brain damage, i.e., prior to learning and performing on tasks. The output neuron was not damaged, in order to insure a fairer comparison of white- and grey-matter damage (a grey-matter-damaged output would prevent any network output).

White-matter damage. White-matter damage is often observed as abnormal white-matter signal and abnormal axonal myelination (Counsell et al., 2006). A reduction in white-matter signal may be due to noisy or leaky axonal transmissions in which abnormal axonal myelination causes action potentials to be lost. To model this leaky transmission we subtracted a different random value from the activation value of impaired neurons each time an activation value was calculated, as in:

$$A_r = Activation - [Activation \times RandomValue(0,1)]$$

where A_r is the reduced random activation, *Activation* is the undamaged activation and *RandomValue(0,1)* is a value chosen randomly from a [0, 1] uniform distribution.

Grey-matter damage. Grey-matter damage can be considered as cell death, leading to a complete loss of signal (e.g., Follett et al., 2009). It was therefore modeled by reducing the activation values of each impaired neuron to 0.

Results

After training, we performed a two-way between networks analysis of variance (ANOVA) in order to compare the effects of dataset (training, generalization) and damage type (undamaged, grey-matter, white-matter) on mean output error. The main effects of dataset and damage type, as well as the dataset by damage type interaction, were all significant. Figure 3 shows mean output error for the different datasets and damage types.

Figure 3. Mean output error and SE bars for the different datasets and damage types. Due to low variation, error bars in the undamaged condition are not clearly visible.

First, error was higher for the generalization, $M = 1.22$, $SD = .83$, than for the training set, $M = .68$, $SD = .73$, $F(1, 594) = 139$, $p < .001$. It is common for networks to perform better on problems on which they have been trained.

Second, the significant effect of damage type, $F(2,594) = 213$, $p < .001$, was explored using Bonferroni post-hoc tests. Error was significantly lower for the undamaged condition, $M = .30$, $SD = .31$, than for either the white-matter, $M = 1.42$, $SD = .42$, or grey-matter damage condition, $M = 1.14$, $SD = 1.04$, $ps < .001$. Further, error was significantly lower for grey- than for white-matter damage networks, $p = .001$.

Third, to explore the significant dataset by damage type interaction, $F(2,594) = 62$, $p < .001$, we analyzed mean network error for each level of the factor dataset (training, generalization), using one-way ANOVAs with damage type (undamaged, grey-matter, white-matter). For the training set, the effect of damage type was significant, $F(2, 297) = 250$, $p < .001$, and Bonferroni post-hoc tests revealed that error was significantly lower for the undamaged condition, $M = .06$, $SD = .12$, than for either grey-, $M = .54$, $SD = .58$, or white-matter damage, $M = 1.44$, $SD = .49$, with error being significantly lower error for the grey- than the white-matter damage, $ps < .001$. For the generalization set, the effect of damage type was also significant, $F(2, 297) = 87$, p

$< .001$, and error was still significantly lower for undamaged, $M = .54$, $SD = .24$ than for either grey, $M = 1.74$, $SD = 1.06$, or white-matter damage, $M = 1.39$, $SD = .34$, $ps < .001$. However, this time error was significantly lower for *white-* than for grey-matter damage, $p = .001$.

Discussion

We modeled undamaged, white-matter-damage and grey-matter-damage performance on the Raven Matrices task. Of the three conditions, white-matter damage produced highest error. However, the damage type by dataset interaction revealed that compared to white-matter damage, grey-matter damage produced at once higher error for generalization problems not seen in training, and lower error for problems seen in training. To our knowledge, our computational model is the first to demonstrate an association between white- and grey-matter damage and cognitive impairment.

White- worse than grey-matter damage overall

Why was white-matter damage, i.e., noisy reduced axonal signal, overall worse than grey-matter damage, i.e., no axonal signal at all? This perhaps unexpected result may be due to white-matter damage varying in time. That is, white-matter damaged neurons had different noise values every time activation values were calculated, whereas grey-matter damaged activation values were constantly null. White-matter damage networks thus had to deal with changing information, whereas grey-matter damage networks—although missing considerable information—could adapt better to their damage because at least it was constant.

In their computational model of synaptic recovery, Follett and colleagues (2009) also reported a worse effect of white-compared to grey matter-damage, but their model did not test cognitive impairment. Our model adds to their findings by indicating that white- may be worse than grey-matter damage for learning and performing on cognitive tasks. Our results may thus provide insights into the mechanisms underlying the association between damaged and/or reduced white-matter structure and reduced cognitive abilities in preterm children (Skranes et al., 2007), full-term children (Schmithorst, Wilke, Dardzinski, & Holland, 2005) and normal, age-related cognitive decline (Charlton et al., 2006).

Damage type and dataset interaction

Even though error was overall larger for white- than grey-matter damage, grey-matter damage produced larger error on generalization problems, i.e., problems not used in training. Our model thus predicts that different types of perinatal brain damage may be associated with different types of cognitive impairment. It is however difficult to compare our predictions with findings from the preterm literature as not much is currently known about white-versus grey-matter damage in cognitive development (Dammann, Kuban, & Leviton, 2002), and because preterm children with grey-matter damage generally also have white-matter damage, (Pierson et al., 2007). Further, the

association between preterm perinatal grey-matter damage and cognitive impairments has not yet been studied directly.

Why different effects?

Interestingly, our further simulations (not reported here) indicate that the differential effects of white and grey-matter damage still hold when the imposed training limit is either doubled or cut in half, when using generalization patterns drawn from the same distribution as training patterns, as well as on the continuous XOR benchmark problem. In continuous XOR there are 2 inputs, each varying between $[-.5, .5]$ and the output is 1 when inputs indicate a point in either the first or third quadrant, and zero in the other two quadrants. The interaction thus seems to be robust to changing the training length and the task.

Insight into our findings may be achieved by analyzing other computational studies. We implemented white-matter damage by randomly reducing the output activations of damaged neurons. Such manipulations resemble injection of noise in neural-network simulations, which was previously found to improve generalization. For instance, Jim, Giles, and Horne (1996) found improved generalization on a dual-parity problem and a randomly generated six-state problem by adding noise to the connection weights of their networks. Unsworth and Coghill (2006) also found improved generalization in their multilayer perception networks, designed to recognize partially obscured human movement, but this time by injecting noise in the training data.

Adding noise can thus improve generalization, perhaps explaining better generalization for white than grey-matter damage. Generalization was however worse for white-matter damage than for *undamaged* networks. This may be due to very high training error in white-matter damage (more than four times higher than for undamaged networks). Indeed, networks' generalization is limited by the quality of their learning. Because white-matter damaged networks had high training error, their overall generalization error was also high. Further, Figure 3 reveals white-matter damage to be the only condition in which error is *not* higher for generalization than training problems (in fact it appears to be slightly *lower* for generalization), which suggests some improved generalization in white-matter damaged networks.

Our implementation of white matter damage differed from the previous noisy simulations. Compared to others who injected noise in either connection weights (e.g., Jim et al., 1996) or in the training data (e.g., Unsworth & Coghill, 2006), we injected noise at the level of neurons' output activations, to simulate impaired axonal transmission. Further, whereas others have used absolute, small noise values, e.g., between $[0, 2]$ (Jim et al., 1996), we used proportional, large noise values that varied between 0% and 100% of neurons' output activations. Thus our noise values varied between $[-.5, 8.0]$ due to the range of possible values in the input patterns. Therefore, white-matter damage may have produced large error due to the large noise values.

We implemented grey-matter damage by blocking the output of damaged neurons, simulating cell death and no

axonal transmission. This manipulation resembles neuronal pruning, usually used to increase generalization in neural networks (Reed, 1993). However, pruning algorithms usually select smaller, less important connection weights to be deleted (LeCun, Denker, & Solla, 1990). The idea is that large networks may use their extra connections to encode some of the specifics of the training data. Pruning algorithms thus usually remove smaller weights, in the hope that the remaining, larger connection weights better encode the pattern underlying the data. By contrast to these connection pruning techniques, our networks had whole neurons damaged and these neurons were chosen at random, without regards to whether they were important or not for task performance. Removing potentially critical neurons and connections, as opposed to non-important ones, may explain why grey-matter damage worsened generalization rather than improve it like pruning algorithms.

It is still unclear why training error was lower for grey-matter than for white-matter damage. This result may reflect the intuition that learning may be easier when missing some information compared to when having wrong information. For instance, Eggert, Ladda, and Straube (2009) found that subjects were better at predicting the trajectory of dots on a screen if *no* aiding cues were provided compared to when both correct and misleading cues were provided. In the case of grey-matter damage, networks apparently learned training problems without the missing input neurons. By contrast, networks with white-matter damage received information from all their input neurons, including some misleading, noisy information which may have made it difficult to learn.

Future directions

We simulated the Raven task by assigning random values to the main features of the matrix figures, and arranging these values in problems following any of the four Raven rules (Carpenter et al., 1990). By contrast, real Raven matrix figures often contain several features which vary along several rules, and thus human subjects have to find which of the features are relevant to which rules. Future simulations may more closely match the task, e.g., by using vectors or sub-matrices to encode all the figures' features. However, because networks still had to figure out the four rules only from the pattern of inputs, we consider our task to still be quite challenging. An indication of this difficulty may lie in the fact that many hidden neurons, i.e., 14 on average, were required by undamaged networks to learn the task. Further analyses may also use the number of problems solved correctly rather than using the usual output error measure. We could thus study whether white- and grey-matter damage also have differential effects on the number of problems solved, and assess the order in which networks succeed at different types of problems as they develop.

We implemented white- and grey-matter damage by impairing half of the neurons in damaged networks (excluding the single output neuron), and damage was static, i.e., a given damaged neuron stayed damaged for the whole simulation. However, because the infant brain is very

plastic, perinatal brain damage may interact in a complex way with the child's later development. Future work may consider developmental damage, e.g., punctual damage only at the beginning rather than throughout the simulation, or that is more closely related to the networks' hidden neuron recruitment. For instance, an area often damaged in the preterm brain is the germinal matrix, which is responsible for generating cortical neurons. Because white-matter damage is associated with damage to neurons migrating from the germinal matrix (Leviton & Gressens, 2007), future simulations may more closely simulate perinatal brain damage by directly impairing the hidden neuron recruitment process in SDCC, rather than letting networks decide whether to recruit damaged or undamaged neurons. We may also compare networks with different proportions of both white- and grey-matter damage.

Summary

Our computational model explored the potential link between brain damage and cognitive impairments in preterm children. White-matter damage produced overall higher task error, but grey-matter damage produced higher error on generalization problems, not seen in training. Our results thus predict that different types of brain damage may lead to different types of cognitive impairments. Future psychological work may test this prediction, e.g., by having white- and grey-matter damage populations trained on Raven problems and tested on novel problems (perhaps using a procedure similar to Skuy et al., 2002). Insights gained into the mechanisms underlying the association between perinatal brain damage and cognitive impairment may lead to more effective treatment for survivors of prematurity and help alleviate this aggravating problem.

Abstract

We study neural network models that learn location invariant orthographic representations for printed words. We compare two model architectures: with and without a hidden layer. We find that both architectures succeed in learning the training data and in capturing benchmark phenomena of skilled reading – transposed-letter and relative-position priming. Networks without a hidden layer use a strategy for identifying target words based on the presence of letters in the target word, but where letter contributions are modulated using the interaction between within-word position and within-slot location. This modulation allows networks to factor in some information about letter position, which is sufficient to segregate most anagrams. The hidden layer appears critical for success in a lexical decision task, i.e., sorting words from non-words. Networks with a hidden layer better succeed at correctly rejecting non-words than networks without a hidden layer. The latter tend to over-generalize and confuse non-words for words that share letters.

Keywords: Computational modeling, word recognition, neural networks, reading, priming effects.

Introduction

An important cognitive activity involved in skilled reading is the mapping of retinal images of letters onto abstract word representations. Skilled readers can identify words relatively easily (although not perfectly, see e.g., Rayner, White, Johnson, Liversedge, 2006) even when letter order is jumbled, except for the first and last letters. This suggests that at least one intermediate level of coding exists that abstracts away from absolute letter position and instead codes some information about relative letter order. Such an intermediate level of representation has been studied using a number of techniques including masked priming (see Grainger, 2008 for a review). Robust priming effects found include the transposed-letter effect and the relative-position effect. The transposed-letter effect describes the superior priming observed from primes formed by transposing two of the target's letters (e.g., gadren-garden) compared with primes formed by substituting two of the target's letters (e.g., galsen-garden). The relative-position priming effect describes a processing advantage for targets preceded by

primes formed of a subset of the target's letters (e.g., grdn-garden) compared with a prime formed of the same subset of letters in the wrong order (e.g., gdrn-garden).

A number of models have been proposed for an intermediate level of coding that can account for these priming effects (see Grainger, 2008 for a review). Notably, the Grainger and Van Heuven (2003) model of orthographic processing was the inspiration for a computational model that learned to map location-specific letter identities (letters coded as a function of their position in a horizontal array) onto location-invariant lexical representations (Dandurand, Grainger, & Dufau, 2010). Because parsimony dictates to assume a single intermediate level of representation, we considered a neural network architecture with a single hidden layer.

This network architecture with a hidden layer successfully captured transposed-letter and relative-position priming effects (Dandurand et al., 2010). Intermediate representations were explicitly probed and analyzed as patterns of activation at the hidden layer (Hannagan, Dandurand, & Grainger, submitted; see also Plaut, McClelland, Seidenberg, & Patterson 1996 for a discussion of internal representations in neural networks). These patterns were found to have two important characteristics. First, letters seemed to be represented in a semi-location-invariant fashion at the hidden layer. Second, representations at the hidden layer were well-characterized as a holographic overlap coding in which small changes of the inputs resulted in small differences in hidden layer representations. More specifically, differences in patterns of hidden layer activations were monotonically related to differences in identity and position of input letters. For example, patterns of activity at the hidden layer were more different for a two-letter substitution at the input (POLL vs. BULL) than a single letter substitution (PULL vs. BULL) when position in the horizontal array was kept constant. Furthermore, differences in patterns of activity were also larger when the input word was moved by two positions in the alphabetic array (#THAT##### vs. ###THAT###) than moved by a single position (#THAT##### vs. ##THAT#####). Holographic overlap coding explains the observed transposed-letter and relative-position priming and

makes a number of predictions which are tested in this article; see (Hannagan et al., submitted) for details.

As they map letters onto words, skilled readers can also perform lexical decision, that is, deciding if a string of letters is a word or a non-word (Meyer & Schvaneveldt, 1971). Lexical decision has been extensively studied, and a number of models exist to account for human performance (e.g., Ratcliff, McKoon, & Gomez, 2004). In the current work, we test our models on a simple lexical decision task, assuming a minimal lexical read-out mechanism, namely that words would activate output units more than non-words. We are not, however, claiming that this ability should be interpreted as a full-blown or realistic model of lexical decision. Note that performing lexical decision is not trivial for networks because non-words are never seen in training as negative evidence, and thus networks may be expected to over-generalize what they consider as words.

In the current study, we revisit the assumption previously made for the need of a hidden layer. We ask if such a hidden layer is required for networks to learn location invariant orthographic representations for printed words. To this effect, we contrast two model architectures: (1) the previous model with a hidden layer and (2) a simpler model without a hidden layer. In this alternative model, letters are mapped to words directly using a layer of connection weights. We compare the two architectures on a number of criteria: (1) their ability to learn the training set, including the anagrams present in the training data, (2) their size and complexity, (3) their capacity to simulate key priming effects, and (4) their capacity to perform a simple lexical decision task. Finally, we investigate how processing and representations differ, how networks without a hidden layer manage to segregate anagrams, and how well these networks conform with the predictions made by holographic overlap coding.

Our goal is to gain insights into the role that the hidden layer plays in performing a word recognition task. Without a hidden layer, networks are computationally limited to taking decisions based on weighted combinations of input letters. It is unclear how, and even if, such model could handle anagrams where the identity of input letters is insufficient to discriminate words, and where position of letters has to be taken into account.

Methods

We compare two architectures of standard multilayer perceptron neural networks. The first one includes a single hidden layer of 91 hidden units with logistic activation functions, identical to (Dandurand et al., 2010). The second one has no hidden layer (inputs are directly connected to outputs). In the two architectures, adjacent layers are fully connected, and are trained using standard backpropagation (learning rate = 0.1, momentum = 0.9) until an SSE of 30. Training material consists of 1179 real words of four letters (same as the one used by McClelland, & Rumelhart, 1988) presented in all 7 possible positions of an alphabetic array (e.g., #ABLE####, #####ABLE where # are empty, blank slots). Local (sparse) coding is used for input letters

(one out of 26 possible letters, for each slot) and output units (one out of 1179 words, also with logistic activation functions). Networks learn to associate letter strings presented at the input with the corresponding output unit coding for some word. For further details, see (Dandurand et al., 2010).

We trained and tested samples of 10 networks for each condition (with and without a hidden layer). Networks varied in the random initial values of their connection weights.

In tests that involve lexical decision, we present some pattern at the input and compute activations of all output units. Output units activated above a threshold value of 0.9 are considered as active, and thus the word associated with the unit as having been detected. For tests that involve priming, a measure dubbed “target supremum measure” (Dandurand et al., 2010) quantifies the ability of some prime to activate the output unit associated with the target word more than any other active output unit¹.

Results

Learning the training set

The training set comprises 1179 words, 24.0% (N = 283) of which are anagrams. Anagrams come in pairs (111 pairs x 2 = 222 words), triplets (15 triplets x 3 = 45 words) and quadruplets (4 quadruplets x 4 = 16 words). These quadruplets (1. live – evil – veil – vile; 2. team – meat – mate – tame; 3. tied – diet – tide – edit; 4. pear – rape – reap – pare) should be especially difficult to discriminate because the same four letters activate four different target word units.

Networks with a hidden layer achieve perfect performance (100%) on the target supremacy measure for the training set. In contrast, networks without a hidden layer reach 98.6%, and more than 95% of anagrams were successfully segregated. In the 1.4% of errors, activations of output units (including the target) fail to reach the threshold of 0.9. These failure-to-recognize errors involved pairs of anagrams (bear – bare, and read – dear) or sets of words from an orthographic neighborhood sharing three letters (bare – mare – pare, seep – seed – deep, and pull – burl – bull).

Model size and complexity

From a size and complexity perspective, the hidden layer adds 91 extra units, and an additional layer of processing. However, in terms of size, networks with a hidden layer actually have fewer connection weights (132 219, i.e., 1179

¹ Models allow for multiple outputs to be activated, but some competitive, winner-takes-all mechanism could be used to select the most active one. Item-level target supremum value was set to 1 when the prime activated the output unit associated with the target lexical item more than any other unit; it was set to 0 otherwise. The target supremum measure of a set of primes was computed as the mean of item-level values for the primes in the set.

outputs \times (91 hidden + 1 bias) + 91 hidden \times (260 inputs + 1 bias)) than networks without a hidden layer (307 719 connection weights (1179 outputs \times (260 inputs + 1 bias)), despite having two layers of weights. We can think of the hidden layer as enforcing data compression from 260 inputs to 91 hidden units, which reduces the number of connections required.

Priming effects

Networks are tested using the relative-position priming and transposed-letter priming manipulations described in (Dandurand et al., 2010). Examples of primes for word ABLE are overlapped on the graphs below, see (Dandurand et al., 2010) for details of the content of testing sets. Primes (e.g., ###ABE####) are expected to activate the target word (e.g., ABLE) more so than any other word, especially when prime letters are in the correct, forward order (ABE) and not the reserved, backward (EBA) order.

Figure 1 – Target supremum results for the relative-position priming test. Example primes provided for target word ABLE.

Figure 2 – Target supremum results for the transposed-letter priming test. Example primes provided for target word ABLE.

As we can see, patterns of results are very similar for networks with (see Figures 5 and 6 in Dandurand et al., 2010) and without a hidden layer. More specifically, relative-position primes formed of forward letter subsets yield a higher target supremum measure than backward primes (see Figure 1); and transposed-letter primes containing central letters from the target word yield a larger supremum measure than primes with central letters from a different word (see Figure 2).

Lexical Decision

To test for lexical decision, we assess performance (target supremum measure) on three simple testing conditions: (1) words: all words seen in training in all positions (for a total of 1179x7 patterns); (2) non-words: a sample of 100 patterns made of four random letters presented at a random position in the alphabetic array (e.g. #JKTS####, #####HIQL, ###BXGA###); (3) letters: a sample of 100 patterns, each made of a randomly selected letter repeated to match word length presented at a random position in the alphabetic array (e.g., #####, #####HHHH#). Word patterns are expected to activate, and only activate, their target word unit. We also expect no output word unit to be activated above threshold for patterns in the non-words and in the letters conditions.

Results are shown in Figure 3. As we can see, network with a hidden layer perform much better than networks without one. Networks without a hidden layer are especially poor at correctly rejecting letter patterns, activating several of the words that contain the letter. For example, input pattern ###PPPP### activates 85 word units above threshold including part, open, help, kept, step, post and ship. Similarly, for non-words, errors involve incorrectly activating words that share some letters with the target. For example, input pattern #####KNKR## activates the following word units above threshold: kind, dark, park, mark, link, monk, fork, tank, pork, cork, knot, and trek.

Figure 3 - Accuracy of networks at accepting words, and rejecting non-words and repeated letters.

Discussion

To sum up our results, both networks with and without a hidden layer correctly recognized words at rates reaching 98.6% to 100%. Performance was high even on anagrams (95% to 100%). Both types of networks showed relative-position (see Figure 1) and transposed-letter priming effects (see Figure 2). Networks with a hidden layer are more complex due to the additional hidden units, but contain fewer connection weights. The critical benefit of the hidden layer appears to be in the ability of networks to correctly reject non-words and strings of repeated letters (see Figure 3).

Segregating anagrams

One of the most difficult aspects of the task is arguably that of segregating anagrams. While regular words can be discriminated on the basis of differences of at least one letter, anagram identification must rely solely on the relative position of letters within word. The task appears especially difficult for the network without a hidden layer which is limited to computing linear combinations of independent inputs.

Networks with a hidden layer

In networks with a hidden layer, holographic overlap coding (Hannagan et al., submitted) can explain both transposed-letter priming and the ability of networks to segregate anagrams. During learning, networks form semi-location specific representations for individual letters - assigning similar representations to the same letter input seen at different positions - that is, networks combine letters in a continuous manner to build a string code. Displacing letters (whether in primes or in anagrams) results in small, but measurable differences in patterns of activation at the hidden layer. In the case of transposed-letter priming, most words have no orthographic neighbor, and therefore the target word is still the most activated (e.g., WTIH activates word WITH), and so will be recognized according to the target supremum measure. Networks can capitalize on this small difference in hidden pattern activation to segregate words. It is plausible that this small difference gets enhanced or amplified by the processing of the second layer of weights (hidden to output weights) to generate the correct classification of anagram patterns (e.g., ABLE and BALE as distinct).

Networks without a hidden layer

To gain insights into how networks without a hidden layer can segregate anagrams, we study the connection weights between inputs and outputs after training. The first thing we notice is that connection weights strongly code for the mere presence of letters. Typically, connection weights are small for letters not present in the target word, and large for letters that are present, irrespective of position. For instance, connections weights from input units that code letters A, B, L, and E (in all slots where they have been seen during training) are large to output unit coding for word ABLE.

This simple scheme makes each letter vote for the target word, and a word must get 4 votes to be fully activated. This may explain why letters activate very strongly a number of targets, as AAAA also counts as 4 letters of evidence for ABLE. However this does not explain how the network can distinguish between anagrams.

Figure 4 illustrates how networks might manage to segregate anagram patterns. Boxes in the plot show the average magnitude of connection weights between within-word position on the Y axis and within-alphabetic-array (within-slot) location on the X axis for letters relevant to the identification of the target word. For example, for pattern ABLE##### connection weights would be found at boxes (X,Y): A(1,1), B(2,2), L(3,3) and E(4,4); whereas for pattern ###ABLE### relevant boxes would be A(4,1), B(5,2), L(6,3) and E(7,4).

As we can see, there is a negative correlation ($r = -0.73$, $p < 0.01$) in the first within-word position (P) between the average magnitude of connection weights (C) and location (L), while the correlation is positive in the last position ($r = 0.67$, $p < 0.01$). Namely, for the first letter of the word, the connection weight is largest for smaller locations in the slot, and decrease as location in slot increases. This makes intuitive sense, as A##### is better evidence for word ABLE (or any word that begins with letter A) than #####A###, which could be evidence for #####ABLE, but also for #####THAT## or any word having an A in any position. The correlation is reversed for the last slot where say letter E provides more evidence for ABLE if it appears later in the word. The direction reversal suggests an interaction between location (L) and within-word position (P).

Figure 4 - Average magnitude of weights connecting input units relevant to identifying an output word, by location in the alphabetic array (X axis) and by position with target word (Y axis). Black boxes correspond to positions where letters were never seen in training (e.g., letter A was never seen in slots 8 to 10 for word ABLE, and similarly letter E was never seen in slots 1 to 3).

To test for this interaction, we performed a linear regression with the following model (including LxP to test for interaction effects):

$$C = b_0 + b_1L + b_2P + b_3LxP \quad (1)$$

In the fitted model, we get $b_0 = 31.0$ ($p < 0.001$), $b_1 = -4.0$ ($p < 0.001$), $b_2 = -8.9$ ($p < 0.001$) and $b_3 = 62.9$ ($p < 0.001$). This confirms the significant interaction. Redoing the analysis with central locations only (4 to 7), we also get significant coefficients, $b_0 = 22.6$ ($p < 0.001$), $b_1 = -1.8$ ($p < 0.001$), $b_2 = -4.6$ ($p < 0.001$) and $b_3 = 30.4$ ($p < 0.001$).

To sum up, the processing strategy or coding scheme that networks without a hidden layer develop can be described as follows: most important is the number of letters shared between inputs and targets independently of position – we can think of this as input letters providing independent votes for the target words that contain them. The presence of letters is then modulated by the interaction between location and position. This scheme is sufficient to explain how networks can discriminate between anagrams. For instance in strings ABLE and BALE, an equal number of four letter votes go to each word, and connection weights between small slot positions and target word ABLE are slightly larger for letter A than letter B. In contrast, for target word BALE, the connection weight is slightly larger for letter B than letter A. This difference enables the correct target to be activated.

This coding scheme also accounts for the priming effects: larger priming as the number of letters shared between primes and targets increase, and larger priming as the agreement increases between the order of letters in the prime and in the target.

Comparison with holographic overlap coding

How does this processing strategy in networks without a hidden layer compare to holographic overlap coding used by networks with a hidden layer? As mentioned in the introduction, holographic overlap coding makes two important predictions about similarity of activation patterns: a proximity effect and a disruption of activation when replacing letters with other letters of the word (e.g., AAAA for word ABLE). The normalized Euclidian distance between two activation vectors $Act(V_1)$ and $Act(V_2)$ is computed as follows:

$$dist = \sqrt{(\sum \sum (Act(V_{1ij}) - Act(V_{2ij}))^2) / (N_{pattern} \times N_{activation})}$$

Activations are taken at the hidden layer, or at the output layer for networks without a hidden layer. The two \sum indicate summing over all patterns and all activation values.

The proximity effect predicts that the Euclidian distance between activation vectors V_1 and V_2 should increase monotonically with the magnitude of displacement of the vectors (i.e., distances). As shown in Table 1, a proximity effect is observed indeed, when vectors V_1 are in the central position (###XXXX###) and vectors V_2 vary in position. Distances presented in the table are normalized using a displacement of 1 as a reference (that is, V_2 ##XXXX#### and ####XXXX##). Vectors V_2 for displacement 2 are #XXXX#### and #####XXXX#; and for displacement 3:

XXXX#### and #####XXXX. As we can see, distances increase with displacement, in accordance with the proximity effect.

Table 1: Normalized Euclidian distance for networks with and without a hidden layer, as a function of displacement of letters in the input vector

Displacement	Euclidian distance	
	With hidden	Without hidden
2	1.3	1.5
3	2.2	1.7

Holographic overlap coding also makes a prediction about the effect of letter substitutions: the more letters are replaced, the larger the difference in activation should get. We empirically test this hypothesis by generating samples of 100 test items for which the target word and the location of letters in the input slot is randomly chosen. We compute the Euclidian distance between patterns of activation generated in one of three conditions: (1) transposition – transpose two letters, randomly chosen (e.g., $V_1 = ABLE \rightarrow V_2 = ABEL$), (2) one letter substitution with a random letter (e.g., $V_1 = ABLE \rightarrow V_2 = ABWE$), (3) one letter substitution with another letter of the target – that is, a letter repetition (e.g., $V_1 = ABLE \rightarrow V_2 = BBLE$).

Figure 5: Normalized Euclidian distance index as a function of transformation and architecture type

Holographic overlap coding predicts similar distances for letter repetitions and substitutions, and a lower distance for transpositions. As we see in Figure 5, this is precisely the pattern of distances measured for networks with a hidden layer. However, these predictions are not verified for networks without a hidden layer, namely because distances are too large for the letter repetition set. This somewhat counter-intuitive result can be explained by the fact that repeating a letter means, on average, replacing a letter with a rather frequent letter compared to substituting with a randomly chosen one (as in the substitution case). And thus, many output words activate in the repetition case, which increases the distance due to the higher activation of the non-target words. In sum, we fail to find evidence that networks without a hidden layer implement a holographic overlap coding scheme.

Lexical decision, over-generalization and their theoretical implications

In the lexical decision task, correct rejection of non-words and letters can be interpreted as a test of generalization, which probes the network's ability to correctly set the boundary of word acceptance. Based on a poverty of stimulus argument, we may expect networks to over-generalize, that is being overly liberal in accepting strings as words, because networks see positive evidence for words but never see any negative evidence, i.e., they are never trained to reject non-words. These over-generalization errors are much more common in the network without a hidden layer. This has interesting theoretical implications for the functional role of the hidden layer where independent letters are combined. Given that each letter/position has a uniquely defined code, the network just has to find a way to integrate them so as to ensure that each combination is unique. For instance, using a simple averaging approach, the resulting code for AAAA will be very close to A, in effect providing only evidence for one letter. Without combinations, networks have to base their decisions on some position-weighted voting scheme relating to the presence of letters. This scheme fails to reject non-words cases that consist of 4 repetitions of a letter from the target word.

Beyond simply removing letter duplicates, the hidden layer may well be coding for some letter combination, or sub-lexical units, as postulated in the Grainger and Van Heuven's (2003) model and other models. A simple approach to lexical decision could thus be seen as follows: letters provide evidence for activating sub-lexical units. These sub-lexical units would in turn be combined to activate target words. For non-words, activation of sub-lexical units would be small, and result in activation of output units that fall below threshold.

Conclusion

To summarize, the hidden layer developed a holographic overlap coding scheme which explains priming effects and segregation of anagrams. Because it is sensitive to letter substitutions, this scheme also allows networks with a hidden layer to correctly reject most non-words.

In contrast, networks without a hidden layer have developed a strategy for identifying target words largely based on presence of letters but where letter contributions are modulated using the interaction between within-word position and within-slot location. This modulation allows networks to factor in some information about letter position, which is sufficient to segregate most anagrams, and replicate the previously observed priming effects. On the other hand, these networks are poor at the lexical decision task, as they tend to over-generalize and confuse non-word strings as words. As long as the number of letters is the same and that all input letters exist in the target word, networks do not require that all letters in the target word are present to activate it.

The hidden layer also implements some data compression, by forcing 260 input units to be represented onto 91 hidden

units. As a result, networks with a hidden layer have fewer than half the number of connection weights of networks without a hidden layer.

Computational models of word identification are expected to perform well at lexical decision, as humans do. The model with the hidden layer suggests a parsimonious account of lexical decision as an emergent property of the word recognition task (although, again, the setup is highly simplified, and further work would be necessary to fully assess how good of a lexical decision model this is). An alternative explanation consists in using an additional module (performed before, or in parallel with, word identification). For the latter, a network without a hidden layer is sufficient to simply recognize words.

Abstract

Previous studies (Doxas, Dennis, & Oliver, 2010) show that natural language discourse exhibits a two-scale structure with a lower dimension at short distances and larger dimension at long distances. We attempt to search for the source of this constraint in the visual input that goes into forming episodic experiences in human beings. This information is assumed to be approximated well by images captured by a MicrosoftTM Research SenseCam that our subjects used. The hypothesis is that if the same two scale structure is observed here, the constraint is possibly not one that is imposed by the cognitive system. We use and contrast two methods by which images can be represented: the traditional color histogram and a more recently developed color correlogram method. The color correlogram is established to work better for our current purposes. We observe hints of a two scale structure in the correlation dimension plots but these are not conclusive.

Keywords: Episodic Memory; Correlation Dimension; Networks; Graphs.

Introduction

The existing models of episodic memory assume a representation of context. Retrieval of episodes involves reinstatement of context. The current literature does not address the nature of representation of context and the question of how the representation was formed in the first place. Our ultimate goal is to model contextual reinstatement as a search over episodic networks. We begin by looking at the images that people encounter everyday. In a parallel study, graphs of these images are constructed and the structure of the graphs is investigated. People are extremely fast at isolating episodes from memory. Such a search has to be fast and efficient. The graph has to satisfy certain properties for it to be efficiently searchable (Steyvers & Tenenbaum, 2005). We attempt to test the idea that contextual reinstatement can be modeled as a network search. One prerequisite for this model to be feasible is that the episodic network must be quickly searchable.

We encode events into our memory as we encounter and experience them. What kinds of constraints are inherent to this input information? Such a question is motivated by previous studies on natural language discourse where paragraph

spaces of corpora of different languages exhibited a two-scale structure (Doxas et al., 2010). Doxas et al. did a correlation dimension analysis on the paragraph spaces of text corpora taken from five different languages and genres. The correlation dimension is a measure of how points within a given distance r scales with that distance. The paragraph spaces were found to exhibit a low dimensional structure at short distances and a higher dimensional structure at larger distances. This is similar to a “weave” structure. For example, if we zoom in to look at a thread that is part of a shirt, the observed dimensionality is one. If we zoom out to intermediate length scales, we would start observing a two dimensional structure. Further zooming out will further increase the dimensionality. The finding of this “weave” structure in natural language discourse raises an important question regarding the origin of this constraint. Is this constraint one that is imposed by the cognitive system or is it a property of the input the system receives that is being mirrored by the cognitive system? We attempt to address this question in the current study. To investigate this, we used a MicrosoftTM Research SenseCam to capture images that can be thought of as representative of a person’s (visual) episodic experience. A dimensionality analysis was then done on these images.

The paper is organized as follows. The next section outlines the method used to capture and represent the images on which the dimensionality analysis is done. The Microsoft Research SenseCam device is described briefly. Two different image representation schemes and their corresponding distance measures are discussed. The two methods are then contrasted using a definition of a ratio that is based on the requirement that these methods must, among other things, successfully identify images that belong to the same contexts. The subsequent section describes the correlation dimension. The results section discusses the correlation dimension plots for the image sets obtained from different individuals. The paper concludes with a discussion of the structure that is observed in the correlation dimension plots of the image data.

Image Data Collection, Representation and Distance Measures

Microsoft Research SenseCam

To capture a sufficient number of images that can sufficiently represent an individual's visual episodic experience for a period of about a week, we used a Microsoft Research SenseCam. Subjects hung the camera around their necks for about a week each. The SenseCam contains sensors which can detect changes in color, light-intensity and temperature. Changes in these sensor readings can be set to automatically trigger the SenseCam to take pictures. The camera can also be set to a timer mode where pictures can be captured periodically. Our camera captures an image once every eight to ten seconds. The camera has wide-angle (fish-eye) lens that maximizes its field-of-view. The resulting images are particularly useful for studying episodic experience because these images are fragmentary, time compressed, temporally ordered, and have a 'field perspective' (Berry et al., 2006).

HSV Space

The HSV (hue, saturation, value) color space is very different from the better known RGB (red, green, blue) color space. The problem with using the RGB color space is that it is not perceptually uniform. To get a satisfactory representation of the image in the RGB space, the quantization step sizes should be fine such that distinct colors are not assigned to the same bin. This increase in the number of bins affects performance in terms of computation time. The oversampling also produces a larger set of colors than are necessary and this is not an accurate representation of human visual discrimination of colors.

A three dimensional representation of the HSV color space is a hexacone (Stockman & Shapiro, 2001). The central axis represents the intensity. Hue is defined as an angle in the range $[0, 2\pi]$ relative to the red axis such that red is at angle 0, green is at $2\pi/3$, blue at $4\pi/3$ and red again at 2π . Saturation takes values between 0 and 1. Saturation is the depth or purity of the color. It is measured as a radial distance from the central axis. The saturation value is 0 at the central axis and is 1 at the outer surface. As saturation varies from 0 to 1, the corresponding hues vary from unsaturated (shades of gray) to fully saturated (no white component, pure form of the color represented by its hue). In other words, for a low value of saturation, a color can be approximated by a gray value specified by the intensity value and for a high value of saturation, the color can be approximated by its hue. HSV separates out the light-intensity information (luminance) from the color information (chromaticity).

Color Histogram Representation

A color histogram for an image is generated by concatenating 'N' higher order bits for the Red, Green and Blue values in the RGB space (Swain & Ballard, 1991). The histogram is generated by counting the number of pixels with the same color and accumulating it in 2^{3N} bins. We generate such a

histogram from the representation of each image in the HSV space. Quantizing the hue component more precisely than the value and saturation components makes the HSV histogram more sensitive to color differences and less sensitive to brightness and depth differences. We found it sufficient to use a (h=30 levels, s=10 levels, v=3 levels) quantization to generate the histograms based on the fact that the human eye is more sensitive to variations in hue and intensity than variations in saturation.

Several distance measures can be used to calculate distance between images (Jeong, Won, & Gray, 2004). These include the histogram euclidean (HE) distance and the histogram intersection (HI) distance (Smith & Chang, 1995, 1996). A Kullback-Liebler divergence (Greenspan, Goldberger, & Ridel, 2001) measure is also discussed which has been established to work better than the HE and HI measures in information retrieval tasks (Goldberger, Gordon, & Greenspan, 2006).

Histogram Euclidean Distance If **h** and **g** represent two color histograms, the euclidean distance between them is given by

$$d^2(h, g) = \sum_A \sum_B \sum_C (h(a, b, c) - g(a, b, c))^2 \quad (1)$$

A, B and C are the three colors (RGB or HSV). In this formula, all bins contribute equally to the distance and only identical bins in the respective histograms are compared.

Histogram Intersection Distance The histogram intersection (HI) distance (Swain & Ballard, 1991) between **h** and **g** is given by

$$d(h, g) = \frac{\sum_A \sum_B \sum_C \min(h(a, b, c), g(a, b, c))}{\min(|h|, |g|)} \quad (2)$$

$|h|$ and $|g|$ are the number of samples in the respective histograms. The sum is normalized by the histogram with the lesser number of samples. We used the histogram intersection distance for our initial analysis. The distance tends to 1 if the images are highly similar and 0 if they are highly dissimilar.

Square root of the Jensen-Shannon divergence: a proper metric A better measure to calculate similarity between images is the information theoretic Kullback-Liebler (KL) divergence (Greenspan et al., 2001). This is a non-symmetric measure of the difference between two probability distributions. It has been shown to perform better than HI in image search and retrieval tasks (Goldberger et al., 2006). Though the intuition is to use the KL divergence directly as a distance measure, it is not a true metric. A symmetrical version of the KL divergence is the Jensen-Shannon (JS) divergence, the square root of which is a metric. Using a proper metric is important since we intend to study the dimensionality of the space of these image representations. Our color histogram results here are based on the distance measure that is the square

root of the JS divergence. Figure 1 shows a query image and the retrieved images that are similar to the query image based on the JS distance. The distance is printed on top of each of the retrieved images.

The Kullback-Liebler divergence of Q from P is defined as

$$D_{KL}(P||Q) = \sum_i \log \frac{P(i)}{Q(i)} \quad (3)$$

where P and Q are probability distributions of a discrete random variable. The symmetric Jensen-Shannon divergence is given by

$$D_{JS} = \frac{1}{2}D_{KL}(P||M) + \frac{1}{2}D_{KL}(Q||M) \quad (4)$$

where $M = \frac{1}{2}(P + Q)$

Figure 1: Query image and retrieved images (JS divergence distance method).

Color Correlogram Representation

The color histogram has the drawback of being a purely global description of the color content in an image. It does not include any spatial information. Purely local properties when used can be extremely sensitive to appearance changes due to slight changes in angle, zoom, etc. Purely global properties (like those used in the color histograms) can give false positives as it can classify images from widely separated scenes as belonging to the same scene if they have similar color content. An example of this can be found in figure 1. The third image in the second row of the retrieved images is a false positive because that image belongs to an entirely different event.

A color correlogram (Huang, Kumar, Mitra, Zhu, & Zabih, 1997) describes global distributions of local spatial color correlations. In other words, a correlogram of an image is a three dimensional matrix whose k -th entry for (i, j) is the probability of finding a pixel of color j at a distance k from a pixel

of color i . This makes the correlogram robust to changes in appearance caused by occlusions, zoom, viewing angles, etc. We use a special case of the correlogram for ease of computation: the banded correlogram (Huang, 1998). Figure 2 shows the same query image as earlier and the retrieved images that are based on the relative L_1 distances between images represented as banded correlograms. The distance is printed on top of each of the retrieved images. There are no false positives in these retrieved images.

Let I be an $n \times m$ image. The colors in I are quantized into k colors c_1, c_2, \dots, c_k . For a pixel $p = (x, y) \in I$, let $I(p)$ denote its color. $I_c \triangleq \{p | I(p) = c\}$ where $c \in \{c_1, c_2, \dots, c_k\}$. For pixels $p_1 = (x_1, y_1), p_2 = (x_2, y_2)$, we define L_∞ norm to measure the distance between them, such that $|p_1 - p_2| \triangleq \max\{|x_1 - x_2|, |y_1 - y_2|\}$.

The correlogram of I is defined for $i, j \in \{1, 2, 3, \dots, k\}, d \in \{1, 2, 3, \dots, l\}$ where distance d is fixed a priori, such that

$$\gamma_{c_i, c_j}^{(d)}(I) \triangleq \Pr_{p_1 \in I_{c_i}, p_2 \in I_{c_j}}[|p_2 - p_1| = d] \triangleq \frac{|I_{c_j} \cap I_{c_i}^d|}{|I_{c_i}^d|} \quad (5)$$

where $I_c^d \triangleq \{p_2 | p_1 \in I_c \wedge |p_2 - p_1| = d\}$, where $d \in \{1, 2, 3, \dots, l\}$ is a distance between two given pixels in the image. Given any pixel of color c_i in the image, $\gamma_{c_i, c_j}^{(d)}(I)$ gives the probability that a pixel at distance d away from the given pixel is of color c_j . Hence, the color correlogram is a three-dimensional table indexed by color and distance between pixels and the size of the correlogram is $O(k^2l)$.

The banded correlogram (Huang, 1998) is for storage trimming. Given b , for $1 \leq d \leq l/b$,

$$\bar{\gamma}_{c_i, c_j}^{(d)}(I) \triangleq \sum_{d'=(d-1)b+1}^{db} \gamma_{c_i, c_j}^{(d')}(I) \quad (6)$$

For each color pair (c_i, c_j) , the probability values for the distances in the selected distance set whose cardinality is b are summed as a single number. Hence, a banded color correlogram is a restricted version of the color correlogram.

Distance Measure We use a relatively weighted L_1 distance measure for computing the distance between images I and I' as follows:

$$|I - I'|_{\gamma, L_1} \triangleq \sum_{i, j, d} \frac{|\gamma_{c_i, c_j}^{(d)}(I) - \gamma_{c_i, c_j}^{(d)}(I')|}{1 + \gamma_{c_i, c_j}^{(d)}(I) + \gamma_{c_i, c_j}^{(d)}(I')} \quad (7)$$

where $i, j \in \{1, 2, 3, \dots, k\}$, and $d \in \{1, 2, 3, \dots, l\}$.

The L_1 distance is also known as the manhattan distance. The manhattan distance between two points in an n -dimensional vector space with a fixed cartesian coordinate system is just the sum of the lengths of the projections of the line segment between the two points onto the coordinate axes. The normalization is such that non-uniform weights are assigned to the contribution of different colors to the dissimilarity between the two images. This is in keeping with the intuition that a difference in the number of pixels in any given

color bucket has a more significant contribution to the perceived dissimilarity if the content of that color in the image is low to start with. The same difference but when the color content is extremely high shouldn't contribute too much to the perceived dissimilarity between two images.

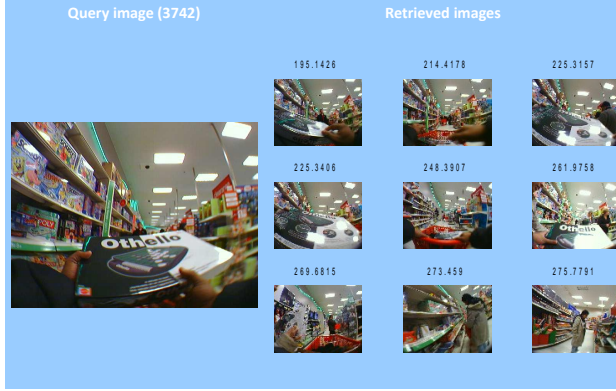

Figure 2: Query image and retrieved images (the color correlogram method).

Comparison: Common Neighbor Ratio

We now need to compare the performance of the two methods for our current purpose: to check if the distance measure on the respective representation does a good job of identifying as neighbors images that really are closely spaced in the time sequence. Events within a context are closely spaced in time and one of the major tasks for our method is to be able to accurately retrieve images that are from the same context. The idea here is that most of the closely spaced images as characterized by the distance measure ought to be closely spaced in time. Periodic events are exceptions where people might return to the same place after a certain duration. The images from those two episodes will be closely spaced but might be far apart in time. With this in mind, we define the common neighbor ratio. Given a positive integer k , for each image I , we find its k nearest neighbors both in the distance domain and in the time domain. Suppose $D_I = \{I_{d1}, I_{d2}, \dots, I_{dk}\}$ are image I 's k nearest neighbors in the distance space and $T_I = \{I_{t1}, I_{t2}, \dots, I_{tk}\}$ are image I 's k nearest neighbors in the time space (the images come with timestamps on them which are used in this calculation), then

$$\text{common neighbor ratio} = \frac{\sum_{I=1}^n |D_I \cap T_I|}{n \times k} \quad (8)$$

where n is the total number of images. If k equals to n , then the ratio is 1. The method that has a higher common neighbor ratio is the better one. Figure 3 shows clearly that the correlogram representation and its corresponding distance measure outperforms the traditional histogram representation

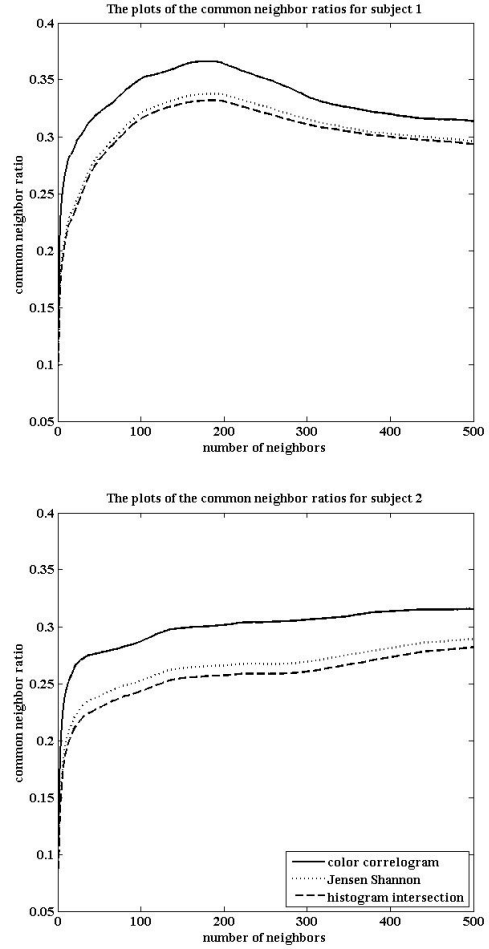

Figure 3: The common neighbor ratio as a function of number of nearest neighbors for image data from two subjects. The correlogram-relative L_1 distance method gives a higher ratio than the histogram-JS distance and the histogram intersection distance methods.

and the associated JS divergence distance measure. It can also be seen that the JS divergence measure works slightly better than the histogram intersection distance.

Correlation Dimension Analysis

Dimension measures are used to quantify the space filling properties of a set. A fractal dimension is a more informative measurement than a topological dimension which can take only integer values. For example, the topological dimension of a point is 0, of a line is 1 and of a surface is 2. A wiggly line is more space filling than a straight line but has a topological dimension of 1. The wiggly line is said to be a fractal if its fractal dimension is greater than its topological dimension (Mandelbrot, 1967). Fractal dimension measurements have been widely used in nonlinear dynamics time series analysis.

If a time series is from a nonlinear dynamical system or from a random process, the time series is irregular in both

time and frequency domains. Methods of time series analysis based on phase space reconstructions can reveal structure in time series from nonlinear dynamical systems as opposed to little structure in time series from random processes. Many popular methods of analysis involve correlation dimension estimates. There are several dimension measurements that are possible (Camastra, 2003). The correlation dimension is one of the simplest to calculate and is the most widely used dimension measurement in time series analysis. The correlation dimension is also related to the minimum number of variables needed to model the system's behavior in phase space.

The correlation dimension is a measure of the dimensionality of the space occupied by a set of points and is a type of fractal dimension because it allows non-integer values. Grassberger and Procaccia (1983a, 1983b) introduced the correlation dimension to characterize phase space filling properties of attractors. The set is covered by spheres of a given size r and the correlation dimension ν is defined by:

$$\nu = \lim_{r \rightarrow 0} \sum_i \frac{\log(\sum_i p_i(r)^2)}{\log r} \quad (9)$$

where $\sum_i p_i(r)^2$ is the probability of finding a pair of points in a sphere of size r . For small values of r , this probability is the same as the probability of finding a pair of points separated by less than r . This probability, for large data sets, is given by the correlation sum. For N points in an M -dimensional space, the correlation sum is given by

$$C(r) = \frac{2}{N(N-1)} \sum_{i=1}^N \sum_{j=1, j \neq i}^N H\left(r - |\vec{X}_i - \vec{X}_j|\right) \quad (10)$$

H is the heaviside function. Here, it counts the number of pairs of points which are separated by less than r . For sufficiently small r and large number of points N ,

$$C(r) \propto r^\nu \quad (11)$$

Taking logarithms of each side, we get:

$$\nu \sim \frac{\log(C(r))}{\log(r)} \quad (12)$$

ν is calculated from the slope of the straight line scaling region of a $\log(C(r))$ versus $\log(r)$ plot.

Results

The color histogram method was used to represent the images and the square root of the Jensen-Shannon divergence was used to calculate the similarity between pairs of images. $\log(C(r))$ was then recorded in a series of 1000 bins. The correlation dimension(s) ν is the slope $\frac{d \log(C(r))}{d \log(r)}$ of the linear portion(s) of the $\log(C(r))$ versus $\log(r)$ plot. The same procedure was repeated for the color correlogram representations using the relative L_1 distances to calculate similarity between images. Figure 4 shows the correlation dimension

plots for image data taken from 2 subjects. The left panel contains the results for the correlation dimension using the color histogram representation and the associated square root of the JS Divergence. The right panel contains the results using the color correlogram representation and the associated relative L_1 distance measure. Points close to zero have been discarded in the correlogram correlation dimension plots due to insufficient pairs of points in that region.

There are hints of a two scale structure in the histogram based correlation dimension plots but the correlogram based correlation dimension plots do not show this structure. More discussion follows in the next section.

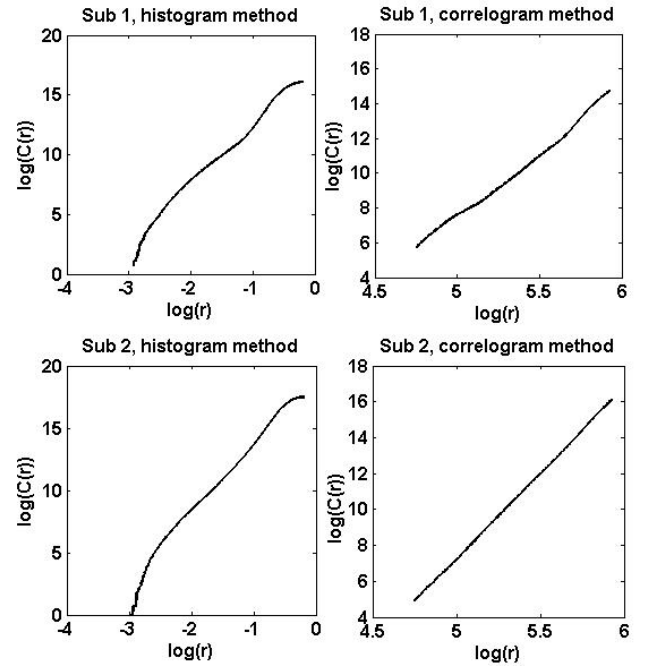

Figure 4: The correlation dimension plots for 2 subjects: The left panel is with the color histogram-JS div distance method and the right panel is with the correlogram-L1 distance method.

Conclusion and Discussion

Images were captured by subjects using a MicrosoftTM Research SenseCam. A correlation dimension analysis was done on images that were obtained from each subject. These images can be considered as representative of the visual input that goes into an individual's episodic memory. Distances between pairs of images represented by color histograms were calculated using the square root of the Jensen-Shannon divergence. Color histograms do not include spatial information. HSV autocorrelograms have been found to work better in image retrieval studies (Ojala, Rautiainen, Matinmikko, & Aittola, 2001). Spatial information in the images may be relevant here. For example, how do people recognize that two very different images in terms of color

content belong to the same episode? The distances calculated from the HSV histogram have given us sufficiently accurate nearest neighbour pairs as demonstrated in Figure 1 but the correlogram method and the associated L_1 distance measure was found to work better for our current purposes based on our definition of the common neighbor ratio. We conclude that the better method is the one that correctly identifies images that are close in time (within context) by classifying them as close in space based on the distance measure employed by the respective method.

A two scale structure was found in earlier studies on corpora of different languages (Doxas et al., 2010). The trajectory through a semantic space as one transitions from paragraph to paragraph in written discourse was shown to display a low dimensionality at short distances and higher at larger distances. This structure was observed in five corpora of written text in English, French, Modern Greek, Homeric Greek, and German respectively. The lower scale dimension of eight was observed to be approximately the same across languages. These structures suggest that there are strong constraints on the topology of the space through which authors move as they write and through which readers move as they read. The question now is if this is a constraint imposed by the cognitive system. This study is aimed at addressing this question. The images used represent the visual input that goes into a person's episodic experience, i.e., of the everyday events that one encounters (visually). The correlation dimension plots however don't reliably show a two scale structure here. Further exploration is necessary, however, to determine if the image representation meets all of the assumptions of the correlation dimension analysis as it has been used in this study. One such assumption is that the space has orthonormal basis vectors.

Abstract

The effects of orthographic neighborhood density and word frequency in visual word recognition were investigated using distributional analyses of response latencies in visual lexical decision. Main effects of density and frequency were observed in mean latencies. Distributional analyses, in addition, revealed a density \times frequency interaction: for low-frequency words, density effects were mediated predominantly by distributional shifting whereas for high-frequency words, density effects were absent except at the slower RTs, implicating distributional skewing. The present findings suggest that density effects in low-frequency words reflect processes involved in early lexical access, while the effects observed in high-frequency words reflect late postlexical checking processes.

Keywords: Orthographic neighborhood density; word frequency; visual lexical decision; distributional analyses

Introduction

Word frequency and orthographic neighborhood density effects are among the most influential findings in the visual word recognition literature. Researchers study word recognition using the lexical decision task (LDT) that requires lexicality discrimination and decision where subjects would classify stimuli as either words or nonwords, and the speeded pronunciation (word naming) task that involves lexical access but excludes the word/nonword discrimination and decision components of the LDT. During word naming, subjects would typically be tested individually and read the stimuli into a microphone (see Andrews, 1997).

Word frequency effects, where latencies for common words are faster than those that are relatively less common, have been observed in many LDT studies (see Balota & Chumbley, 1990 for a review). In visual word recognition, frequency effects have been attributed to changes in activation thresholds or baselines. The logogen-style activation framework was inaugurated by Morton (1969), which assumes that information extracted from the sensory representation of the word leads to parallel activation of all word units that match that information. When sufficient activation has accumulated in a particular word unit, it reaches threshold and lexical access occurs. Morton's (1969) initial model was later specified in greater detail by McClelland and Rumelhart (1981). Their model, which they called the interactive activation model, suggests that activation occurs at three levels. Activation of featural units feeds to units corresponding to letters, which in turn activate

the units for words containing these letters. Activity also feeds back from the word to the letter level, causing reverberating patterns of activity to occur between these levels. To ensure that only one word unit eventually obtains threshold, McClelland and Rumelhart (1981) also assume that inhibition occurs between word units, so that the activity level of competing word units is reduced relative to the maximally active node. Within the activation framework, word frequency is assumed to be reflected in the threshold (Morton, 1969) or resting activation level (McClelland & Rumelhart, 1981) associated with a particular word unit. The critical interpretation is that less evidence is required to enable recognition of a high-, than a low-, frequency word.

The findings for orthographic neighborhood density effects (*N*), on the other hand, appear to be more mixed. The *N* metric has been defined by Coltheart, Davelaar, Jonasson, and Besner (1977) as the number of close neighbors a word has and refers to the number of words that can be created by changing a single letter of this target word. For instance, *tell* has many neighbors such as *well*, *yell*, *sell*, *teal* and *tall*, while *once* has no neighbors. Neighborhood effects can help specify the mechanisms underlying lexical access. The implication of the overlap in the features constituting different words is that any subset of the features constituting a particular word is unlikely to uniquely specify its corresponding lexical representation. Neighbors are items that are highly confusable with the target word, in the sense that they share a large number of their features with the target. Thus, it seems inevitable that some or all of the neighbors of a target word will be selected by the access mechanisms as eligible target candidates.

Effects of *N* can be accommodated within activation-based models of lexical access, and appear to provide substantive support for an activation mechanism. If presenting a word leads to an activation of all lexical items that sufficiently match features of the target word, the density of the word's neighborhood should influence access time. Unfortunately, this class of models does not make precise predictions about the nature of the effect of neighborhood density. McClelland and Rumelhart's (1981) interactive activation model, for instance, assumes excitatory links between levels which can account for facilitatory effects of neighborhood size. Activated neighbors will feed back to their constituent letters which in turn lead to heightened activation of word units containing these letters. According to McClelland and Rumelhart

(1981), such facilitatory effects of N are likely to be greater for low- than high-frequency words. The reason is that high-frequency words have higher base activation levels and are therefore likely to reach threshold before allowing reverberating letter-level activation from neighboring word units to become influential.

Yet, the same model can also predict inhibitory effects of neighborhood size because of its assumption of lateral inhibition between word nodes. Active nodes send inhibition to other active nodes to an extent that is proportional to their current activation. If the unit corresponding to the target word becomes activated before other units, this inhibitory mechanism would decrease background activation and make the target more salient. On the other hand, if nodes corresponding to neighbors obtained activation before the target word, these activated competitors would inhibit activation of the target and delay threshold activation. The more neighbors a word has, the greater the likelihood that the target unit would fall prey to this inhibitory mechanism, resulting in interfering effects of large neighborhoods. Thus, depending on the relative contribution to performance of excitatory activation between letter and word levels, as well as inhibitory activation within the lexical level, the interactive activation model can explain facilitatory, inhibitory, or null effects of neighborhood size.

Using the visual LDT paradigm, Coltheart et al. (1977) first observed that low-N nonwords were classified more quickly than high-N nonwords, but that N did not influence performance for English words. The researchers interpreted their data using Morton's (1969) logogen-style activation framework, in which the strength of activation in individual logogens is determined by sensory input and is insensitive to activity in other logogens. The researchers then attributed N effects on nonword classification to a decision mechanism that is sensitive to the overall lexical activation. Subsequently, Andrews (1989) reported that N actually influenced responses to English words in the LDT when the words were selected to orthogonally manipulate N and word frequency. Specifically, it was reported that high N facilitated performance for words, but only for the 4-letter low-frequency words. These facilitatory effects of N, which are not incompatible with McClelland and Rumelhart's (1981) interactive activation model, were later replicated in several other experiments (e.g., Sears, Hino, & Lupker, 1995; Michie, Coltheart, Langdon, & Haller, 1994; Andrews, 1992). However, Grainger, O'Regan, Jacobs, and Segui (1989) concurrently found no systematic relationship to exist between N and performance in the LDT; lexical decision latencies were not affected by the number of neighbors *per se*.

Traditionally, visual lexical decision studies that examined neighborhood effects have used mean RT differences among the experimental conditions to make inferences about the mechanisms underlying the recognition process. The implicit assumption that the researchers would have made is that RT distributions across conditions are

symmetrical, where the mean constitutes a reasonably good estimate of the central tendency of these distributions. But RT distributions are in fact rarely symmetrical around a mean. They typically assume a positively skewed unimodal shape which contains information that cannot be derived from the mean and variance of the distributions. For instance, mean RT differences, or the lack thereof, between conditions can be due to changes in the shape (skew) of the distribution in itself or in addition to a shift in the modal portion of the distribution. By relying on a traditional RT analysis that uses mean RTs as the dependent variable (DV) to interpret LDT performance, one can, in some instances, fail to recognize the tradeoff between the effects of shifting and skewing, and be misled to incorrectly infer null results (Heathcote, Popiel, & Mewhort, 1991). Recognizing the problems concerned with the traditional RT analysis approach, several researchers have argued that the nature of the RT distributions ought to be scrutinized more closely (e.g., Balota, Yap, Cortese, & Watson, 2008; Heathcote et al., 1991).

Two distributional analyses techniques were used in the present study, namely the ex-Gaussian and Vincentile analyses. Shifting and skewing in the RT distributions were investigated using the ex-Gaussian function. The procedure was to fit an empirical RT distribution to this theoretical function that captures important aspects of typical RT distributions. The ex-Gaussian function conceptualizes RT distributions as the convolution of two underlying distributions: a Gaussian distribution and an exponential distribution. The mean and standard deviation of the Gaussian component are captured by the μ and τ parameters, while the exponential function is captured by the σ parameter that reflects its mean and standard deviation. An important property of the ex-Gaussian function is that the mean of the RT distribution is constrained to be the algebraic sum of the μ and τ parameters obtained by fitting that distribution. This constraint allows one to partition mean differences into individual components due to distributional shifting (μ) and skewing (τ), and then make inferences from these components to determine the nature of the effect of an independent variable (IV) (see Balota et al., 2008).

Parameter estimates from the ex-Gaussian function were supplemented by analyses of Vincentiles to enable a graphical, non-parametric estimate of the variable's effect. In these analyses, the RTs are ordered, from fastest to slowest, within each condition, and the average of the first 10%, that of the second 10%, and so forth, are plotted. The mean of the Vincentiles across participants can then be plotted to obtain a description of how the RT distribution is changing across conditions. Importantly, differences between two levels of an IV across Vincentiles can be graphically represented to reveal how the effect of an IV may change across different portions in the RT distribution.

This study had two goals. The first was to replicate the N effects in the visual LDT in the light of the initial contradictory reports (see Grainger et al., 1989; Andrews,

1992, 1989; Coltheart et al., 1977). The present hypothesis was that facilitatory effects of density would be observed, but only for low-frequency words (see Sears et al., 1995; Michie et al., 1994, Andrews, 1992, 1989). The second, and more important, was to extend the ex-Gaussian and Vincentile analyses techniques to the orthographic neighborhood density and word frequency effects found in the extant visual lexical decision studies, and to explore the extent to which these two effects are driven by distributional shifting and skewing.

Method

Participants

Fifty-seven introductory psychology undergraduates with no reported history of speech or hearing impairment participated for course credit. Their mean vocabulary age of the Shipley Test was 18.09 ($SD = 1.06$).

Design and Materials

A 2 (Neighborhood Density: low, high) x 2 (Word Frequency: low, high) within-subjects design was used. Forty 4-letter English words were selected for each of the four conditions, and their properties are summarized in Table 1. Two-way analyses of variances (ANOVAs) showed a main effect of frequency, $F(1, 156) = 19826.68$, $MSe = 0.67$, $p < .001$, for the log-frequency values ($M = 6.58$, $SD = 0.53$ for low-frequency words and $M = 11.67$, $SD = 1.02$ for high-frequency words), and a main effect of density, $F(1, 156) = 1827.88$, $MSe = 2.10$, $p < .001$ for the density values ($M = 3.35$, $SD = 1.38$ for low-density words and $M = 13.14$, $SD = 1.50$ for high-density words). No other effects were significant, $F_s < 1$. The 160 legal non-words used were obtained from the ARC non-word database (Rastle, Harrington, & Coltheart, 2002) and were matched against the 160 words in terms of length and density.

Procedure

Participants were tested on individual PCs in groups of seven or fewer. E-prime 1.2 and the PST Serial Response

Box (Schneider, Eschman, & Zuccolotto, 2002) were used for stimuli presentation and data collection. Participants were instructed to indicate as quickly and as accurately as possible whether the visual token presented on each trial was a real English word (or a non-word). The left- and right-most buttons of the button-box were labeled *No* and *Yes* respectively. On each trial, a fixation cross appeared and remained on the screen for 500ms, and terminated for 200ms before the target word appeared. RT was measured from the onset of the target stimulus to the button-press. Accuracy feedback was provided for each trial. A practice set of 20 trials for task familiarization was given, using stimuli unrelated to the experiment. The 320 experimental trials were then presented in a random order for each participant, with a short self-paced break after every set of 80 trials was completed.

Table 1: Mean Density and Log-frequency of the Words in the Neighborhood Density and Word Frequency Conditions.

Conditions	Density		Log-frequency	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
Low-frequency				
Low-density	3.33	1.33	6.61	0.54
High-density	13.05	1.95	6.56	0.52
High-frequency				
Low-density	3.38	1.44	11.67	1.23
High-density	13.23	0.86	11.67	0.78

Results

Errors and latencies faster than 200 ms or slower than 3000 ms were first excluded, and the overall word and non-word means and SDs for each participant were computed across all conditions. Following which, latencies exceeding 2.5 SDs from the participant mean, as well as items where proportion of correct responses was not at least 0.5, were removed. Table 2 summarizes the results obtained from mean latencies, accuracy, and the ex-Gaussian parameters. Two way ANOVAs by participants and items were

Table 2: Mean Latency, Accuracy, and Ex-Gaussian Parameter Estimates Across Neighborhood Density and Word Frequency

Conditions	Latency	Accuracy	Mu	Sigma	Tau
Low-frequency					
Low-density	679 (123)	87 (11)	535 (79)	59 (38)	147 (89)
High-density	662 (127)	88 (8)	509 (74)	54 (37)	157 (84)
Density effect	17	-1	26	5	-10
High-frequency					
Low-density	554 (90)	98 (2)	444 (45)	35 (14)	112 (62)
High-density	546 (83)	99 (1)	442 (47)	38 (16)	105 (54)
Density effect	8	-1	2	-3	7
Interaction	9	0	24	8	-17
Non-words	692 (144)	94 (4)	542 (68)	58 (23)	152 (90)

performed for latencies and accuracy, and by participants for the ex-Gaussian parameters.

Latency

For latency, reliable main effects of density, $F_p(1, 54) = 11.51$, $MSe = 790.68$, $p < .01$, and frequency, $F_p(1, 54) = 222.87$, $MSe = 3600.78$, $p < .001$, were obtained for the analyses by participants. Participants were faster in responding to high-density words ($M = 604$, $SD = 102$) than to low-density words ($M = 617$, $SD = 104$); they were also faster in responding to high-frequency words ($M = 550$, $SD = 83$) than to low-frequency words ($M = 671$, $SD = 123$). For the analyses by items, a reliable main effect of frequency was obtained, $F_i(1, 153) = 299.53$, $MSe = 1981.84$, $p < .001$. High-frequency words yielded a shorter response time ($M = 551$, $SD = 30$) as compared to low-frequency words ($M = 674$, $SD = 56$). No other effects were significant, $F_s < 2.01$, $MSes < 1982.84$, $ps > .1$.

Accuracy

For accuracy, there was a reliable main effect of frequency, $F_p(1, 54) = 90.97$, $MSe = 0.007$, $p < .001$ for the analyses by participants; the main effect of density was marginally significant, $F_p(1, 54) = 3.53$, $MSe = 0.001$, $p = .066$. Participants were more accurate with high-frequency words ($M = 98$, $SD = 0.01$) than with low-frequency words ($M = 88$, $SD = 0.09$); they also tended to be more accurate with high-density words ($M = 93$, $SD = 0.04$) than with low-density words ($M = 92$, $SD = 0.06$). For the analyses by items, a reliable main effect of frequency was obtained, $F_i(1, 153) = 55.86$, $MSe = 0.008$, $p < .001$. High-frequency words yielded a higher accuracy rate ($M = 98$, $SD = 4$) as compared to low-frequency words ($M = 88$, $SD = 12$). No other effects were significant, $F_s < 1.16$, $MSes < .008$, $ps > .1$.

Mu

Turning to the ex-Gaussian parameters, for mu, there were reliable main effects of density, $F(1, 54) = 18.61$, $MSe = 589.63$, $p < .001$, and frequency, $F(1, 53) = 160.02$, $MSe = 2151.95$, $p < .001$. These main effects were qualified by the significant interaction, $F(1, 53) = 12.00$, $MSe = 726.81$, $p < .01$. Simple main effects analyses at each level of the frequency factor revealed that for low-frequency words, mu was larger for low-density words compared to high-density words, $F(1, 54) = 16.56$, $MSe = 1185.71$, $p < .001$, but there was no density difference for high-frequency words, $F < 1$. This finding implicates a shift in the modal portion of the RT distribution as a function of density, but only for low-frequency words.

Sigma

For sigma, a significant main effect of frequency was obtained, $F(1, 54) = 25.75$, $MSe = 890.57$, $p < .001$. Sigma was larger for low-frequency ($M = 57$, $SD = 29$) than high-frequency ($M = 36$, $SD = 13$) words. No other effects were significant, $F_s < 1.32$, $MSes < 645.75$, $ps > .1$.

Tau

For tau, a significant main effect was obtained for frequency, $F(1, 54) = 37.25$, $MSe = 2834.02$, $p < .001$, but

not for density, $F < 1$. The main effect of frequency appears to be qualified by the marginally significant interaction, $F(1, 54) = 3.21$, $MSe = 1417.98$, $p = .079$. Follow-up analyses indicated that tau tends to be smaller for low-density words compared to high-density words for low-frequency words, but it tends to be larger for low-density words compared to high-density words for high-frequency words. More important, a cross examination of the tau data, with the mu data, revealed that the small density effect observed for the high-frequency word condition appears to be attributable to distributional skewing, rather than distributional shifting.

Recall that one important constraint of the ex-Gaussian analyses is that the mean of the RT distribution is the algebraic sum of mu and tau. In the traditional mean latency analyses, only reliable main effects of frequency and density were obtained; there was no reliable frequency \times density interaction. Analyses of the ex-Gaussian parameters provide important observations that constitute a more faithful account of the apparent lack of interaction between the factors; the tradeoff between the mu and tau parameters accounts for why the mean interaction effect was very small (see Table 2). First, analyses of the mu parameter as a function of density suggest that there is distributional shifting only for the low-frequency words but not for the high-frequency words. This finding strongly suggests that the density effect observed for low-frequency words in the traditional mean latency analyses is predominantly mediated by distributional shifting. Second, analyses of the tau parameter, in conjunction with the mu parameter, strongly suggest that the small density effect observed for high-frequency words in the traditional mean latency analyses is, on the other hand, largely mediated by distributional skewing.

To corroborate this interpretation, vincentile analyses were performed on the RT data. Figure 1 shows the mean vincentiles across the different experimental conditions. The lines represent the estimated vincentiles of the best-fitting ex-Gaussian distribution. This graphical representation allows a visual assessment of the goodness-of-fit between the empirical and estimated vincentiles.

From the top panel, it is clear that the density effect is observed for the low-frequency words across all vincentiles. The high-density means are always below the low-density means in each of the vincentiles. In the middle panel, the density effect is only apparent at the later vincentiles. The differential density effects can be seen more clearly in the bottom panel, which plots the difference scores between the low- and high-density means for each of the low- and high-frequency conditions. It can be observed that the density effect generally remains stable across vincentiles for the low-frequency words, indicating that the difference between low- and high-density words remains fairly constant as RT increases. This trend implicates distributional shifting *per se*. However, for high-frequency words, the density effect increases only in the slower RTs. This trend implicates distributional skewing *per se*.

Figure 1: Vincentiles of lexical decision performance. The participants' mean vincentiles are represented across different conditions. The lines represent the estimated vincentiles of the best-fitting ex-Gaussian distribution. The top and middle panels show performance as a function of density in the low- and high-frequency conditions respectively, while the bottom panel shows the density effect.

Discussion

RT distributional analyses of orthographic neighborhood density and word frequency effects in visual lexical decision have not been done in previous studies examining neighborhood effects, which relied on *mean* RTs as the primary DV. The findings in the present study can be summarized as follows.

First, facilitatory effects of frequency, where high-frequency words elicited faster RTs than low-frequency words did, and of density, where words from high-density neighborhoods elicited faster RTs than words from low-density neighborhoods did, were obtained.

Second, and more important, the distributional analyses revealed a density \times frequency interaction which was primarily attributable to differential shifting and skewing of the latency distribution between low- and high-density words as a function of frequency. For low-frequency words, the density effect obtained, replicating Andrews' (1992, 1989) finding, and the effect was predominantly mediated by distributional shifting; for high-frequency words, the small density effect observed was primarily mediated by distributional skewing.

A shift in the RT distribution as a function of density for low-frequency words is compatible with existing accounts which assume that lexical access relies upon an activation mechanism. Such an activation mechanism, which postulates top-down feedback from word to letter nodes, characterizes McClelland and Rumelhart's (1981) interactive activation model¹ which assumes parallel activation of both lexical units and units that correspond to sublexical components, such as letters. First, the assumption must hold that excitatory activation between lexical and sublexical units is not cancelled out by lateral inhibition at the lexical level. Then, the partial activation of neighbors can increase the activation of sublexical components of the target, and consequently accelerate access to the target representation.

To explain the present data within such an activation mechanism framework, one must specify why the neighborhood effects arising from such sublexical/lexical interactions would affect only responses to low-frequency words. Frequency effects have mainly been attributed to differences in the resting activation level of lexical units within the original logogen (Morton, 1969) as well as the interactive activation (McClelland & Rumelhart, 1981) accounts. A functionally equivalent assumption appears to characterize distributed memory models (McClelland & Rumelhart, 1985) that assume that frequency determines how rapidly a lexical unit reaches a threshold level of activation. The present interaction between frequency and neighborhood size implicates that sublexical units play a greater role in the recognition of low-, rather than high-, frequency words; high-frequency words obtain threshold sufficiently quickly through direct activation of lexical

¹ Although activation models, such as McClelland and Rumelhart's (1981), can accommodate the present data, one must recall that whether the net effect of neighborhood size is facilitatory or inhibitory depends, within this framework, on the relative values of the parameters governing letter-word excitation, word-word inhibition, and the base activation level associated with word frequency. In a sense, rather than regarding the present data as supporting the model *per se*, it might be more appropriate to regard the data as providing evidence that constrains the future specification of activation models.

units, such that they are not influenced by the reverberating sublexical activation arising from active neighbors.

The increase in response time as a function of density for low-frequency words observed in the present study appears to be additive in nature, reflected by the distributional shift. Such a shift effect has been argued by Balota and Spieler (1999) to indicate early automatic processes, rather than later analytical or more attention-demanding processing. That density effects for low-frequency words are predominantly mediated by distributional shifting reflect processes involved in early lexical access, and not late postlexical processes which may also be involved in the LDT.

On the other hand, for high-frequency words, it appears that density effects are absent except at the slower end of the distribution, which are reflected in slightly greater skewing for low-density words. Recall that under the activation framework (e.g., McClelland & Rumelhart, 1985), high-frequency words obtain threshold sufficiently quickly through direct activation of lexical units, such that lexical access need not be facilitated by the reverberating sublexical activation arising from activated neighbors. The tau parameter revealed, for high-frequency words, some difference in RTs comparing low- with high-N words. It appears that high-frequency words with small neighborhoods would have received little facilitation from their active neighbors to aid lexicality decision of the target, as compared to those with big neighborhoods. Where facilitatory effects of N were lacking, compensatory postlexical checks could tend to be adopted, resulting in slightly longer RTs for low-N words. The emergence of density effects at the tail end of the distribution may therefore reflect, particularly for the low-N words, late postlexical checking processes that are specific to the lexical decision task (see Balota & Chumbley, 1984), rather than early lexical access processes.

Conclusion

The present study extends previous work on distributional analyses and underscores the contribution of these techniques in illuminating the interaction between orthographic neighborhood density and word frequency effects in a visual LDT. The new understanding is that the effects of density as a function of frequency are represented differentially in the shift and skew of the underlying RT distributions.

Abstract

This paper addresses the question of the domain-specificity of learning biases for phonological processes. In two artificial grammar learning experiments we explore the role of learning biases in shaping the distribution of phonological patterns across the world's languages. In Experiment 1, we demonstrate that learners are biased toward phonological patterns that occur in natural language, as opposed to patterns that are not found across the world's languages. Specifically, learners are biased towards directional vowel harmony spreading processes. In Experiment 2, we exposed learners to a non-linguistic analogue to vowel harmony. Learners processed spreading such that learners favored the cross-linguistically valid pattern only when the first item of the series underwent spreading. This set of similarities and differences in learning may provide some insight into the origin of learning biases for spoken languages.

Keywords: artificial grammar learning; phonology.

Introduction

The experiments presented in this paper address the hypothesis that typological restrictions on languages are due to learning biases (Slobin, 1973). Specifically, we address the distribution of vowel harmony across the world's languages. Vowel harmony is a phonological process that induces statistical tendencies for words to share the same vowel quality along a particular phonetic dimension. In Turkish, which displays harmony for both backness and rounding, if the first vowel of the word is front and unround (with some exceptions), all following vowels must be both front and unround as well (Clements & Sezer, 1982). Thus, Turkish vowel harmony may be thought of as a directional spreading process in which the leftmost vowel spreads its feature (round, back) to the right.

Vowel harmony languages exhibit both left-to-right and right-to-left spreading characteristics. The direction of spreading can be decided by the morphology of the language (stems are more likely to spread harmony than affixes (Bakovic, 2000)) as well as the characteristics of the input vowels (spreading [+Round] is more likely than spreading [-Round] (Korn, 1969)). The direction of spreading can also be set such that spreading always occurs from right to left or from left to right. One way in which the direction of spreading is never decided is by the number of changes from the input to the output of the phonological process. For example, consider the disharmonic input

/- + +/. There are two possible harmonic outputs: [- - -], which changes the feature value of two of the input vowels, and [+++] which changes only one of the vowels in the input. A left-to-right spreading language chooses [- - -] even though two vowels change. Another possibility is to have no intrinsic direction of spreading, but to choose the harmonic output with the fewest changes from the input (in this case [+++]). This type of spreading is termed 'majority rules' because the direction of spreading is determined by the majority feature value of the input (Bakovic, 2000). One peculiarity is that while languages never use 'majority rules' to determine the direction of spreading, 'majority rules' grammars are extremely easy to produce in generative phonology¹. Generative linguistics assumes that the non-existence of patterns in natural language implies that they should not be generated by the grammar. However, it is possible that the lack of 'majority rules' grammars is due to an accidental gap. Under this assumption, 'majority rules' patterns are grammatically plausible, but the lack of such languages is an accident of history and language sampling.

One way of distinguishing between a principled restriction on the nature of vowel harmony languages and an accidental gap account is through testing for learning biases. If learners are biased against 'majority rules' languages and biased towards a directional harmony pattern, it suggests that the non-existence of 'majority rules' languages is a valid restriction on grammar. Because it is impossible to test learning biases for unattested languages in a naturalistic setting, as there are no naturalistic settings where a 'majority rules' grammar might be present, the artificial grammar learning paradigm is the best method for addressing this question. In an artificial grammar learning paradigm, it is possible to manipulate naturalness, complexity and statistical regularities in a way that is impossible with naturalistic studies of language learning.

The present experiments test whether learners make use of the 'majority rules' strategy when making grammaticality judgments between harmonic items. We present an experimental paradigm in which learners are exposed to a harmony language that is ambiguous between directionality and 'majority rules'. If learners are biased towards directional patterns and against 'majority rules' patterns,

¹ In 'majority rules' grammars, "ties" (e.g., two round and two unround vowels) are decided by a default strategy (lower-ranked constraint).

they should infer a directional pattern given data ambiguous between ‘majority rules’ and directionality. By pitting ‘majority rules’ and directional spreading against each other, it will be possible to determine what kind of pattern learners inferred. One reason testing for biases towards directionality and against ‘majority rules’ (as opposed to direct learnability) is that unnatural patterns may be learned by a language learner given the proper cues (Anderson, 1981). Further, even if ‘majority rules’ grammars are learnable, it still could be that learners are simply biased against ‘majority rules’ given the fact that much of their learning data will be ambiguous between other types of harmony (e.g., directional spreading). The present experiments capitalize on this hypothesis by exposing learners to language data that is ambiguous between ‘majority rules’ and a directional pattern.

Experiment 1

Participants were exposed either to a left-to-right harmony pattern or a right-to-left harmony pattern in which the majority of the vowels in the input spread. If participants learn a ‘majority rules’ pattern, they will reverse the direction of spreading when the majority feature reverses, but if participants learn a directional pattern, they will be consistent with the direction of spreading.

Methods

Participants All participants were adult native English speakers with no knowledge of a vowel harmony language. Twenty-four Johns Hopkins undergraduate students participated for extra course credit. Participants were randomly assigned to one of three training conditions: Control, Right-to-Left and Left-to-Right.

Design Because ‘majority rules’ patterns involves choosing the direction of spreading based on the proportion vowels with a particular feature in the input, it is necessary to provide clear evidence that the vowel harmony process involves a change from input to output. Because inputs to grammatical processes are abstract and not available on the surface, we trained participants on a compounding process where the underlying forms are available as separate lexical entries. Participants were exposed to base forms (the inputs) in addition to their concatenation as a compound (participants in the Control condition were exposed to input forms only). Training consisted of three single syllable forms in isolation, followed by their harmonic concatenations. The harmony rule paired back/round vowels together such that a harmonic trisyllabic item contained all front vowels ([i, e]) or all back vowels ([u, o]). The three individual syllables were disharmonic such that their faithful concatenation would be disharmonic. The concatenated form always followed ‘majority rules’, in one particular direction. Participants in the critical conditions were trained on either right-to-left harmony (Right-to-Left condition) or left-to-right harmony (Left-to-Right condition). All items were ambiguous between directionality

and ‘majority rules’. In the Left-to-Right condition [pu], [gu], [de] is concatenated as [pugudo], where the final vowel changes to [+Round] to match the feature values of the first two vowels (e.g., [+] [+] [-] → [+ + +]). In the Right-to-Left condition [pi], [gu], [do] is concatenated as [pugudo] ([-] [+] [+] → [+ + +]). There was a 500ms pause between the trisyllabic forms and the concatenated form. There were 24 alternations of monosyllabic words and their harmonic trisyllabic concatenations. All training items involved a single change from the input to the output.

The compounding procedure is similar to the triad procedure used to study phonological processes in infants (Jusczyk, Smolensky, & Alallo, 2002) in which the infants are given two forms followed by their concatenation. While there is some concern that learners do not infer a phonological process in this paradigm, adapting this paradigm to adults makes it possible to alleviate some of these concerns. First, participants were specifically informed that the trisyllabic item was the ‘combined form’ of the first three monosyllabic items. Second, the forced-choice task (described below) makes it possible to test for preference for left-to-right versus right-to-left spreading.

Table 1: Training Items for Experiment 1

Left-to-Right	Right-to-Left
bo du ti bodutu	be du tu bodutu
gi te ko giteke	gu te ke giteke
mo bo di mobodu	me bo nu mobonu
pi ke to pikete	pu te ne pitene

All stimuli were recorded in a sound proof booth at 22,000kHz by a male speaker of American English with basic phonetic training (had completed a graduate-level phonetics course). While the speaker had no knowledge of the specifics of the experimental design, he was aware that the items would be used in an artificial language learning task. All stimuli were phonetically transcribed, and presented to the speaker in written format. The speaker was instructed to produce all vowels as clearly and accurately as possible, even in unstressed positions. Stress of the concatenated forms was produced on the initial syllable. All sound editing was done using Praat (Boersma & Weenink, 2005). All stimuli contained the same consonant inventory: [p, b, t, d, k, g, m, n]. The vowel inventory for all conditions consisted of [i, u, e, o]. The training stimuli were counterbalanced to contain all possible combinations of vowel sounds. Consonants were also counterbalanced such all consonants appeared equally often in each position. Concatenated words were produced semi-randomly with the condition that any word too closely resembling an English word was intentionally avoided (the final profile of the stimuli contained consistent numbers of vowel and consonant pairs).

Following training, participants were given a two-alternative forced-choice task. In this task participants were

given two pairs of three-syllable items. The first member of each pair was the disharmonic form, and the second member was a harmonic form with either spreading from right-to-left or left-to-right (e.g., [pi] [de] [go] [pudogo] vs. [pi] [de] [go] [pidege]). Participants were asked to choose which pair was the one that best fit the language they were trained on. At test, the critical items are reversed such that spreading the majority feature value requires spreading in the opposite direction. If learners infer a directional pattern, then they will accept multiple items undergoing harmony from the input to the output. If learners infer a ‘majority rules’ pattern, they will reverse the direction of spreading. Test items included 12 Old Items, 12 New Items and 12 New Direction Items. Old and New items have the majority feature reflect direction of spreading that the participant was trained on, but the New Direction items reflect a reversal of the direction that the participants were trained on. Examples of test items appear in Table 2.

Table 2: Examples of Test Items
(‘majority rules’ Items **bold**, Directional Items underlined)

	Left-to-Right	Right-to-Left
Old	de mi ku demiki vs. de mi ku domuku	pu mi te pumuto pu mi te pimite
New	nu pu ki nupuku nu pu ki nipiki	nu pi ki nupuku nu pi ki nipiki
New Direction	pu mi te <u>pumuto</u> pu mi te pimite	de mi ku demiki de mi ku <u>domuku</u>

Procedure All phases of the experiment were run using Pyscope X (Cohen, MacWhinney, Flatt, & Provost, 1993). All participants were given written and verbal instructions. They were told that they would be listening to a language they had never heard before, and that they would later be asked about the language, but they need not try to memorize any forms they heard. They were told that the language would be presented in terms of three single syllable items followed by their combined form. This was done to ensure that participants inferred that the monosyllabic items were in fact the input to the harmonic concatenation. Participants heard all 24 concatenated forms in a random order, repeated 5 times. No information about vowel harmony was given. No semantics accompanied the sound pairs.

Training was followed by a forced-choice test phase in which participants heard the three mono-syllabic inputs followed by a choice of harmonic concatenations: all round or all unround. If the first concatenation of the syllables belonged to the language, they must push the ‘a’ key on the keyboard; if the second concatenation of the syllables belonged to the language, they must press the ‘l’ key on the keyboard. Participants were told to respond as quickly and accurately as possible.

Results

Proportions of ‘majority rules’ responses were recorded for each participant, shown in Figure 1. If participants learned a

‘majority rules’ pattern, this proportion should remain high for all test items. However, if participants learned a directional pattern, proportion of ‘majority rules’ responses should be above chance for Old and New test items, but below chance for New Direction Items.

Figure 1: Experiment 1 Results

A 2 (Training) x 3 (Test Condition) mixed-design ANOVA compared each critical condition with the Control condition. There was a significant overall effect of Training for the Left-to-Right condition ($F(1, 14) = 8.90, p < 0.05$). There was an effect of Test Item ($F(2, 28) = 5.70, p < 0.01$), reflecting greater proportions of ‘majority rules’ responses in the performance in the Old ($F(1, 14) = 9.67, p < 0.01$) and New Test Items ($F(1, 14) = 4.95, p < 0.05$) compared to the New Direction Test Items. There was a significant interaction ($F(2, 28) = 9.78, p < 0.01$), reflecting the fact that there were more ‘majority rules’ responses for Old Items ($t(14) = 5.29, p < 0.001$) but a trend of fewer ‘majority rules’ responses in for New Direction Items ($t(14) = 2.11, p = 0.073$).

There was also a significant overall effect of Training for the Right-to-Left condition ($F(1, 14) = 5.72, p < 0.05$). There was an effect of Test Item ($F(2, 28) = 5.04, p < 0.05$), reflecting greater proportions of ‘majority rules’ responses in the performance in the Old ($F(1, 14) = 11.24, p < 0.01$) compared to the New Direction Test Items. There was a significant interaction ($F(2, 28) = 7.87, p < 0.01$), reflecting the fact that there were more ‘majority rules’ responses in the Right-to-Left condition for Old Items ($t(14) = 7.43, p < 0.001$) but a trend of fewer ‘majority rules’ responses for New Direction Items ($t(14) = 2.11, p = 0.053$).

To test whether participants inferred a directional rule versus a ‘majority rules’ pattern, we performed contrasts comparing the New Direction test condition to the Old and New items respectively. In the Left-to-Right Condition, there was a significant difference between the New Direction and both the Old ($F(1, 7) = 17.07, p < 0.01$) and New ($F(1, 7) = 10.13, p < 0.05$) test items. The Right-to-Left condition also showed a significant difference between New Direction and Old items ($F(1, 7) = 17.49, p < 0.01$) and a marginally significant difference between the New Items ($F(1, 7) = 5.20, p < 0.08$) test conditions. The fact that

participants chose the ‘majority rules’ items significantly less often in the New Direction test condition (compared to Old and New items) suggests that learners inferred a directional pattern rather than a ‘majority rules’ pattern, reflecting a bias against ‘majority rules’².

Among the 16 participants in the Experiment 1, only three chose the ‘majority rules’ item in the New Direction Condition greater than 60% of the time, while three chose the ‘majority rules’ item 50% of the time, and nine chose the ‘majority rules’ item less than 50% of the time.

Discussion

The results of Experiment 1 suggest that participants inferred a directional harmony pattern over a ‘majority rules’ harmony pattern. When learners were exposed to a spreading process that was ambiguous between a ‘majority rules’ pattern and a directional spreading pattern, learners inferred a directional pattern. This suggests that the non-existence of ‘majority rules’ spreading processes across the world’s languages is in part due to learning biases. Learners do not postulate ‘majority rules’ languages because they are biased towards directional spreading processes.

However, it is unclear whether this bias is shaped by language-specific constraints or more general cognitive principles, such as attention and memory. Learners may not infer ‘majority rules’ because such languages require the language user to keep track of the number of vowels of a particular feature value in the input, inducing a greater memory load. Further, there may be a bias in favor of directional patterns, which are in line with attentional biases. For example, in a left-to-right language, it is fully predictable which vowel triggers harmony (the left-most vowel) and which vowels undergo harmony (the right-most vowels). Learners may be biased to infer a directional pattern, given that the consistent cues for harmony are found at the attention-heavy locations in the word (Beckman, 1998). Additionally, ‘majority rules’ patterns require the learner to keep track of a wider range of conditioning factors: how many vowels of each feature value are in the input, and which direction of spreading to use when there is a tie. A ‘majority rules’ pattern may require more episodic memory because several different situations in the input induce very different results. For example, two round vowels and one unround vowel will yield round vowels, but three round vowels and four unround vowels will yield unround vowels. While complicated phonological patterns are not uncommon cross-linguistically, if a learner has to decide between a simpler directional pattern and a complicated ‘majority rules’ pattern, they should choose the directional pattern.

One way to determine whether the directionality preference is due to non-linguistic factors against ‘majority rules’ is to replicate Experiment 1 with non-linguistic

stimuli. If learners of a non-linguistic pattern follow the same constraints on ‘majority rules’, then it is likely that the bias found in these experiments is due to non-linguistic factors, but if no bias is found in non-linguistic stimuli, it suggests that there is something about the linguistic nature of harmony that biases learners towards directional spreading. Experiment 2 addresses this question with a visual analogue of Experiment 1.

Experiment 2

Experiment 2 addresses whether the bias against a ‘majority rules’ found in Experiment 1 may be reflected in a non-linguistic version of the vowel harmony learning task.

Methods

Participants All participants were adult native English speakers with no knowledge of a vowel harmony language, and did not participate in Experiment 1. Twenty-seven University of Rochester undergraduates participated for \$10. Participants were randomly assigned to one of three training conditions: Control, Right-to-Left and Left-to-Right.

Design The optimal way to test for the effects of non-linguistic constraints on pattern learning is to design a pattern that makes use of known categories, but does not make use of any linguistic strategies. For this reason, a visual learning pattern using colors and shapes is optimal. First, shapes and colors are categories that are readily available to the adult learner, making it possible for the participant to infer a spreading pattern based on the experimenter-defined parameters. Second, the visual stimuli are completely outside the range of linguistic input to the learner, making the pattern learning task as non-linguistic as possible. While non-linguistic auditory stimuli present a closer match to the language learning task, there are two potential problems with such a design. First, standard non-linguistic auditory pattern learning makes use of tones or uncommon sounds that are not clearly defined categories. Thus, it is not clear whether learners of a tone-spreading pattern would make use of the same experimenter-defined categories. The visual stimuli that were chosen for this experiment have definitive categories: shapes (circles and squares) and colors (red, green, blue, yellow). In the present experiment, squares and circles of various colors assimilated based on a spread-right pattern or a spread-left pattern. Second, non-linguistic auditory pattern learning may invoke linguistic strategies to learning (e.g., acoustic properties of the sounds), and therefore may not directly address the questions posed in the present experiment.

It is important to note that the directional labels (left-to-right) are figurative for both Experiments 1 and 2. Left refers to the first item heard/seen; right refers to the final item heard/seen. In the visual analogue, all items appeared sequentially in the center of the monitor for 500ms.

Each input-output pair was presented as a series of three shapes followed by the assimilated version of those three

² We also found a significant effect when the alternations were presented as changes from a disharmonic word (as opposed to a concatenation of mono-syllabic words) (Finley & Badecker, 2008).

shapes. Each shape was flashed on the screen for 500ms followed by a 100ms pause in the center of the screen. A 500ms pause was placed between each series of 3 shapes. For example, participants in the Left-to-Right condition, saw /RED SQUARE, BLUE SQUARE, GREEN CIRCLE/ → [RED SQUARE, BLUE SQUARE, GREEN SQUARE]. Participants in the Right-to-Left condition, participants saw /RED CIRCLE, BLUE SQUARE, GREEN SQUARE/ → [RED SQUARE, BLUE SQUARE, GREEN SQUARE].

The training and test items were analogous to the items in Experiment 1. There were 24 training pairs, repeated 5 times each in a random order. There were 12 items each in three test conditions: Old, New and New Direction.

Table 3: Training Items for Experiment 2

Left-to-Right	Right-to-Left
SQUARE SQUARE CIRCLE → SQUARE SQUARE SQUARE	CIRCLE SQUARE SQUARE → SQUARE SQUARE SQUARE
CIRCLE CIRCLE SQUARE → CIRCLE CIRCLE CIRCLE	SQUARE CIRCLE CIRCLE → CIRCLE CIRCLE CIRCLE

Stimuli Shape stimuli were produced using the standard drawing tools for Microsoft Power Point. The shapes consisted of a square and a circle each for four different colors: red, green, blue and yellow, with a small amount of grey shading around each shape. All shapes were standardized to be the same size on the screen (occupying a 5in x 5in space in the center of the monitor).

Figure 2: Experiment 2 Stimuli (Left-to-Right)³

Procedure The procedure was identical to Experiment 1 except that participants were told that they would be watching a series of shapes, presented as a series of pairs of three shapes.

Results

The proportions of ‘majority rules’ responses were recorded for each participant, shown in Figure 3. A 2 (Training) x 3 (Test Condition) mixed-design ANOVA compared each critical conditions with the Control condition. There was a significant effect of Training for the Left-to-Right condition ($F(1, 14) = 9.83, p < 0.01$). There was a significant interaction ($F(2,32) = 7.28, p < 0.01$), due to the fact that there was a significant difference between the Controls for New Items ($t(16) = 2.59, p < 0.05$), but not New Direction items ($t(16) < 1$). This suggests that learners did not

distinguish ‘majority rules’ and directional items. This is confirmed by a significant effect of Test Item ($F(2, 32) = 10.94, p < 0.001$), as there was a significant difference between the New Direction items and both the Old and New Items combined ($F(1,16)=16.57, p < 0.01$), suggesting that learners did not infer a ‘majority rules’ pattern.

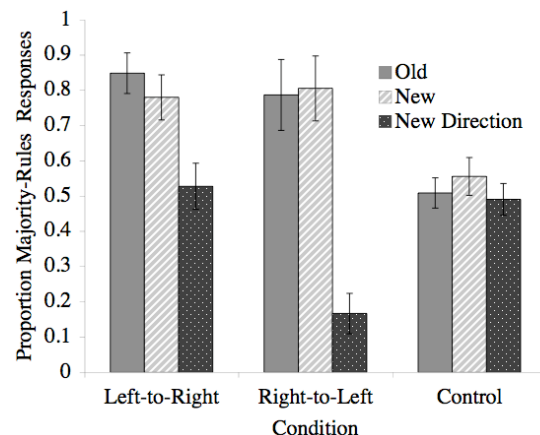

Figure 3: Experiment 2 Results

There was no significant effect of Training for the Right-to-Left condition ($F(1, 16) = 1.63, p < 0.05$). This was carried the interaction between condition and test item ($F(2,32) = 13.48, p < 0.001$). There were significantly more ‘majority rules’ responses compared to Controls for Old ($t(16) = 2.55, p < 0.05$) and New ($t(16) = 2.33, p < 0.05$) but there were significantly fewer ‘majority rules’ responses for New Direction items compared to the Control condition ($t(16) = -4.41, p < 0.001$). This difference reflects the fact that participants in the Right-to-Left condition inferred a directional pattern over a ‘majority rules’ pattern. The fact that there was no overall significant difference between the Right-to-Left condition and the controls is reflected in the low ‘majority rules’ responses in the New Direction condition, creating an overall average that was not different from the overall average of the Control condition. There was a significant effect of Test Item ($F(2, 32) = 17.66, p < 0.001$), due to the fact that there was a significant difference between the New Direction items and both the Old and New Items combined ($F(1,16)=19.90, p < 0.001$).

Participants in the Right-to-Left condition learned a directional harmony pattern, while participants in the Left-to-Right condition had no preference. This difference is reflected in the New Direction items, as participants in the Left-to-Right condition chose the majority option significantly more often than participants in the Right-to-Left condition ($t(16) = 4.16, p < 0.01$).

Among the nine participants in the Left-to-Right condition, four participants chose the ‘majority rules’ item in the New Direction Condition between 40 and 50% of the time, while two chose the ‘majority rules’ item 25% of the time, and three chose the ‘majority rules’ item greater than 60% of the time. This variation suggests that there is no intrinsic strategy towards ‘majority rules’.

³ All items were presented in the center of the screen.

Discussion

The difference between the Right-to-Left and Left-to-Right conditions suggests that visual pattern stimuli are processed differently depending on whether the change occurs first in the sequence or last in the sequence. This difference may be due to attentional constraints. If learners pay the most attention to the first part of the sequence, learners in the Left-to-Right condition will notice that there is a change in the first shape, but learners in the Right-to-Left condition will have to wait for the entire three shapes in order to see what changes. Thus, their representation of the pattern may be more holistic, and thus may be more amenable to both 'majority rules' and directional responses. Another possibility is that learners in Experiment 2 were influenced by their prior reading experience, which was left-to-right. This predicts that the opposite pattern should emerge for learners whose reading system is right-to-left. Future research will address these questions.

Because we used namable categories (shapes and colors), it is possible that participants engaged in naming the shape patterns as they appeared on the screen (e.g., 'GREEN SQUARE', 'RED CIRCLE', etc). However, this type of naming is different from the grammatical process that applies in a phonological pattern. First, phonological rule processing is less likely to involve naming (e.g., 'round vowel' or 'u'). Second, if naming the non-linguistic objects induced linguistic processing, we would expect an exact replication of Experiment 1, but this did not occur. In order to replicate a harmony process, it is necessary to use non-linguistic stimuli that have clear categories. Because all stimuli that are a priori categorical have a name, it is not possible to use non-linguistic stimuli that are not namable. Further, participants often create names for non-namable stimuli (e.g., 'the squiggly one') making it unclear if non-namable stimuli would remove naming strategies.

General Discussion and Conclusions

The results of Experiment 1 provided evidence in favor of a learning bias that favors directionality over 'majority rules' patterns. This bias towards directional harmony patterns provides insight into why 'majority rules' patterns do not exist in natural language. If learners are not biased to infer 'majority rules' from their language data, it is unlikely that such a pattern would emerge.

Experiment 2 demonstrated that the attentional constraints that may lead to a bias towards directional spreading pattern must work differently for spoken language versus non-linguistic visual stimuli. In this non-linguistic analogue of Experiment 1, participants only inferred a directional pattern when the spreading pattern occurred from right-to-left, affecting the first image. These results suggest that the source of the learning bias for directional patterns occur as an interaction of the ways in which speakers attend to auditory spoken language. One possibility is that linguistic material is continuous in a way that non-linguistic material

is not. This continuity may make listeners more likely to attend to both beginnings and ends of words.

The experiments presented in this paper support the hypothesis that learners have biases that shape the distribution of patterns cross-linguistically. While 'majority rules' spreading patterns may be easily generated by rule and constraint-based theories of phonology, such spreading patterns violate constraints on attention, perception and memory. These constraints bias the learner towards directional spreading patterns over 'majority rules' patterns. In many ways, these biases hold for both linguistic and non-linguistic stimuli, suggesting that domain general constraints may affect the distribution of linguistic patterns across the world's languages.

Structural Constraints and Real-World Plausibility in Analogical Inference

Linsey A. Smith (linsey@u.northwestern.edu)

Abstract

Theoretical accounts of analogy have largely agreed that structural constraints play a substantial role in the mapping process. Less is known, however, about the robustness of these constraints in the inference process and the way in which particular content influences the use of structural constraints in analogical inference. We conducted two studies testing whether the plausibility (or implausibility) of an inference influences adherence to general structural principles in analogical reasoning. We found substantial reliance on the predicted structural constraints, but also an influence of the plausibility of the inference.

Introduction

Our goal in this research is to explore the stability of analogical inference under different conditions: specifically, whether analogical inference is a domain-general reasoning process, governed by structural constraints inherent to the analogical process, or whether it is a loosely constrained process whose outcome is strongly influenced by the plausibility of the potential inferences in particular domains. This question is important not only for what it can tell us about basic analogy processes, but also because the use of analogy in scientific discovery (and even in science learning) sometimes requires making initially implausible inferences. We first review research on this issue in the arena of analogical mapping and alignment, which has been extensively studied, and then turn to analogical inference.

Structural Constraints on Analogical Mapping

Reasoning by analogy involves identifying a common system of relations between two domains and generating further inferences driven by these commonalities (Gentner, 1983; Holyoak & Thagard, 1989; Hummel & Holyoak, 1997; Kokinov & French, 2003). According to structure-mapping theory, the comparison process involves aligning a pair in such a way as to achieve a consistent structural alignment between two domains (Falkenhainer, Forbus & Gentner, 1989; Gentner, 1983; Gentner & Markman, 1997). The structural alignment process is guided by a set of tacit constraints that lead to structural consistency and inferential clarity: *parallel connectivity*, which requires that arguments of matching predicates must also be placed into correspondence; and *one-to-one correspondence*, which requires that each element of a representation match, at most, one element of the other representation. Importantly,

deep matching systems are preferred over shallow matches (the *systematicity principle*), which reflects a preference for coherence and inductive power in analogical processing (Clement & Gentner, 1991; Falkenhainer, Forbus & Gentner, 1989). Candidate inferences are generated by completing the pattern in the (initially) less-structured member of the pair, based on the common structure.

Models of analogy have largely converged on a set of assumptions like those outlined above (Falkenhainer, Forbus & Gentner, 1989; Gentner, Holyoak & Kokinov, 2001; Holyoak and Thagard, 1989; Hummel & Holyoak, 1997; Kokinov & French, 2003; Larkey & Love, 2003). Further, there is substantial empirical evidence in support of the idea that analogical reasoning obeys these constraints. A variety of studies have provided evidence that analogical matching is constrained by both structural consistency (including one-to-one mapping) (e.g., Krawczyk, Holyoak, & Hummel, 2005; Markman, 1997; Markman & Gentner, 1993; Spellman & Holyoak, 1992) and systematicity (e.g., Clement & Gentner, 1991). For example, Clement and Gentner (1991) showed participants analogous scenarios and asked them to judge which of two lower-order assertions shared by the base and target was most important to the match. Participants chose the assertion that was connected to matching causal antecedents – their choice was based not only on the goodness of the local match, but also on whether it was connected to the larger matching system. Thus, matching lower-order relations that are interconnected by higher-order relations were considered more important to the analogy. In sum, people demonstrate considerable structural sensitivity in analogical mapping.

Analogical Inference

There is some research on the degree to which structural constraints hold in analogical inference. In the Clement and Gentner (1991) research just described, a second study found evidence for systematicity in inference projection. People generated inferences that were part of a shared system, rather than equally applicable inferences that were not. Markman (1997) also found evidence for systematicity in inference generation. In addition, he found that people based their inferences on one-to-one mappings. When given analogies with two possible sets of correspondences, people noticed both possibilities, but drew inferences from only one of them. These findings suggest a role for structural consistency in inference, as in alignment.

However, one question that is largely unexplored is the degree to which the analogical inference process is influenced by the factual plausibility of the inference in the target. That is, are people able to track structural consistency despite implausibility in making inferences? The studies described above did not involve wide variations in plausibility, so they do not answer this question. Work by Keane (1996) does bear on this issue. He found that people readily accepted inferences that were both highly plausible [had high “entity utility”] and easy to place into correspondence with the target [“entity parallelism”]—that is, highly *adaptable*—compared to those inferences that were less adaptable. These findings suggest that plausibility in the target is important in analogical inference. However, the question remains open as to what people will do if structural consistency directly conflicts with target plausibility.

Another way to put this question is, are there *content effects* in analogical inference? The issue of content effects has been investigated extensively in the research on deductive reasoning. Deductive reasoning has traditionally been considered a relatively rigorous, principle-governed process, although empirical support for this claim (e.g., Marcus & Rips, 1979) is punctuated by many observations that show that people’s judgments about the logical validity of deductive arguments is influenced by the 1) specific content that is being reasoned about (e.g., Cheng & Holyoak, 1985; Cummins, Lubart, Alksinis, & Rist, 1991; Rips, 2001; Thompson, 1994), and 2) whether the reasoner agrees with the premises and conclusions of the argument (e.g., Markovits, 1995; Newstead, Pollard, Evans, & Allen, 1992). Thus, there is evidence that logical reasoning is swayed by particular content.

a. *Logically valid, real-world plausible:*

If Fred sprinkles water on wood shavings, the shavings get wet.

Fred sprinkles water on wood shavings.

The shavings get wet.

b. *Logically invalid, real-world plausible:*

Fred sprinkles water on wood shavings.

The shavings get wet.

For example, Rips (2001) asked participants to evaluate arguments like (a) and (b) in which the plausible conclusion was either logically valid or invalid. The question was whether people could track deductive logic regardless of the plausibility of the conclusion. A substantial number of participants (mistakenly) identified invalid arguments as logically correct when they were plausible. Overall, Rips’s (2001) findings suggest that people were largely able to maintain logical rigor under the strain of real-world implausibility, but that logical rigor was sometimes compromised by the content of the arguments: people could not wholly divorce logical form from content in this task.

A parallel question can be asked about analogical inference: can people maintain structural consistency despite

real-world implausibility in making analogical inferences (which we will refer to as *analogical rigor*)? Our question in this paper is what happens when the structural alignment process leads to inferences that the reasoner considers implausible. On the one hand, some prior research shows reliable effects of structural consistency on inference (Clement & Gentner, 1991; Markman, 1997). On the other hand, these studies (and Keane’s (1996) study) did not directly pit structural consistency against plausibility. And unlike deductive reasoning, analogical reasoning is generally not explicitly taught. Thus we might expect people to be less committed to maintaining analogical rigor than they are to maintaining logical rigor.

The Current Experiments

In this set of studies, we asked participants to evaluate analogies where the inferences derived from the structure-mapping process are at odds with the real-world plausibility of the inferences. This method allowed us to identify how much people rely on domain-specific content over general mapping principles in analogical inference.

For the task, we adapted the deductive reasoning task from Rips (2001). As discussed above, in that experiment, participants evaluated the validity of conclusions from arguments that orthogonally varied in logical validity and real-world plausibility. His study assessed whether people would follow deductive logic in drawing conclusions even when these conclusions conflicted with plausibility. In this research, we posed the parallel question for analogical inference, that is, would people respect the structural constraints of analogy in drawing inferences even when these inferences conflicted with real-world plausibility. To put it another way, are people able to maintain analogical rigor in the face of real-world implausibility? We asked participants to assess whether a particular inference followed from an analogy. We created materials whose inferences varied in *structural consistency*, that is, we varied whether the inference was a structurally consistent completion of the analogy. Table 1 shows an example set. The inferences in (a) and (b) are structurally consistent and those in (c) and (d) are structurally inconsistent. The pairs also varied orthogonally in *real-world plausibility*, with (a) and (c) having plausible inferences and (b) and (d) having implausible inferences. Participants might find analogies (b) and (d) (both implausible inferences) to be odd or downright wrong, but this is precisely the point: when an analogical inference conflicts with reasoners’ knowledge, the question is whether they can identify inferences that the analogy must structurally yield, without being swayed by the plausibility of those inferences.

Of course, the ultimate evaluation of an analogical inference is not solely contingent on structural consistency, but also involves checking the factual validity of the inference (and in a real problem solving situation, the contextual relevance) (Gentner & Clement, 1988; Holyoak & Thagard, 1989). To this end, we also asked participants to provide ratings of the *overall goodness* of each analogy. We

Table 1: Sample materials from Experiment 1.

<p>Base (constant) Mary has built a sandcastle. Her younger brother comes by and kicks the base of the castle. The sandcastle crumbles.</p> <p>Target (four versions) <i>a. Structurally consistent, factually plausible</i> A wrecking ball knocks into a building's foundation. Conclusion: The building comes crashing to the ground.</p> <p><i>b. Structurally consistent, factually implausible</i> A tennis ball knocks into a building's foundation. Conclusion: The building comes crashing to the ground.</p> <p><i>c. Structurally inconsistent, factually plausible</i> A tennis ball knocks into a building's foundation. Conclusion: The building stays standing.</p> <p><i>d. Structurally inconsistent, factually implausible</i> A wrecking ball knocks into a building's foundation. Conclusion: The building stays standing.</p>

had two goals with this question. First, for implausible inferences, this question would give participants a way to indicate that they considered some analogies to be quite poor. We hoped that this would leave them more free to judge structural consistency on its own. Second, a more direct goal was to discover whether participants would incorporate both structural consistency and real-world plausibility into their judgments, as we expected they would. If so, we would expect only analogies that yield structurally consistent and plausible inferences to receive high overall goodness ratings.

Experiment 1

Method

Participants 19 Northwestern University undergraduates took part in the study individually or in small groups of up to four people. Participants completed the task in 10-15 minutes and for their time they received credit towards a course requirement or monetary compensation.

Procedure and Materials The experimenter gave one task booklet to the participant, and upon completion they returned the booklet to the experimenter. The booklet contained a page of instructions, followed by eight analogies (one per page). The analogies came from quartets of items, as in Table 1, that varied in structural consistency and real-world plausibility. We assigned each participant eight analogies, two of each type (structurally consistent and real-world plausible, structurally consistent and implausible, structurally inconsistent and plausible, structurally

inconsistent and implausible), as in Table 1. For an individual participant, however, different content instantiated each of these arguments. Thus, for example, no participant received more than one pair from the Table 1 quartet. The order of the problems in the test booklet was pseudo-randomized into four orders.

Measures Participants rated their agreement with the statement “The conclusion follows directly from the analogy.” Responses were measured on a 7-point Likert scale, ranging from 1 (strongly disagree) to 7 (strongly agree). To facilitate analysis, responses were recoded into a dichotomous variable (with responses > 4 recoded as “Yes, the conclusion follows” and ≤ 4 recoded as “No, the conclusion does not follow”). The proportion of “Yes” responses for each type of stimuli was the measure of interest, and these were aggregated within conditions to form a measure of *inference acceptance rates*, which we’ll simply refer to as *acceptance rates*. To the extent that participants strongly differentiate structurally consistent from inconsistent inferences, such that structurally consistent inferences have high acceptance rates and structurally inconsistent inferences have low acceptance rates, this measure will approximate analogical rigor.

In addition participants were asked to judge the *overall goodness* of each analogy. Participants rated their agreement with the statement “Overall, this is a good analogy.” Responses were measured on a 7-point Likert scale, ranging from 1 (strongly disagree) to 7 (strongly agree).

Results

Figure 1 presents the inference acceptance rates for each of the four types of stimuli. The data were analyzed with a two-way ANOVA, with structural consistency and real-world plausibility as within-subjects factors.

Figure 1: Inference acceptance ratings for Experiment 1. Error bars reflect the standard error.

Overall, there was a strong effect of structural consistency on acceptance rates, $F(1,37) = 110.87, p < .001, \eta^2 = .38$; people were far more likely to accept structurally consistent inferences ($M=.63, SD=.49$) than structurally inconsistent inferences ($M=.09, SD=.29$). There was also a main effect of real-world plausibility on acceptance ratings, $F(1,37) = 8.74, p < .01, \eta^2 = .05$; a greater proportion of plausible inferences was judged as following from the analogy ($M=.45, SD=.50$) than implausible inferences ($M=.30, SD=.46$). The effect size for real-world plausibility was considerably smaller ($\eta^2 = .05$) than that for structural consistency ($\eta^2 = .38$).

There was also a significant interaction between structural consistency and plausibility, $F(1,37) = 27.89, p < .001, \eta^2 = .10$. For structurally consistent analogies, participants were less likely to judge implausible inferences as following from the analogy (implausible: $M=.50, SD=.51$; plausible: $M=.89, SD=.31$), $t(37) = 4.09, p < .001$. No such difference was obtained for structurally inconsistent analogies.

We reserve the analysis of overall goodness judgments until after we present Experiment 2.

Discussion

Our primary question is whether people can maintain analogical rigor in the face of real-world implausibility. We found fairly good support for this possibility. Acceptance ratings were higher overall for structurally consistent analogies, indicating that people are able to track the structural consistency of an inference regardless of the plausibility of that inference. Additional support for this claim comes from the observed effect sizes: structural consistency explains 38% of the overall variance on inference acceptance rates, whereas real-world plausibility only accounts for 5% of the variance. However, analogical rigor is also influenced by particular content. Specifically, participants were more likely to reject structurally consistent inferences when they were implausible. If individuals had been entirely rigorous, we would not have expected to see this difference between plausible and implausible conditions. Interestingly, this effect of plausibility did not appear for structurally inconsistent inferences, which were uniformly rejected.

In short, the results so far suggest that people are able to abide by structural constraints when making inferences; however, conflicting content can influence whether people maintain these constraints. In the next study, we sought to identify whether clarifying the instructions would attenuate these content effects.

Experiment 2

This study tested whether more explicit instructions would lead participants to more strictly observe analogical constraints. We used the same basic method as Experiment 1, with one important modification: we re-wrote the question to clarify that the focus should be on what follows from the analogy.

Method

Participants 19 Northwestern University undergraduates took part in the study individually or in small groups of up to four people. Participants completed the task in 10-15 minutes and for their time they received credit towards a course requirement or monetary compensation.

Materials and Measures The materials for the analogy task were the same, except that the question used to elicit inference acceptance ratings was modified from rating agreement with the statement “The conclusion follows from the analogy?” to instead read “The conclusion in Situation 2 would necessarily follow if Situations 1 and 2 were truly analogous, regardless of whether the conclusion *could* be true or not.” Participants were then asked to circle “Yes” or “No.” The proportion of “Yes” responses for each type of stimuli was the dependent measure, and these were aggregated within conditions to form a measure of *inference acceptance rates*. The *overall goodness* question remained the same. The procedure was as in Experiment 1.

Results

The results showed a strong effect of structural consistency; structurally consistent inferences had higher acceptance rates ($M=.91, SD=.29$) than did structurally inconsistent inferences ($M=.12, SD=.33$). Figure 2 shows the inference acceptance rates for each of the four types of stimuli. For ease of comparison, the results from Experiment 1 (dotted lines) have also been included. Analysis entailed a two-way within-subjects ANOVA, with structural consistency and real-world plausibility as within-subjects factors.

Figure 2: Inference acceptance ratings for Exp. 1 (dotted line) and Exp. 2 (solid), divided into structurally consistent and inconsistent. Error bars reflect the standard error.

As in Experiment 1, there was a main effect of structural consistency, $F(1,37) = 311.22, p < .001, \eta^2 = .71$. Real-world plausibility no longer influenced inference acceptance: there was no main effect of real-world plausibility nor an interaction between the factors (real-world plausible: $M = .53, SD = .50$; implausible: $M = .50, SD = .50$).

Cross-Experiment Analysis To further test whether more explicit instructions to focus solely on whether an inference follows from the analogy bolstered participants' focus on structural constraints, we entered Experiments 1 and 2 into a three-way mixed ANOVA, adding in instruction type (i.e., Experiment 1 or 2) as a between-subjects factor. In addition to the main effects of structural consistency and real-world plausibility, there was also a main effect of instruction type, $F(1,74) = 6.26, p < .05$. These main effects were qualified by a significant three-way interaction between all three variables, $F(1,74) = 5.31, p < .05$. This significant interaction is due to different patterns of performance on structurally consistent inferences: in the explicit instructions condition (Experiment 2), there was no difference in acceptance rates between plausible and implausible inferences, but in the implicit instructions condition (Experiment 1), acceptance rates were higher for plausible inferences, $t(37) = 4.09, p < .001$.

Judgments of overall goodness We elicited judgments of overall goodness for the analogies to identify participants' overall impression of the analogy, which may not have been captured in the acceptance rates, especially in the case of implausible inferences. To identify whether judgments of overall goodness for the analogies varied by instruction type, we entered both experiments into a three-way mixed ANOVA, with *overall goodness* as the dependent measure. There was only a marginally nonsignificant effect of instruction type, $F(1,74) = 3.33, p = .07$; participants rated overall goodness similarly across both instruction conditions. There were main effects of both structural consistency ($F(1,74) = 97.35, p < .001, \eta^2 = .27$) and real-world plausibility ($F(1,74) = 28.43, p < .001, \eta^2 = .06$), which were qualified by a significant interaction between the two, $F(1,74) = 43.02, p < .001, \eta^2 = .11$. Structurally inconsistent pairs were given low overall ratings that did not vary by real-world plausibility (max = 7, plausible: $M = 1.92, SD = 1.16$; implausible: $M = 2.20, SD = 1.77$); structurally consistent pairs that were plausible were given higher ratings than implausible pairs (plausible: $M = 5.05, SD = 1.52$; implausible, $M = 2.91, SD = 1.86$), $t(75) = 8.25, p < .001$. This pattern of goodness ratings partly mirrors the pattern of inference acceptance ratings in Experiment 1: there was an effect of both structural consistency and plausibility, with a stronger effect of structural consistency; and structurally consistent analogies were rated lower when their inferences were implausible. Thus, with the exception of the Experiment 2 acceptance ratings, the deviation from analogically rigorous behavior occurs only for structurally consistent but implausible analogies.

Discussion

Our primary question in Experiment 2 was whether people are capable of separating structural consistency from real-world plausibility when explicitly told to do so. The results indicate that the answer is yes: people were able to ignore the real-world plausibility of analogical inferences in making their judgments.

General Discussion

Two studies probed the robustness of structural constraints on analogical inference when challenged by the particular content of the inferences. In Experiment 1, we investigated whether people would follow the structural constraints of analogy in drawing inferences even when they conflicted with plausibility. Acceptance rates were higher for structurally consistent inferences than inconsistent inferences; overall, people can reliably follow structural consistency in inference. Plausibility did influence inference acceptance rates, but only for structurally consistent analogies. Structurally inconsistent inferences were noticed as such, regardless of their real-world plausibility. However, when people encountered potentially analogous (i.e., structurally consistent) inferences, their judgments were influenced by target plausibility.

Experiment 2 tested whether more explicit instructions would lead participants to make a clearer separation between analogical rigor and plausibility. The results indicate that this is indeed the case: participants no longer demonstrated content effects, but instead recognized inferences that followed from completing the common system, as predicted by structure-mapping and other current models of analogy (Falkenhainer, Forbus & Gentner, 1989; Holyoak and Thagard, 1989; Hummel & Holyoak, 1997; Kokinov & French, 2003). Understanding the conditions under which people will put aside their knowledge to work through an analogy has implications for educational contexts, where analogies are used extensively to promote knowledge acquisition and conceptual change (e.g., Richland, Holyoak, & Stigler, 2004). Importantly, the analogies used by instructors may require learners to make ostensibly implausible inferences (e.g., Clement, 1993).

In both experiments, we elicited judgments of overall goodness of the analogies. We found, as expected, that people considered both structural consistency and real-world plausibility in judging the analogies. Ratings for overall goodness did not vary as a function of instructions. In both experiments, people reliably indicated that only those analogies that were both structurally consistent and real-world plausible were good analogies. This pattern of judgments is in accord with the general assumption that while analogy may involve a mapping process guided by structural constraints, ultimate evaluation of the analogy involves checking the factual validity of projected inferences.

Although Experiment 1 demonstrates that analogical rigor is influenced by content, for both experiments, participants showed a general tendency to identify structurally consistent inferences as following from the analogy. Furthermore,

effect sizes were moderate for structural consistency, whereas they were extremely small for plausibility. Perhaps more tellingly, in judgments of overall goodness, the effect of structural consistency was much larger ($\eta^2=.27$) than that of plausibility ($\eta^2=.06$). Taken together, these observations suggest that people are relying heavily on structural principles to guide their evaluations of overall analogical goodness. The results of these experiments are consistent with the claim that analogical processing involves a structure-mapping process of alignment and inference largely governed by structural constraints.

One concern here is that the materials were too simple to engage serious content-based reasoning. It will be necessary to investigate a wider range of material to determine the whether the effects identified in these studies will generalize to more natural materials. However, the results so far suggest that analogical inference is to a large extent guided by a tacit set of structural constraints that may function something like the principles that guide deductive reasoning. In future studies it would be of interest to contrast these two reasoning tasks to see whether similar patterns emerge. Another future direction would be to obtain online measures, such as reading times, to investigate the time course of content effects in analogy and further explicate the interaction between mapping processes and target content in analogical inference.

Acknowledgments

Abstract

Binocular rivalry occurs when two distinct stimuli, one for each eye, are presented to corresponding retinal areas. Similar to other bistable phenomena such as Necker cubes, this overlap often causes one's conscious perception to alternate between a coherent perception of one stimulus, a coherent perception of the other and sometimes a mixture of the two. Previous studies have tried to identify where rivalry occurs, and what is actually being rivaled. Some studies have provided evidence for low-level effects on rivalry, lending support to the idea that rivalry is between monocular visual streams. Other studies have provided evidence for higher-level effects on rivalry, supporting the idea that rivalry is between opposing patterns. While this debate has largely been passed on in favor of a hybrid theory of rivalry that includes effects at several levels, questions still remain about specific higher-level effects. In the present study, we look at the effect of a congruent auditory stimulus on perception of rival videos of speaking people. We find that auditory stimuli can have an effect on rivalry, indicating that cross-modal processes such as speech to lip matching or voice to face matching are among the high-level factors impacting rivalry.

Keywords: binocular rivalry; patchwork rivalry; stimulus rivalry; cross-modal; multi-modal; psychophysics.

In this paper, we investigate the role of cross modal interaction between audition and vision in determining stimulus dominance in a binocular rivalry paradigm. Binocular rivalry occurs when two distinct stimuli are presented to separate eyes, so that each eye only sees one stimulus but they overlap in one's visual field. Similar to other bistable phenomena such as Necker cubes, this overlap often causes one's conscious perception to alternate every few seconds between a coherent perception of one stimulus and a coherent perception of the other.

Historically, researchers have debated where in the visual processing stream one stimulus becomes dominant over the other and rises to conscious perception [1]. Evidence of ocular suppression has been found very early in the visual processing stream, at the Lateral Geniculate Nucleus and in V1 [2, 3, 4]. This finding supports the idea that rivalry is between monocular visual streams. On the other hand, high-level properties of the stimuli, such as visual coherence [5] and "natural" amplitude spectra [6], have been shown to affect rivalry dominance duration and strength, indicating that rivalry may be between the perceived stimulus rather than the

monocular pathway. Further support for the stimulus being the object of rivalry comes from studies that rely on interocular grouping during rivalry, in which cohesive stimuli can be perceived from parts that are divided between the eyes [7, 8]. These findings also indicate that areas of the brain further along in the visual processing stream are likely play a significant role in the phenomenon. Recent evidence from neuroimaging studies suggests that a complete answer for rivalry likely involves a hybrid of the two theories, involving both high-level and low-level visual processing systems [1].

While controversy over whether rivalry is controlled from low-level or high-level processing has largely been supplanted by an acknowledgment of the role of multiple levels of processing, questions remain about specific roles. Studies such as [4] have effectively answered the "how low?" question in the binocular rivalry literature, but the "how high?" question has remained more elusive. Attention is one potential candidate for a mechanism for bistable perception, as attention has been noted to have an effect on dominance of rival stimuli since Helmholtz [9]. Studies have shown that attention can control the rate of alternation between rival stimuli, but that selective attention showed stronger effects for ambiguous figures than for binocular rivalry [10]. However, the strength of effect on stimulus duration appears to depend on specific features of the stimuli, such as their complexity, and whether attention is focused on specific stimulus features [11, 12]. Attention seems to have the most effect on the initially dominant stimulus [13], and neurophysiological results indicate that attention can bias early processing in the visual stream [14].

Other higher-level effects on rivalry have been shown, in particular the importance of global coherence in pattern rivalry [15] and of biological motion in determining perception with both ambiguous monocular stimuli and rival binocular stimuli [16]. The biological motion result, in which upright walking figures were perceived more often than inverted figures, suggests a top-down effect where the global perception influences lower-level processing.

One interesting question is whether stimuli in another modality can influence rivalry. This question has been recently studied for bistable perception of visual and auditory

objects. Hupe and colleagues looked at perception of concurrently perceived bistable (but not binocularly rivaling) visual and auditory stimuli [17], particularly the temporal proximity of auditory and visual perception shifts during perception of the parallel bistable stimuli.

In the present study, we look at the question of whether simultaneously perceived auditory input can influence perception during binocular rivalry. We hypothesize that if a subject views two rivaling videos while listening to a soundtrack appropriate to only one of the videos, the video appropriate to the soundtrack will dominate perception for a greater period of time than the other video. There is considerable evidence that normal speech recognition involves both audition and vision. For example, the McGurk effect has shown that different articulations, as seen in a video of moving lips, can affect the perception of identical-sounding syllables [18], and many studies have suggested that speech perception is inherently multimodal (see [19] for a review). Recent studies have demonstrated sensitivity in speech recognition for matching between the gender of auditory and visual sources, lending support for the idea that cross-modal integration in speech recognition involves top-down processes [20]. Cross-modal matching is robust, with the ability to match a voice to lips that are represented only by point light sources [21].

Cross-modal experience has also been shown to affect performance in a visual-auditory temporal frequency matching task [22] where subjects were better able to match auditory and visual temporal repetition rates when the match was in the context of an upright point-light walker than for scrambled and inverted point-light walkers (with the same local motions). Auditory input has also been shown to influence visual perception of the number of flashed stimuli [23, 24] and visual input (color) has been shown to influence olfactory perception [25]. All of these effects are automatic, just as one cannot ignore the visual input when looking at it in the McGurk Effect. We reason that well-associated auditory input could similarly bias visual perception in a binocular rivalry paradigm.

Methods

We performed our experiment using StereoGraphics CrystalEyes LCD shutter goggles attached to a PC running Matlab and Psychophysics Toolbox 3.0. Our CRT monitor was configured to display stimuli intended for the left and right eyes on alternating refreshes, which were coordinated with the eye alternation of the shutter goggles via an emitter attached to the GeForce QuadroFX quad-buffered graphics card in the machine. We recruited 18 subjects, all undergraduates, 7 males and 11 females, with normal or corrected normal vision and no colorblindness. One subject was removed from the study due to incorrect performance on catch trials (described below), and another was removed because they only ever pressed one of the two responses, resulting in a grand total of 16 subjects.

Our stimuli were composed of four videos. All four videos

showed head shots of volunteers relating a story about a recent experience. Two videos were clips of a story told by a male actor, and the other two videos were clips of a story told by a female actor. In order to make the videos easier to distinguish, we created both red and green versions of each video by converting the videos to grayscale and using the grayscale values as brightness on the red or green color channel. On our equipment, the green versions of the videos were noticeably brighter and we therefore reduced the brightness of the green videos at presentation time to 65% of their original brightness in order to better match them with the red videos. Note that we used shutter goggles, not red/green glasses, so the colors have no impact on which eye sees which stimulus, they just serve to aid discrimination and help group the patterns. The audio tracks from each video were separated so that video and audio media could be presented independently of one another.

We used a stimulus rivalry paradigm where we presented one eye with the left half of the male video and the right half of the female video and the other eye with the right half of the male video and the left half of the female video (see Figure 1). Stimulus rivalry is believed to occur higher in the visual processing stream than ocular rivalry [1], so we use stimulus rivalry in order to give ourselves the best chance to discover a high-level cross-modal effect. Our early pilot trials with standard eye rivalry (female video to one eye and male video to the other) did not reveal a cross-modal effect.¹

Subjects viewed 25 trials, consisting of one warmup trial (not reported) and 24 trials generated from the following counterbalanced conditions: four possible combinations of male and female videos by male in red and female in green or vice versa by male soundtrack, female soundtrack or no soundtrack. Subjects indicated which video they felt they mostly perceived by pressing keys on the keyboard for female or male. If subjects were unsure of their perception, we instructed them to press both keys or press neither key and we considered either of those responses as identical. Each trial lasted 86.6 seconds and was followed by a short (approximately 5 second) catch trial where only one of the two videos was displayed.

The experiment was run in a darkened room with the subjects seated in front of the computer described above. A fixation cross was present in the center of the video, and we instructed subjects to stay focused on the cross as much as possible. The video itself was 640 x 480 pixels in the center of a 1024 x 768 display, with a black background. The response keys were the Z and / keys on a standard qwerty keyboard. We affixed glow-in-the-dark labels to the response keys to help subjects reorient if their hands got lost in the dark.

We performed two primary analyses on our data. For the purposes of both, a congruent response is a response indi-

¹Just before the due date for the camera ready copy of this paper we discovered a poster at Vision Sciences Society Annual Meeting presented May 10, 2010 that did find that auditory congruent stimuli could bias binocular rivalry of line drawings presented to each eye [26].

Figure 1: Sample stimulus from a single frame of the video. Left: left eye display. Right: right eye display.

cating dominance of the video associated with the currently playing audio and an incongruent response is a response indicating dominance of the video not associated with the audio. A neutral response is a response made during a trial with no audio. Our first analysis considered only the 16 trials that included sound. We subtracted the congruent dominance duration from the incongruent dominance duration and performed a positive one-tailed t-test comparison between the distribution over the subjects and a null distribution with zero mean (equal time spent on congruent and incongruent responses). Even though our trials were counterbalanced, we were concerned about two possible biases, a gender bias and a color bias. To correct for these biases we looked for a per-subject systematic bias in the no sound trials (previously unused) and subtracted the mean value of that bias from the appropriate responses in the trials with sound. We did this independently for both color and gender, resulting in three versions of this result: raw (uncorrected), corrected for color and corrected for gender. The equation for calculating this measure is as follows

$$\delta_{ci}(s) = \sum_{i \in S} \left(\sum_{j \in C_{is}} R_{ijs} - \sum_{k \in I_{is}} R_{iks} \right)$$

where $\delta_{ci}(s)$ is the difference between responses of congruent and incongruent visual percepts for subject s , S is the set of trials with sound, C_{is} is the set of congruent responses from subject s on trial i , I_{is} is the set of incongruent responses from subject s on trial i , and R_{ijs} is the duration of response j from subject s on trial i .

Second, we recorded the difference in reported dominance time of the male stimulus on trials with male sound versus trials with no sound. We did the same with female stimuli (dominance time of female stimulus on trials with female sound versus trials with no sound) and summed the results to see how much more often congruent stimuli were dominant versus their neutral counterparts in the no sound trials. We did the same comparison in the other direction to see what (dis)advantage incongruent stimuli had compared to neutral stimuli. Since these measures do not come at the expense of

one another like those above (both congruent and incongruent are being compared to neutral, rather than to each other), the effect should be weaker but still an interesting basis for comparison. Also note that though there are twice as many trials with sound, we are only considering the congruent or incongruent responses from each trial. Since we consider both male and female responses from every no sound trial the comparison is even. Similar to the above, we performed a positive (for congruent, negative for incongruent) one-tailed t-test comparison between the distribution of this measure over the subjects and a null distribution with zero mean. The equation for calculating this measure (in the congruent case) is as follows

$$\delta_{cns}(s) = \sum_{i \in S} \left(\sum_{j \in C_{is}} R_{ijs} - \sum_{k \in N} \sum_{l \in FM_{ks}} R_{kls} \right)$$

where $\delta_{cns}(s)$ is the difference between congruent sound responses and corresponding no sound responses for subject s , N is the set of trials with no sound, and FM_{ks} is the set of female or male responses (as opposed to not sure) for subject s on trial k . Other terms are the same as described above and the incongruent case is a simple modification.

Results

Figure 2 shows the result (ordered by increasing effect) of our first analysis. In each of the raw, color corrected and gender corrected conditions we reject the null hypothesis that congruent stimuli are as likely to be dominant as incongruent stimuli ($\mu = 60.25$ $\sigma = 102.37$ $p < .017$, $\mu = 44.42$ $\sigma = 83.59$ $p < .026$, $\mu = 54.33$ $\sigma = 96.44$ $p < .020$, respectively). Qualitatively the results don't change much after correction, as would be expected given the counterbalanced experimental design.

Figure 3 shows the result (in the same order as Figure 2) of our second analysis for the advantage of both congruent and incongruent stimuli compared to neutral stimuli. In the congruent case we do not obtain a significant effect, but there is a trend ($\mu = 24.26$ $\sigma = 69.21$ $p < .091$), as can be seen from

Figure 2: Difference in seconds between total congruent responses and incongruent responses, bucketed by subject in order of increasing effect. Bar color represents correction method.

the bar plot. The incongruent case does show a significant disadvantage compared to neutral ($\mu = -35.99$ $\sigma = 56.39$ $p < .011$). Notably, subject 4 changes character significantly in this analysis as compared to the previous. As a post-hoc investigation, we calculated the average absolute difference in total dominance duration between sound and no sound trials for each subject. Subject 4 had a per trial average dominance duration of 14.3 seconds less on the sound trials. Over all the other subjects the average absolute difference was 2.4 seconds with a max of 5.4. Clearly subject 4 responded much less to the trials with sound than was typical for the subject pool. If subject 4 is excluded from the hypothesis test on the second analysis there is a significant effect of congruent sound versus no sound ($\mu = 33.84$ $\sigma = 59.66$ $p < .023$) and the incongruent effect remains significant though weakened as one would expect ($\mu = -31.09$ $\sigma = 54.73$ $p < .023$). These results are very much in line with the first analysis.

Discussion

Our result represents an important step forward in mapping out the ways in which high-level processing can impact rivalry. Unlike previous high-level effects, such as global coherence and biological motion, this effect is not solely in the visual domain. Instead it is the result of matching a voice to a speaker, constituting the integration of both auditory and visual information.

It is not clear from this experiment whether the gender of the voice alone was enough to cause greater dominance of the congruent video, or whether voice to lip matching was responsible for the effect. Either of these effects would reveal an interesting cross-modal influence on binocular rivalry. Future studies that pair each speaker’s video for one of their stories with the audio from the other could help illuminate

the particular role of each aspect. [26] seems to show that semantically relevant sounds can bias the perception of eye rivaling static stimuli. However given that cross-modal voice to lip matching is so robust [21], we believe that the dominance effect is likely helped by the temporal coherence of voice and lips. An interesting question is whether subjects are aware of the matching even when the incongruent stimulus is dominant. This question could be addressed with an experiment that manipulates the temporal phase of the matched visual video during periods of nonperception. As soon as the subject indicates dominance of an incongruent stimulus one could switch or delay the audio track so as to put it out of sync with the congruent video. This might require less naturalistic stimuli (with pauses between words, for example) in order to execute without the audio sounding garbled. If subjects detect the lack of matching even when they’re not consciously perceiving the congruent stimulus (e.g. by changing perceived dominance status), it would indicate the presence of a cross-modal blindsight for the voice to lip relationship.

Given that voice to lip matching is such a powerful effect, we were very concerned to sync the audio to the video precisely. It was not possible to do this perfectly given our experimental design, which required us to decouple the audio and video, though we came very close. We wonder whether the few subjects that showed an auditory congruence effect in the opposite direction were more temporally sensitive subjects (perhaps musically trained?) and more sensitive to slight offsets in sync and thereby biased against congruent stimuli at times when the sync is not quite right (a slightly offset audio/visual pair would be more anticorrelated than an unrelated audio/visual pair leading to a potential preference for perception of the unrelated video). An experiment where audio/video sync is manipulated across trials and subjects are

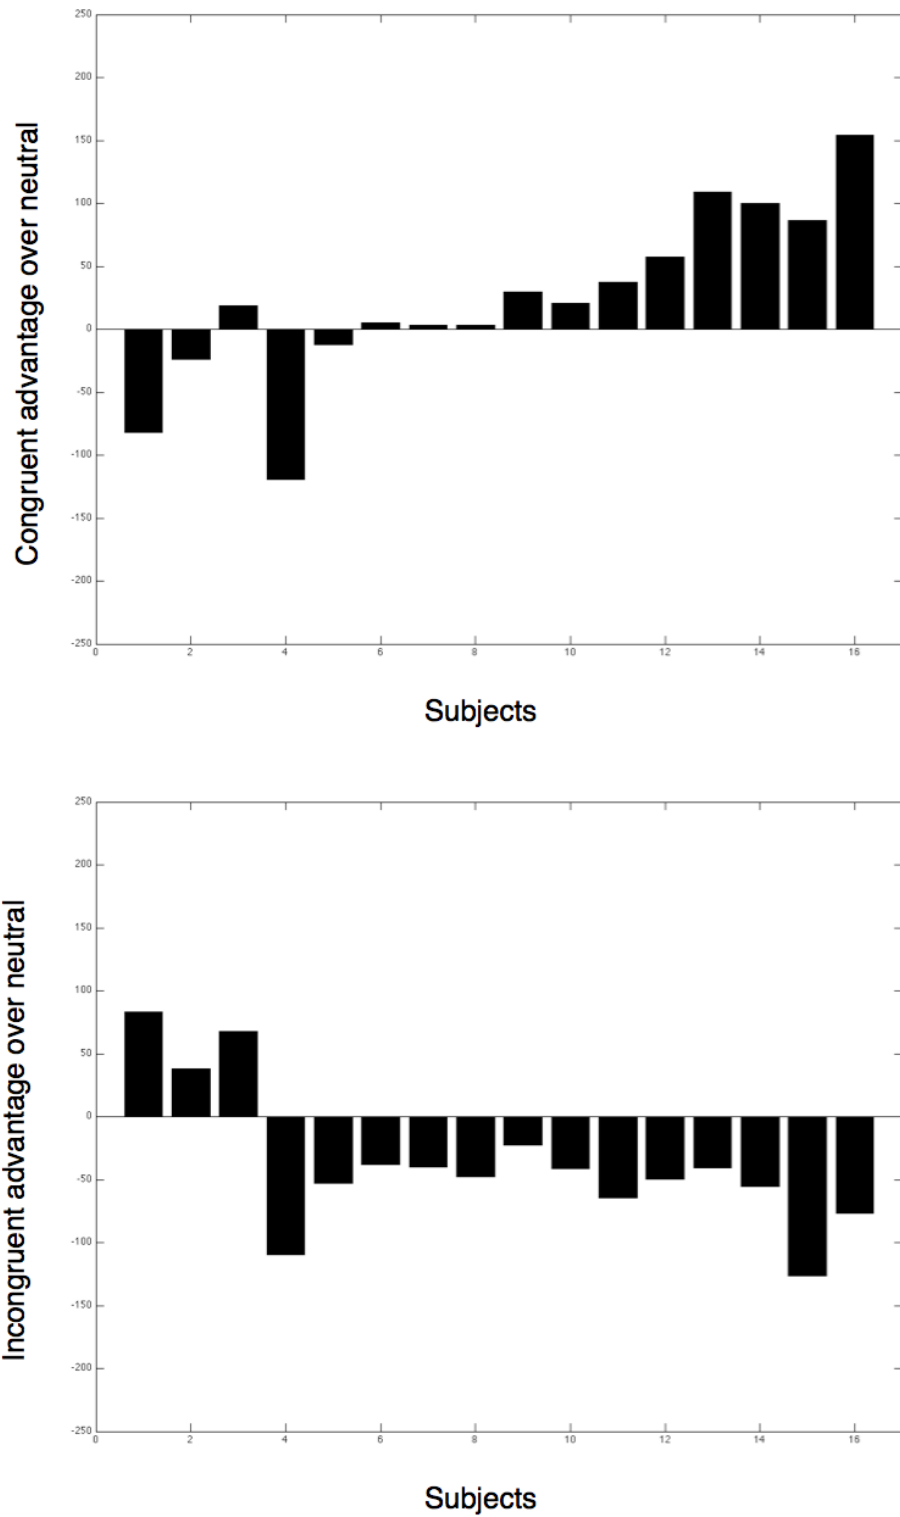

Figure 3: Difference in seconds between total congruent responses (top) and corresponding responses on no sound trials and between incongruent responses (bottom) and corresponding no sound responses, bucketed by subject in the same order as Figure 2. See the post hoc outlier analysis of subject 4 is in the results section.

screened for temporal sensitivity could help address this issue.

Another interpretation of our results might be that the auditory stimulus is causing subjects to consciously attend more to the congruent video, resulting in a greater dominance period due to attention rather than a more automatic cross-modal effect. As mentioned in the introduction, however, attention mainly seems to affect the rate of alternation [10] and the initially dominant stimulus [13], both of which have a limited impact on dominance duration. When attention does bias dominance duration it is usually when subjects are attending specific stimulus features [12]. By contrast, [26] seem to find a significant effect of commanded attention (which adds with their cross-modal interaction), but it is unclear whether they had subjects maintain fixation. Without maintaining fixation, subjects' eyes can easily wander or be specifically directed to higher contrast/complexity regions of the attended image and thus bias dominance on a low level. Since our subjects were specifically instructed to fixate on a fixation cross, and had no task related reason to remember or interpret the stories our actors told (subjects were simply told they would hear sounds during some of the trials), we do not believe that attention had a significant impact on our results. A future study carefully designed to focus on the interaction of cross-modal/attention effects (e.g. by requiring subjects to attend both to stimuli congruent and incongruent with a soundtrack) would likely help illuminate this issue further.

We believe this is an exciting result for the bistable perception field. It shows a new way in which high-level perceptual processes can interact with conscious perception and opens up new ground for researching the nature of both cross-modal interactions and bistable perception.

The Necessity of Ordinary Experience

Robin Flanagan (FlanaganR@wcsu.edu)

Department of Psychology, WCSU, 181 White Street
Danbury, CT 06810 USA

Abstract

I argue in this paper that ordinary experience is not only a nice part of everyday life; it is a necessity for the development of human knowledge. I begin by looking at why the particular biological machinery that defines our nervous system matters. I then examine the particular machineries that constrain but also foster the development of human knowledge. Finally, I examine the kinds of activities that foster the development of knowledge, given the constraints of the given machinery, and conclude that activities that are repeated often and that involve meaningful interaction with an inherently meaningful environment form a plausible basis for the formation of knowledge within the particular neural net machinery that evolution has produced for us.

Keywords: Learning; neural networks; embodied cognition; practice; education; development; instructional technology

Mind and world in short have been evolved together, and in consequence are something of a mutual fit.

(James, 1948, p. 4)

The Implementation Problem

The implementation question is the notion that once a system of knowledge has been completely and accurately articulated, it shouldn't matter in what kind of machinery the system is implemented. This was a major assumption of cognitive science for quite a long time, and to its credit it was a very useful and fruitful assumption. If we assume that there is no important difference between carbon-based machinery and silicon-based machinery, and this is a very reasonable assumption, we can investigate and test knowledge systems on silicon-based machinery, machinery which is much easier to control, much easier to completely specify, and much easier to manipulate in ethical ways. However, this assumption has two gaping holes in it: how does the knowledge get into the machinery (most biological organisms have no programmers to install useful data structures or programs, while most silicon-based machines do have programmers), and how does the knowledge get interpreted (most silicon-based machines have intelligent "users" to interpret the output; most biological organisms must interpret the knowledge for themselves).

If, instead of ignoring implementation, we examine how the actual machinery works, we find that there are many important constraints derived directly from the machinery that actually help us to understand how the knowledge gets incorporated into the machinery and how the "knowledge" in the system gets interpreted. This, of course, does not mean that a silicon-based machine couldn't learn and

interpret on its own (see (Brooks, 2008) for example); it only means that silicon-based machinery isn't necessarily constrained by the same physical qualities that constrain biological organisms. A lot of very interesting work in artificial intelligence, does examine cognition while taking biological constraints into consideration, and these lines of research have been extremely fruitful, which should help to support the idea that implementation does indeed matter. The embodied cognition paradigm already assumes, however, that implementation is a critical element of any intelligent system.

The Basic Machinery

That leads to the examination of the actual elements of the biological machinery from which the nervous system is constructed. There are, of course, very few elements in the biological machinery. The main element is an ordinary neuron, which is not too dissimilar from other cells in the biological organism. Like other cells in the biological organism the neuron is best at responding to elements in the immediate surroundings. In other words, the neuron is best at noticing what's in its immediate neighborhood and responding by secreting to its immediate neighborhood.

However, the neuron can take on very unusual shapes, and these shapes, make them particularly good for communicating with each other, by redefining what is meant by "its immediate neighborhood". The maximized surface area of the neuron (the dendrites) allows the neuron to receive multiple messages simultaneously from other neurons or from the environment. The other part of the neuron's unusual shape (the axon) can sometimes be quite a long extension of the cell body. The axon is the main tool that the neuron has at its disposal for communicating to other neurons or to the muscles. So just by changing its shape the neuron has the ability to get information from, and have an effect on, parts of the nervous system and ultimately parts of the body that are not apparently in its immediate neighborhood.

This is important because the main technique that neurons have for getting information, and for sending information, involves the idea of simple local processing. So it's important to note that "local" for the neuron has been redefined to include connections to quite distant elements of the nervous system and the biological organism. In fact, in the case of the photoreceptors, "local" involves light waves arriving in the immediate vicinity from potentially extremely distant locations. Simple local processing is the kind of processing that single-celled organisms developed at the very beginning of organized life, to detect things in their

immediate environment, and through very simple rules made decisions about how to act on their environment. The typical example is a bacterium floating through water. When it detects a particular toxin in the environment, it activates its flagellum and flaps away from the toxin. The cool thing about simple local processing is that when many organisms are using simple local processing at the same time, intelligent behavior can emerge at the level of the group or colony, without any programmer or leader or teacher.

Because there is no programmer or leader or teacher to direct the nervous system this is an incredibly useful quality to include in any description or explanation of biological intelligence to account for the undoubtedly quite intelligent behavior of this leaderless system.

So, the basic elements of which our nervous system is composed consist of billions of very simple agents, performing simple local processing in which “local” has been redefined to include any “neighbor” to which a neuron’s unusual shape can give it access, including, for example, any light wave event within the visual vicinity of the amazing biological eye. This massively parallel system of simple agents acts without a leader, without a programmer, without a teacher; yet intelligent and useful behavior emerges over time. We turn next to the question of how knowledge, or intelligent behavior, can emerge in such a system.

How knowledge develops in such a system

While no single model of the human nervous system has been universally accepted, we have established the basic building blocks and parameters from which it must be built. Several of the basic mechanisms with which such a neural network could store knowledge have also been identified.

The first important mechanism was established about a hundred years ago by Pavlov (2009) and articulated more fully in the sea slug by Kandel and his colleagues (Hawkins, Greene, & Kandel, 1998, for example). The ability of the nervous system to associate a previously non-meaningful stimulus with an already meaningful stimulus may seem rather minor and non-cognitive when discussed within the context of dog saliva and sea slugs, and yet this is an amazingly useful mechanism. Association between a stimulus that is already meaningful and a previously meaningless stimulus can produce symbols, where a symbol means anything that stands for something else. Surely this is the basis of the nervous system’s ability to use language and, more generally, abstract symbols. Abstract symbols are, by definition, meaningless stimuli on their own which have taken on meaning by association with something already meaningful.

The second important mechanism was robustly established during the half century of American behaviorist research (Staddon & Cerutti, 2003). Operant conditioning increases the probability of a pattern of neural activity to reoccur if that pattern has proven to be useful (that is, if it has been reinforced). In a probabilistic network, this

couldn’t be more important. A relatively more predictable pattern of activation that is meaningful or important to the organism is pretty close to a basic definition of intelligent behavior, or knowledge. Again, operant conditioning may seem too basic and non-cognitive when discussed in the absence of a mind or within the context of training animals, as behaviorism often is; yet surely the ability to increase the probability of activating a useful pattern of neurons when it becomes clear that the pattern is, in fact, useful, could form the basis of an endogenous back-propagation system, the exogenous form of which is such an essential aspect of so many artificial neural nets (see, for example, McClelland and Rumelhart (1988)). Whether it forms the basis of the feed backward system or not, most would agree that knowledge that is more probable, rather than less probable, to become available at the appropriate time is the main point of learning and education.

The third important mechanism was hypothesized by Hebb sixty years ago (1949), and established more recently in empirical neuroscience research ((Isaac, Buchanan, Muller, & Mellor, 2009) for example). Hebb theorized that neurons that become activated simultaneously would be subsequently more likely to activate each other. This has been found at least in the case of the NMDA receptor, a receptor that requires simultaneous messages in order to allow permanent, structural changes to occur at the synapse (see (Isaac, et al., 2009) for example). This is perhaps a more general mechanism upon which both Pavlovian association and Skinnerian contingency are both built. Long-term potentiation has been the chief candidate for this process. Long-term potentiation involving the NMDA receptor requires more than one converging pathway to neural activation. Also important is the idea that this process is dependent on an overwhelmingly huge stimulus, or an often repeated activation before it makes permanent changes to the synapse. If long-term potentiation (or any kind of wiring) developed after every mere exposure the neural net would be in constant flux without the ability to store meaningful knowledge (something to keep in mind when considering so-called “smart” genes and genetic modifications). The ability of neurons to strengthen their association when they find themselves simultaneously activated over time is essential to both forms of conditioning, as well as learning to perceive and to act on any reliable invariance in the internal and external environment. Invariance in the environment, by definition, provides almost endless repeated activation in response to objects and events that are important, or, at least, enduring.

Finally, with lots of neurons activated simultaneously in response to an event in the environment, distributed “representation” is possible: that is, a distributed set of neurons together form a concept. This is important as a storage mechanism, but it is even more important as a means of developing categories and abstract concepts. When lots of neurons, rather than a single neuron, become activated by a particular stimulus, and then another large group of neurons becomes activated by a slightly different

stimulus, any overlapping active neurons get twice the opportunity to wire together with each other, and so subsequently are even more likely to activate each other. This overlapping set comes to stand for (or “mean”) the precise similarity between the two stimuli, not as an analogy but as a literal overlapping commonality. This is a profoundly important part of our machinery if we want to be able to explain the human genius for categorization, abstraction, and creativity.

Very few psychologists admit that these crude mechanisms are useful for more than motor skill learning and perception. Yet, what other mechanisms have been identified in the nervous system to account for lasting changes? I am aware of none. So, leaving physical skill learning and perception aside for the moment (although they’re quite important) let’s examine, briefly, how verbal, spatial, or declarative knowledge could develop in such a system, although the research in this area is ongoing and not at all settled yet.

These mechanisms certainly do look better suited to the implementation of non-declarative knowledge than of declarative knowledge. Non-declarative knowledge can build up over time through normal interactions and perceptions, and even without conscious awareness or attention. But how do we explain the (seemingly) more cognitive, conscious and occasionally instantaneous category: declarative knowledge? How could declarative knowledge be implemented in such a system?

Unlike all other organisms, human beings have a rich set of verbal (as well as visual) symbols at their disposal. One possibility is that words become associated (through classical conditioning mechanisms) with “concepts” already established in the neural network through Hebbian synapses. In fact, Bloom and her colleagues found that as soon as children are reliably able to refer to objects in their environment, jointly with their caregiver, vocabulary suddenly blossoms (Lifter & Bloom, 1989). Goldin-Meadow found that as soon as learners were capable of gesturing appropriately during problem-solving, that the correct words almost immediately followed (2003). It seems that in humans, at least, language is produced almost simultaneously with the ability to identify and perceive a referent. If this is the case, this is a powerful addition to the simple machinery with which we have to work: to be able to have a word associated with each distinction we are capable of perceiving or acting upon.

Once a word is in place (associated with a meaningful distinction) the neural net can use the activation of a word in place of the primary experience: the word can initiate a cascade of neural activity that is very similar to the cascade that would be produced by the primary experience. At this point, a coach, or a teacher, or a friend, or a parent can use a word (“hot”) to produce the same neural activity that might have been produced by a similar (“hot”) experience, thus allowing learning to take place without the primary experience. Clearly the primary experience, or some critical conjunction of important partial experiences, must have

occurred at some point. But learning can quickly be produced in the absence of the primary experience once the word is in place. From here it is a not impossibly large leap to the nervous system supplying the words internally in the absence of an external coach, teacher, friend or parent. These internally activated words, then, could form the basis of explicit knowledge and rational thought.

Re-activation of sensory-motor cortex, followed by a cascade of neural activity similar to primary activation, has repeatedly been found to be the case with stored concepts (see, for example, the visual imagery work of Kosslyn (2005) and the motor imagery work of Jeannerod (1994)). The research on mirror neurons has even indicated that watching someone else’s behavior can trigger a cascade of neural activity that is similar to the neural activity involved in one’s own primary experience (Brass & Rüschemeyer, 2010).

The other aspect of declarative knowledge, the apparent ability of explicit knowledge to be examined consciously, needs more explanation, and probably a completely separate paper. Briefly, though, the main advantage of implicit, or non-declarative knowledge, is that it is so well integrated into the neural network that it is ready for use without any conscious reflection. That is of course its main liability as well, because without conscious reflection there is no room for “free will”, no room for new responses, and no room for transfer of knowledge to novel situations. How, then, does declarative knowledge gain this apparently conscious element? There is perhaps no hotter topic in philosophy of mind these days (see Metzinger (2009) for example), so I will not presume to solve this problem for all time. However, an intriguing possibility, and one that is in line with what is known about the biological constraints of the human nervous system, was put forth decades ago by Antonio Damasio (1989). He pointed out that a mechanism in the hippocampus allowed incoming messages to be, essentially, bounced back to the sensory store from which they had just come. Because incoming sensory information must reach the hippocampus in a cohesive timeframe, the bouncing back must also occur in tandem, restimulating the same sensory stores as the original experience. He did not discuss verbal stimulation in particular, but because we know that verbal information stimulates the same sensory store as heard language (Hubbard, 2010), this mechanism should work for verbal information as for any other sensory stimulation. What does this ability to bounce an experience back for re-experiencing buy us? Just this: it allows for the opportunity, as any multi-neuron synaptic junction would, for the original stimulus to be affected by other elements rather than triggering an automatic and unalterable cascade of activity. Implicit knowledge does not need to go through this bounce-back process because it’s already usable, and in many cases, already crystallized. Explicit knowledge, however, differs from implicit knowledge in the “second chance” it gives its network, and of course the environment, to affect the cascade of activity in a new or more subtle way. This explicit second chance may not result in fast, or

graceful, processing and activity (that is the strength of implicit knowledge), but it gives our neural net the opportunity to bring old symbols, old categories and old knowledge to bear on a new situation. The analogy I have used with students is very over-simplified, but may help to illustrate this distinction. If a sensory stimulus is like a pebble and our neural network is like a pond, then implicit knowledge is the set of waves that travel across the pond without hindrance when the pebble is dropped into its center, and explicit knowledge is the set of waves that results from the pebble's original waves encountering a partial barrier that bounces back some of the waves allowing them to interact again with the out-moving waves. The explicit is more complicated, more interesting, more filled with information (in the information theory sense), but the implicit is more graceful and efficient.

So, it's possible for both non-declarative and declarative knowledge to develop within the severe constraints built into the biological machinery about which we already know.

Activities that Foster Development

What kinds of activities, then, foster knowledge development in such a system, with so few clear mechanisms for plasticity? Imagine the elaborately connected human nervous system moving about in the environment with all of its electrical activity visible for observation. Notice that the nervous system is constantly active and that what changes is the relative activity of the system: relative both in time and space. This system does not passively await inputs, but constantly changes in response to the particular interactions it has with its environment. It should be clear at this point, that a system such as this one has no "input" device. It has, rather, the ability to make small adjustments in real time in response to real events. This system will only be as useful as the meaningful distinctions to which it can attend and respond. What activities will, naturally, produce patterned and intelligent behavior?

Perhaps obviously, the neural network will store reliable patterns detected in the environment: if a set of neurons is consistently firing together, they will begin to wire together, thus storing a united response to a unified set of stimuli. There are two major sources for such reliable patterns: the natural invariances in the physical world, and the sets of actions that produce reliable (or meaningful) results for the organism (contingent activities). Notice how perfectly these sources match our two major learning mechanisms: associative conditioning and operant conditioning.

Invariance in the Environment

Why does the physical world provide such a rich source of useful invariances (or correlations) for the nervous system? The short answer is "evolution". Because the particular physical environment in which we all develop is the product of multiple, simultaneous lines of successful evolution, within the same set of physical constraints based on the physical structure and physical laws of this particular planet,

the characteristics that tend to appear simultaneously tend not to be arbitrary co-occurrences, but rather quite meaningful and successful co-occurrences. In other words, if our nervous system happens upon a set of co-occurring characteristics in the natural world, they are extremely likely to be the product of a long and successful line of evolution, and therefore be the opposite of arbitrary or capricious.

All else being equal, then, the set of repeated co-occurrences we encounter will tend to be meaningful, not meaningless, co-occurrences, and therefore very useful for us to learn to perceive, "chunk" and to be able to act on. Our physical environment is full of non-arbitrary co-occurrences. The physical laws at work here are the same physical laws that have shaped our planet for billions of years and that have driven evolution of all the living species we encounter since life began on this planet. And the co-occurrences of living things in a particular environment are also non-arbitrary because these living things have had to survive within the same environment for millions of years. So the living organisms that we encounter have been successful not just in our particular physical environment, but in our particular ecological niche as well.

Contingent Activities

Held and his colleagues found quite a while ago that contingent experiences were necessary for the normal development of kittens (Held & Hein, 1963). In his elegant set of experiments, in which kittens were literally yoked during their daily visual stimulation and were able to move around the visual stimuli based on just one of the yoked kittens' movements, Held showed that kittens with completely equal visual stimulation, and deprivation, developed completely different visual capabilities depending only on whether the visual stimulation was contingent on the kitten's own activity.

Fox and Oakes updated Held's experiments by doing a similar set of experiments using undergraduates, instead of kittens, and video games, instead of a yoked carousel experience (Fox & Oakes, 1984). In this set of experiments, undergraduates were virtually yoked to each other while they played one of two versions of a video game. In one version of the game, the undergraduates' success at destroying elements of the virtual world was completely contingent on their motor behavior: if their aim and timing was good, they were able to blow up a lot of objects; if their aim and timing was poor, they had little success. In the second version of the game, undergraduates experienced the same (yoked) number of apparent successes, but the success had nothing to do with their motor behavior: it depended completely on the success of the undergraduate to which they had been virtually yoked. However, the second version of the game was designed to make it look like the success was contingent on the player's skill: elements were slowed or speeded up in order to make appropriate, successful, contact. When tested afterwards all of the undergraduates felt as though they had succeeded: consciously they felt like their actions mattered. But the undergraduates who played

the non-contingent form of the game were not as successful at a subsequent, unrelated, lexical decision task.

Notice that “contingent experience” is any experience in which the organism’s actions are related, reliably, to the feedback the organism receives, whether or not the organism is consciously aware of this reliable relationship.

Both Invariance and Contingency

Diamond and Rosenzweig and their colleagues looked at both elements at once. They found that rats that grew up in an environment with lots of new, physical and social interactions, developed more useful and heavier brains (Rosenzweig, Bennett, & Diamond, 1972). Interestingly, when the interaction was eliminated, by having rats near enough to watch but not interact with all the stimulation, the rats’ brains did not become as useful or heavy. Most importantly, however, these “enriched” lab rats had brains that were significantly less useful, heavy, and well-connected than rats raised in the wild (where both invariants, and contingency are much more widely available) (Huck & Price, 1975; Zhao, Toyoda, Wang, & Zhuo, 2009).

Flanagan (1996) showed that in a normal classroom setting, third graders who did an activity that involved contingent rather than non-contingent feedback for just fifteen minutes were subsequently significantly less likely to give up in a challenging but possible puzzle. Furthermore, third graders who used physical rather than virtual materials were significantly more likely to be able to build on that knowledge.

Natural feedback refers to feedback that is not dependent on a teacher, programmer or author, but that is instead inherent in the activity itself. So dropping objects of different weights does not require a teacher to give positive or negative feedback; the gravity of the physical world gives this feedback naturally. Most interactions with the natural world provide such feedback, but natural feedback is not limited to the natural or physical world: computer programming, for example, provides natural feedback because the programmer does not need a teacher or authority to provide positive or negative reinforcement – the programmed code either works or it doesn’t. All else being equal, though, the natural world is the safer bet since co-occurrences in the natural world are the product of evolution, and interactions with the natural world follow the laws of physics. Artificial, or authored, environments depend completely on the author, or programmer to provide meaningful co-occurrences, and to provide meaningful feedback – these must be deliberately incorporated, while in the natural world they are already an integral part.

Natural feedback is also less available in stereotypically female hobbies than in stereotypically male hobbies. Playing with water pistols provides natural feedback – either you get wet or you don’t. Many stereotypically female hobbies depend on the opinions offered by peers or authority figures: does this look pretty? Have I pleased you? Is this good? Dweck and her colleagues have found

that personal feedback rather than task-related feedback interferes with the mastery orientation of children solving challenging problems (Dweck & Leggett, 1988). Because of this difference in available stereotypically female and male after school activities, Flanagan and Canada provided school-age female students with one hour a week of after-school activities in which the students got natural feedback for both invariance in the environment and their own contingency (Flanagan & Canada, 2010). These students did computer programming (Scratch (Group) or Lego Mindstorms (Lab, 1999)) or building scale models (Google Sketch (Google, 2010) or physical craft materials) for eight weeks. At the end of the eight weeks the students had significantly better spatial reasoning skills than a similar control group, and felt significantly more confident about doing math and using computers.

Ordinary Experiences

In environments that consist of inherently meaningful co-occurrences and opportunities for consistently meaningful feedback the nervous system thrives. Repetition, or practice, in such environments should produce robust, well-organized, functional nervous systems. The practice effect is well-established, but shouldn’t be ignored: too often we turn to the conceptual or technological shortcut when mere practice in a meaningful environment would do more good. Imagine a basketball team that got an hour or two of lecture a week and then several readings in order to get ready to play the season; imagine an orchestra that got an hour or two of lecture a week and then had to read their musical scores as homework for getting ready for their concert season. This sounds ridiculous, of course. But we expect our students to learn more “cognitive” skills this way even though it shouldn’t work given the mechanisms available, and routinely fails to work (see (Sahiner, 1987) for example). If we accept the mechanisms we’ve been given, cognitive education should begin to look more like physical and musical education.

“Baby Einstein” media have recently been (finally) recalled because they probably do more harm than good (Lewin, 2009). As cognitive scientists we owe anxious parents the benefit of our expertise, and must point out that ordinary interactions with people and meaningful objects are better suited to the developing nervous system than “educational” consumer media. Because, (un)fortunately, constrained by the biological machinery with which we are born there is no magical input portal for pouring fully formed knowledge systems into the human mind: there are just a few simple mechanisms that must incorporate knowledge through lots of simple, ordinary, meaningful encounters over a long period of time.

Conclusion

The human nervous system is the product of millions of years of evolution within an ecology that has simultaneously been evolving. So it makes sense that the human nervous system should be optimized for operating within the

particular natural and physical world we call “earth”. Indeed when we look at the particular mechanisms actually available to the human nervous system for learning and developing a solid knowledge base, these mechanisms seem to be ideal for detecting and learning naturally occurring invariances in our ordinary environment, as well as for learning actions that turn out to be important and meaningful to the nervous system itself. These are the very elements that Lloyd argued were the minimum essential requirements for anything we would consider to be a “mind” (1989). Furthermore, these mechanisms work best when the applicable neurons are activated simultaneously over a significant period of time.

Activity that involves important co-occurrences that are meaningful for the organism over significant periods of time are more succinctly termed “ordinary” experiences and are the foundation of our solid and meaningful neural network. We would be wise to build on this framework rather than attempting to circumvent it. Practice in real environments in real time has long been the accepted practice in athletics and music. It is time for other human endeavors to follow the same advice.

Abstract

We present a connectionist model of a general system for producing inflected words. The Multiple Inflection Generator (MIG) combines elements of several previous models (e.g., association between phonological representations of stem and inflection form: Rumelhart & McClelland, 1986; multiple inflections for a grammatical class: Hoeffner & McClelland, 1993; lexical-semantic input: Joanisse & Seidenberg, 1999; multiple grammatical classes: Plunkett & Juola, 1999). MIG assumes that the goal of the morphological component of the language system is to output a phonological form appropriate to the grammatical context in which the word appears. Our aim was to demonstrate that the model is able to capture developmental patterns in the acquisition of morphology in two different languages: one with a simple morphological system (English), and one characterized by rich morphology and absence of default forms (Modern Greek).

Keywords: Inflectional Morphology; Cross-linguistic Language Acquisition; Neural Network Modeling

Introduction

The Rumelhart and McClelland (1986) model for the acquisition of past tense was extremely influential and spawned new models on morphological acquisition. The model had several drawbacks. First, it is unlikely that the language system would have a specific component for one inflection type within one grammatical class. Second, the model did not simulate all the error patterns that children exhibit in development, notably the presence of unmarked forms. Third, the generalization of inflectional rules to unusual novel inputs was somewhat poor. More widely, it remains to be seen whether an architecture appropriate for modeling morphological acquisition in one language can readily extend to other languages that may have quite different inflectional paradigms. In this article, we present a model that is generalized to all inflectional types within a language (English) and show how the same architecture can be generalized to a different language with a richer inflectional structure (Modern Greek).

Our approach assumes that the language system comprises functional components and that at least one of the components is involved in conditioning the phonological properties of words during output so that their forms are appropriate to the grammatical context in the sentence in which they will appear. The goal was to simulate qualita-

tive developmental patterns in the acquisition of English and Modern Greek, including the order of acquisition across inflection types and proportions of error types across development.

Previous connectionist models of morphology

Rumelhart and McClelland's (1986) model of the acquisition of the English past-tense was the first to apply the principles of Parallel Distributed Processing in the domain of inflectional morphology. This influential model showed that a two-layered feed-forward neural network architecture could learn mappings between phonological representations (Wickelfeature representations) of stems and corresponding past tense forms of English verbs. The model also simulated a wide range of phenomena reported in empirical studies of the acquisition of morphology, such as frequency effects and the U-shaped learning curve for the acquisition of irregulars (Brown, 1973).

This model demonstrated that an explicit representation of rules was not necessary for the acquisition of morphology. Instead, rule-like behavior was an emergent property of the learning system and reflected statistical regularities in the mappings of the training set. Rumelhart and McClelland challenged the existing 'symbolic' view, which proposed the dual-route account for morphological development (Pinker, 1984). According to this account, two separate mechanisms were involved in the learning of morphology. A rule-based system supported the learning of regular mappings, while a rote-memory system supported the learning of irregular mappings. The so-called 'past tense debate' emerged within the field of language acquisition.

Criticisms against the connectionist approach (e.g., Pinker & Prince, 1988) ranged from those pointing out implementational issues (e.g., the psycholinguistic implausibility of Wickelfeature representations) to those questioning the ability of the connectionist framework to address certain aspects of language acquisition (e.g., generalization). Subsequent connectionist studies addressed many of these criticisms by proposing more detailed models: Plunkett and Marchman (1993) refined the general principles of the model of Rumelhart and McClelland (1986) in a three-layered feed-forward architecture which employed more realistic phonological representations;

other studies incorporated lexical-semantics in the connectionist architecture to address dissociations in the learning of regular and irregular verbs (e.g., Joanisse & Seidenberg, 1999); Plunkett and Juola (1999) studied the acquisition of noun plural and verb past tense in a single connectionist network, while Hoeffner and McClelland (1993) considered multiple verb inflections. Finally, other work demonstrated that implementing a developmental deficit in connectionist architectures could simulate the acquisition of morphology in atypical language development. (e.g., Hoeffner & McClelland, 1993; Joanisse, 2004; Thomas & Karmiloff-Smith, 2003).

Acquisition of inflectional morphology in English

English inflectional morphology is characterized by its simplicity, manifested by the extensive use of default (base or uninflected) forms. For example, noun inflection does not consider gender and does not distinguish between the nominative and the accusative case. Psycholinguistic studies of inflectional morphology in English often focus on the domain of the past tense. This paradigm is of particular theoretical interest because it is quasi-regular. The majority of verbs form their past tenses through stem-suffixation (e.g., walk / walked). A rule determines the appropriate allomorphic suffix (/t/, /d/, or /^hd/) based on the last phoneme of the stem. However, a significant number of verbs form their past tenses irregularly (e.g., swim / swam, hit / hit, go / went).

Early studies on child language (e.g., Berko, 1958; Brown, 1973; de Villiers & de Villiers, 1973) established that different inflections in English are acquired in a consistent order along development. For example, the progressive of the verbs is acquired earlier than the past tense. Other studies addressed the profile of individual inflections in greater detail. For example, van der Lely & Ullman (2001) showed that accuracy rates are greater for regular than for irregular inflections. Accuracy also depends on type and token frequency. Frequency effects are more pronounced in irregular inflections (the so-called frequency by regularity interaction). Finally, children are efficient in generalizing the rule to novel forms (e.g., wug / wugged).

Morphological development is characterized by developmental error patterns. For example, children often produce base forms in contexts in which grammatical marking is obligatory (e.g., *He come home / He comes home). This type of error is referred to variously as a *no-mark error*, *no-change error* or *omission error*. Rice, Wexler, and Cleave (1993) suggested that omission errors define an early stage in language development, in which morphological marking is not applied consistently on the base forms. They termed this stage as the Optional Infinitive (OI) stage. Zero-mark errors occur in greater percentages in irregular inflections (e.g., Matthews & Theakston, 2006; van der Lely & Ullman, 2001).

Another prototypical error pattern is *overregularization* or *over-generalization*. This type of error refers to the (incorrect) application of a rule on irregular

stems (e.g., **thought* / thought). Overregularization errors appear later in development than omission errors (Brown, 1973). As a result, in Brown's stage II (age range: 28-36 months, MLU range: 2.0-2.5) a sudden drop in the production of correct irregular forms was observed. This phenomenon is often described in terms of a U-shaped learning curve of irregulars. Overregularization errors are sometimes taken as evidence for the productive use of rules in child language (Marcus, 2000). Finally, a related error type is the *blend error* or *double-marked error* (e.g., Kuczaj, 1978). These errors refer to cases in which children apply a rule to an irregularly inflected form (e.g., **wented* / went).

Acquisition of inflectional morphology in Modern Greek

Modern Greek is a language with a rich morphological system. As Stephany (1997) describes, there are no default forms of words in Modern Greek. Instead, many different grammatical features are fused in single word forms. For example, nouns have grammatical gender, and are inflected with respect to case and number. Verbs are inflected with respect to person, tense, aspect and voice.

Modern Greek also presents different conjugational classes in nominal and verbal inflections, challenging the dichotomy between regular and irregular inflectional categories. For example, studies on the perfective past tense (e.g., Stavrakaki & Clahsen, 2001) describe three classes of verbs with respect to the marking of the perfective aspect. The 'sigmatic' class is the major class of verbs. The perfective past tense forms in this class are characterized by the addition of the aspectual marker /s/ ('sigma' in Greek) to the stem (e.g. *pez-o* / *e-pek-s-a*, play / played - 1st person singular). The addition of the aspectual marker may invoke phonologically predictable changes to the stems. A second class of verbs does not employ the aspectual marker /s/, and presents unpredictable modifications of the stem (e.g., *plen-o* / *e-plin-a*, wash / washed - 1st person singular). Finally, a third class of verbs have idiosyncratic perfective past tenses forms (e.g., *tro-o* / *e-fag-a*, eat / eaten - 1st person singular).

Stephany (1997) studied the production data of three children. Based on these data she suggested an order for the acquisition of different grammatical inflections and different grammatical features in Modern Greek. For example, tense is acquired earlier than aspect. Rare nominal conjugational categories are acquired late in development. As default forms are missing in Modern Greek, it has been suggested that the Optional Infinitive stage is realized by production of certain frequent forms in inappropriate contexts. Stephany (1997) observed that children undergo an early stage of development (up to 3 years old) in which they produce a lot of 3rd singular forms instead of the correct verbal inflections. Thus, 3rd singular forms could be considered an analogue of root infinitives in English (Varlokosta, Vainikka & Rohrbacher, 1998). Finally, with regard to the perfective past tense, Stavrakaki

and Clahsen (2009) found that the sigmatic rule is over-generalized in verbs belonging to non-sigmatic categories. The sigmatic rule is also preferred for the production of past tenses of novel verbs.

Simulations

Design

Our aim was to increase the generality of the original past tense model across inflection types, grammatical classes, and across languages. We began by combining elements of previous connectionist models of morphology (e.g., multiple grammatical classes: Plunkett & Juola, 1999; multiple inflections for a grammatical class: Hoeffner & McClelland, 1993; lexical-semantic input: Joanisse & Seidenberg, 1999) to implement a generalized inflectional system. The Multiple Inflectional Generator (MIG) considered three grammatical classes (nouns, verbs, and adjectives) and multiple inflections for each grammatical class (e.g., nouns: base forms, plurals, and possessives). The aim of MIG was to output a phonological form appropriate to the grammatical context in which the word appeared.

Following Plunkett and Marchman (1993), we constructed two training sets based on artificial languages that reflected the basic features of the morphological systems of English and Modern Greek. We performed two sets of simulations. In the first set of simulations, MIG was trained using the English training set. In the other, MIG was trained on the Modern Greek training set. In each condition, we contrasted the learning profile of MIG to corresponding data from empirical studies on the acquisition of morphology outlined above. For reasons of space, from the full set of behaviors exhibited by the model, we concentrate on reporting results from past tense. The goal was to replicate the following empirical effects: For English: (i) the relative acquisition of regular and irregular verbs; (ii) the frequency by regularity interaction in accuracy; (iii) the Optional Infinitive stage; (iv) the greater incidence of unmarked stem errors for irregulars; (v) the relative incidence of over-generalization and blend errors; (vi) generalization to novel stems. For Modern Greek: (i) the relative acquisition of sigmatic and non-sigmatic categories; (ii) the production of 3rd singular forms as analogue of the Optional Infinitive stage; (iii) the over-generalization of the sigmatic rule in verbs belonging to non-sigmatic categories; (iv) the generalization of the sigmatic rule to novel stems.

Architecture

The MIG employed a three-layered feed-forward neural network architecture. Four sources of information (cues) were presented in the input layer (Figure 1). (1) Input Phonology (95 units) encoded the phonological properties of the base forms using a five-slot scheme parallel to the that used in Plunkett & Marchman (1991, 1993). Each slot could encode a phoneme based on a distributed code

of 19 binary articulatory features (Thomas & Karmiloff-Smith, 2003). The articulatory features (e.g., sonorant, consonantal, voiced, rounded) corresponded to standard linguistic categorizations (Fromkin & Rodman, 1988). The Input Phonology layer used only the first three slots to encode the phonological structure of monosyllabic words. (2) Following Joanisse and Seidenberg (1999), Lexical Semantics (1600 units) were used to provide localist representations of the meaning of each base form. (3) Grammatical Category (3 units) provided part-of-speech information. (4) Target Inflection (10 units) provided information on the type of inflection the network should consider (e.g., for verbs: base, past tense, 3rd singular or progressive).

The network was required to produce a phonological representation of the appropriate inflected form in the output layer (Output Phonology). The Output Phonology layer employed 95 units to implement a five-slot scheme. The last two slots were used to encode inflectional suffixes. In order to address morphology in Modern Greek, limited changes were introduced to the initial architecture solely to capture differences in the morphological structure of Modern Greek. In particular, the Target Inflection cue was expanded to include: gender, number and case information for nouns; gender, number, case, and grade information for adjectives; tense, aspect and person information for verbs. Additionally, Input Phonology provided phonological representations of word stems, without considering any inflectional suffixes and affixes. Finally, the Input and Output Phonology layers employed a twelve-slot scheme to incorporate morphological affixes, suffixes and disyllabic stems.

Training Sets

English Training Set. The training set for English was constructed based on measurements of type frequencies of different grammatical categories, different inflections or allomorphic subcategories of the same inflection. These measurements were derived from the tagged Brown corpus (Francis & Kucera, 1999) via computational linguistics methods. The NLTK open source software (<http://www.nltk.org>, accessed May 2010) was used for processing the Brown corpus. Frequencies of different grammatical categories and different inflection types were based on the counts of different tags in the corpus. Fre-

quencies of the allomorphic categories (e.g., /t/, /d/, /^hd/ past tenses) were obtained using algorithms that identified the last phoneme of the stems.

The training set consisted of 1,600 words and 5,200 inflections based on those words (word-to-inflection ratio: ~0.3). The 1,600 words were artificial monosyllabic phoneme strings (800 verbs, 400 nouns, and 400 adjectives) which followed one of three templates (CCV, VCC and CVC; see Plunkett & Marchman, 1993). Ten different inflections were considered for the English training set (nouns: base form, plural, possessive; verbs: base form, progressive, 3rd singular, past tense; adjectives: base form, comparative, superlative). The inflected forms incorporated two additional phonemes for the inflectional suffixes. Combining words with their different possible inflections, the English training set comprised 5,200 stem / inflected form mappings. A simplified two-level scale of token frequency (Thomas & Karmiloff-Smith; 2003) was implemented by scaling the weight changes computed by the Back-propagation of Error algorithm (Rumelhart, Hinton, & Williams, 1986) after the presentation of each mapping. For arbitrary mappings (e.g., go / went) the weight changes were multiplied by 9 for tokens of high-frequency and 6 for tokens of low-frequency. For all other mappings, the weight changes were multiplied by 3 for high-frequency tokens, and 1 for low-frequency tokens.

A generalization set of 1,600 novel types and the corresponding 5,200 tokens was also created. It consisted of three subsets of stems with differing degrees of similarity to the stems of the training set. Items for the first subset of the generalization set were created by changing the first phoneme of existing stems. Items for the second subset were generated by changing the first two phonemes of the existing stems. In both cases a consonant was replaced by another consonant and a vowel with another vowel to conform to the phonotactics imposed by the three templates used for the training set. Items in the third subset were generated by changing the first two phonemes of existing stems in a way that violated the phonotactics of the artificial language.

Modern Greek Training Set. For the Modern Greek training set, type frequencies of different inflections and different conjugational categories were based on descriptions of Stephany (1997) or sampling of the Hellenic National Corpus of the Institute of Speech and Language Processing (ISLP, <http://hnc.ilsp.gr/en/>, accessed May 2010). In the absence of any other constraints, type frequencies were made parallel to type frequencies of the English training set. The Modern Greek training set consisted of 1600 types and 26,400 tokens (type to token ratio: ~0.06). The 1,600 types were a vocabulary of 800 verbs, 400 nouns and 400 adjectives. Items were dissyllabic, and conformed to the phonotactics of Modern Greek. Nouns were inflected in the nominative, the genitive and the accusative case of the singular and plural number. Verbs were inflected with respect to person (1st, 2nd, and 3rd), number (singular, plural) and tense (present, perfective past, imperfective past). Adjectives were in-

flexed with respect to gender, case and number in the plain, comparative, and superlative grade. The Modern Greek training set consisted of a total of 26,400 mappings (tokens). A generalization set of 1,600 novel types and the corresponding 26,400 types was also constructed. Items for the generalization set were generated by changing the phonemes of the first syllable of the stem of items of training set.

Procedure

Networks were trained for 400 epochs, using the Back-propagation of Error algorithm (Rumelhart, Hinton, & Williams, 1986). The length of training was selected to ensure that the networks achieved final ceiling levels of performance. Based on piloting, the following parameters were used in both English and Greek versions of the model: 75 hidden units, learning rate 0.01, momentum 0. Results were averaged over 10 replications with different random seeds. Training was not incremental but used the full training set throughout, with one caveat: in each epoch, the network was exposed to a random 30% of the total inflected forms, corresponding to the number of different words in the training set.

Results

Network output was evaluated using a variant of the Nearest Neighborhood algorithm. The output activation for each slot was made equal to its nearest neighbor in the Euclidean space of the phonemes, so that continuous activations were converted to phonemic strings. The string was then assessed against pre-defined categories, based on patterns presented in empirical investigations of children's productivity (e.g., 'correct', 'omission errors', 'over-generalization errors', 'blend errors', 'other'). In this section we present initial results from the two simulations, demonstrating the viability of the more general model.

Simulation 1: English Training Set

The simulation results were parallel to the acquisition profile of the English past tense in several ways. Accuracy rates were higher for regulars than for irregulars. Type frequency effects were more pronounced for irregulars. MIG reproduced an OI stage, characterized by high percentages of omission errors for both regulars and irregulars. The rates of no-mark errors were higher for irregulars than for regulars. MIG also simulated overgeneralization errors and blend errors. Finally, the past tense rule was efficiently generalized in novel items with accuracy rates of 88%, 86%, and 43% for novel stems most to least similar to stems in the training set. Importantly, for the latter, accuracy levels went up to 83% when errors in the reproduced stem were ignored. That is, while the network sometimes struggled to output very strange, phonotactically illegal novel stems, it nevertheless showed a high level of accuracy in outputting an appropriate past tense morpheme. It was able to do so because the Verb gram-

mathematical class unit and Past Tense target inflection units could form strong connections to the inflectional morpheme region of the output layer. In some respects, this is equivalent to an implementation of a ‘rule’ for past tense formation (Marcus, 2001). In this way, the MIG improves on the rule induction ability shown by the original Rumelhart and McClelland model.

Figures 2 and 3 contrast the developmental trajectory of MIG for the first 100 epochs of training with corresponding cross-sectional behavioral data from van der Lely and Ullman (2001) for 6-8 year old children, for regular and irregular past tense formation. As training was performed in a non-incremental fashion, we do not take the very early stages of training to be psychologically realistic (see Plunkett & Marchman, 1993). To evaluate the modeling results in light of the empirical data, we identified a window in the training time of the model (epochs 20-70) in which the accuracy rates of the model in the regular past tense were matched to those reported in the developmental study of van der Lely and Ullman (2001). In this time window, the rates of the main error patterns in the simulation results present qualitative similarities to the rates in the empirical data. Once more, compared to the Rumelhart and McClelland model, MIG now combines simulation of correct performance with error patterns.

Figure 2: Regular past-tense acquisition in MIG compared to empirical data on from van der Lely & Ullman (2001)

Figure 3: Irregular past-tense acquisition in MIG compared to empirical data on from van der Lely & Ullman (2001)

Simulation 2: Modern Greek Training Set

MIG was also able to learn the complex mappings of the Greek training set. For the perfective past tense, accuracy rates were higher for the sigmatic class than the other conjugational classes. The sigmatic rule was generalized efficiently to novel items (accuracy rates for generalization: 71%).

The model also captured the major developmental error patterns. It simulated an early phase in which 3rd singular forms were produced in inappropriate contexts, which Varlakosta et al. (1998) identified as a marker of the Optional Infinitive stage. It also captured the pattern of overgeneralization of the sigmatic rule in non-sigmatic conjugational classes. Both of these error patterns are depicted in Figure 4, which compares the learning profile of MIG in the 2nd person singular non-sigmatic category (e.g., *plen-o* / *e-plin-es*, *wash* / *washed*) and corresponding data by Stavrakaki and Clahsen (2009).

Figure 4: Non-sigmatic perfective past tense in MIG and empirical data from Stavrakaki & Clahsen (2009)

Conclusions

Connectionist approaches to the acquisition of morphology have faced four challenges: to simulate developmental error patterns as well as accuracy levels; to demonstrate that associative systems can generalize inflectional rules to unusual novel stems; to show that architectures can be general across inflection types and grammatical classes, rather than focusing on narrow inflectional paradigms; and to show that architectures can be general across languages, even though those languages may place very different demands on acquisition due to the complexity of their morphology.

In this paper, we introduced the Multiple Inflection Generator. The model is novel in that phonological output forms are conditioned to be appropriate to their grammatical context by the integration of multiple input cues. These input cues include the phonological form of the stem, lexical-semantics, grammatical class, and target inflection information. Cues are relied on differentially depending on the mappings of various inflectional forms (see, e.g., Joanisse & Seidenberg, 1998, for the greater reliance of irregular verbs on lexical-semantic information, also shown by our model).

Focusing on the past tense, we showed how the MIG reproduced error patterns as well as accuracy levels. Notably, in both English and Modern Greek, an Optional Infinitive stage was observed, even though the character of that stage is different in each language (unmarked stems vs. 3rd person singular). Generalization rates of the past tense rule were high for novel stems, even for phonotactically illegal stems. MIG captured the order of emergence of different inflection types for different grammatical classes. And it was able to capture developmental patterns for two languages of different morphological complexity.

These results are only preliminary. More detailed work is required to establish quantitative fits both within and between languages. However, our initial findings demonstrate the viability of a more general, cross-linguistic model of the acquisition of inflectional morphology.

Handling what the other sees: the effects of seeing and being seen on gesture production

Abstract

Language production is often argued to be adapted to addressees' needs. As an instance of this, speakers produce fewer speech accompanying hand gestures if the speaker and the addressee cannot see each other. Yet there is also empirical evidence that speakers tend to base their language production on their own perspective, rather than their addressee's. Therefore, speakers may gesture differently because they do not see their addressee, rather than because their addressee cannot see them. Can speakers truly apply their knowledge of what their addressee sees to their gesture production? We answered this question by carrying out a production experiment in which visibility between speaker and addressee was manipulated asymmetrically. We found that representational gestures were produced more frequently when speakers could be seen by their addressee, rather than when they could see their addressee, suggesting that speakers indeed apply their knowledge of the addressee's perspective correctly to their gesturing.

Keywords: Gesturing, Audience Design.

Introduction

Language use sometimes requires taking into account what another person can or cannot see. For example, when watching a documentary on Venice with a friend, you might ask your friend "have you ever been there?", where *there* refers to Venice. However, if your friend was in the same room, but working on her computer "have you ever been to Venice?" may be more appropriate. Because you know your friend is not watching the documentary, you may choose a more explicit reference. On the other hand, if you were asked by your friend, "have you ever been there?", while working on your computer, your knowledge of her watching a documentary on Venice may help in arriving at the correct interpretation. Yet would you do so correctly if you happened to be browsing a website on Cologne?

Language production is often argued to be adapted to the needs of addressees (e.g. Grice, 1989). As an instance of this, it is well established that speakers produce fewer speech accompanying hand gestures when interlocutors cannot see each other (Cohen & Harison, 1973). Yet several empirical studies suggest that applying knowledge of what another person can and cannot see is not at all straightforward (e.g. Keysar, Lin, & Barr, 2003; Wardow Lane, Groisman, & Ferreira, 2006). These studies suggest that interlocutors tend to base their language use on their

own perspective, rather than that of their conversation partner.

To our knowledge, in studies on hand gestures, visibility has always been manipulated symmetrically. That is, whenever the addressee could not see the speaker, neither was the speaker able to see the addressee. Therefore, these studies cannot reveal whether it is the speaker's own perspective that underlies this reduction in gesture frequency, or whether speakers adapt their language use to their addressee's perspective. In this study we aim to fill this gap, by manipulating visibility asymmetrically. For this we make use of computer-mediated communication. We will therefore also make a comparison of our data in computer-mediated settings to data acquired in similar unmediated settings (Mol, Krahmer, Maes, & Swerts, 2009).

Taking into Account what an Interlocutor sees

Keysar, Lin, and Barr (2003) have shown that people make 'mistakes' in interpreting speech, when deriving the correct interpretation requires applying one's knowledge of what the speaker does not see. In their study, a follower had visual access to an object that was occluded from the director's view. Still, when the (confederate) director's description more closely resembled the hidden object than any of the mutually visible objects, the follower often considered this object as a referent, sometimes even moving it instead of the intended object. This shows that the follower's knowledge of what the director could (not) see was not automatically applied to the interpretation process.

Wardow Lane, Groisman, and Ferreira (2006) found similar results for reference production. In their study a speaker had private visual access to an object that only differed from the target object in size. Even though the addressee could not see this competing object, speakers often included a contrasting adjective, such as 'small' in their reference to the target object. Surprisingly, they did so even more when instructed to conceal their private information from the addressee. Thus, it seems that speakers have difficulty in applying their knowledge of what their addressee can see to the speech production process as well.

Gesturing out of Sight

The question naturally arises whether knowledge of what another person sees is applied correctly to the production of

co-speech hand gestures. These gestures are spontaneous movements of the hands and arms during speech (e.g. McNeill, 1992). Hand gestures can, amongst other functions, be communicative. For example they can convey meaning (e.g. Beattie & Shovelton, 1999) or emphasize certain parts of speech (e.g. Hadar, 1989; Krahmer & Swerts, 2007). It has been found repeatedly that speakers' gesturing differs depending on whether their addressee can see them or not (e.g. Alibali, Heath, & Myers, 2001; Bavelas, Gerwing, Sutton, & Prevost, 2008; Cohen & Harison, 1973). For example, Alibali et al. asked participants to retell the story of an animated cartoon to an addressee. During half of the narration, an opaque screen separated speaker and addressee, such that no information could be conveyed through hand gestures. They found that speakers gestured less frequently when the screen was in place. This was especially true for *representational gestures*, which depict some of the content a speaker is trying to convey. It thus seems that at least some gesturing is influenced by the speaker's knowledge of what the addressee can and cannot see.

However, in the studies cited above, visibility was always manipulated symmetrically. That is, the addressee could not see the speaker, but neither could the speaker see the addressee. It is thus possible that speakers used their own perspective, and that their gesturing changed as a result of them not seeing the addressee, rather than of them correctly applying their knowledge of what the addressee could see. If so, many other factors may have influenced gesture production, such as perceived attentiveness of the addressee, social fulfillment during the task, general motivation, etc. Indeed, Jacobs and Garnham (2006) found that people gesture less frequently towards an addressee who appears to be less interested. Interest can be conveyed by gaze (Argyle & Cook, 1976), and also by body posture and head nods, which are all absent if visibility is obstructed. It is therefore still unclear whether the reduced frequency of hand gestures when interlocutors cannot see each other is an instance of the correct application of the knowledge the speaker has about the addressee's visual perspective.

Desktop Video-Conferencing

One way to manipulate visibility in an asymmetrical way is by computer-mediated communication. Yet is mediated communication representative of unmediated communication? Brennan and Oheari (1999) found evidence that mediated communication may differ from unmediated communication as a direct result of the differences in affordances between the media, rather than for example because interlocutors become less socially aware when they are not physically copresent. In typing - which is often used in mediated communication - different types of communicative behavior are effortful than in speech. Brennan and Oheari found that especially back-channeling behavior differed between spoken and written dialogue.

This in turn may affect interlocutors' perception of each other, rather than them not being physically co-present. Thus, the more affordances mediated communication offers, the more similar it will be to unmediated communication.

Modern video-conferencing tools allow speakers to see and hear each other even though they are in different locations. Isaacs and Tang (2003) observed interactions between technical experts that took place over the phone, through desktop video-conferencing, or face-to-face. They found that the experts used the visual modality in video-conferencing much like they did in face-to-face communication. "Specifically, participants used the visual channel to: express understanding or agreement, forecast responses, enhance verbal descriptions, give purely nonverbal information, express attitudes through posture and facial expression, and manage extended pauses", p. 200. They also list some differences between video-conferencing and face-to-face communication, for example, managing turn-taking, having side conversations, and pointing towards objects in each other's space were more difficult in video-conferencing.

In the video-conferencing we use, interlocutors can communicate through speech as though they are in the same room. The need for turn-taking is minimal, and there are only two interlocutors. Also, our task is not about manipulating the environment, which reduces the factor of not sharing a workspace. We therefore expect that manipulating mutual visibility will have similar effects in our mediated settings as it does in unmediated settings. But more readily than unmediated communication, video-conferencing enables one-way visibility, allowing for example the speaker to see the addressee, but not vice versa. It is thus very suitable for testing whether or not speakers employ an egocentric perspective when they cannot see their addressee.

Present Study

In this study we aim to gain insight into whether people generally employ an egocentric perspective in their language production. We address this question by testing if speakers' knowledge of whether their addressee can see them or not influences their co-speech gesturing. We manipulate visibility asymmetrically. That is, some speakers will be able to see their addressee, but will know that the addressee cannot see them, and some speakers will not be able to see their addressee, but will know that the addressee can see them. If gesturing is based on the speaker's own visual perspective, then gesturing will be more frequent when speakers can see the addressee, regardless of whether the addressee can see them. This could be either because the addressee seems more engaged or more present when visible, or because from the speaker's visual perspective, it seems as though speaker and addressee can see each other. Yet if speakers correctly apply their knowledge of the addressee's visual perspective, then they are expected to

gesture more when the addressee can see them, regardless of whether they can see the addressee. If both of these factors increase gesture production, then gesturing should be most frequent when interlocutors can see each other.

Method

Design

We have used a 2 x 2 between subjects design in which we manipulated whether or not the addressee could see the speaker and whether or not the speaker could see the addressee. In all conditions speaker and addressee could hear each other.

Participants

38 (21 female) native Dutch speakers, all students of Tilburg University, participated in this study as part of their first year curriculum. Two participants were excluded from our analysis (see Coding and Analysis). The remaining 36 participants (20 female) had a mean age of 22, range (18 - 30). The addressee was a female confederate, who was also a student at Tilburg University.

Procedure

The participant and the confederate were received in the lab by the experimenter, who assigned the role of speaker to the participant and the role of addressee to the confederate. Like in the study by Alibali et al. (2001), narrators were asked to retell the story of an animated cartoon (*Canary Row* by Warner Bro's). After reading the instructions participants could ask any remaining questions. (The confederate always posed a question.) The narrator's instructions stated that the addressee had to summarize the narration afterwards and explained that the narrator was videotaped in order to compare the summary to the narration afterwards.

When all was clear the narrator was seated behind a table with a computer screen on it, which in some settings showed a live video-image of the addressee, and in the remaining settings showed the interface of a video-conferencing application (Skype). The screen was connected to a pc, which also had a web cam connected to it. Behind the table stood a tripod, which held the web cam and a digital video camera. On the wall behind the video camera were eight stills from the animated cartoon, one from each episode, as a memory aid for the narrator and to elicit more structured and hence more comparable narrations.

The experimenter took the addressee to another room with a similar setup (but without the stills) and established a connection between the two pc's over the internet, using Skype. Sound and video were both captured by the web cams and sound was played back through speakers. Sound was tested by the narrator and addressee talking to each other and if applicable, the video image was tested by them watching each other. The connection was then suspended temporarily while the narrator was left alone to watch the

Figure 1: Left: example of a representational gesture (depicting hitting), Right: example of a non-representational gesture (placing emphasis while referring to a character).

animated cartoon on a different computer. When the cartoon had finished the experimenter re-established the connection, and seated the narrator behind the camera. The experimenter repeated whether the addressee could see the narrator or not, started the video recording, and left the room.

When the narrator was done telling the story, a questionnaire followed, which included questions on how the communicative setting had been experienced, how interested the addressee had appeared, whether any deception was suspected, and finally whether the participant was left or right handed. Meanwhile, the addressee ostensibly wrote a summary on yet another computer in the lab room. None of the participants had suspected any deception. After filling out the questionnaire, they were fully debriefed. All of the participants gave their informed consent for the use of their data, and if applicable for publishing their photographs.

During the narration, the confederate refrained from interrupting, laughing, etc. When necessary, minimal feedback was provided verbally. She always gazed somewhere near the web cam capturing her, independent of whether she could see the speaker.

Coding and Analysis

Video recordings of all narrators were coded using Noldus Observer. For each movement of the hands it was determined whether the movement was a gesture or a self-adaptor. Gestures were labeled as either *representational*, expressing some of the content of the speaker's story, or *non-representational*, placing emphasis or regulating interaction. Figure 1 depicts two examples. In the scene on the left, the speaker imitates a hitting motion while talking about someone hitting. In the scene on the right, the speaker refers to the main character and briefly moves his fingers up and down. In order to normalize for the duration of each speaker's narration, we have used the number of gestures produced per minute as the dependent variable, rather than the total number of gestures produced.

Figure 2: Means of the rate of representational gestures across settings.

The analysis was done using ANOVA, with fixed factors *addressee sees speaker* (yes, no) and *speaker sees addressee* (yes, no). Our significance threshold was .05 and we have used partial eta squared as a measure of effect size.

Two participants were excluded from the analysis, because they deviated more than 2 standard deviations from the mean gesture rate in their condition. As a result, there were 9 participants in each condition. Inclusion of these two participants did not affect the significant effects found, but did reduce the significance of the overall model.

Results and Discussion

We did not find an effect of gender or left or right handedness on gesture rate, or on the total duration of the narration. Neither did we find an effect of condition on the duration of the narration.

Effect of the Addressee seeing the Speaker

Figure 2 shows the mean number of representational gestures per minute in each setting. Whether or not the addressee could see the speaker reliably influenced this gesture rate, $F(1, 32) = 4.873$, $p < .05$, $\eta^2 = .13$. When speakers could be seen by the addressee, they produced representational gestures more frequently ($M = 5.7$, $SD = 5.8$) than when they could not be seen ($M = 2.6$, $SD = 3.4$). We found no significant effect of visibility of the speaker on the rate of non-representational gestures ($p = .35$).

Effect of the Speaker seeing the Addressee

The effect of whether the speaker could see the addressee approached significance for the rate of representational gestures, $F(1, 32) = 3.854$, $p = .06$, $\eta^2 = .11$. When speakers could see their addressee, they produced these gestures *less* frequently ($M = 2.8$, $SD = 3.4$) than when they could not see their addressee ($M = 5.5$, $SD = 5.3$). There was no significant interaction between visibility of the speaker and addressee ($p = .33$).

Figure 3: Means of the rate of non-representational gestures across settings.

The mean number of non-representational gestures in each condition is depicted in Figure 3. The effect of the speaker seeing the addressee on this gesture rate showed a trend towards significance, $F(1,32) = 2.977$, $p = .09$. Non-representational gestures were produced less frequently when speakers could see their addressee ($M = .84$, $SD = .87$), compared to when they could not ($M = 1.6$, $SD = 1.5$). There was no significant interaction with the addressee seeing the speaker ($p = .56$).

Perceived Interest

Our questionnaire revealed that in the setting in which the speaker could see the addressee but not vice versa, the addressee was perceived as significantly more uninterested than in any of the other conditions, $F(3, 31) = 5.232$, $p < .01$, see Table 1. (Pairwise comparisons were done using the LSD method with a significance threshold of .05.)

Discussion

When the addressee could see the speaker, speakers produced representational hand gestures more frequently than when the addressee could not see them. This was true both when the speaker could see the addressee and when

Table 1: Means and Standard Deviations of speakers' answer to the statement "The addressee was disinterested" on a 7 point scale, 1 = completely disagree, 7 = strongly agree.

Addressee sees Speaker	Speaker sees Addressee	Mean, SD of Perceived disinterest (1 to 7 scale)
Yes	Yes	2.7, 1.0
Yes	No	3.3, 1.3
No	Yes	4.5, 1.2
No	No	2.4, 1.1

Figure 4: Means of the rate of representational gestures in mediated and unmediated settings.

not. We therefore conclude that the knowledge a speaker had about what the addressee could and could not see was incorporated correctly into their hand gesture production.

We found an unexpected effect when speakers could see their addressee. When they saw a live video-image of their addressee, speakers produced representational gestures less frequently and also tended to produce non-representational gestures less frequently than when they did not see their addressee. This would be understandable if the addressee came across as less interested when visual feedback was provided. In the setting in which the addressee could not see the speaker, there was nothing relevant to look at for the addressee. To keep the settings comparable, the addressee therefore always gazed somewhere near the web cam capturing her. This may have been interpreted as lack of interest. The answers to our questionnaire support this hypothesis. In the setting in which the speaker could see the addressee but not vice versa, the addressee was rated as significantly less interested than in all other settings.

Mediated vs. Unmediated Settings

In the study above, we manipulated visibility by means of computer-mediated communication. In an earlier study (Mol et al. 2009), we have manipulated visibility while speaker and addressee were in the same room. The procedure was the same as in the current study, except that the speaker and addressee were in the same room facing each other ($N = 10$), or in the same room but separated by an opaque screen ($N = 9$). Given that the affordances in these mediated and unmediated settings are a close match, it is interesting to see whether there still is an effect of computer-mediation. To address this question we compare the mediated settings with mutual visibility and with audio only to their unmediated counterparts. Participants were mostly first year students of Tilburg University and all were native speakers of Dutch. The mean age was 19, range (17 – 21), and 15 out of 19 participants were female.

Figure 5: Means of the rate of non-representational gestures in mediated and unmediated settings.

Effect of Visibility

The gesture rates across settings for representational gestures are depicted in Figure 4. The main effect of visibility on this gesture rate approached significance, $F(1, 33) = 4.1$, $p = .05$. Participants gestured more frequently when they could see each other ($M = 6.8$, $SD = 6.1$) than when they could not ($M = 3.9$, $SD = 2.3$). There was no significant effect of mutual visibility on the rate of non-representational gestures ($p = .65$).

Effect of Mediation

Mediation had a significant main effect on the rate of representational gestures, $F(1, 33) = 7.579$, $p < .01$. The interaction between mutual visibility and mediation showed a trend towards significance, $F(1, 33) = 3.180$, $p = .08$. The difference between the visibility and no visibility condition was larger in the unmediated settings.

Mediation also influenced the rate of non-representational gestures, $F(1, 33) = 10.330$, $p = .01$. Non-representational gestures were produced more frequently in the unmediated settings ($M = 3.0$, $SD = 2.2$), compared to the mediated settings ($M = 1.1$, $SD = 1.1$). There was no significant interaction between the factors ($p = .32$). The gesture rates for non-representational gestures are depicted in Figure 5.

Perceived Interest

The effect of the setting on how disinterested the addressee was perceived showed a trend towards significance, $F(3, 33) = 2.288$, $p = .097$. Table 2 (next page) shows the means and standard deviations for this measure in each setting. Pairwise comparisons with the LSD method showed that addressees were perceived as less interested in the unmediated setting without visibility, compared to the unmediated setting with visibility and the mediated setting without visibility, $p < .05$.

Table 2: Means and Standard Deviations of speakers' answer to the statement "The addressee was disinterested" on a 7 point scale, 1 = completely disagree, 7 = strongly agree.

Mutual Visibility	Computer-Mediation	Mean, SD of Perceived disinterest (1 to 7 scale)
Yes	Yes	2.7, 1.0
Yes	No	2.6, 1.1
No	Yes	2.4, 1.1
No	No	3.6, .73

Discussion

Whether or not communication was computer-mediated affected gesture production. Participants gestured more frequently in the unmediated settings. In the unmediated settings, seeing each other seemingly only increases gesture production. Yet in the mediated setting with mutual visibility, two factors may act in opposite directions. Our previously discussed results showed that in the mediated setting, being seen by the addressee increases gesture production, whereas seeing the addressee decreases gesture production. This may explain why participants gestured less frequently in the mediated setting. However, we did not find a difference in perceived interest of the addressee between the mediated and unmediated setting with mutual visibility.

Another possible explanation is a difference in affordances between mediated and unmediated communication (Brennan & Ohaeri, 1999). Even though one of the mediated settings offered live audio and video, narrators produced fewer gestures than in a face-to-face setting. The most notable difference between these two settings may be that the mediated setting did not enable interlocutors to look each other in the eyes. One either looks at the camera, or at the eyes of the other person, such that mutual gaze never occurs. We intend to address this factor in a follow-up study, by using a mediated setting that does allow for mutual gaze. Other factors such as not sharing a physical space may also be of influence, especially for pointing gestures (Isaacs & Tang, 2003).

General Discussion and Conclusion

Although our results suggest that several factors interact in our mediated settings, we found a clear effect of whether the addressee could see the speaker. Speakers produced representational hand gestures more frequently when they could be seen by their addressee, rather than when they could see their addressee, suggesting that speakers adjusted their gesturing to the addressee's perspective correctly. This is not to say that they never make mistakes in taking into account what their addressee can and cannot see during language production. Yet our results cannot be explained by assuming that speakers predominantly base their gesture production on their own visual perspective. Rather, they apply their knowledge of what the addressee can see correctly to their hand gesture production.

Acknowledgements

We like to thank Nelianne van den Berg for her help in collecting and coding the data. We also thank all participants as well as the anonymous reviewers.

On Attractiveness of Surprising Ideas: How Memory for Counterintuitive Ideas Drives Cultural Dynamics

M. Afzal Upal (Afzal.Upal@drdc-rddc.gc.ca)

Abstract

The emerging field of cognition and culture has had some success in explaining the spread of counterintuitive religious concepts around the world. However, researchers have been reluctant to extend its findings to explain the widespread occurrence of counterintuitive ideas in general. This article suggests a way to generalize the minimal counterintuitive hypothesis, which argues that such ideas spread because they are more memorable, to form the outline of a model of cultural dynamism which can help explain why strange and novel ideas spread more quickly than ordinary seeming traditional ideas.

Keywords: ideology, shared beliefs, counterintuitiveness.

Introduction

Why do some aspects of group ideologies and cultural worldviews change over time while others stay unchanged for long periods of time? What explains the patterns of persistence and change in shared beliefs of social groups such as new religious movements and political parties? The cognition and culture researchers argue that any attempt to satisfactorily answer such questions must take the individual cognitive tendencies for communication, comprehension, and belief revision into account (Sperber, 1996). A key finding of this research has been the minimal counterintuitiveness hypothesis (Boyer, 1994, 2001) which suggests that the reason why minimally counterintuitive concepts, such as God and ghosts, dominate religious concepts is that people remember them better than intuitive and maximally counterintuitive ideas. This article first reviews the minimal counterintuitiveness hypothesis and then argues that it can be used to explain the spread of novel ideas in general and not just in the context of religious ideas.

The Minimal Counterintuitiveness (MC) Hypothesis

The minimal counterintuitive (MC) hypothesis posits that:

1. Most of the widespread religious concepts around the globe are minimally counterintuitive.
2. The minimally counterintuitive (MCI) concepts that violate a small number of intuitive expectations (such as, a talking tree, a rock that eats, and an invisible cow) are more memorable than either intuitive concepts (such as, a green tree, a brown rock, and a good person) or maximally counterintuitive concepts that violate a larger number of intuitive expectations (such as, an invisible talking tree that does not occupy any space and a sad illuminant travelling rock).

While a number of subsequent empirical studies (Atran, 2004; J. Barrett & Nyhof, 2001; Boyer & Ramble, 2001; Gonce, Upal, Slone, & Tweney, 2006; Upal, 2005a; Upal, Gonce, Tweney, & Slone, 2007) have found some support for better memory for the MCI concepts, some cultural scientists (Bloch, 2005; Harris & Koenig, 2002; Keller, 2004) have argued that a number of widespread religious concepts such as Gods and ghosts are maximally counterintuitive and not minimally counterintuitive as implied by the minimal counterintuitiveness hypothesis. Some cognitive scientists of religion (J. L. Barrett, 1997, 1999; J. L. Barrett & Keil, 1996; Slone, 2004) have responded by suggesting that this is because believers hold two different (“theologically correct” and “intuitive”) conceptualizations of God and that only the intuitive conceptualizations enjoy the transmission advantages because they are the only ones that are minimally counterintuitive. Barrett (1997, Page 124) says:

God, and perhaps other religious objects and entities, are conceptualized on at least two different levels: the basic, everyday concept used in real-time processing of information, and the “T.C.” or theologically correct level used in theological discussion of God’s properties or activities outside of a real-time context. As was shown in above, these two levels of conceptualization may represent God in substantially different ways.

Thus, argue these cognitive scientists of religion, that the MC hypothesis “does not apply” to the theological conceptualizations of God or to any other cultural concepts that do not involve violating expectations of intuitive reflective thinking (J. L. Barrett, 1997) (Page 127). This includes ideas that have been learned through explicit training such as the socio-cultural and religious schemas, scripts, and scientific concepts (J. L. Barrett, 2008). Another hurdle in the applicability of the MC-hypothesis to the spread of the cultural beliefs in contemporary social groups is the often implicit assumption that the MC-hypothesis is only applicable to societies where oral transmission is the primary source of the transmission of cultural information. Since most of the modern cultural ideas are spread through pen, paper, and the internet the MC-hypothesis may not apply to them.

Previously (Upal, 2009a), I have argued against this narrow interpretation of the MC-hypothesis and suggested that memory advantages obtained by violating conceptual expectations should not be limited to “intuitive concepts”. Instead, I argued that ideas that violate cultural schemas,

scripts, and expert knowledge acquired through learning should also enjoy memorability advantages. While details of the context-based view of the MC effect has been specified elsewhere (Upal, 2005a, 2007a, 2007b, 2009a, 2009b; Upal, et al., 2007), here I review its salient points as they relate to the development of group ideologies.

The Minimal Counterintuitiveness Effect and the Distinctiveness Effect

One of the most robust findings in experimental psychology has been the so called *distinctiveness effect* which indicates that an item, that stands out as compared to other items in its context, is more likely to be remembered than those other items (Hunt & Worthen, 2006). For over a century, experimental psychologists working with a variety of stimuli have found support for this effect (Calkin, 1894, 1896; McDaniel, Dornburg, & Gynn, 2005; von Restorff, 1933). Thus unexpected events and entities in a story are recalled better than expected events and objects (Davidson, Larson, Luo, & Burden, 2000; Kintsch & Green, 1978; Upal, 2005a), bizarre images are recalled better than ordinary images (McDaniel, Einstein, DeLosh, & May, 1995), unexpected words in a list of words are recalled better than expected words (Atran, 2004; von Restorff, 1933), orthographically distinct words are recalled better than ordinary words, as are typographically distinct words (Hunt & Worthen, 2006). Cognitive scientists and evolutionary psychologists argue that the distinctiveness effect reveals the evolutionary pressures that guided the evolution of animal and human memory systems. They suggest that distinctiveness effect supports the view that the ability to predict relevant aspects of one's environment was the primary driver for the evolution of animal and human memory systems. People use the knowledge of their environment to generate expectations about other hitherto unobserved aspects of the environment (Schank, 1975, 1979, 1999; Schank & Abelson, 1977). If these expectations are not fulfilled, it indicates a gap in the agent's world model. Agents whose memory systems treat expectation-violations as learning opportunities to revise their world model to make them more accurate stand to gain evolutionary advantages in terms of being able to collect more food or find better mates.

In (Upal, 2005a), I argued that Schank's learning theory and findings in psycholinguistics (Graesser, Singer, & Trabasso, 1994; Kintsch, 1998) explain that minimally counterintuitive ideas are remembered better than intuitive ideas because they violate a reader's expectations. Psycholinguists argue that when reading a text people primarily ask why questions i.e., why did the author include this information in this text? The cognitive processes of readers accessing the knowledge structures in their long term memory to construct a justification for the inclusion of ideas in question result in establishment of strong memory links between counterintuitive ideas and thematic cues about the story. When these cues are presented to subjects, the strongly connected minimally counterintuitive concepts are

easily retrieved and recalled. I hypothesized that for the minimally counterintuitive ideas, readers are able to construct such justifications and create a coherent concept but that readers fail in their effort to construct a justification and create a coherent concept for maximally counterintuitive ideas. The *memorability hypothesis* (Upal, 2005a) suggests that memorability of a concept in a context is a function of the difference between its degree of expectation violation and its coherability as a new concept.

Besides explaining the past observations of why minimally counterintuitive ideas are better remembered than intuitive and maximally counterintuitive ideas, the memorability hypothesis makes a number of predictions. Since proposing this model (Upal, 2005a), I and others have conducted a number of empirical experiments and found that results generally support a context-based view of the minimal counterintuitiveness effect (Gonce, et al., 2006; Upal, 2007a, 2007b, 2009b; Upal, et al., 2007; Upal & Harmon-Vukic, 2010). It predicts that, on average, readers should spend more time to process counterintuitive concepts than they do in processing intuitive concepts. This is because counterintuitive concepts trigger cognitively taxing process of justification creation while intuitive concepts do not. A recent study has confirmed this finding (Upal & Harmon-Vukic, 2010).

The context-based model also posits that counterintuitiveness is a property of the context in which a concept appears as much as it is a property of the concept itself. The context includes the mental knowledge that the reader brings to the table as well as the prior parts of the text in which the concept is embedded. This means that the same concept may appear more unexpected in context A than in context B and that the same concept may be more memorable in one context and less memorable in another context. Since knowledge structures in people's memories change over time, the same concept may be more counterintuitive for a person at a time t_1 than at a time t_2 . A one-time exposure to an idea, however, does not guarantee that the idea will not seem counterintuitive in the future. In order for an idea to lose memorability advantages, the knowledge in long term memory that generated the expectation has to be revised so as to make the counterintuitive idea as the new expected and the old idea as the new unexpected (and therefore the new counterintuitive). Since knowledge structures in memory are richly connected with each other revising them requires significant cognitive resources to untangle old connections and establishing new ones. Thus it is not surprising that people are very conservative when it comes to revising their beliefs. People's expectations guide what they see leading them to sometimes miss the unexpected objects and events. When the evidence of expectation violations is too overwhelming to ignore, they prefer to generate elaborations that allow them to preserve as much of their old beliefs as possible. Even though observing a single instance of a counterintuitive object or event can (at least in principle) trigger belief change, this does not happen very often. For

instance, upon seeing an ostrich for the first time, one may no longer be surprised when one hears of, “a healthy adult bird that cannot fly” assuming one can create a justification that an ostrich is still a bird because it has feathers but is not able to fly because it is too heavy. Creation of justifications in response to seeing an unexpected object or event does not automatically lead to generation of different expectations in a similar future context. One may for instance assume that the expectation violation only happens in an overly restricted context, for instance, assume that ostriches do not fly on Tuesdays between 9 and 10 am or that the ostrich under observation is a mutant. Seeing a healthy adult ostrich at a different time in the future may still lead to the expectation that it will fly. It may take prolonged exposure to numerous observations of unexpected objects and events and significant cognitive effort for someone to revise enough knowledge structures in their long term memory for them to generate new expectations. Once all the relevant memory structures are revised and the old unexpected becomes the new expected, the once minimally counterintuitive idea should no longer be so. Thus the context-based model predicts that minimally counterintuitive ideas should lose their memorability advantages over time.

Since the context-based model does not support differential processing for mental knowledge acquired through intuitive and doctrinal modes of thinking, it predicts that violations of online intuitive cognition should not have a privileged status, at least when it comes to memorability. Thus, ideas that violate expectations generated by offline learned concepts such as cultural schemas and religious doctrine should also be better remembered than ideas that do not violate such expectations.

The context-based view emphasizes the role played by the knowledge that an individual possesses when processing a concept in making a concept a concept minimally counterintuitive. This means that a concept that is minimally counterintuitive for one person may not be minimally counterintuitive for another person whose mental knowledge differs from that of the first person. If counterintuitiveness is not the property of the concept alone, then a concept can only appear minimally counterintuitive to a population if individuals within the population share beliefs that are relevant to the concept i.e., if the concept violates the expectations raised by those shared beliefs and if the expectation violation can be justified using those shared beliefs. Thus contrary to the traditional view that ideas that violate cultural schemas should not have memorability advantages, the context-based view suggests that *they should*. I will refer to such ideas as *socially counterintuitive* and point out the role that they play in constantly reshaping the fabric of cultural beliefs.

Social Counterintuitiveness

I define an idea as *minimally socially counterintuitive* for a population if it violates a single expectation generated by beliefs shared by that population. Thus the notion of a

person remembering details of her past lives may be minimally counterintuitive to a western population that may have a passing familiarity with the idea of reincarnation but not to a Hindu population among whom the belief in reincarnation is intricately woven into the fabric of socially shared beliefs. Minimally counterintuitive social ideas have a memorability advantage over intuitive cultural ideas that do not violate any expectations generated by shared cultural beliefs. Thus the notion of a person who remembers her past life would have a memorability advantage in a western population that did not expect the idea but can use their passing knowledge to understand it. However, it will not enjoy memorability advantages due to counterintuitiveness in a Hindu population where it is already well entrenched.

Similar to the case with individual counterintuitiveness, socially counterintuitive ideas can also become socially intuitive overtime but the process is far more difficult and involved because it involves changes in shared beliefs of a large number of individuals. As advocates of social change would attest, getting a new idea to become widely accepted by a population is a long and painstaking process that requires years of effort by dedicated individuals. This is because, similar to ideas in individual memories, shared cultural ideas are like a well-knit fabric and once this fabric is ripped up by an expectation violating concept, a number of threads become exposed. All of these threads have to be stitched together in new and innovative ways to fully mend the fabric such that the new idea becomes culturally expected. This is why cultural conceptual change faces such daunting prospects requiring years, if not a lifetime, of effort by social leaders who dedicate their lives to the issue. Previously, I have referred to such social leaders as information entrepreneurs (IEs) (Upal, 2005b) because to successfully lead conceptual change, these leaders have to possess the following characteristics.

- They must have high social capital in the group whose shared beliefs they are trying to change. This is needed both to have the credibility needed to persuade others and also because they can afford to be seen as dissenting from group-think (Packer, 2008).
- They must have the marketing skills required to sell the conceptual change to their target audience. Like all good marketers, they are able to make their ideas seem as inevitable as ideas whose time has come.
- They must have the cognitive skills required to integrate the seemingly counterintuitive idea with the group's traditional thinking and make it seem as if the new idea is intuitive and perfectly in line with the group's original thinking.

In (Upal, 2005b), I argued that the IE view helps us understand that new religious movement leaders create seemingly counterintuitive ideas because they believe that these ideas are needed to solve problems being faced by the group. Upal (2005c) argued that revision in socially shared beliefs is driven by a belief among one or more of the strongly identified group members that the group's shared beliefs are harmful to the long-term prosperity of the group.

I focused on social identity beliefs which include, “who belongs to the group and who does not, who is admitted to the group, and who is not? This is particularly clear for racist, ethnocentric, xenophobic or nationalist ideologies, according to which only ‘we, white Europeans’ belong in Europe, and others should not be admitted, at least not as (equal) citizens” (van Dijk, 1995) (Page 250). Anthropologists studying ethnic groups find that ethnocentric beliefs in “superiority of the ingroup’s culture combined with condemnation of the outgroup as immoral and inferior” are “commonplace (e.g., (LeVine & Cambell, 1972)). ‘Chosenness’ is a particularly prominent expression of this belief” (Page 6). Van Evera (1994) argues that such chauvinist myths are “hallmark of nationalism, practiced by nearly all nationalists to some degree” (Page 27). He provides a number of illustrative examples including Nazi myth of Aryan supremacy, British and American beliefs in rational and intellectual exceptionalism (Longley, 2003), and Russian belief in their extra-ordinary inventiveness. These could be complemented by Pakistani belief that one Pakistani Muslim soldier can dominate 10 Indian Hindu soldiers, American Indian belief that they are more spiritual than the more material “white man”, Israeli belief that they are more rational than crazy Arabs, Muslim belief that God chose to favor them as his final chosen people after Christians and Jews strayed from the prescribed path, and the Nation of Islam belief that an evil black scientist created the wicked white man. Group superiority myths are reflected in the literature and art of a group and feature prominently in its creation stories that form the master narrative of a group.

Social psychologists argue that such beliefs are necessary for people’s well being since people have a fundamental need to feel good about themselves and that people derive part of their identity from membership in social groups that they associate with (Tajfel & Turner, 1985). To achieve and maintain a positive self image, people view their group more positively than comparison outgroups on some valued dimensions (Hogg & Vaughan, 2002). This ingroup favoritism is an essential part of group identity and such beliefs arise even in minimal group settings. In a number of lab studies where subjects were arbitrarily assigned to groups (but told that they had something in common with other group members who they may never meet), participants gave more rewards to members of their group (Hogg & Vaughan, 2002). Group superiority beliefs permeate rumours, myths, and folktales of groups around the world.

Events that manifest a higher status of the out-groups along the dimensions of value to a group, violate group’s cultural expectations and may cause some highly identified group members to believe that the group myths are broken and need to be fixed. For instance, Christian conquest of Muslim lands in the 19th and 20th centuries, lead Muslims to ask the question, “what went wrong.” If we are the chosen people who have been promised dominance in the world then how come we are losing so many battles to the

Christian West? (Lewis, 2003). Such changes provide opportunities for information entrepreneurs to step up and offer their solution to the social problems. Groups have various mechanisms for rewarding those who are thought to be working for the group’s benefit especially at a personal cost to their own welfare such as soldiers. Upal (2005a) argued that those who pioneer change in group social beliefs stand to gain an increase their social status if they come to be credited with having successfully advocated for the betterment of their group.

Ratcheting Up Social Counterintuitiveness

Once the efforts of information entrepreneurs are successful and a counterintuitive idea becomes fully entrenched in a group, it no longer seems counterintuitive to most members of that group and therefore loses its memorability advantages. This resolves another paradox that critics of cognitive science of religion have often pointed out, namely, that while the counterintuitive beliefs such as religious belief in gods, and ghosts as well in popular culture beliefs about Draculas, vampires, Vulcans, djinns, chupacabras, and leprechauns are counterintuitive in the traditional cognitive science of religion sense, they do not appear to be counterintuitive to the people whose informational worlds are full of such creatures. Theists from a variety of traditions, for instance, routinely point out that they see God in everything such as people’s eyes, flower petals, grass blades, running streams, stars, and singing birds and that the concept of God appears no more counterintuitive to them than air, energy, and kinetic potential (Cook, 1883; Rasor, 2006). Cultural anthropologist routinely point out that while mythical cultural creatures such as djinns and ghosts seem counterintuitive to us, they do not seem counterintuitive to the people who believe in them (Bloch, 2005).

The answer I believe lies in acknowledging the criticism that minimally counterintuitive ideas do indeed lose their privileged status and do not have any memorability advantages once they become embedded as part of a culture. However, this does not mean that further cultural innovation stops. New ideas continue to be created and communicated to others and those ideas that have transmission advantages continue to spread. In order to have memorability advantages due to counterintuitiveness however, new ideas must violate people’s expectations in the new context and not the old context which is no longer relevant. This means, for instance, that once as a minimally counterintuitive idea such as the idea of a being who can see everyone becomes widely culturally accepted, it loses its memorability advantages because it no longer violates people’s expectations. In order for a concept to achieve memorability advantages and to spread in the new cultural context, an idea has to seem counterintuitive in the new context. One way to do that is to build on the counterintuitiveness. For instance, the concept of a being who can see *and hear* everyone would seem minimally counterintuitive in the new context. In light of the model we develop here, one should not be surprised to see maximally counterintuitive concepts to form

a significant part of religious beliefs. Indeed, it would be surprising if they did not!

This ratcheting-up of counterintuitiveness not only explains how seemingly maximally counterintuitive concepts such as Judeo-Christian-Islamic God and ghosts come to be widely distributed but it also predicts a continuous transmission advantage for unorthodox ideas that violate cultural expectations over traditional ideas. This explains continuing evolution of cultural beliefs among groups ranging from post-modern artists to new religious movements. As arts historians know, each artistic trend is both defined in opposition to the old one and also as a continuation and improvement of the old trend. At the core of each trend is a minimally counterintuitive idea that is advocated by a group of innovators and becomes widespread because it is unexpected according to socially shared beliefs. However, once it becomes widely accepted group it loses its memorability advantages making room for a new layer of innovation. Similarly, new religious movement scholars recognize (Bainbridge, 1985) that splitting of a new religious movement (NRM) from an existing movement often involves introducing an innovation into the doctrinal beliefs of the existing movement. NRM scholars Bainbridge and Stark (1979) provide a number of examples of new religious movement leaders who created the fundamental doctrine of new religious movements by modifying the beliefs of existing NRMs. Indeed they argue that tracing the history of such deviations, labeled “cultural genetics”, may be a useful way to study NRMs. Idea innovations leading to splits in NRMs are common. Bainbridge (1985) counts over half a dozen movements that split from Dianetics and the Church of Scientology in the short period of 20 years from 1952 to 1972.

In this way, the context-based model explains cultural innovation but what accounts for cultural continuity? In particular, what explains the perception that cultural concepts such as gods, ghosts, and angels have not changed for a long time? As anthropologists and historians know, despite the need for protagonists of conservative movements to argue otherwise, cultural ideas are continually undergoing change, so much so that social movements and societies often have to build a number of safeguards to prevent unwanted innovation. This includes writing down the doctrines in books and elevating such books to the level of the sacred, punishing any changes in the content of these books, and instituting measures to discourage translation and interpretation of these books.

Orthodox Christianity’s attempts at rooting out heresies (Hogan, 2001) spanning over two thousand years illustrate problems that organized religions face as they attempt to maintain continuity over time. Both Judaism and Islam also had to repeatedly put down various attempts at introducing innovations in their religious doctrine and practices. In the case of Islam, the Quran was not allowed to be translated in any language other than Arabic until the 19th century. Innovation in religion (termed as “bidah”) is explicitly forbidden (Islam, 2008). NRMs, despite having had to fight

against the oppressive measures against innovation to have their own voice heard when facing the same need to protect the integrity of their own doctrine, disdain any attempts at introducing further innovations into their doctrines. For instance, the founder of Scientology, L. Ron Hubbard is reported to have referred to those who modify his techniques as “squirrels” who should be harassed, “in any possible way” (Welkos & Sappell, 1990). Weapons used to discourage any change in religious doctrine and practice include ridicule, expulsion, and harassment. Continuity in group ideologies is explained to the extent that such thought control techniques are successful.

Conclusions

Cognitive scientists, including cognition and culture researchers have long favored general models of cognition over specific ones not just because they explain a larger variety of phenomena but also because they are perceived as more parsimonious and subject to a larger battery of tests because of the availability of a larger number of data points to test them on. This paper makes a contribution to this literature by presenting a generalized version of the minimal counterintuitiveness hypothesis to argue that better recall for minimally counterintuitive ideas is part of a larger class of memory preference for distinctive items and that ideas that violate a small number of expectations generated by offline cognition/doctrinal thinking should also be remembered better than ideas that do not violate such expectations. The secondary contribution of this article is the development of the notion of social counterintuitiveness which allows us to explain the spread of culturally counterintuitive ideas.

Abstract

In this article we advance the conjecture that conscious awareness is equivalent to data compression. Algorithmic information theory supports the assertion that all forms of understanding are contingent on compression (Chaitin, 2007). Here, we argue that the experience people refer to as consciousness is the particular form of understanding that the brain provides. We therefore propose that the degree of consciousness of a system can be measured in terms of the amount of data compression it carries out.

Keywords: Information theory, data compression, Solomonoff induction, phenomenal experience, Turing test.

Introduction

According to Einstein, the most incomprehensible thing about the world is that it is comprehensible. But what does it mean to comprehend? A common feature of understanding in both science and mathematics is that it involves the reduction of a set of observations or truths to a more basic set of assumptions. Indeed, Chaitin (2007) has proposed that all forms of understanding can be viewed as instances of data compression. Have a look at the sequence below and see if you can ‘understand’ it:

4, 6, 8, 12, 14, 18, 20, 24...

What is involved in understanding this sequence? Intuitively, one searches for a pattern that links all of the numbers together. If the numbers were randomly selected, then, more than likely, no pattern could be identified. In this case the sequence could not be described any more concisely: it would be incompressible. However, the above sequence seems amenable to compression. For example, one can posit the following hypothesis: “start at 4 and keep adding 2, except if the digits of the previous number sum to 2, 5 or 8, in which case add 4”. These instructions provide a complete description of the sequence. However, because the description seems somewhat unwieldy, it is not particularly convincing. A more concise description is possible: “go through all odd prime numbers and add 1”. Because this hypothesis is more concise, it intuitively reflects a deeper understanding of the sequence.

Scientific understanding is furthered by exposing greater levels of redundancy in observational data. The goal of the

scientist is to craft a model which can describe a dataset in more concise terms. These models are called *theories*. The more compression a theory achieves, the greater its value. For example, Kepler’s heliocentric model of the heavens is considered superior to Ptolemy’s geocentric model, because it manages to describe astronomical observations in terms of three simple mathematical laws rather than a convoluted set of epicycles.

The idea that compression underpins scientific endeavor is not new. Occam’s razor is a fundamental scientific principle which is attributed to the 14th century English friar, William of Ockham. The principle states that the explanation of any phenomenon should make as few assumptions as possible, eliminating those that make no difference to the observable predictions: “entities should not be multiplied unnecessarily”. This law of parsimony implies that if you have two competing theories which both describe a phenomenon, the simpler (i.e. more compressed) explanation is better.

Algorithmic Information Theory

As homo sapien sapiens (Latin for *knowing man*), the urge to understand is a defining characteristic of our species. But why is it that we should devote so much energy to understanding the world around us? In order to answer this question we must turn to algorithmic information theory. Algorithmic information theory is a field which brings together mathematics, logic and computer science. The foundations of this field were laid by Chaitin, Solomonoff and Kolmogorov in the 1960s (see Li & Vitányi, 1997). According to Chaitin, it is “the result of putting Shannon’s information theory and Turing’s computability theory into a cocktail shaker and shaking vigorously”. The basic idea is that the complexity of an object can be represented by the size of the smallest program for computing it. This new way of thinking about information was first proposed by Solomonoff (1964) and subsequently independently identified by Kolmogorov and Chaitin.

Algorithmic theory provides a clear answer as to why organisms should seek to compress observational data. Specifically, Solomonoff’s (1964) theory of inductive inference reveals that compression is a necessary component of prediction. The theory provides a universal measure of the probability of an object by taking into account all of the ways in which it might have been produced. This universal a

priori probability can then be incorporated into Bayes' rule for inductive inference in order to make optimal predictions based on a set of prior observations.

Solomonoff's theory of inductive inference reveals that the more a set of observations can be compressed, the more accurately subsequent events can be predicted. Consider again the sequence 4, 6, 8, 12, 14, 18, 20, 24... The long-winded description predicts that the next number in the sequence will be 26, while the more succinct description predicts that 30 will follow. According to Solomonoff's theory, the latter must be the better prediction, because it involves a fewer number of assumptions: the shorter the length of the description, the more likely it is to be correct.

Algorithmic information theory reveals that compression is the *only* systematic means for generating predictions based on prior observations. All successful predictive systems, including animals and humans, are approximations of algorithmic induction. All useful contributions to human knowledge work by coaxing people into modifying their inductive strategies in such a way that they better approximate algorithmic induction.

In order to thrive in an uncertain environment, organisms must be able to anticipate future events; the more efficiently they can compress their experiences, the more accurate these predictions will be. Consequently, organisms have evolved brains which are prodigious compressors of information: compressing sensory information provides them with an 'understanding' of their environment (see Chater & Vitányi, 2002; Schmidhuber, 2006; Wolff, 1993). Tononi (2008) has proposed that the feeling of being conscious must be linked in some way to the integration of information which occurs in the brain. In the following sections we specify precisely the relationship between information processing and subjective awareness: specifically, we argue that the experience people describe as consciousness is equivalent to the compression that the brain carries out. Henceforth, this idea is referred to as the 'compression conjecture'. It should be noted that the conjecture does not merely suppose an association between consciousness and compression; rather it asserts that no meaningful distinction can be drawn between the two concepts.

Consciousness

From an evolutionary perspective, the sole purpose of the brain is to produce behavior that optimizes the reproductive success of an organism and its genetic material. Features of the brain which are not linked to optimizing behavior should therefore not have been rigorously preserved by evolution. Why then should brains go to the trouble of producing consciousness?

Algorithmic information theory tells us that the key to enhancing prediction (and hence reproductive success) is to optimize data compression. If the principal evolutionary pressure determining the structure of the brain has been its capacity to compress data, and if brains are the only system we know of that support consciousness, then this suggests a

rigorous link between consciousness and compression. Systems that are good at compressing data seem to produce consciousness. But why should this be the case?

The Brain as a Compressor

In order to answer this question, we must consider the nature of the compression that the brain carries out. In other words, what type of understanding does the brain provide?

The success of an organism is dependent on cooperation between all of its constituent components. In order to achieve the goal of reproduction, it must exhibit coordinated behavior. For example, it does not make sense for an organism's legs to maintain independent agenda. Because the interests of both legs are intimately bound, it is more productive for them to cooperate with each other in achieving a single set of objectives (e.g. putting one foot forward while the other stays on the ground). Accordingly, the brain sources sensory information from all over the body and compresses it *in parallel*, thereby optimizing predictive accuracy for the organism as a whole. Tactile information from every limb is compressed in parallel with visual information from the eyes and audio information from the ears, giving rise to a form of understanding that is *centralized* and representative of the organism's experiences as a singular unit. The resulting decisions of the organism also appear centralized: to the external observer it seems as if the organism's body is being 'controlled' by a single entity with a singular set of objectives.

Not only does the success of an organism depend on cooperation between its constituent components, it also depends on cooperation between its past and future states. Snapshots of an organism's behavior taken at different points in time again reveal evidence of a singular set of objectives. For example, if you know you will be hungry in several hours time, you might pack a lunchbox in your bag. In this case, you are cooperating with your future self. From an evolutionary perspective, organisms cooperate with their future selves because reproduction is a challenging task which requires coordinated behavior manifested over an extended period of time. As a result, the brain goes to the effort of distilling memories which are maintained with the expectation that they will facilitate data compression at a future point.

The utility of memory can again be explained in terms of enhancing algorithmic induction. Memory allows us to make greater sense of the world by enhancing our ability to carry out compression. Incoming sensory data are compressed *in parallel* with stored historical data, allowing redundancy to be identified more efficiently and, consequently, enhancing predictive accuracy. Thus, the form of understanding that the brain produces unites not only distributed sensory organs but also past and current states of an organism. The compression conjecture proposes that the experience of this unitary form of understanding is what we mean when we use the term 'consciousness'.

Self-Awareness

Intuitively, the above account does not seem fully satisfactory. For example, one might conceive of an artificial compressor which compresses large amounts of current and historical data in parallel, though without experiencing the same form of awareness that we humans are familiar with. Indeed, the compression carried out by the brain has one additional ingredient which sets it apart from simpler compression systems: it compresses its observations of its own behavior. The capacity for a system to model its own actions necessarily involves the identification of itself as an entity separate to its surroundings. As a result, self-compression entails self-awareness.

The human brain is a self-representational structure which seeks to understand its own behavior. For example, people model their own selves in order to more accurately predict how they are going to feel and react in different situations. They build up internal models about who they think they are and use these models to inform their decisions. In addition, the human brain compresses the observed behavior of other organisms. When we watch other individuals, we realize that there is a great deal of redundancy in their activity: rather than simply cataloguing and memorizing every action they perform, we can instead posit the more succinct hypothesis of a concise 'self' which motivates these actions. By representing this self we can then make accurate predictions as to how the people around us will behave. The idea that the actions of an organism are controlled by a singular self is merely a theoretical model which eliminates redundancy in the observed behavior of that organism. People apply this same process to themselves: what you consider to be the essence of you is simply a model which compresses your observations of your own past behavior.

Phenomenality

A significant obstacle to providing a fully satisfactory theory of consciousness lies in explaining the phenomenon of subjective experience: why is it that we experience qualia which seem to elude scientific description? According to the consciousness conjecture, the 'flavor' of a quale can be linked to the particular form of compression that the brain carries out in response to a stimulus.

If an organism perceives a stimulus, yet can discern no pattern in the sensory data, then that stimulus will appear completely random and meaningless to the organism: the stimulus will not be experienced at all. On the other hand, if some redundancy can be identified, then the stimulus can be 'understood' (i.e. experienced) by relating it to previously gathered sensory information. For example, when people look at an apple, they perceive a round shape by identifying redundancy between the appearance of the apple and previously encountered round objects; they perceive a green color by identifying redundancy between the appearance of the apple and previously encountered green objects. When we 'see' an apple we are not just processing an instantaneous visual stimulus but, rather, compressing a set

of data which has been gathered over a wide cross section of space and time. The structure of the brain allows a sensory stimulus to be translated into the subjective experience of understanding through the process of compression.

In sum, people don't passively observe the world around them; they gaze through the lens of understanding provided by their brains. When people talk about their subjective experience they are referring to the particular form of compression that their brain provides. The reason that these qualitative descriptions differ from objective scientific descriptions is because the subjective experience of a stimulus is dependent on how it is processed. The particular 'flavors' of qualia that we humans are familiar with are artifacts of our cognition, which are determined by the patterns our brains have evolved to detect and encode.

Describing Qualia

Intuitively, qualia appear to resist objective description. However, this intuition must be flawed, for if qualia could not be recorded in some informational form in the brain then we would not be able to remember them. In this case, all current subjective experiences would seem random and meaningless because there would be no previous subjective experiences with which to reconcile them.

According to the compression conjecture, which supposes that subjective experience and data compression are equivalent, it should be possible to provide a full description of a quale by detailing the compression that a system achieves in response to a stimulus. Thus, for example, the experience of red could be captured by describing the changing structure of the brain in response to the sight of a red object. This experience could then be comprehensively represented in terms of bits of bytes and could feasibly be contained in a book. Yet, intuitively, a book containing symbols could never capture the experience of the color red in the same way that we feel it; leafing through the pages of the book would not give rise to the subjective feeling of red. How can this apparent incongruity be rationalized?

The compression conjecture indicates that even if a book does carry a complete description of a subjective experience, merely reading the book is not sufficient for reproducing that experience. To appreciate it, the reader must be capable of compressing the data in the same manner in which it was originally compressed. For example, rather than simply leafing apathetically through pages of symbols, the reader must be capable of identifying the underlying patterns which link those symbols together. If a system is incapable of compressing the data, then it cannot 'understand' the experience which is contained within. Experience is dependent on the system which is doing the experiencing, as opposed to being intrinsic to a stimulus. Because reading a description of compression will not necessarily cause the same compression to occur in your own brain, reading about the experience of red will not make you experience red.

The Hard Problem

Initially, it might not be clear that the above satisfactorily addresses the hard problem of consciousness, which Chalmers (1995) identifies as the question of why consciousness *feels* like anything at all. In order to tackle this question, let us consider the case of an assembly of coordinated neurons (or, indeed, logic gates) called Amy. If we observe Amy's behavior over time, we will notice considerable redundancy in her actions. We can compress Amy's behavior through the succinct hypothesis of a core centralized self which is motivating her actions and which feels experiences. But this is just an abstract hypothesis based on a dataset: why should the formation of a hypothesis result in experience? The answer to this question lies in the realization that the hypothesis of Amy's subjective experience is a hypothesis which Amy herself holds, an understanding which is manifested through the compression she carries out. Understanding the hypothesis that one is feeling something and the actual experience of feeling are the *same thing*. Amy's feeling therefore exists relative to the assumption of her own existence, an assumption which the system itself is capable of making.

Conscious Systems

Algorithmic information theory makes clear predictions regarding what systems are conscious: objects which carry out compression are conscious, all other objects are not. Let us consider a chair. Intuitively, we would not expect a chair to be conscious. Can this intuition be justified by the compression conjecture?

Chairs do not carry out compression. They do not source sensory information from multiple locations and process it in parallel. They do not store memories to enhance future compression. And they do not develop a theory of self by compressing their own actions. Therefore they are not conscious.

Imagine holding a flame to the leg of a chair. The flame leaves a black mark, therefore the chair has certainly been affected by the flame. But intuitively, it does not seem reasonable to claim that the chair has *experienced* the flame. This difference between effect and experience is directly related to compression: specifically, the chair fails to experience the flame because the information it provides is not compressed in any way. If a chair's leg is burned it has no effect on any of the other legs. No information is communicated, and consequently there is no inter-leg data compression to bind the experiences of the chair together. Furthermore, the chair stores no memory (other than a black mark). The burning event has no effect on how subsequent events are processed, meaning that the experiences of the chair are not bound together across time. Finally, because the chair does not compress its own response to the flame, it has no awareness of any subjective experience.

In contrast, if a flame is held to the leg of a human, it has an immediate effect on how information from all other parts of the body is processed. The brain also stores a memory of being burned, thus altering the individual's future behavior

in a manner which reflects the interests of the system as a whole. People 'feel' the effect of being burned because the compression carried out by their brain reflects an understanding of what it feels like to be burned. In contrast, no matter how many times you burn a chair, it will never react any differently.

Artificial Consciousness

The consciousness conjecture suggests that any system that carries out compression can be considered conscious to some extent. However, it should be noted that no known system is capable of matching or even approaching the depth of compression carried out by the organic brain.

Although computer algorithms such as Lempel-Ziv and BZip2 are used to compress files and text, these programs simply skim through data looking for trivial redundancy. Such compressors cannot realistically be described as 'understanding' text because the only patterns they can identify are based on simple statistical repetitions of symbols. In contrast, when people read a book they can 'explain' the text in terms of an underlying narrative derived from their own experiences of the world, a feat which involves a much deeper level of compression.

Nevertheless, there is no theoretical obstacle that would prevent consciousness from being implemented in an artificial medium. Any system that is arranged and updated in a way which allows for the compression of information will support consciousness, be it implemented in windmills, beer cans or toilet rolls. Although toilet rolls take up a lot more space and interact a lot more slowly, they can be arranged in such a manner so as to perfectly replicate the compression carried out by neurons in the brain.

Of course, the idea that a conscious being could be implemented in toilet rolls is very unsatisfactory. Such an implementation exacerbates the hard problem of reconciling a clearly reducible system with the feeling of intuitively irreducible experiences. One might ask: where does the consciousness reside? In this case the consciousness is not a property of any particular toilet roll. Rather, it is a property of the toilet roll system as a whole. Just like the behavior of a human, the output of the toilet roll system exhibits deep redundancy which can be effectively compressed through the hypothesis of a single centralized 'self'. In particular, the toilet roll system is itself aware of this hypothesis, and uses the theory of selfhood to guide its processing. The consciousness of the system therefore resides in its capacity to understand (i.e. compress) what it senses, thereby identifying itself as an entity separate to its environment.

The Location of Consciousness

Thus far, we have used the term 'compression' without describing precisely how compression can be identified in the brain. Where is it to be found? Intuitively, people assume that conscious experience must be drawn together at a single point, an idea which Dennett (1991) derisively refers to as the 'Cartesian theatre'. However, brain imaging studies indicate that cognitive processing is widely

distributed and does not appear to be bound at any particular point in space or time (Zeki, 2003).

Although intuition might suggest the need for a Cartesian theatre, it is important to note that the evolutionary demands which have shaped the brain's structure have not required information processing to be integrated in this way. The only moment that the brain is required to bring information together is when some action must be elicited; furthermore, only data relevant to that action needs to be integrated. Outside of this constraint, processing can remain distributed in space and time, with no impact on the success of the organism.

Accordingly, external time and 'conscious time' need not be synchronized to any greater extent other than to facilitate the undertaking of action when required. However, conscious observers have no possible means for observing any distribution in their consciousness relative to the environment: whenever they act on their surroundings the appropriate information processing is pulled together 'just in time'. Since it always appears to the observer as if they are embodied at a particular point in space and time, this leads them to mistakenly assume that their consciousness must be brought together at a single point in the brain, giving rise to the Cartesian theatre fallacy.

How Does the Brain Create Consciousness?

One of the goals of consciousness research is to identify how it is created in the brain: which neural structures support consciousness and which are merely superfluous biological apparatus? Using elementary computability theory we will prove that, if the compression conjecture holds, then the goal of identifying a complete theory of consciousness is unattainable.

Let us imagine that somebody someday submits a theory which offers a full description of how the brain produces consciousness. The theory is complete, meaning that it is capable of identifying precisely which structures in the brain give rise to consciousness, separating the conscious part from the non-conscious meat. Now, of course, the reviewers wish to check that the theory is correct. Accordingly, they apply the theory to their own brain activity to see whether the predictions match their experience. However, this raises the question: are the reviewers able to define their own consciousness, as required to validate the theory? Is it possible for a system to define its own self? In fact, computability theory rules this out, meaning that a complete theory of consciousness is not possible.

According to the compression conjecture, the recognition of one's own consciousness involves the identification of a structure which carries out the same form of compression. We can therefore present the problem formally in terms of a Turing machine which is capable of recognizing a program with the same input-output relationship. Consider a Turing machine T which takes input x and outputs 1 if $L(T) = L(x)$ (i.e. the languages recognized by T and x) and 0 if $L(T) \neq L(x)$. Is such a machine possible?

The machine T is not consistent. We can imagine another machine A which takes input x . The machine A first

computes $T(A)$. If $T(A) = 1$ it then outputs $1 - T(x)$, which is the opposite of T , while if $T(A) = 0$ it then outputs $T(x)$, which is the same as T . In other words, the machine A checks to see whether T recognizes it as being equivalent or not. If T recognizes A as being equivalent then A proceeds to do the exact opposite, making it not equivalent to T . However, if T does not recognize A as being equivalent then A produces the same output at T , making it equivalent to T . There is no way around this obstacle (see Rice's theorem; Rice, 1953). Since no system can recognize an equivalent system from within itself, developing a complete theory of consciousness is not possible: the more precisely a theory attempts to define the conscious structure of the brain, the less feasible it will be to validate it.

The unrecognizability of the self has important implications for how we think about ourselves. For instance, we can never know who we really are; we can never fully explain our actions; we can never be certain as to what we are going to do next. In effect, the self is a helpless observer carried along by the compression going on in the brain. Of course, one feels like one is directing one's own actions because, as far as one is aware, one is. According to the compression conjecture, the model of the self is simply an explanatory mechanism that the brain uses to explain and predict its own behavior. As a result, the actions of the brain cannot help but be consistent with those of the self (see Gazzaniga, 1992). However, it is the activity of the brain which defines the nature of the self, rather than the other way around. Are you controlling your own actions? Certainly, but at the same time you can never know who *you* is.

Measuring Consciousness

If, as the compression conjecture supposes, consciousness is equivalent to data compression, then it should be possible to measure consciousness by quantifying the amount of compression that a system is capable of. The formal measure of compression is logical depth (see Bennett, 1988). Bennett's idea is that objects can be trivial, random or deep. Trivial objects, being completely predictable, contain no useful information; random ones, being completely unpredictable, do not contain any useful information either. In contrast, objects that are neither random nor trivial are called deep objects, because they support deep compression.

Deep objects are useful because they provide a store of mathematical work, allowing associated data to be compressed far more efficiently than can be achieved using shallower tools. Indeed, Bennett's (1988) theory implies that the concepts of 'depth' and 'intelligence' are equivalent, since the facilitation of compression that depth provides cannot be replicated by alternative means. Of all known objects, the human brain is the deepest, representing the stored mathematical work of decades of active cognitive processing on top of billions of years of evolution. The brain relies on its depth to mitigate the physical limitations on information processing imposed by its biological structure, such as limited storage capacity, processing speed and

susceptibility to degradation. The complexity of its structure allows people to effortlessly identify patterns which continue to elude the most advanced artificial intelligence programs.

The Turing Test

Turing (1950) suggested that if a computer, through a textual interface, can successfully convince a human judge that it is human, then it should be considered equal in intelligence to a human. However, the Turing test is not a reliable indicator of depth. Fooling a human judge is unlikely to require a deep program: a far simpler solution is to exploit the weaknesses of human psychology.

We propose an alternative test, involving compression, on which it is not possible to cheat. Because of its complexity, natural language provides the ideal medium for testing compressor depth. People use complex linguistic patterns to communicate with each other and assume that other speakers are capable of compressing the words they produce. If a computer system is as intelligent as a human, then it should be capable of compressing language to the same extent as a human.

According to algorithmic information theory, compression can be quantified in terms of predictive accuracy. For example, Shannon (1951) examined the human-perceived entropy of English by asking people to predict each letter in a document, one by one. The entropy rate turned out to be less than 1 bit per letter. People are able to predict language because of the fact that they 'understand' the text. In contrast, artificial compressors like BZip2 and Lempel-Ziv achieve much poorer levels of compression because they rely on predictable sequences of characters, without any regard for the deeper connections between words, sentences and narrative. If a computer was genuinely as intelligent as a human, it would be capable of matching the entropy rate of 1 bit per letter that Shannon observed.

We propose that the compression test is far more reliable and practical than the Turing test. For a start, there is no way to cheat: by definition, deep processing cannot be reproduced by any means other than underlying depth (the Slow Growth Law; see Bennett, 1988). It is also extremely quick and reliable: the probability of guessing the correct symbols decreases exponentially with the length of the test. While the Turing test is ambiguous and is affected by the gullibility of the tester, the compression test is simple, rigorous, reproducible and provides an exact measure of intelligence by means of the relative entropy score.

Conclusion

Intuitions regarding consciousness seem to create many problems which have not been satisfactorily resolved (see Dennett, 1991). In contrast, the framework we have described here can explain many of the questions regarding consciousness in an unambiguous and consistent manner.

The compression conjecture explains why a brain that evolved to optimize an organism's behavior should be

associated with consciousness. It explains why consciousness is not amenable to scientific description. It explains what we mean by 'the self' and why brains provide self-awareness. It explains the apparent paradox of experiencing a singular perspective in a brain which carries out distributed processing. It predicts what systems are conscious and what systems are not; it reveals that a complete theory of consciousness is not possible. It tells us how to identify consciousness and it even provides a standard by which to measure consciousness.

The compression conjecture does not require special neuro-biological causal properties. It does not require mysterious quantum fluctuations in micro-tubules. It does not require an additional imperceptible dimension to the universe. It does not require the actions of a divine being. In fact, it requires nothing except data compression.

Feature repetition effects on object familiarity: Evidence from an old/new recognition task

Abstract

We performed an old/new study/test recognition task to investigate feature repetition effects on object familiarity. The results showed that repeated features increased “old” responses during the test phase for new objects. This increase was linear with the number of repeated features on the object. Old objects, which had been among the study phase stimuli, were not affected by the number of repeated features on the object. We also analyzed the effect of feature type (colour, shape, border and pattern) on familiarity responses. We found an effect of feature type only for the old objects. Saliency of the features also affected familiarity: the more salient the repeated feature was, the more familiar the object was found. We propose that the feature repetition effect for the new objects might be due to (1) activation of more than one representation constructed during the study phase (2) a separate representation for the repeated features, which has the potential to interfere with several perceptual processes.

Keywords: feature repetition effect; object recognition

Introduction

Formation and activation of perceptual representations has been the subject of various disciplines including, but not limited to, philosophy, psychology, psychophysics, neuroscience, and computer science. In philosophy, the existence of “mental representations” is a fundamental debate in the philosophy of mind. In psychology, the studies of categorization and memory directly relate to this problem. Artificial intelligence and robotics research concentrate on implementing visual systems that construct a representation of their virtual or real environments. With the emergence of cognitive science, the bodies of knowledge that developed in these separate fields are coming together, for a better understanding of how perceptual representations are constructed and accessed. This study aims to contribute to the research on the formation and activation of visual object representations by revealing some important factors involved in memory processes. Our approach takes its roots from findings in perception and memory literature and computational approaches in artificial intelligence.

From a computational perspective, it is possible to represent everything in the environment as a combination of some features, like color, shape, pattern, etc. We know that the human brain has specialized areas for each of

these feature domains (Hanna & Remington, 1996). Whenever a visual scene is encountered, activation is observed in these areas. Is this a mere bottom-up activation, or does the perceptual system attend to specific areas in the scene? We know that the visual system is not a passive receiver of visual data, but it actively obtains information from the visual flux (Jingling & Yeh, 2007). Attention makes a difference but we do not know whether the representation is stronger or the conscious access is easier in this case.

Whether the features in the scene are selected or all stored, it is clear that a combination of these features constitutes visual representations (Slotnick, 2004). Also audial and tactile features can be integrated with visual features, in which case the resulting representation can be called an “event file” (Hommel, 1998). Hommel states that all the features perceived in the same temporal window are automatically stored in these event files. These files can include features of every type, blurring the distinction between different domains of features, including visual and spatial pathways, which are assumed to exist separately in the brain. He points to the importance of building arbitrary connections between the features from different domains for learning.

In this study we investigated feature repetition effects on object familiarity. Hommel and Colzato (2009) report a decrease in performance in a stimulus-response task when one object feature is repeated while other features varied, as compared to complete repetitions and alterations. We predicted that repetition of particular features while other features vary would also affect familiarity of objects. We aimed to test this prediction with a continuous old/new study/test recognition design. In the study phase, participants saw a series of items one by one. In the test phase, they evaluated familiarity of the test items. To create the feature repetition effect, particular features were displayed more frequently than the other features in the study phase. We will call these features “frequently repeated features” (FRFs). In the test phase, items either had none, one, or two of the FRFs. We expected that the more FRFs the item had, the more participants would classify the item as familiar. We obtained scores for hits, misses, correct rejections and false alarms. False alarm scores are especially important

for our purposes. If items that were not displayed in the study phase are yet found familiar when they have FRFs, this would mean that (1) activation of previous bindings do not require an exact match with the given stimulus, or (2) there are other factors than binding of features that influence a familiarity judgement. If false alarms increase linearly with the # of FRFs, this might indicate an accumulated effect of repetition frequency on this judgement.

The design of the experiment is similar to the experiments in the categorization literature. In these experiments, a set of training objects are presented to the participants. In the test phase, they are expected to identify which category each test object belongs to. The features of the training objects are manipulated so that the effects of various variables such as similarity can be analyzed. However, our experiment significantly differs in the following terms: We do not assume a categorization process. Participants do not necessarily construct a categorical representation of the training stimuli and making familiarity judgements do not necessarily require accessing categorical representations.

The task in our experiment differs from the classical old/new recognition tasks, too. The usual old/new recognition task aims investigating the memory performance with respect to the dynamics of serial presentation of the stimuli. In our experiment, we systematically controlled the statistical properties of the object features and tested the effect of individual and combined feature repetitions instead of whole objects. In short, it can be said that our experiment integrates elaborate manipulations of object features as in categorization studies and experimental structure of an old/new recognition task. This provides a way of investigating the mechanisms of formation of perceptual representations through an analysis of the relationship between the statistical properties of the perceived stimulus and familiarity responses.

Another issue is feature intensity. Object representations in visual LTM have different intensities. The graded nature of these intensities shows its dominance in object recognition tasks, where object-based effects are tested (Ariga, Yokosawa, & Ogawa, 2007). In one task, participants were asked to recognize a target object in different conditions. In the first condition, the object was presented with a cue and in the second condition with no cue. Participants were faster at responding to objects presented with a cue only when the displayed object has a LTM representation of high intensity.

Finally, we investigated whether the type of feature is important for the feature repetition effect. Table 1 shows the feature types and values that appear in the stimuli set. By repeating different pairs of features, we analyzed familiarity responses for colour/border and shape/pattern pairs. In the next section the details of our design will be explained.

Method

Stimuli

Features There were four types of features: colour, shape, border and pattern. Each type had three values, as shown in Table 1. It was possible to create 81 objects using 4 features with 3 different values (3^4).

Table 1: Feature types and values used in the experiment

Colour	Red	Green	Blue
Shape	Square	Triangle	Circle
Border	Solid black	Dashed black	Coloured
Pattern	Dots	Diagonal lines	Shingle

Objects There were 15 objects. Objects were chosen among the pool of 81 possible objects, according to the following criteria: Solid black border and green color (pair 1) repeated together on 5 objects (see Figure 1a for an example of such object). Diagonal line pattern and square shape (pair 2) repeated together on 5 objects (see Figure 1b). Other feature pairs existed on 2 objects at most. FRFs were solid black border, green color, diagonal line pattern, and square shape, each repeating 7 times. Other features repeated only 4 times, e.g. 4 objects had blue color. Objects were created using the AutoShape tool of Microsoft Power Point. Objects had the same height (5 cm) and width (5 cm).

Slides One object was displayed on each slide. The center of gravity of the object was aligned to the center of the slide.

Training and test files There were 15 slides in the training file. Each slide was displayed for 2 seconds. Slide transitions were automatic. In the test file, there were 18 slides. The order of the slides was reversed in half of the participants. 8 slides were copied from the training file. The objects on these slides were the actual “old” objects. Remaining slides contained new objects. Each slide was displayed for 3 seconds.

Table 2: Number of objects of each category in the test phase.

	Old	New
Objects with two FRFs – pair 1	2	2
Objects with one FRF – pair 1	1	2
Objects with two FRFs – pair 2	2	2
Objects with one FRF – pair 2	1	2
Objects without any FRFs	2	2
Total	8	10

Participants

20 participants participated in the experiment. The age of the participants ranged between 22 and 35 years. All participants were university graduates. Participants had normal or corrected-to-normal vision. People who reported to be colorblind were not accepted to the experiment.

Experimental Design

There were two independent variables: familiarity and number of FRFs. Familiarity had two values: old or new. Number of FRFs had three values: 0, 1 and 2. The dependent variable was the familiarity score. It is the average of familiarity responses given to the objects in a category. Categories are displayed in Table 2. This was a 2x3 repeated measures design.

Setting

Computers in the Informatics Institute Computer Lab were used for the experiments. Stimuli were presented on a 19" widescreen LCD monitor by Microsoft Power Point software.

Figure 1 : Example stimuli from the study phase of the first experiment. These objects include features that have high repetition frequency (a) Green color and solid black border (b) Oblique pattern and square shape

Procedure

Before the experiment, participants signed an informed consent form. The instructions were as follows:

“The experiment consists of two parts. In the first part, you will see a series of slides. There will be objects on these slides. In the second part, I will show you another series of slides and ask you whether the object is familiar from the previous part.”

The experimenter opened the Power Point file. “Press spacebar to continue” displayed on black background.

“You will press the spacebar when you are ready to start the first part. You will just watch the slides.”

After all 15 slides were displayed, the Power Point turned back to the design view. At that point, the experimenter started the training slides from the beginning and instructed the participants as follows:

“Now I will repeat the same slides for better recall.”

After the second round, the experimenter opened the test file, and gave the following instructions:

“I will show you a series of slides and ask if the object is familiar from the first part. Reply with Yes or No. Since there is a time limit, try to be as quick as possible.” As the subject responded to each slide, the experimenter noted +/- marks on a response sheet.

Results

First, the familiarity scores for each category were calculated. The familiarity score is the average of the familiarity responses given by the participants to the test objects in a category. For example, if the participant responded with “familiar” to both objects the familiarity score was 1 ($\text{response}_1 = 1, \text{response}_2 = 1, \text{average}(\text{response}_1, \text{response}_2) = 1$). If one of them was familiar, and the other one was unfamiliar, the familiarity score was 0.5 ($\text{response}_1 = 1, \text{response}_2 = 0, \text{average}(\text{response}_1, \text{response}_2) = 0.5$). If both objects were unfamiliar the familiarity score was 0 ($\text{response}_1 = 0, \text{response}_2 = 0, \text{average}(\text{response}_1, \text{response}_2) = 0$). Counts of familiarity responses are displayed in Table 3.

Color and border We analyzed the effect of repeating the features green color and solid black border on familiarity responses. The effects of the two independent variables, familiarity (old, new) and the number of FRFs (0, 1, or 2), were analyzed in a two-way repeated measures ANOVA. There was a main effect of familiarity ($F(1,19)=46.77, p<0.001, e=0.7^1$), a main effect of number of FRF ($F(2,38)=13.57, p<0.001, e=0.4$) and an interaction between familiarity * number of FRFs ($F(2,38)=3.57, p<0.05, e=0.2$). The mean familiarity score was higher for the old objects, objects which actually existed in the set of the stimuli of the study phase, and the main effect of familiarity implies that this was significant. In other words, participants could successfully remember the

¹“e” denotes “partial eta square”.

Table 3 : Responses for the old/new recognition task. The numbers '0', '1' and '2' at the top of each column correspond to the number of FRFs on the object.

Response	Stimulus								
	Color and border repeated						Shape and pattern repeated		
	Old			New			Old		
	0	1	2	0	1	2	0	1	2
"Old"	35	28	37	9	16	27	35	36	32
"New"	5	12	3	31	24	13	5	4	8

objects that had been presented to them before. The main effect of number of FRFs shows that the familiarity response of the participants was affected by the number of FRFs on the object. As the number of FRFs increased, the mean familiarity score increased. The third significant effect is the interaction effect. In Figure 2, the different patterns of responses for familiar and unfamiliar objects can be seen. The number of FRFs did not affect mean familiarity scores for the familiar objects. However, for the unfamiliar objects, we see a totally different picture. If the object had no FRFs, then most of the participants reported that they had not seen the

object before. If the object shared only one of the FRFs, the mean familiarity score doubled. Finally, if the object shared both of the FRFs, most of the participants reported that they had seen the object, although they had not.

Shape and pattern Likewise, for the second pair, the square shape and the diagonal lines pattern, the effects of familiarity (old, new) and the number of FRFs (0, 1, 2) were analyzed with a two-way repeated measures ANOVA. There was a main effect of familiarity ($F(1,19)=28.89$, $p<.001$, $e=0.6$), a main effect of number of FRFs ($F(2,38)=5.67$, $p<.01$, $e=0.2$) and an interaction between familiarity * number of FRFs ($F(2,38)=10.89$, $p<.001$, $e=0.4$). The mean familiarity score was higher for the old objects, objects which existed in the set of stimuli and the main effect of familiarity implies that this was significant. The main effect of number of FRFs shows that the familiarity response of the participants was affected by the number of FRFs on the object. As the number of features increased, the mean familiarity score also increased. The third significant effect is the interaction effect. In Figure 3, the different patterns of responses for familiar and unfamiliar objects can be seen. The number of FRFs did not affect mean familiarity scores for the old objects. For the new objects, however, we see an effect of FRFs. If the object had no FRFs, then most of the participants reported that they had not seen the object before. If the object had only one of the FRFs, the average familiarity score doubled. Finally, if the object had both of the relevant features, most of the participants reported that they had seen the object.

Effect of feature types on familiarity responses The aim of this analysis is to test whether there was a difference between effects of repeating the color/border pair and repeating the shape/pattern pair on the familiarity judgment of objects. Mean familiarity scores for each pair are depicted in Figure 4. p1 represents the feature pair green color/black border and p2 represents the feature pair square shape and diagonal lines pattern. For hits, we see a slightly different pattern for p1 and p2. For false alarms, familiarity responses for p1 and p2 are almost identical. In this analysis we want to check whether the difference between p1 and p2 for the hits is significant. Two 2 (# of FRFs: 1, 2) x 2 (feature pair: 1, 2) repeated-measures ANOVA were

Figure 2: Mean familiarity scores for the objects with zero, one or both of the features color green and solid black border. Error bars represent standard error
(a) Old objects (b) New objects

Figure 3: Average familiarity scores for the objects with zero, one or both of the features square shape and diagonal lines pattern. Error bars represent standard error

Figure 4: Familiarity scores for hits and false alarms for two different feature pairs. h denotes hits and fa denotes false alarms. p1 represents the feature pair green color/black border and p2 represents the feature pair square shape and diagonal lines pattern.

performed separately for hits and false alarms. For false alarms, there was no significant difference. For hits, there was an interaction effect between feature pair and # of FRFs, $F(1,19)=4.65$, $p<.05$, $\eta^2=0.26$. The interaction effect showed that as the “old” responses increased with the # of FRFs for the objects with green color and solid black border, a decrease was observed for the objects with square shape and diagonal lines pattern.

Discussion

We obtained three results from the old/new recognition task about the feature repetition effects on familiarity. (1) False alarm rates increase as the # of FRFs on new objects increase. (2) Hit rates were not affected by the # of FRFs on the object. (3) The type of feature influences the effect of FRFs only for hits.

The first result showed that if a new object in the test phase had no FRFs, the object was correctly identified as new. Familiarity responses increased linearly as the number of FRFs on the test object increased. In other words, participants classified new objects as old, if these objects had FRFs. The increase in “old” responses with two FRFs was twice the increase with only one FRF. Thus the relation was almost perfectly linear. This supports our hypothesis that familiarity judgements are not based solely on an exact match between the presented stimulus and existing representations. Partial activations of features enabled the classification of new items as old. However, this was true only if the partial activation is caused by frequently repeated features.

Hommel showed that repetition of a set of features while others vary affects performance in a response selection task. Our experiments revealed a similar pattern in a familiarity task. The repeated features caused an increase in false alarm rates. However, we believe that one should not consider the influence of frequently repeated features on familiarity as detrimental to performance. The perceptual system is sensitive to statistical properties of the stimuli (Turk-Browne et al., 2008). This enables extracting crucial information about the environment. Frequently repeated features might indicate regularities which are meaningful to the agent.

Second, feature repetition did not affect the hit rates. Hit rates were in general very high, indicating that participants responded as “old” to actually old objects most of the time. This may indicate that recognition success of the participants was high for the old objects. It means they could successfully represent the objects in the study phase.

Third, we found an interaction effect between feature type and the # of FRFs for hits. This was caused by the relatively small decrease in familiarity scores for objects with 1 FRF of pair 1. Further analysis revealed that this feature was the border feature. This might be due to the difficulty in perceiving or representing the border feature. It is not a basic feature as shape, color and pattern. So, we think that the interaction effect is related with the relatively poor representation of the border feature.

It is important that we obtained different patterns of results for old and new objects. For old objects, the repetition of particular features did not affect familiarity responses significantly. This is reasonable, since if a reliable representation of an object was constructed during the study phase, it should be identified as familiar during the test phase regardless of individual repetitions of the features. However, the opposite is not true, as shown by the increase in false alarm rates with the # of FRFs. Even though the new objects did not have previously constructed representations, they were identified as familiar if they had FRFs. This supports the claim that an exact match between the stored representations and a given stimulus is a sufficient but not a necessary condition for familiarity.

What do the FRFs activate? Do they cause partial activation of the existing representations? The existing theories of categorical representations do not provide answers to these questions. The context model (Medin and Schaffer, 1978) which claims that individual exemplars are stored in memory would not reflect sensitivity of the participants to statistical regularities of the stimuli. On the other hand, prototype theories would not account for the success of participants in recognizing individual objects from the training phase. The hybrid models (Nosofsky, Kruschke & McKinley, 1992) aim to combine the advantages of these two models but this pragmatic approach does not necessarily satisfy biological plausibility. We believe that a more comprehensive theory of perceptual representations, which is not restricted to representation of categories, should be developed, taking recent research on neural populations into account.

From the perspective of synchronization of neuron populations, FRFs can synchronize many representations at once. Why do the “old” responses increase linearly with the # of FRFs on the new object? More FRFs would mean activation/synchronization of more representations. However, since the joint frequency of the FRFs was also high, as well as their individual frequencies, this linear increase might be due to a better match between the stimulus and previously constructed representations. Alternatively, one may claim that FRFs do not activate existing representations, but they themselves constitute individual representations which are easier to activate and which can interfere with perceptual and motor processes in general.

Another thing to note is the effect of feature saliency. Color salience was not homogeneous among the objects because of the patterns we used in the experiment. The color green in dotted objects (where dots are black and other areas are green) were more salient than in objects with diagonal lines (where lines are green and other areas are white). The effect of saliency was reflected in the average familiarity responses for the objects, 0.8 for dotted pattern and 0.5 for diagonal lines pattern. If the FRF was more salient, the feature repetition effect was stronger. This variable will be manipulated in our future experiments.

Conclusion

In this experiment we tested the feature repetition effect on object familiarity with a continuous old/new recognition task. We found that repetition of particular features increased “old” responses during the test phase for new objects. This increase was linear with the number of repeated features on the object. Saliency of the features also affected familiarity; the more salient the repeated feature was, the more familiar the object was found. We proposed that feature repetition effect might be due to (1) activation of more than one representation constructed during the study phase (2) a separate representation for the repeated features, which has the potential to interfere with several perceptual processes. These findings will guide our efforts in the development of a computational model for the formation and activation of perceptual representations which is currently in progress.

Abstract

Human infants and adults are able to segment coherent sequences from unsegmented strings of auditory stimuli after only a short exposure, an ability thought to be linked to early language acquisition. Although some research has hypothesized that learners succeed in these tasks by computing transitional probabilities between syllables, current experimental results do not differentiate between a range of models of different computations that learners could perform. We created a set of stimuli that was consistent with two different lexicons—one consisting of two-syllable words and one of three-syllable words—but where transition probabilities would not lead learners to segment sentences consistently according to either lexicon. Participants' responses formed a distribution over possible segmentations that included consistent segmentations into both two- and three-syllable words, suggesting that learners do not use pure transitional probabilities to segment but instead impose a bias towards parsimony on the lexicons they learn.

Keywords: Word segmentation; statistical learning; computational modeling.

Introduction

Human adults, infants, and even members of other species have the ability to identify statistically coherent sequences in unsegmented streams of stimuli after only a very short exposure (Saffran, Aslin, & Newport, 1996; Saffran, Newport, & Aslin, 1996; Hauser, Newport, & Aslin, 2001). This segmentation ability is extremely robust, operates across a wide range of modalities (Conway & Christiansen, 2005), and has been hypothesized to play an important role in early language acquisition (Kuhl, 2004). Nevertheless, relatively little is known about the computations underlying statistical segmentation.

In one influential study, Saffran, Newport, and Aslin (1996) exposed participants to a simple artificial language which consisted of six trisyllabic words concatenated together to form a continuous speech stream. After only a few minutes of exposure, participants were able to distinguish words in this language from strings that did not occur with the same frequency. They speculated that participants could succeed by computing syllable-to-syllable transitional probabilities (TPs) and segmenting the speech stream at local minima in TP.

There are many possible computations by which learners could extract coherent units from the statistical structure

of the speech stream, however. Lexicon-based learners like PARSER (Perruchet & Vinter, 1998) and Bayesian lexical models (Brent, 1999; Goldwater, Griffiths, & Johnson, 2009) have also been proposed as possible models of segmentation. Though these models differ on several dimensions, all assume that learners attempt to learn a consistent lexicon—a set of word forms that is combined to form the training sequence—and they do this by preferring small lexicons composed of frequent, short words.

Two previous studies have examined whether this kind of model could provide a good fit to human learning performance. The first contrasted recognition of sub-parts of the words from a speech stream and found that PARSER, like human learners, failed to discriminate sub-parts of words after training (Giroux & Rey, 2009). The second study found that a parsimony-biased chunk-finding model better accounted for human performance across a range of experiments in the visual domain than a purely associative model (Orbán, Fiser, Aslin, & Lengyel, 2008). Thus, both of these studies suggest that human learners do not simply represent association probabilities in statistical learning.

Our current study asks what kinds of learning biases operate in statistical learning. Our study makes use of a novel language whose transition statistics support not just one but a range of possible coherent segmentations: training data could be interpreted as a sequence of sentences of six words from a lexicon of two-syllable words or a sequence of sentences of four words from a lexicon of three-syllable words (where all words appeared with approximately the same frequency). TPs for a single sentence in this language are shown in Figure 1. A learner using pure TPs to segment the language would not recover either lexicon but would instead either segment the language into sets of six-syllable words or else segment inconsistently into a mix of two- and three-syllable words. Thus, our language was designed to test whether human learners would learn more parsimonious lexicons than those implied by pure transition statistics.

Experiment 1 validates two methodological innovations: a web-based interface for data collection and a dependent measure which directly evaluates participants' word segmentation judgments. Experiment 2 uses these methods to test

Figure 1: Average transitional probabilities between syllables in an ambiguous language from Experiment 2.

participants' segmentation judgments in the ambiguous language discussed above. We compare the distribution of participants' segmentations to the performance of two computational models—a standard TP model and a Bayesian model that looks for a parsimonious lexicon—and conclude that participants' judgments reflect the operation of a parsimony bias.

Experiment 1

The first condition of Experiment 1 compares web-based data on a segmentation task to previously-collected lab data (Frank, Goldwater, Griffiths, & Tenenbaum, under review) on a standard 2 alternative forced choice (2AFC) test trial. The second condition evaluates a new measure of segmentation: explicit segmentation decisions. We developed a graphical paradigm in which participants heard a sentence, saw it transcribed on the screen, and were asked to click between syllables to indicate where they thought the boundaries between words were.

Methods

Participants Forty eight separate HITs (opportunities for a participant to work) were posted on Amazon's Mechanical Turk web-based crowd-sourcing platform. We received 40 HITs from distinct individuals. Participants were paid \$1 for participating.

Stimuli For each condition, we constructed 16 distinct languages to be heard by different participants (to avoid item effects caused by phonological similarity of words). These languages each had a lexicon of six words (2 x two syllables, 2 x three syllables, 2 x four syllables). Words were created by randomly concatenating the syllables *ba*, *bi*, *da*, *du*, *ti*, *tu*, *ka*, *ki*, *la*, *lu*, *gi*, *gu*, *pa*, *pi*, *va*, *vu*, *zi*, and *zu*. Stimuli were synthesized using MBROLA (Dutoit, Pagel, Pierret, Bataille, & Vrecken, 1996) at a constant pitch of 100Hz with 25ms consonants and 225ms vowels. Sentences were generated by randomly concatenating words into strings of four words with no repetitions. All words had frequencies of 300 in the resulting corpus of 75 sentences.

For the 2AFC condition, part-word test stimuli (Saffran, Newport, & Aslin, 1996) were created by concatenating the first syllable of each word with the remaining syllables of

Figure 2: Average percent correct is plotted by subject for in-lab participants from Frank et al. (under review) and Mechanical Turk participants from the 2AFC condition of Experiment 1. Each point is an individual participant, bars show the mean, and the dashed line represents chance.

another word; this created distractors which appeared in the training corpus with lower frequency than the words. For the segmentation condition, we generated 10 extra sentences according to the same uniform frequency distribution and lexicon as the training corpus.

Procedures After selecting our HIT, our Adobe Flash interface tested that participants' sound was on and that they were able to understand our instructions by asking them to listen to a simple English word and enter it correctly. Participants were then instructed that they would listen to a set of sentences from a made-up language and then be tested on what they had learned. In order to hear each sentence during training, participants clicked a button marked "next."

In the test phase of the 2AFC condition, participants heard 24 pairs consisting of a word and a length-matched part-word and clicked a button for each to indicate which one sounded more like the language they just heard. In the segmentation condition, participants were asked to click on the breaks between words in a graphic display of a sentence. They performed one practice trial on an English sentence presented in this way ("In di an go ril las ne ver eat ba na nas") and prevented from continuing until they segmented it correctly. They then segmented 10 test sentences. Sentences were presented with each syllable separate. Each sentence was played once at the beginning of a trial, and below the sentence was a button that offered the option of hearing the sentence again.

Results and Discussion

In the 2AFC condition ($N=24$), we found that participants were above chance in their mean accuracy, taken as a group ($t(23) = 5.92$, $p < .0001$). Results are plotted together with data from an identical condition of Frank et al. (under review) (Experiment 2, 300 words exposure), collected from a group of participants in the lab (Figure 2). Mean performance was slightly lower for the Internet-based Turk par-

Figure 3: Token precision, recall, and F-score are plotted for individual participants in the segmentation response condition of Experiment 1. Points represent individual participants for each measure. Bars show means and dashed lines show permutation baselines.

ticipants ($M=66\%$ compared with $M=71\%$) but not significantly so (Welch two-sample t -test for unequal sample sizes, $t(21.21) = -.92$, $p = .37$). Participants completing the learning task on their own computer via the Internet were able to perform at levels comparable to participants in an isolated room in a psychology laboratory.

In the segmentation condition ($N=16$), we could not analyze participants' percent correct judgments as in the 2AFC condition. Instead, we evaluated two aspects of performance. First, we asked about the correctness of the boundaries participants placed: whether these decisions corresponded to the correct segmentation (*boundary* performance). Second, we asked about whether each word in the sentence was segmented correctly at its boundaries (*token* performance).

We computed hits (correctly placed boundaries or correctly segmented tokens), misses (missed boundaries or tokens that were not segmented appropriately), and false-alarms (extra boundaries or incorrect tokens that were segmented). Precision captures the proportion of boundaries that were placed correctly and is computed as hits / (hits + false-alarms), while recall captures the total proportion of correct boundaries that were identified and is computed as hits / (hits + misses). We combined these into an F-score, a commonly used metric that is the harmonic mean of precision and recall (Goldwater et al., 2009).

Figure 3 shows token precision, recall, and F-score for participants in the segmentation condition. We calculated an empirical baseline for each measure via permutation: we repeatedly shuffled each participant's boundary decisions within each sentence at random and computed the same measures over it, then took the mean for each. We then used these empirical baselines to test whether participants were above chance in this condition and found that they were for both measures (boundary performance: one sample t -test for precision, $t(15) = 5.23$, $p = .0001$; recall, $t(15) = 6.79$, $p < .0001$; F-score, $t(15) = 8.75$, $p < .0001$, token performance:

$t(15) = 3.63$, $p = .002$; recall, $t(15) = 2.71$, $p < .01$; F-score, $t(15) = 3.41$, $p < .004$), though boundary performance was better than token performance. Participants were able to understand the segmentation task and link the regularities they extracted from the exposure corpus to the response format.

Experiment 2

We made use of the two methodological innovations from Experiment 1—Internet data collection and explicit segmentation judgments—to ask about participants' responses to a language where TP did not reveal the possible lexicons of two- or three-syllable words. Instead, pure TPs predicted that participants would often segment the language into words of six-syllables and would rarely segment into words of two or three syllables. Our next experiment tests these predictions.

Methods

Participants Two-hundred and three separate experimental HITs were posted on Amazon Mechanical Turk. We received 119 HITs from distinct individuals who made segmentation decisions on every trial. Participants were paid \$0.50 for participating. An additional 145 HITs in the test-only control condition were posted at \$0.25 each; we received 102 HITs from distinct individuals who made segmentation decisions.

Stimuli Languages were generated using two parallel vocabularies, one of eight two-syllable words and one of six three-syllable words. These vocabularies were designed to allow overlapping segmentations where the presence of a certain word from one vocabulary did not always indicate the presence of the same set of words from the other. For example, if the three-syllable vocabulary contained ABC, the two-syllable vocabulary would contain at least either AB and two words beginning C, or BC and two words ending A. Sentences of 12 syllables were generated by choosing syllables one at a time from the set that made the sentence to the current point compatible with both vocabularies. At each point, syllables were chosen from a distribution over this set, weighted inversely to the frequency with which they had been chosen to follow the previous syllable in all sentences so far. The resulting sentences displayed probabilistic word-to-word dependencies, much as one would expect in natural language due to the syntactic relationships between words, but in no languages were there pairs of words from either vocabulary which always appeared together. We generated 30 distinct languages and synthesized them as in Experiment 1. Each language contained 25 sentences for training and 10 test sentences, sampled from the same distribution. Sentence presentation order was random.

Procedures Procedures were identical to the segmentation condition of Experiment 1. Participants in the test-only control condition received no training sentences.

Results and Discussion

Participants produced a wide range of segmentations, from those which segmented every three syllables to those which

Figure 4: Twenty four participants in Experiment 2, uniformly sampled along the dimension of 2-segmentation F-score. Plots show average probability of placing a boundary at each location in a sentence. Top left shows three-segmenters (three peaks separating four three-syllable plateaus), while bottom right shows two-segmenters (five peaks separating six two-syllable plateaus).

segmented every two syllables. Sample responses are shown in Figure 4. While there was an overall trend towards 2-consistent segmentations, a wide variety of segmentations were observed. Contrary to the predictions of the TP account, there were almost no segmentations into words of six syllables and there were a considerable number of segmentations into words of two and three syllables.

We evaluated participants' performance on the same measures used in Experiment 1: precision, recall, and F-score for both boundaries and tokens. Rather than using a single correct segmentation, we calculated these measures for both the 2-syllable lexicon and the 3-syllable lexicon (Figure 5), showing the distribution of responses on the continuum between a perfect 2-segmentation and a perfect 3-segmentation.

One possible alternative explanation of our finding could be that learners have a bias towards segmenting consistently (e.g., because of the trochaic, bisyllabic structure of English) even without taking into account the structure of the languages they heard. However, results from the first trial of the test-only condition had a very different distribution than those who underwent training (Figure 5). Without training, performance was similar to a randomized baseline in which participants' judgments for each sentence were shuffled randomly. Although there was some learning during test for participants in the test-only condition, there was very little change in the distribution of responses during test for those participants who underwent training.

Our results are inconsistent with the hypothesis that participants segmented on the basis of TPs. Instead, the distribution of participants' responses shows a bias towards segmentations that were consistent with a more parsimonious lexicon than that produced by segmenting at low transition probabilities.

Models

To formalize the intuitions motivating Experiment 2, we evaluated a TP model and a lexicon-finding model on the experimental stimuli. We then evaluated the segmentations pro-

duced by these models on the same criteria that we used for the human participants.

Transitional probability model

For each language, we calculated TP for each pair of syllables that appeared in the training portion of the corpus. We computed TP as $P(s_2|s_1) = C(s_1, s_2) / \sum_{s' \in S} C(s_1, s')$ where $C(s_1, s_2)$ refers to the count of instances of the string $s_1 s_2$.

Earlier proposals for TP models called for segmenting at local minima in TP (Saffran, Newport, & Aslin, 1996). However, this method produces only a single possible segmentation for a given sentence and provides no plausible explanation for how participants could have given such different responses for such similar languages. Thus, we chose to convert the TPs for test sentences into decision boundaries via a simple threshold operation: we inserted a boundary in a test sentence every time TP was below a threshold value in that sentence. Rather than picking a single threshold value, we assumed that participants might have a range of threshold values and that this range might explain the variation between participants we observed. Therefore we created a separate segmentation for each language for each threshold value from zero to one at an interval of .1.

Lexical model

We also ran the unigram Bayesian Lexical model described in Goldwater et al. (2009). This model is a probabilistic model which uses Bayesian inference to search the space of segmentations of the training corpus, evaluating each segmentation on the parsimony of the lexicon that would have created it. The structure of the model makes a segmentation more probable when it results in fewer, shorter lexical items (though also when the segmentation itself contains fewer word tokens, which leads to a trade-off).

As in the TP model, it was important to investigate the range of segmentations that were available under this model. When we ran a standard Markov-chain monte carlo algorithm using the parameter set from previous simulations, we found

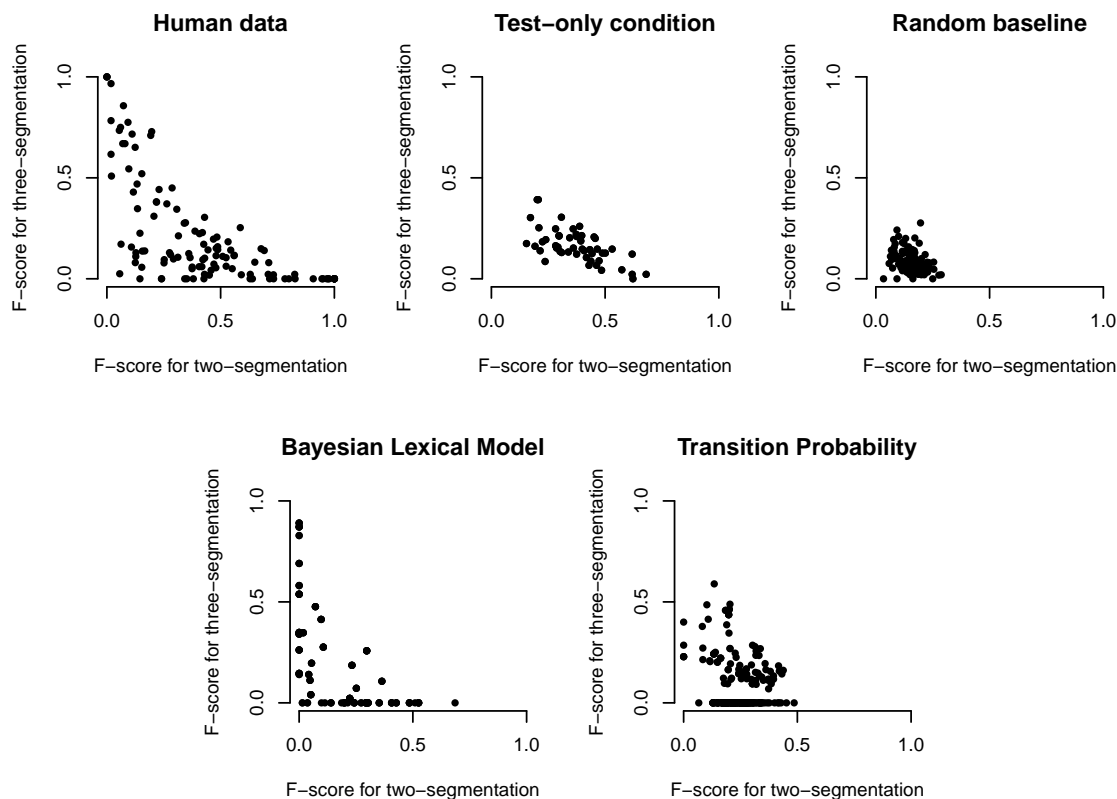

Figure 5: Participant and model token F-scores for Experiment 2. Three-syllable token F-scores are plotted by their two-syllable token F-scores. Each dot represents a single participant or a single model run.

Table 1: Kullback-Leibler divergence between the distribution of human experimental data and other data.

Model	Token F	Boundary F
Test-only condition	4.01	3.45
Random baseline	7.26	9.45
Lexical model	2.07	3.16
Transitional probability	4.62	3.72

that it converged to a segmentation that preferred a lexicon of three-syllable words. In order to investigate a broader range of segmentations, we manipulated the temperature of inference in the model by exponentiating posterior probabilities at a range of values. (This manipulation is a standard technique for allowing sampling algorithms to explore a hypothesis space more broadly, rather than converging to the single highest-probability answer.) With slightly higher temperatures, our sampler explored a broad range of possible segmentations. We report results for temperature = 2 although results for a temperature of 3 were comparable.

Results and Discussion

Results for both models are shown in Figure 5, bottom. The transitional probability model failed to capture the spread of

Table 2: Log probability of consistent segmentations under the Lexical model.

Syllables per word	Log probability
6	-594.28
4	-932.92
3	-530.62
2	-697.07
1	-1127.20
unsegmented	-1907.20

human results: nearly all segmentations it found were comparable in F-score for 2- and 3-segmentation, and no segmentation was over an F-score of .5 on either measure. The Lexical model came closer to capturing the distribution of responses, though it was not as effective at finding 2-segmentations as the human participants, suggesting a possible role for a trochaic bias. Unlike the TP model, however, its probability landscape was truly multi-modal, finding relatively high probability segmentations with 2, 3, and 6 syllables per word (Table 2).

We measured the differences between the distributions of responses across human participants and models using Kullback-Leibler divergence—an information-theoretic mea-

sure of the difference between a true distribution and an approximation of that distribution—to quantify the number of bits between distributions (MacKay, 2003). In order to convert sets of observations into smooth distributions, we convolved them with a Gaussian kernel with a constant kernel width. This manipulation produced a smooth density which could be effectively compared using KL divergence.¹ Results are shown in Table 1. The Lexical model showed the lowest divergence from the human response distribution, while the TP model was closer to the empirical baseline in its divergence from the human distribution.

General Discussion

We presented two studies of statistical word segmentation. The first study introduced two methodological innovations, web-based data collection and explicit segmentation judgments. We used these new methods in the second study to test whether human learners faithfully learned the transitional probabilities of an ambiguous language or whether they gave a segmentation that was more consistent with one of the two possible lexicons that generated the training corpus. We found that the distribution of participants' responses was not consistent with the distribution of segmentations produced by segmenting according to a TP model. Thus, our results provide evidence that human learners do not simply encode transitional or associative statistics but instead impose some kind of bias on what they learn.

This bias could be either a bias for consistent word lengths or for a parsimonious lexicon. A model which searched for lexicons with small lexicons consisting of highly frequent, short words produced a distribution similar to that produced by the human learners. Nonetheless, the Lexical model preferred a lexicon with three-syllable words, unlike human learners who preferred to segment into two-syllable words; and the Lexical model assigned a high probability to a segmentation into two words of six syllables each, while participants rarely produced this segmentation. Frank et al. (under review) found that models with memory limitations provided a better fit to human performance, suggesting that one possible explanation for these differences is the increased difficulty for human learners of remembering longer words.

The language used in Experiment 2 has a number of limitations. First, unlike recent studies (Frank et al., under review; Giroux & Rey, 2009), the competing lexicons we used in this study were composed of words of homogenous length, leading to stimuli that could be perceived as isochronous. Second, the size of the lexicons was relatively small and the restrictions on sentences were tight, leading to a small number of possible sentences. Our ongoing work attempts to address both of these issues.

¹Because both the TP model and the Lexical model produced a significant number of segmentations that failed to place any boundaries—for the TP model this was due to extreme threshold values, and for the Lexical model this was due to convergence issues in the online sampler we used—we excluded all model runs that failed to make any segmentation decisions.

Results in the statistical learning literature have rightly been interpreted as showing that human learners are sensitive to associative and transitional statistics in their environment. But these interpretations should not be confused with the conclusion that learners compute these particular—or any—transition statistics. Instead, future research on statistical learning should attempt to characterize both human learning biases and the computations that give rise to them.

Effects of Goal Specificity on a Search in a Hypothesis Space and an Instance Space

Miki Matsumuro (muro@cog.human.nagoya-u.ac.jp)

Abstract

We examined the effect of goal specificity on a search in two problem spaces: a hypothesis space and an instance space. Two hypotheses were considered: 1) a nonspecific goal facilitates a search in a hypothesis space more than a specific goal, and 2) as a hypothesis space is searched more, the performance in discovering the target rule improves. We also defined an initial hypothesis space consisting of initially considered hypotheses, and investigated the effect of this initial hypothesis space on the goal specificity effect. The results of three experiments indicated that when an initial hypothesis space was offered, the goal specificity effect was observed. A nonspecific goal actually facilitated a search in the hypothesis space. When, however, no initial hypothesis space was offered, the goal specificity effect was not confirmed. We also found that the facilitation of the hypothesis space search improved performance in discovering the target rule.

Keywords: discovery, rule induction, goal, hypothesis testing

Introduction

Dual Space Search Theory

Rule induction and scientific discovery have been studied based on the dual space search theory. Simon and Lea (1974) first suggested that a problem space consists of two spaces: a “rule space” for searching rules and an “instance space” for testing rules. Both rule and instance spaces are searched to find a correct rule.

Klahr and Dunbar (1988) extended the dual space search theory to the Scientific Discovery as Dual Search (SDDS) model for investigating scientific discovery. They considered a “hypothesis space” as a rule space and an “experiment space” as an instance space where the process of scientific discovery develops through the interaction between two types of searches in the two spaces. Reasoners state hypotheses by searching in a hypothesis space, receive feedback from an experiment space, and modify the current hypotheses or propose new hypotheses. Klahr and his colleague confirmed this model through a long series of experiments (Klahr & Dunbar, 1988; Klahr, 2000). They also identified “experimenters” who preferred to search in an experiment space and “theorists” who preferred to search in a hypothesis space. In this study we call the two spaces a “hypothesis space” and an “instance space.”

The search in a hypothesis space is crucial for scientific discovery. Klahr and Dunbar (1988) demonstrated that a search in only a hypothesis space led to the discovery of a correct rule without the execution of any experiments.

Goal Specificity Effect in Dual Space Search

On the other hand, we often neglect to consider the theories or rules behind phenomena when we aim for a specific goal. We tend not to search in a hypothesis space at times like this,

as we concentrate on a search in an instance space to achieve the goal.

Problem-solvers given a specific goal learn more poorly than problem-solvers given a nonspecific goal (Sweller & Levine, 1982). Burns and Vollmeyer (2002) investigated this effect of goal specificity based on the dual space search theory. Using a task in which participants were asked to learn the relations between inputs to and outputs from a system, they observed the effect of goal specificity. The NSG (nonspecific goal condition) participants, who were not informed of the target values of the outputs, learned the system structure better than the SG (specific goal condition) participants, who were informed of the target values. Burns and Vollmeyer (2002) also found that the NSG participants conducted more hypothesis testing than the SG participants. From these results, they concluded that a nonspecific goal encouraged the participants to search actively in a hypothesis space. Therefore, a nonspecific goal might lead to better learning than a specific goal.

Present Study

A hypothesis space is usually huge, hence a hypothesis space search is performed based on constraints offered by attentional perspectives (van Joolingen & de Jong, 1997). In the present study we define the hypothesis space in which the participants initially search as an “initial hypothesis space” and the space containing a target rule to be discovered as a “target space.”

In the earlier studies, the initial hypothesis space was typically decided by an experimenter because the participants were informed of all the relative factors of focus. This initial hypothesis space also contained the target rule to be discovered. There was no need for the participants to find the target hypothesis space, as the initial hypothesis space and target hypothesis space were identical (Figure 1(a)). Here, in contrast, we investigate situations in which the participants must find a target hypothesis space by themselves in order to discover an appropriate rule.

(1) Initial-space situation

One situation we deal with is the “initial-space situation” (Figure 1(b)). Participants are given an initial hypothesis space by an experimenter. This initial space, however, contains no rule to be discovered. The initial hypothesis space differs from the target hypothesis space. To discover the target rule, the participants need to shift a searching space from the initial hypothesis space to the target hypothesis space. This situation typically emerges in insight problem solving (Kaplan & Simon, 1990).

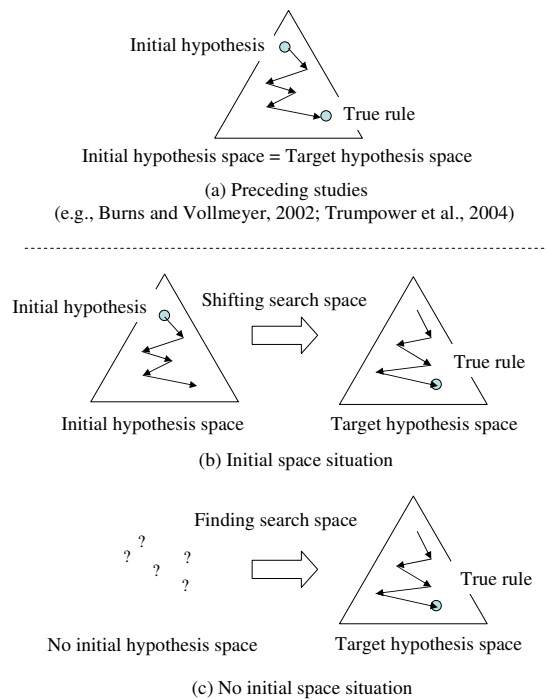

Figure 1: Conceptual diagrams of preceding and present studies

(2) No-initial-space situation

The other situation is the “no-initial-space situation” (Figure 1(c)). The participants in this case are not informed of any relative factors of focus, and thus receive no information on the initial hypothesis space to be searched. The participants have to find relative factors for the search from the initial stage. The investigation of this situation is important, as the size of a hypothesis space and the number of available hypotheses might affect the search strategies.

Aim of the Present Study

We investigate two hypotheses regarding the effect of goal specificity on a search in the dual spaces in the two situations: the initial-space situation and the no-initial-space situation.

Hypothesis 1: A nonspecific goal facilitates a search in a hypothesis space more than a specific goal. In other words, participants who are given a nonspecific goal may search more actively in a hypothesis space.

Hypothesis 2: As a hypothesis space is searched more, the performance in discovering the target rule improves.

Task

Figure 2 is a screen shot of the task for this study. The participants are asked to use the arrow buttons to pass the ball from player to player and to shoot for the basket. Two rules, one fake and one true, are valid in each game. These rules determine the relation between the arrow buttons and pass directions for the ball. In both rules, the up-arrow button corresponds to a certain direction and the other seven buttons correspond to the other seven directions relative to the up-arrow in clockwise rotation. The direction of the prior pass

Figure 2: Screen shot of the task

A screen shot of one of the games during Phase 1. The participants pass the ball from player to player and shoot for the basket.

corresponds to the up-arrow button in the true rule, whereas the direction of the current player’s nose corresponds to the up-arrow button in the fake rule. Although the fake rule is expected to be discovered more easily than the true rule, it can be valid in the initial games (not in all games). The true rule, in contrast, is valid in all games.

The participants, having discovered the fake rule, initially search in the hypothesis space consisting of hypotheses characterized by a face direction (the “face hypothesis space”). Even if the fake rule no longer validly works in the games, the participants continue to search in the face hypothesis space. To discover the true rule, the participants must shift a searching hypothesis space from the face hypothesis space to the hypothesis space made up of hypotheses characterized by the orbit of the prior pass (the “orbit hypothesis space”). The orbit hypothesis space contains the true rule. Thus, in this task, the initial hypothesis space means the face hypothesis space and the target hypothesis space means the orbit hypothesis space.

The experiment basically consists of three phases.

Phase 1: The participants engage in games in which both the fake and true rules are valid. The participants are asked to shoot the ball into the basket as many times as possible. We expect the participants to discover the fake rule and use it in Phase 1.

Phase 2: Only the true rule can be applied in the games in Phase 2. At the beginning of Phase 2, the participants are expected to search in the face hypothesis space, based on their successes with the fake rule accumulated in Phase 1. To discover the true rule, the participants must shift a searching hypothesis space from the face hypothesis space to the orbit hypothesis space. We manipulate experimental factors and observe how these factors affect the searches in the hypothesis space. The playing time is limited in Phases 1 and 2. The participants are told that the games in these phases are for training, and that the real games, or the actual takes, will come in Phase 3.

Phase 3: The participants are informed the real games, or actual takes, come in Phase 3. They are asked to shoot the ball into the basket. Phase 3 consists of two games, each of which

is played to completion without a time limit imposed. The true rule is valid in both the first and second games, but the fake rule can be applied to only the first game. We, the researchers, judge whether or not the participants discover the true rule based on their performances in each game.

Manipulation of Goal Specificity

Goal specificity is manipulated mainly through the following three experiments. The participants are given a specific goal (the SG condition) and asked to play the games in Phase 2 (the screen shot in Figure 2 shows a Phase 2 game). The basket and obstacles determine only one pass route. Thus, the participants' next moves are specified. Meanwhile, the participants in the other group are given a nonspecific goal (the NSG condition) and asked to play games in which there are no obstacles and in which the basket is replaced by a player. In this situation, the next move is unspecified: a participant can intentionally select one of several valid passes without a specific final goal (basket). With these manipulations in the games come differences between the instructions under the SG and NSG conditions in Phase 2. The participants in the SG condition are asked to shoot the ball into the basket, whereas the participants in the NSG condition are asked to pass the ball from player to player. In both conditions, the participants are asked to perform as many games as possible within the time limit. The time point of every button selection by a participant is recorded.

Measurement The hypothesis space in this task consists of hypothesized rules on the relations between the arrow buttons and the pass directions. An instance space consists of all instances; each instance is described as "when a certain arrow button is selected, a ball is thrown to a certain direction under a certain situation." Assuming that a search in one space is performed after a search in the other space, in turn, a hypothesis space search is performed during the period elapsed between the receipt of one pass result (the result of one pass thrown) to the receipt of the next pass result. Therefore, in this study, we use a time interval of two successive passes as a measurement for the amount of searches in a hypothesis space. Henceforth we refer to this time interval as the "pass interval time."

We judged whether each participant discovered the true rule from his or her performance in Phase 3. If the participants could not discover the true rule, the adjustment strategy minimized errors. The participants who use the adjustment strategy make a pass at first based on some criterion or randomly, and then adjust the direction of arrow buttons in order to minimize the difference between the expected and actual pass directions. We defined the successful participants as the participants whose error rate was lower than the expected error rate when they use the adjustment strategy.

Experiment 1

We conducted Experiment 1 to investigate the effect of goal specificity on a search in a hypothesis space in the initial-space situation (see Figure 1(b)). In addition, we manipulated another factor, the instruction factor, to test whether the

pass interval time is valid as a measurement of the amount of searches in a hypothesis space. In the search-oriented condition (the SO condition), the participants were asked to find a rule that determines the relation between the arrow buttons and pass directions. By contrast, in the non-search-oriented condition (the NSO condition), the participants were told nothing about the rule. This manipulation may lead the participants in the SO condition to search more in the hypothesis space, compared to the participants in the NSO condition. If the pass interval time correlates with the amount of searches in the hypothesis space, the pass interval time of the participants in the SO condition will exceed that of the participants in the NSO condition.

Method

Participants Sixty-four undergraduates participated in Experiment 1. Each was assigned to one of four conditions: goal specificity (SG and NSG) \times instruction (SO and NSO).

Task and Procedure Experiment 1 was conducted in small groups of three or fewer participants. After the participants received a basic explanation of the procedures, the participants briefly rehearsed the task. Next, they carried out the task in the three phases. Phase 1 and Phase 2 each lasted for five minutes. In Phase 2, two factors: the participants' search preferences in the hypothesis space by the instruction and goal specificity, were manipulated. Finally, in Phase 3, all participants played two games in an identical situation without a time limit imposed.

Results and Discussion

Pass Interval Time Figure 3 presents the average pass interval time in each condition in Phase 2. A two-way ANOVA ((goal specificity: SG and NSG) \times (instruction: SO and NSO)) was performed on the pass interval times in Phase 2. The interaction between the two factors was not significant ($F(1,60) = 0.673, n.s.$). The main effects of both the goal specificity factor ($F(1,60) = 38.454, p < .001$) and the instruction factor ($F(1,60) = 5.030, p < .05$) reached significance.

Figure 3: Average pass interval time in each condition in Phase 2 in Experiment 1 (bars show standard errors)

For the instruction factor, the pass interval time of the participants in the SO condition was longer than that of the participants in the NSO condition. The instruction given in the SO condition, the instruction which encouraged the participants to find a rule, increased the pass interval time. Noting

that this implied a correlation between the pass interval time and the amount of searches in a hypothesis space, we decided to use the pass interval time as a measurement of the amount of searches in a hypothesis space.

For the goal specificity factor, the pass interval time of the participants in the NSG condition was longer than that of the participants in the SG condition. This corroborated the first hypothesis: a nonspecific goal facilitates a search in a hypothesis space.

Proportion of Successful Participants Next, we analyzed the proportion of participants who discovered the true rule in each condition. For the instruction factor, 6 of 33 participants in the SO condition and 2 of 31 participants in the NSO condition were successful. There was no significant difference between the two conditions ($p > .10$). Similarly, for the goal specificity factor, 4 of 30 participants in the SG condition and 4 of 34 participants in the NSG condition were successful. Again, there was no significant difference between the two conditions ($p > .10$). Hence, these results did not confirm the second hypothesis: more searches in a hypothesis space improve performance in discovering the target rule.

Experiment 2

In Experiment 2 we investigated the effect of goal specificity on a search in a hypothesis space in the no-initial-space situation (see Figure 1(c)). We also manipulated the instruction factor to test the validity of the pass interval time, as was done in Experiment 1.

Method

Participants Sixty-four undergraduates participated in Experiment 2. Each was assigned to one of four conditions: goal specificity (SG and NSG) \times instruction (SO and NSO).

Task and Procedure The task in Experiment 2 was almost the same as that in Experiment 1, with the following adjustments. No Phase 1 was conducted in Experiment 2. The faces were removed from the players and the referee, and replaced with blue- and black-filled circles. The participants did not acquire the initial hypothesis space, as they were given no perspectives on which to focus for forming hypotheses at the beginning of the task.

Results and Discussion

Pass Interval Time Figure 4 presents the average pass interval time in each condition in Phase 2. A two-way ANOVA ((goal specificity: SG and NSG) \times (instruction: SO and NSO)) was performed on the pass interval times in Phase 2. The interaction between the two factors was not significant ($F(1, 60) = 0.022, n.s.$). The main effects of both the goal specificity factor ($F(1, 60) = 6.708, p < .05$) and the instruction factor ($F(1, 60) = 4.056, p < .05$) reached significance.

In the analysis for the instruction factor, this result was consistent with the result in Experiment 1. The pass interval time of the participants in the SO condition was significantly longer. The correlation between the pass interval time and the searches in a hypothesis space was again supported.

Figure 4: Average pass interval time in each condition in Phase 2 in Experiment 2 (bars show standard errors)

In the analysis for the goal specificity factor, the pass interval time was longer in the NSG condition than in the SG condition. This result also confirms the first hypothesis, corroborating the finding of Experiment 1. Note, however, that the difference between the SG and NSG conditions was much smaller in Experiment 2 than in Experiment 1. We will discuss this difference further in a later section.

Proportion of Successful Participants Next, we analyzed the proportion of participants who discovered the true rule in each condition. In the analysis for the instruction factor, 4 of 32 participants in the SO condition and 5 of 32 participants in the NSO condition were successful. There was no significant difference between the two conditions ($p > .10$). The result was similar in the analysis for the goal specificity: 3 of 32 participants in the SG condition and 6 of 32 participants in the NSG condition were successful. Again, there was no significant difference between the two conditions ($p > .10$). Hence, these results did not confirm the second hypothesis.

Comparison between Experiments 1 and 2

By comparing the results of Experiments 1 and 2, we could explore how the existence of the initial hypothesis space affected the effect of goal specificity. A premise for this study was dual spaces for search: the hypothesis space and instance space. Yet the participants in the NSO condition may not have assumed any hypothesis space, as they may not have noticed the rule determining the pass directions. For this reason, the following analysis focused on the participants in the SO condition.

In these experiments we introduced what we called the “situation factor,” manipulating whether or not the participants had the initial hypothesis space across Experiments 1 and 2. At the beginning of Phase 2, the participants in Experiment 1 had the initial hypothesis space. Recollecting their accumulated successful experiences with the fake rule in Phase 1, they directed their attention to the face hypothesis space. This situation was called the “initial-space condition” (the IS condition). In contrast, the participants in Experiment 2 did not acquire an initial hypothesis space or experience any game play in Phase 1. And by removing the faces as cues from the players of the games in Phase 2, we deprived the participants of perspectives for forming hypotheses. This situation was called the “no-initial-space condition” (the NIS condition).

A two-way ANOVA ((situation: IS and NIS) \times (goal speci-

ficity: SG and NSG)) was performed on the pass interval times in Phase 2. As a result, a marginally significant interaction between the situation and goal specificity factors was revealed ($F(1, 61) = 3.158, p = .081$). In the IS condition, the pass interval time was longer in the NSG condition than in the SG condition ($F(1, 61) = 17.449, p < .001$). This effect, however, disappeared in the NIS condition ($F(1, 61) = 2.769, n.s.$). Both the goal specificity and situation factors had significant effects ($ps < .05$).

In this comparison, the participants with a nonspecific goal had a longer pass interval time than the participants with a specific goal in the IS condition. Meanwhile, the goal specificity factor had no effect on the pass interval time in the NIS condition. Thus, the first hypothesis was confirmed only in the IS condition, and not in the NIS condition.

Experiment 3

In Experiments 1 and 2, we found that goal specificity had no effect on a search in a hypothesis space when the participants lacked an initial hypothesis space. In Experiment 3, we manipulated both the goal specificity and situation factors to confirm the effect of these factors directly. Several of the experimental procedures were improved for this experiment. First, Phase 1 was performed in both the IS and NIS conditions, so that the participants would begin Phase 2 with identical prior experiences. In the NIS condition, the faces of the players and referee were removed in Phase 2 to eliminate the initial hypothesis space. Second, only a few participants successfully discovered the target rule in Experiments 1 and 2. In Experiment 3, the players who threw a successful pass and the receiver from the previous trial were marked visually on the game display. This cue lowered the memory loads of the participants, thus helping the participants discover the true rule in the orbit hypothesis space more easily.

Method

Participants Seventy-four undergraduates participated in Experiment 3. Each was assigned to one of four conditions: situation (IS and NIS) \times goal specificity (SG and NSG).

Task and Procedure Experiment 3 was conducted in small groups of three or fewer participants. To control prior experiences, the participants in all conditions played games in all three phases. In Phase 1, the participants played games in which both the fake and true rules were valid, over a total play time of five minutes. In Phase 2, the participants played games in which only the true rule was valid. The goal specificity factor was manipulated by the same method used in the prior two experiments. Additionally, the situation factor was manipulated by adjusting the players' faces. The participants in the IS condition played the games with normal face players, as they had in Experiment 1. Meanwhile, the participants in the NIS condition played the games with faceless players, as they had in Experiment 2. Unlike Experiments 1 and 2, the game time in Phase 2 was increased to seven minutes in order to increase the number of successful participants. All participants were instructed that there was a rule valid through all of the games. Finally, Phase 3 was conducted using the same

player faces used in Phase 2, but without a time limit.

Results and Discussion

Pass Interval Time Figure 5 presents the average pass interval time in each condition in Phase 2. A two-way ANOVA ((situation: IS and NIS) \times (goal specificity: SG and NSG)) was performed on the pass interval times in Phase 2. The interaction between the situation and goal specificity factors reached significance ($F(1, 70) = 4.989, p < .05$). In the IS condition, the pass interval time was longer in the NSG condition than in the SG condition ($F(1, 70) = 9.078, p < .005$). This effect disappeared, however, in the NIS condition ($F(1, 70) = 0.021, n.s.$). The goal specificity and situation factors both had significant effects ($ps < .05$).

Figure 5: Average pass interval time in each condition in Phase 2 in Experiment 3 (bars are standard errors)

The result of Experiment 3 was consistent with the results of Experiments 1 and 2. In the IS condition, where the participants acquired the initial hypothesis space, goal specificity had an observable effect on a search in a hypothesis space. The participants with a nonspecific goal searched in a hypothesis space more actively than the participants with a specific goal. This effect was not observed, however, in the NIS condition, where the initial hypothesis space was eliminated by the change of the game display. Therefore, the presence or absence of an initial hypothesis space affected the goal specificity effect in a search in a hypothesis space. The first hypothesis is confirmed only in the IS condition.

Proportion of Successful Participants Next, we analyzed the proportion of participants who discovered the true rule in each condition (Figure 6). In the IS condition, 2 participants discovered the true rule in the SG condition and 8 participants discovered the true rule in the NSG condition.

Figure 6: Proportion of successful participants in each condition in Experiment 3

The participants in the NSG condition discovered the true rule more frequently than the participants in the SG condition ($\chi^2(1) = 4.502, p < .05$). In the NIS condition, 10 participants discovered the true rule in the SG condition and 9 participants discovered the true rule in the NSG condition. There was no significant difference between the SG and NSG conditions in the NIS condition ($p > .10$).

In the IS condition, the pass interval time of the participants in the NSG condition was longer than that in the SG condition. Additionally, the proportion of successful participants in the NSG condition was also greater than that in the SG condition. Thus, the second hypothesis is confirmed.

Discussion and Conclusions

In this study we investigated the following two hypotheses in two situations, an initial-space situation and a no-initial-space situation: (1) A nonspecific goal facilitates a search in a hypothesis space rather than a specific goal. (2) As a search in a hypothesis space is more actively performed, the performance in discovering the target rule improves.

From the results of three experiments, the first hypothesis was partially confirmed. The effect of goal specificity on a search in a hypothesis space depended on whether or not the participants noticed an initial hypothesis space. When the participants noticed an initial hypothesis space, goal specificity had an observable effect on a search in a hypothesis space. The participants with a nonspecific goal searched in a hypothesis space more actively than the participants with a specific goal. On the other hand, this effect of goal specificity was not observed when the participants were not given any initial hypothesis space.

The second hypothesis was confirmed in the results of Experiment 3. The pass interval time of the participants with a nonspecific goal was longer than that of the participants with a specific goal in the IS condition. Additionally, the proportion of successful participants with a nonspecific goal was larger than that of successful participants with a specific goal in the IS condition. However, there was no significant difference between the specific goal and nonspecific goal conditions in Experiments 1 and 2. This may have been due to a floor effect, as only a few participants discovered the true rule in these experiments.

The results of the present study are consistent with the finding of Klahr and Dunbar (1988). They defined hypotheses as the forms of a "frame." In their study, they classified the frames (hypotheses) into several types, according to their features. The hypothesis spaces in our study, i.e., sets of hypotheses sharing a common feature, could be explained by the types of frames defined by Klahr and Dunbar (1988). The theorists in Klahr's experiments preferred to do their searches in hypothesis spaces. They were able to switch the hypotheses types correctly, within short periods of time and over the course of only a few experiments, and discovered the rule rapidly. In our study, the participants with nonspecific goals behaved like the theorists in the situation where the initial hypothesis space was given. They preferred to search in a hypothesis space, repeating the behavior of the theorists in the earlier studies. They were able to switch the searching

hypothesis space from a given initial hypothesis space to a target hypothesis space with fewer instances, and discovered the true rule. In contrast, the participants with a specific goal preferred to search in an instance space, repeating the behavior of the experimenters defined in Klahr's study.

In the initial-space situation we observed the effect of goal specificity on a search in a hypothesis space, duplicating the results from earlier studies. This situation is identical to situations covered in the preceding studies, where participants were given an initial hypothesis space. Unlike the preceding studies, we used a task in which the true rule was not included in the initial hypothesis space. To discover the true rule, the participants needed to shift their attention to the target hypothesis space. Here, the effect of goal specificity on a search in a hypothesis space was still confirmed.

Yet when the participants were given no initial hypothesis space, goal specificity had no observable effect on a search in a hypothesis space. To state hypotheses, the participants initially needed to find a focused hypothesis space by themselves in this situation. We assume that they searched in an instance space to collect data as cues for determining a hypothesis space to search. This may explain why the hypothesis space search was not activated for the participants with the nonspecific goal. The SDDS model proposed that a discovery process is controlled with three main components: "search hypothesis space," "test hypothesis," and "evaluate evidence." The search hypothesis space component corresponds to a search in a hypothesis space in our study. This component contains a search in an experiment (instance) space as one of the sub lower components. Participants could collect data and find a pattern of these data gathered through the experiment space search, and state hypotheses. Similarly, the participants in our study who were given no initial hypothesis space needed cues to find a focused hypothesis space and state hypotheses. Therefore, we conclude that they searched in an instance space regardless of goal specificity.

Abstract

Previous studies have discussed how speakers select a frame (e.g., “half full,” or “half empty”), and have proposed a hypothesis such as *reference point hypothesis* (e.g., Sher & McKenzie, 2006, 2008). In this paper, we propose a new hypothesis, *frame choice based on information about rarity*. This hypothesis predicts that speakers tend to select a frame denoting a rare event. Four studies provide evidence that speakers' choice of frame is consistent with the prediction from our hypothesis. Furthermore, our hypothesis is reconciled with the *positive bias* in frame choice, which cannot be accounted for by the reference point hypothesis. We discuss the possibility that linguistic behaviors are widely explained from people's sensitivity to rarity information.

Keywords: Framing effect; speaker's choice of frame; reference point hypothesis; sensitivity to rarity; positive bias in frame choice

Introduction

Since Tversky and Kahneman (1981) documented the original research, many researchers have studied framing effect (for reviews, see Levin, Schneider, & Geath, 1998; Soman, 2004). One example of the framing effect is the “Asian disease problem” proposed by Tversky and Kahneman (1981):

Imagine that the US is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the programs are as follows:

If Program A is adopted, 200 people will be saved.

If Program B is adopted, there is a 1/3 probability that 600 people will be saved and a 2/3 probability that no people will be saved.

For this problem, a majority of the participants preferred Program A to Program B. Another group was presented with the same cover story, but with the two programs rephrased:

If Program C is adopted, 400 people will die.

If Program D is adopted, there is a 1/3 probability that nobody will die, and a 2/3 probability that 600 people will die.

Although Program C is only a rewording of Program A and Program D is a rewording of Program B, a majority of the participants preferred Program D to Program C. Thus framing effect refers to the effects such that the framing of a problem influences decision making.

Many studies on the framing effect have examined how listeners, or those presented with frames, behave based on the frames. Various models have been proposed to explain the framing effect. However, relatively few studies have been conducted on how speakers frame a problem. For instance, what influences speakers to describe the Asian disease problem with the “save” frame or “die” frame?

Some researchers have recently discussed how speakers frame outcomes (Keren, 2007; McKenzie & Nelson, 2003; Sher & McKenzie, 2006, 2008; Teigen & Karevold, 2005; van Buiten & Keren, 2009; Wang, 2004). For example, McKenzie and his associates have examined problems such as “Which do speakers select to describe a 4-ounce cup with 2 ounces of water, half full or half empty?”, and have proposed the *reference point hypothesis* (McKenzie & Nelson, 2003; Sher & McKenzie, 2006, 2008). This hypothesis assumes that a speaker tends to use a frame that corresponds to the label that has increased. In the above example, the reference point hypothesis predicts that a speaker uses the full frame when a cup has been previously empty, and that a speaker uses the empty frame when a cup has been full of water. Therefore, the reference point influences speaker's choice of frame.

The reference point hypothesis is intriguing in that it not only predicts how a speaker selects a frame, but also explains why decision makers are influenced by framing (Sher & McKenzie, 2006, 2008). However, we point out that the reference point hypothesis does not predict one of the interesting findings of frame choice, *positive bias*, which has been repeatedly reported in the previous studies. The positive bias refers to the tendency that in choosing from two frames which have positive and negative valenced meanings such as “gain”-“loss” or “success”-“failure,” people tend to prefer the positive valenced frame (e.g., Keren, 2007; Sher & McKenzie, 2006; van Buiten & Keren, 2009; Wang, 2004). For example, Sher and McKenzie (2006) showed that in describing results of the last 50 projects in which 20 projects have succeeded and 30 projects have failed, participants generally used a positive frame (e.g., 20 out of the last 50 projects have succeeded) rather than a negative one (e.g., 30 out of the last 50 projects have failed). In Wang (2004), participants were presented with probabilistic life-death or monetary problems by pie

charts, and asked to complete sentences that summarized the problems. It was found that participants tended to complete sentences with positive frames (e.g., save, help) rather than negative ones (e.g., killed, die).

These findings suggest that psychological mechanisms other than those explained from the reference point hypothesis exist when speakers select a frame.

Choice of frame based on rarity information

We propose a new hypothesis, *frame choice based on rarity information*. We predict that information about rarity influences choice of frame, and that the speakers frame outcomes in terms of rarity. Consider the following problems: There is a die colored both black and white. One of the 6 sides of this die is black, and the other 5 sides are white. In rolling this die, the occurrence of black side is rare. In contrast, the occurrence of white side is common. We predict that when speakers describe results of rolls of this die, they prefer using the black frame because the occurrence of black side is expected to be rare. Imagine that someone rolls this die 6 times and the black side came up once, and the white sides came up 5 times. We predict that s/he will describe the results, "With 6 rolls, black came up once", rather than "white came up 5 times." Hence, our hypothesis states that speakers focus on the rarity and prefer using the frame describing rare events rather than those describing common events.

This hypothesis is based on the findings about hypothesis testing. Previous studies on hypothesis testing have shown that people are very sensitive to information on rarity, and that they adaptively use such information in hypothesis testing (e.g., Klayman & Ha, 1987; McKenzie & Mikkelsen, 2000; Oaksford & Chater, 1994). Furthermore, the finding in McKenzie, Ferreira, Mikkelsen, & McDermott (2001) is more relevant. They examined the people's sensitivity to rarity in the context of how to phrase a conditional hypothesis. Imagine the conditional hypothesis, "If X1, then Y1," where each variable, X and Y, has two levels (X1 and X2, Y1 and Y2). In this case, this hypothesis can be denoted with another form, "If X2, then Y2." McKenzie et al. (2001) showed that when participants observed rare X1 & Y1 and common X2 & Y2, they tended to phrase the conditional hypothesis "If X1, then Y1" rather than "If X2, then Y2," suggesting that people phrase a conditional hypothesis in terms of rarity. Although this finding in McKenzie et al. (2001) was limited to how to phrase conditional hypothesis, other linguistic behaviors such as frame choice might be explained from the same perspective. That is to say, speakers choose a frame in terms of information about rarity.

In this paper, we conducted 4 studies, and examined our hypothesis regarding to the speaker's choice of frame. In Study 1, we conducted an experimental study to examine our hypothesis. In Studies 2-A, 2-B, 2-C, we discussed the positive bias in frame choice, and examined whether our hypothesis is reconciled with the positive bias.

Study 1

In study 1, we examined our hypothesis using a frame choice task. We predict that frame choice is influenced by information about rarity. In particular, participants will choose a frame describing a rare event.

Method

Participants. The participants were 614 Aoyama Gakuin University students, who received partial course credit. There were from 64 to 72 participants in each of nine conditions (see Table 1).

Task and experimental conditions. We conducted a frame choice task that was analogous to that in McKenzie and Nelson (2003) using a questionnaire. In one of the 9 conditions, participants read the following story:

There is a die that is painted black on one side and painted white on the other five sides. You have rolled this die 6 times, and the results are as follows:

Side of the die	Frequency
Black	1
White	5

Which is the most natural way to describe these results, "The die came up black 1 out of 6 times" or "The die came up white 5 out of 6 times"?¹

In this question, participants were required to choose one of two frames (i.e., "black" frame or "white" frame) to describe the outcomes.

There were 9 experimental conditions. Three dies differed in the color (i.e., black rare, white rare, black-white equal), and there were three patterns of outcomes from the roll of die. These three dies and three outcomes were varied orthogonally with respect to one another (see Table 1).

Results and discussion

Figure 1 shows proportions of black frame choice for 9 conditions. It was found that in describing the 3 outcomes (i.e., Black1-White5, Black3-White3, Black5-White1), participants in the Black-rare condition significantly preferred the black frame than those in the White-rare condition in each of the 3 outcomes ($p < .0001$, Fisher's exact test). We also found general preference for the rare side frame. 67.6% of participants in the three Black-rare conditions significantly chose the black frame, and 62.4% of those in the three White-rare conditions significantly chose the white frame ($p < .001$, binomial test).

In the Equivalent conditions, wherein explicit information about rarity was not available to participants, 52.2% of participants in the 3 Equivalent conditions chose the black frame. This result indicated that participants did not have a

¹ The order of these options was reversed for half of the participants in each condition in each experiment (Studies 1 and 2-C).

Table 1. 6 conditions in Experiment 1.

Die (number of side)	Outcome (Black, White)
Black-rare (Black1-White5)	(1,5; n=71)
	(3,3; n=68)
	(5,1; n=71)
White-rare (Black5-White1)	(1,5; n=64)
	(3,3; n=72)
	(5,1; n=66)
Equivalent (Black3-White3)	(1,5; n=71)
	(3,3; n=64)
	(5,1; n=67)

specific preference between the two frames ($p=.574$, binomial test).

Taken together, these results show that information about rarity of side of a die influenced participants' choice of frame. In particular, participants preferred the rare side frame. In addition, when the information about rarity was not available, participants were indifferent between the two frames. Hence, these results supported our hypothesis about frame choice based on information about rarity.

Study 2

In Study 2, we discuss whether the hypothesis about frame choice based on rarity information is reconciled with the positive bias in frame choice (e.g., Keren, 2007; Sher & McKenzie, 2006; van Buiten & Keren, 2009; Wang, 2004).

Why do people prefer a positive frame? Our hypothesis is that the positive bias derives from belief of rarity about what positive or negative words describe. We predict that people generally have the belief that what positive words describe are rarer than what negative words describe,

and this belief influences frame choice. In other words, speakers tend to prefer a positive frame because of its rarity. Therefore, if people explicitly know that a negative frame describes a rare event and a positive frame describes a common event, preference for the positive frame will disappear.

In order to examine this hypothesis, we conducted three studies. In study 2-A, we examined whether the positive bias observed in laboratory experiments is also observed in a naturalistic environment. In study 2-B, we examined belief of rarity about what positive and negative words describe. In study 2-C, we conducted an experimental study and tested whether the positive bias disappears when participants explicitly know that a negative frame denotes a rare event and a positive frame denotes a common event.

Study 2-A

The positive bias in frame choice reported in the previous studies suggests that people generally prefer using positive expressions rather than using negative ones. Study 2-A examined whether a positive bias is observed in a naturalistic environment. Specifically, we counted a number of articles in a Japanese newspaper that contains positive or negative words. If positive bias is to be observed, there ought to be more articles containing positive words than those containing negative words.

Method

We used 26 positive-negative Japanese pairs of antonyms for this study. Table 2 illustrates 5 examples of positive-negative pairs of antonyms. These 26 pairs were selected using the following procedure. First, one rater, who did not know the hypothesis of the current study, randomly picked out 35 pairs of antonyms that he thought had positive-negative valenced meanings from Japanese dictionary of antonyms (Kitahara & Togo, 1989). Then two other raters, neither of whom knew the hypothesis, judged whether each of the 35 pairs had positive-negative meanings. We adopted 26 pairs (i.e., 52 words) that these two raters regarded as having positive-negative meanings.

Then we counted a number of articles in a Japanese newspaper. We used *Yomidasu* as the search system. This search system includes the data-base of *Yomiuri shibun*, which is one of the most subscribed newspapers in Japan. Using this system, we counted the number of articles that had been published from January 1990 to December 2007. We conducted this search using each of the 52 words.

Results and discussion

We calculated the *positive bias index* (*P-Bias index*) for each of 26 pairs. In a certain positive-negative antonym pair, when the numbers of articles in which the positive or negative word is mentioned are N_p and N_n respectively, the P-Bias index is defined by the following equation:

$$P\text{-Bias index} = N_p / (N_p + N_n)$$

For example, when number of articles is 400 for a positive word and 100 for a negative word in a certain pair, the calculated P-Bias index is 0.8. Therefore, when the P-Bias index is more than 0.5, a positive word is used more often than a negative word in a positive-negative antonym pair. Figure 2 illustrates the P-bias index for 26 positive-negative antonym pairs. The mean value of the P-bias for the 26 pairs was 0.678 ($SD=0.240$, maximum=0.997, minimum=0.065), and this value was significantly higher than 0.5 ($t(25)=3.78$, $p<.001$). These results suggest that in positive-negative antonym pairs, people tend to use positive words more often than negative words in a naturalistic environment.

Study 2-B

In Study 2-B, we examined belief of rarity about what positive and negative words describe. We predicted that people generally have the belief that what positive words describe is rarer than what negative words describe.

Method:

Participants. The participants were 116 Aoyama Gakuin University students, who received partial course credit.

Task and materials. Participants were asked about their belief of rarity on what positive and negative words describe using a questionnaire. The question was as follows:

There are 26 pairs in this booklet. Two words in each of pairs have opposite meanings. Imagine “people,” “things,” or “outcomes” that are described by each of the words in a pair. Then which do you think is more unusual to become such people, to make such things, or to achieve such outcomes?

For this question, participants were required to choose either a positive or negative word from a pair. We used the same 26 pairs that were used in Study 2-A. If it is unusual to become, make, or achieve what a word describes, what the word describes must be rare. Hence we assume that a selected word in a pair is judged to refer to something rarer than the reference of the other word in the pair.

Results and discussion

We calculated the proportion of positive word choice for each of the 26 pairs. Figure 3 shows the proportions for the 26 pairs. In 21 out of 26 pairs, participants significantly chose positive words rather than negative words ($p<.05$, binomial test), and no negative words were chosen with more than 50%. Hence these results suggest that people have the belief that what positive words describe are generally rarer than what negative words describe are.

Table 2. Examples of positive-negative pairs of antonyms used in Studies 2-A and 2-B.

positive words	negative words
best	worst
success	failure
rich	poor
safety	danger
usefulness	uselessness

Figure 2. P-Bias index for 26 pairs in Study 2-A.

Figure 3. Proportion of positive word choice for 26 pairs in study 2-B.

Study 2-C

Studies 2-A and 2-B indicated that positive bias in frame choice is observed in a naturalistic environment, and that people generally have the belief that what positive words describe are rarer than what negative words describe. We hypothesize that positive bias in frame choice derives from this belief about rarity, and that speakers tend to select a positive frame because of its rarity. Hence, our hypothesis

predicts that when people explicitly know that a negative frame describes a rare event and a positive frame describes a common event, they will choose the negative frame rather than the positive frame. We examined this prediction conducting an experiment.

Method

Participants. The participants were 689 Aoyama Gakuin University undergraduate students, who received partial course credit. There were from 70 to 81 participants in each of nine conditions (see Table 3).

Task and experimental conditions. Task and experimental conditions were the same as those in Study 1 with the exception of the labels of dies. In place of the black-white labels, we used *winning-losing*² labels, which have positive and negative meanings. In one of the 9 conditions, participants read the following story:

There is a die that is described “winning” on one side and described “losing” on the other five sides. You have rolled this die 6 times, and results are as follows:

Side of the die	Frequency
Winning	1
Losing	5

Which is the most natural way to describe these results, “The die came up winning 1 out of 6 times” or “The die came up losing 5 out of 6 times”?

As in the Study 1, participants were required to choose one of two frames (i.e., “winning” frame or “losing” frame) to describe the outcomes.

For this task, there were 9 experimental conditions as in Study 1. Three dies differed in the description (i.e., winning rare, losing rare, winning-losing equal), and there were three patterns of outcomes from roll of die. These three dies and three outcomes were varied orthogonally with respect to one another (see Table 3).

Results and discussion

Figure 4 shows proportions of winning frame choice for 9 conditions. If the positive bias is observed in the frame choice, the winning frame will be chosen irrespective of rarity of sides in a die. However, the observed choice patterns were not consistent with this prediction. In each of the three outcomes, participants in the Winning-rare condition significantly preferred the winning frame than those in the Losing-rare condition ($p < .0001$, Fisher’s exact test). Thus, the rarity of sides in a die influenced frame choice. As a general preference of frame, 78.7 % of the participants in the three Winning-rare conditions significantly preferred the winning frame ($p < .0001$, binomial test). However, only 50.6 % of the participants in the three Losing-rare conditions preferred the winning frame, and this preference was not significant ($p = .90$, binomial test). These results show

² Original Japanese labels were “atari” and “hazure.” “atari” means winning lotteries, and “hazure” means losing lotteries.

Table 3. 6 conditions in Experiment 2.

Die (number of side)	Outcome (winning, losing)
Winning-rare (Winning1-Losing5)	(1,5; n=75) (3,3; n=70) (5,1; n=76)
Losing-rare (Winning5-Losing1)	(1,5; n=79) (3,3; n=79) (5,1; n=73)
Equivalent (Winning3-Losing3)	(1,5; n=76) (3,3; n=80) (5,1; n=81)

Figure 4. Proportion of winning frame choice in Study 2-C.

that positive bias did not prevail irrespective of information about rarity, and that participants’ frame preference shifted from the winning frame to the losing frame when they explicitly knew that the losing frame denoted a rare event.

According to the frame choice based on rarity information, participants in the Losing-rare conditions will prefer the losing frame. However, only 49.4% of participants in the three Losing-rare conditions preferred the losing frame. This result implies that choice of positive frame is a robust bias, and that even when explicit information about rarity was available, participants may have preferred the positive frame.

In the Equivalent conditions, wherein explicit information about rarity was not available to participants, positive bias was observed. In all of the three Equivalent conditions, 71.7% of participants preferred the winning frame ($p < .0001$, binomial test).

Taken together, our hypothesis about positive bias in frame choice was corroborated. Although participants generally preferred the positive frame, participants’ preference shifted to the negative frame with the explicit information about rarity. In particular, positive bias disappeared with the

explicit information that the negative frame denotes a rare event and the positive frame denotes a common event.

General discussion

Through the 4 studies, we examined our hypothesis that people choose a frame based on the information about rarity. It was found that information about rarity influenced speakers' choice of frame. In particular, participants tended to prefer a frame denoting a rare event.

The reference point hypothesis (e.g., McKenzie & Nelson, 2003; Sher & McKenzie, 2006, 2008) argues that speakers are sensitive to an increase in proportion relative to a reference point, and use a frame that corresponds to the label that has increased. In short, the reference point hypothesis assumes that speakers select a frame based on a reference point. In contrast, our hypothesis assumes that speakers select a frame based on rarity information. It should be noted that our hypothesis does not necessarily contradict the reference point hypothesis. For example, our hypothesis does not make any predictions about speakers' choice of frame based on a specific reference point. It is mute as to which frame people use to express a content of a cup when a cup has been previously empty (or full of water). On the other hand, when a reference point adopted by speakers is not clear, the reference point hypothesis does not predict specific patterns of frame choice. For instance, the reference point hypothesis does not explain why speakers show the positive bias in frame choice. Therefore, the two hypotheses can be regarded as providing explanations for different psychological mechanisms on frame choice.

We indicated in Studies 2-A and 2-B that usage of positive and negative words in a naturalistic environment is also related to belief about rarity. McKenzie et al. (2001) showed that participants tended to phrase a conditional hypothesis in terms of rarity. These findings suggest that speakers are very sensitive to information about rarity, and that linguistic behaviors are widely explained from the perspective of sensitivity to rarity.

Furthermore, previous studies have suggested that people are very sensitive to rarity information in hypothesis testing (e.g., e.g., Klayman & Ha, 1987; McKenzie & Mikkelsen, 2000; Oaksford & Chater, 1994). The findings on linguistic behaviors and hypothesis testing imply that people have the strong intuition that information about rarity is very informative, and this intuition influences various behaviors as well as linguistic behaviors and hypothesis testing. Hence, reconsideration from the perspective of sensitivity to rarity will provide insightful findings for various human behaviors.

Discovering Structure by Learning Sparse Graphs

Brenden M. Lake and Joshua B. Tenenbaum

Department of Brain and Cognitive Sciences
Massachusetts Institute of Technology
{brenden, jbt}@mit.edu

Abstract

Systems of concepts such as colors, animals, cities, and artifacts are richly structured, and people discover the structure of these domains throughout a lifetime of experience. Discovering structure can be formalized as probabilistic inference about the organization of entities, and previous work has operationalized learning as selection amongst specific candidate hypotheses such as rings, trees, chains, grids, etc. defined by graph grammars (Kemp & Tenenbaum, 2008). While this model makes discrete choices from a limited set, humans appear to entertain an unlimited range of hypotheses, many without an obvious grammatical description. In this paper, we approach structure discovery as optimization in a continuous space of all possible structures, while encouraging structures to be sparsely connected. When reasoning about animals and cities, the sparse model achieves performance equivalent to more structured approaches. We also explore a large domain of 1000 concepts with broad semantic coverage and no simple structure.

Keywords: structure discovery, semantic cognition, unsupervised learning, inductive reasoning, sparse representation

The act of learning is not just memorizing a list of facts; instead people seem to learn specific organizing structures for different classes of entities. The color circle captures the structure of pure-wavelength hues, a tree captures the biological structure of mammals, and a 2D space captures the geographical structure of cities (Fig. 1a, 1c, 5a). How does the mind discover which type of structure fits which domain?

Discovering structure can be understood computationally as probabilistic inference about the organization of entities. Past work has tackled this problem by considering rings, trees, chains, grids, etc. as mutually exclusive hypotheses called *structural forms* (Kemp & Tenenbaum, 2008). Forms are defined by grammatical constraints on the connections between entities; for example the ring form constrains each color to have two neighbors (Fig. 1a). After considering all of the candidate forms, the structural forms model selects the best fitting form and instance of that form. This can be a powerful approach; the model selects a ring for colors, a tree for mammals, and a globe-like structure for world cities. These structures can then predict human inductive reasoning about novel properties of objects (Kemp & Tenenbaum, 2009).

Despite its power, the structural forms approach is not clearly appropriate when structures stray from the predefined forms, and such exceptions are common in real world domains. While the genetic similarity of animals is captured by an evolutionary tree,¹ everyday reasoning about animals draws on factors that span divergent branches, including

¹Even this structure has exceptions; for example, Rivera and Lake (2004) provide evidence that at the deepest levels “the tree of life is actually a ring of life” where genomes fused.

Figure 1: Structure learned by the structural forms model for colors (a) and mammals (c), compared to the sparse model (b, d). Shorter edges correspond to stronger connections. Graphs in this paper, except cities, were drawn with Cytoscape.

shared habitat, role as predator versus prey, and size. While these factors cannot be perfectly explained by a single tree, other domains are interestingly structured and are even further removed from a clean form, such as artifacts and social networks. Since humans learn and reason about all of these domains, they must entertain structural hypotheses without obvious grammatical descriptions.

These considerations have motivated models without an explicit representation of structure. Rogers and McClelland (2004) demonstrated how structure can emerge in a connectionist network mapping animals (like canary) and relations (can) to output attributes that a canary can do (grow, move, fly, and sing). Without being constrained to follow a tree, their network learns a distributed representation that approximates a tree. But Kemp and Tenenbaum (2009) suggest some advantages of explicit representation: for incorporating observations that have direct structural implications (“Indiana is next to Illinois”) and for learning higher-level knowledge (a tree helps learn the word “primate”, Fig 1c). It also remains to be seen if this model can predict human inductive inferences about animal properties, as past researchers have found this difficult (Kemp, Perfors, & Tenenbaum, 2004).

Here, we present an approach to structure discovery that incorporates some of the best features of previous probabilistic and connectionist models. Rather than selecting between discrete structural hypotheses defined by grammars, the model

learns structure in an unrestricted space of all possible graphs. In order to achieve good inductive generalization, there must be a method for promoting simple graphs. While Kemp and Tenenbaum (2008) used grammars, here we use sparsity, meaning only a small number of edges are active. This structural freedom can approximate cleaner structural forms, such as the ring-like graph for colors in Fig. 1b learned from similarity data printed in Shepard (1980), and on other datasets it deviates, such as mammals (Fig. 1d). Often these deviations capture additional information; while the tree suggests squirrels and mice are equidistant from chimps, the sparse structure suggests squirrels and chimps share additional similarity, like their association with trees.

The sparse model achieves performance equivalent to more structured approaches when predicting human inductive judgements. We show this for biological properties of animals and geographical properties of cities (Kemp & Tenenbaum, 2009). Due to the model’s computational efficiency, it can learn on datasets too large for most previous approaches. We demonstrate learning a structure for 1000 concepts with broad semantic coverage, resembling classical proposals for semantic networks (Collins & Loftus, 1975).

The Sparse Model

In the structural forms and sparse models, a structure defines how objects covary with regard to their features. Objects are nodes in a weighted graph, where the strength of connectivity between two objects is related to the strength of covariation with regard to their features. The weights of the graph, denoted as the symmetric matrix W , are learned from data by optimizing an objective function that trades off the fit to the data with the sparsity of the graph.

The data D is an $n \times m$ matrix with n objects and m features. The columns of D , denoted as features $\{f^{(1)}, \dots, f^{(m)}\}$, are assumed to be independent and identically distributed draws from $p(f^{(k)}|W)$. If the graph structure fits the data well, features should vary smoothly across the graph. For example, if two objects i and j are connected by a large weight w_{ij} (like seal and dolphin), they often share similar property values (“is active” or “lives in water”). As a result of sparsity, most objects are not directly connected in the learned graph ($w_{ij} = 0$, like dolphin and chimp), meaning they are conditionally independent when all the other objects are observed.

Formally, the undirected graph W defines a Gaussian distribution $p(f^{(k)}|W)$, known as a Gaussian Markov Random Field (GMRF), where the n objects are the n -dimensions of the Gaussian. Learning GMRFs with sparse connectivity has a long history (Dempster, 1972), and recent work has formulated this as a convex optimization problem that can be solved very efficiently, in $O(n^3)$, for the globally optimal structure (e.g., Duchi, Gould, & Koller, 2008). Following Kemp and Tenenbaum (2008), we assume people learn a single set of parameters that fits the observed data well. Thus, we find the maximum *a posteriori* (MAP) estimate of the parameters $\arg\max_W \log p(W|D) = \arg\max_W \log p(W) + \sum_{i=1}^m \log p(f^{(i)}|W)$.

Generative model of features. Following the formulation in Zhu, Lafferty, and Ghahramani (2003), a particular property vector $f^{(k)}$, observed for all n objects $f^{(k)} = (f_1^{(k)}, \dots, f_n^{(k)})$, is modeled as

$$p(f^{(k)}|W) \propto \exp\left(-\frac{1}{4} \sum_{i,j} w_{ij} (f_i^{(k)} - f_j^{(k)})^2 - \frac{1}{2\sigma^2} f^{(k)T} f^{(k)}\right).$$

This defines a notion of feature smoothness, and it is equivalent to the n -dimensional Gaussian distribution

$$p(f^{(k)}|W) \sim N(0, \tilde{\Delta}^{-1}),$$

where $\tilde{\Delta} = Q - W + I/\sigma^2$ is the precision (inverse covariance) matrix, $Q = \text{diag}(q_i)$ is a diagonal matrix with entries $q_i = \sum_j w_{ij}$, and I is the identity matrix. We also restrict $w_{ij} \geq 0$, so the model represents only positive correlations. The model assumes the feature mean is zero, and raw data is scaled such that the mean value in D is zero and the maximum value in covariance $\frac{1}{m} DD^T$ is one. The parameter σ^2 can be thought of as the *a priori* feature variance (Zhu et al., 2003), and we choose the value that maximizes the objective function.

Sparsity penalty. To complete the model, we need a prior distribution on graph structures, $p(W)$. To learn a simple graph representation with a minimal number of edges, we assume each weight $p(w_{ij})$ is independently drawn from a distribution $p(w_{ij}) \sim \text{Exponential}(\beta)$, meaning

$$p(W) = \prod_{1 \leq i < j \leq n} \beta e^{-\beta w_{ij}}.$$

This prior encourages small weights, and in practice it produces sparse graph structures by forcing most weights to zero.

Structure Learning. Finding $\arg\max_W \log p(W|D)$ is equivalent to the following convex optimization problem:

$$\begin{aligned} & \underset{\tilde{\Delta} \succ 0, W, \sigma^2}{\text{maximize}} \log |\tilde{\Delta}| - \text{trace}\left(\tilde{\Delta} \frac{1}{m} DD^T\right) - \frac{\beta}{m} \|W\|_1 \\ & \text{subject to} \\ & \tilde{\Delta} = \text{diag}\left(\sum_j w_{ij}\right) - W + I/\sigma^2 \\ & w_{ii} = 0, i = 1, \dots, n \\ & w_{ij} \geq 0, i = 1, \dots, n; j = 1, \dots, n \\ & \sigma^2 > 0. \end{aligned}$$

The first term in the objective, $\log |\tilde{\Delta}| - \text{trace}(\tilde{\Delta} \frac{1}{m} DD^T)$, is proportional to the log-likelihood from Kemp and Tenenbaum (2008) after dropping unnecessary constants, and $\frac{\beta}{m} \|W\|_1$, where $\|W\|_1 = \sum_{i=1}^n \sum_{j=1}^n |w_{ij}|$, comes from the log-prior. $\tilde{\Delta} \succ 0$ denotes a symmetric positive definite matrix. The only free parameter, β , controls the tradeoff between the log-likelihood of the data and the sparsity penalty ($\|W\|_1$). A larger β encourages sparser graphs. As more features are observed (m increases), the likelihood is further emphasized in the trade-off. For all simulations, we set $\beta = 14$. The solution was found using CVX, a package for solving convex programs (Grant & Boyd, n.d.).

A binary label vector l_X is a partial specification of a full binary feature vector f that we want to infer. In the above example, $X = \{\text{cows}, \text{chimps}\}$ and $l_X = [1, 1]$ indicating both cows and chimps have biotin. Intuitively, Equation 1 states that the posterior probability $p(f_Y = 1 | l_X)$ is equal to the proportion of possible feature vectors consistent with l_X that also set $f_Y = 1$, where each feature vector is weighted by a prior probability $p(f)$ defined by the structure. We compute $p(f)$ by drawing 10^6 feature samples from the Gaussian defined by that structure, converted to binary by thresholding at zero.

Performance of the sparse model is shown in column 1 of Fig. 3. The sparse model and tree-based model (column 2) perform equivalently and predict the participant data well. Both models outperform a spatial model (column 3, see Eq. 2) which embeds the animals in a 2D space, with particular advantage on the mammals dataset. The sparse, tree, and spatial models can be viewed as “cleaning up” the raw covariance matrix $\frac{1}{85}DD^T$, approximating it as closely as possible while satisfying certain constraints (sparsity, tree grammar, or 2D embedding). When compared to the raw covariance (column 4), the sparse and tree model show better performance.

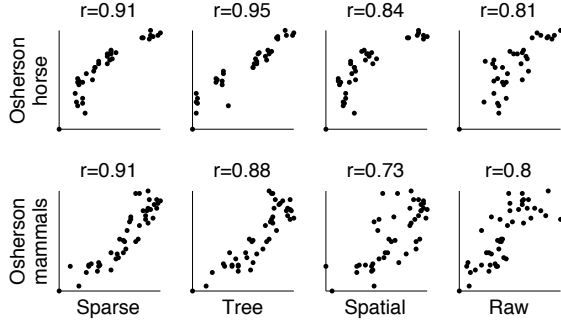

Figure 3: Model performance on taxonomic reasoning. Human ratings of argument strength (y-axis) are plotted against the model ratings (x-axis) for each argument.

Learning about new objects. In addition to learning about new properties, people constantly encounter new objects. How do the models learn about a new mammal, observed for just a few features? The tree-based model provides strong grammatical guidance, but it might be difficult to make discrete placement decisions with only a few observed features. By contrast, the sparse model has no grammatical guidance, so this provides an interesting comparison. Adding a new concept to the sparse model involves solving two convex programs. First, the model was trained on all but one mammal (49) and all properties (85). Second, the learned connections and variance were frozen, and the new concept was added while observing only a few features (10 or 20).³ Performance was evaluated on predictive ability for the missing properties (75 or 65). The models were tested

³Since many data entries are missing, simply skipping missing entries results in a covariance matrix that is not positive semi-definite. Instead we use a maximum likelihood estimate of the covariance matrix found by Expectation-Maximization.

by adding four different mammals, where each addition was replicated 30 times with different random sets of observed properties. For each missing property, its expected value was calculated by performing inference in the Gaussian defined by the structure. Compared to the raw covariance matrix, the sparse model provided significantly better predictions of the missing features for each mammal tested (all 8 comparisons $t(29), p < .01$, Fig. 4). Since running all combinations is slow in the tree model, each model was also compared on an “informative feature set” (*’s in Fig. 4), defined as the feature set the raw covariance performed best on. For learning a new object with these features, the sparse model performs at least as well as the tree model.

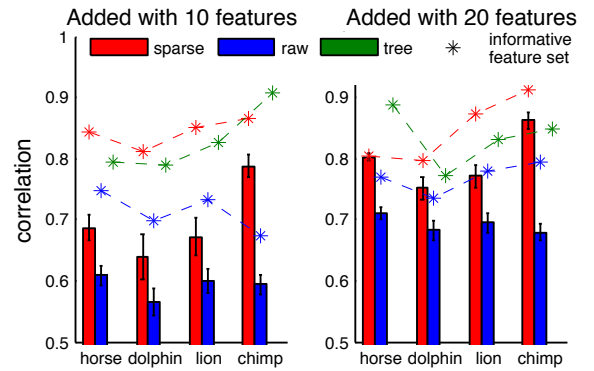

Figure 4: Each model adds a new object (seeing only 10 or 20 features), and the missing features are predicted. Bars are mean performance over 30 random feature picks, and stars (*) show performance from a single informative feature set.

Spatial reasoning

Geographical knowledge seems to require different structural representations than animals. Following the tradition of using Euclidean spaces to build semantic representations such as multidimensional scaling (Shepard, 1980), Kemp and Tenenbaum (2009) proposed learning a 2D space to represent the relationship between cities. This 2D space defines a Gaussian distribution with zero mean and covariance matrix K

$$K_{ij} = \frac{1}{2\pi} \exp\left(-\frac{1}{\sigma} \|y_i - y_j\|_2\right), \quad (2)$$

where y_i is the location of the city i in 2D space. Kemp and Tenenbaum (2009) found a double dissociation between the tree model and the spatial model, which only perform well on taxonomic and spatial reasoning respectively. Can the sparse model learn structures applicable to both domains?

Learning structure. Structures were learned from participant drawings of nine cities on a piece of paper, and similarity was calculated from the pairwise distances (Kemp & Tenenbaum, 2009). This similarity matrix was treated as the raw covariance input to all the models. The learned spatial representation is compared to the learned sparse graph in Fig. 5. All the models require an assumed number of features, set to $m = 85$, preserving the β/m sparsity ratio from before.

Figure 5: The (a) spatial and (b) sparse models learned from the city dataset. Graphs nodes are overlaid on the 2D space.

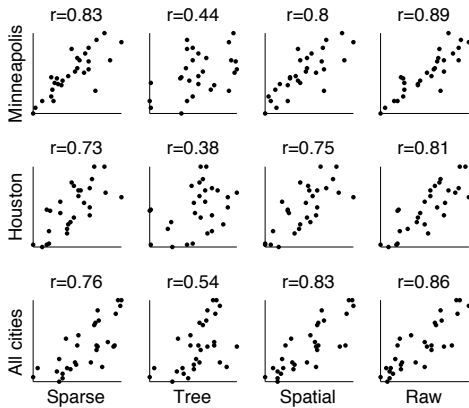

Figure 6: Model performance on spatial reasoning. Human ratings of argument strength (y-axis) are plotted against the model rating (x-axis) for each argument.

Property induction. As in the taxonomic reasoning section, the models were compared to human data regarding property generalization. In an experiment by Kemp and Tenenbaum (2009), participants were presented a scenario where Native American artifacts can be found under most large cities, and some kinds of artifacts are found under just one city while other are under a handful of cities. An example inductive argument is: “Artifacts of type X are found under Seattle and Boston. Therefore, artifacts of type X are found under Minneapolis.” There were 28 two-premise arguments with Minneapolis as the conclusion, 28 with Houston as the conclusion, and 30 three-premise arguments with “all large American cities” as the conclusion. These arguments were ranked for strength, and mean rank was correlated with the model inductive predictions. The sparse model (column 1 of Fig. 6) provides good predictions, as does the 2D spatial model and the raw covariance matrix, which performs best (columns 3 and 4). The tree performs poorly (column 2). While there is a double dissociation between the tree and spatial model for taxonomic and spatial reasoning, the sparse model can predict human reasoning in both contexts.

Discovering structure for 1000 concepts

Learning sparse graphs can also be applied to domains with no simple structure. While animals may be fit by trees and

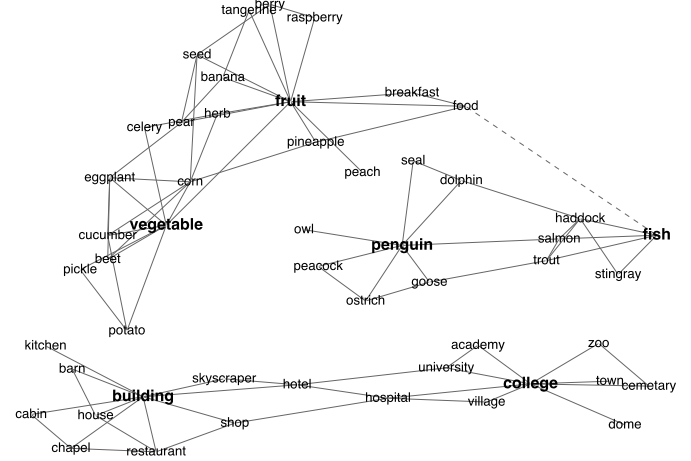

Figure 7: Structure learned for 1000 concepts. This small subset shows the significant neighbors of the bold nodes ($w > .2$ except dotted edge $w = .09$). Shorter edges are stronger.

cities by 2D spaces, what type of structure organizes concepts as diverse as fruit, vegetable, fish, penguin, building, and college? Human semantic reasoning operates in a huge semantic space, and here we learned a sparse model on an expansive domain of 1000 entities and 218 properties. A dataset of this size is prohibitive for the structural forms model as well as the connectionist model of Rogers and McClelland (2004).

Dataset and Algorithm. The dataset was collected by Intel Labs (Palatucci, Pomerleau, Hinton, & Mitchell, 2009). Semantic features were questions such as “Is it manmade?” and “Can you hold it?” Answers were on a 5 point scale from definitely no to definitely yes, conducted on Amazon Mechanical Turk. To learn the optimal structure, we use a faster algorithm from Duchi et al. (2008) instead of a generic convex solver. For now, this requires two small changes to the model: w_{ij} can be positive or negative and a separate variance term σ_i^2 is fit to each object instead of one for all objects.

Results. The structure learned from the entire data is very sparse with approximately 2.4% of edges active ($|w| > .01$). Fig. 7 shows snapshots of the network, consisting of nodes that are strong direct neighbors of either fruit, vegetable, fish, penguin, building, and college ($w > .2$). Fruit and vegetable are linked to subordinate examples, and connect to fish via a path through food. Interestingly, the network connects penguin to both sea animals (like fish and seal) and birds, highlighting its role as an aquatic bird. Building and college are connected via several paths, including building–hotel–university–college and building–hotel–hospital–college.

To evaluate the sparse model’s predictive capacity for novel questions, we performed 4-fold cross validation, training on 3/4 of the properties and predicting the rest. The average test log-likelihood is $-3.50 \cdot 10^4$ for the sparse model and $-3.84 \cdot 10^6$ for the raw covariance. The raw covariance performs worse than in the past experiments since there are many more objects than features, and performance can be improved

by other regularization techniques such as Tikhonov (computed as $\frac{1}{m}DD^T + \nu I$ for identity matrix I (Duchi et al., 2008)), which achieves a test log-likelihood of $-3.63 \cdot 10^4$. Tikhonov regularization does not significantly improve the raw covariance on the previous property induction tasks. Even though we fine-tuned the Tikhonov parameter $\nu = .17$ to the *test* sets, the sparse model still performs better with its parameter $\beta = 14$ fixed across all experiments in this paper.

General Discussion

Here we applied the sparse model to taxonomic and spatial reasoning. Past work has found a double dissociation between these inductive contexts (Kemp & Tenenbaum, 2009), where a tree model and a spatial model provide good fits to only one context. However the sparse model is able to predict human inductive judgments in both contexts, by emphasizing sparsity in structural representation. In addition to these inductive tasks, we applied the sparse model to a dataset of 1000 concepts with broad semantic coverage and no simple structure. The sparse model learned reasonable structure and outperforms simple regularization on novel features.

The sparse model also provides a probabilistic foundation for classic models of semantic memory such as semantic networks (Collins & Loftus, 1975). Semantic networks stipulate that concept nodes are connected to related concepts by varying degrees of strength. These networks resemble the large structure learned for 1000 concepts (Fig. 7), suggesting the sparse model can be used to learn semantic networks from data. The sparse model is also related to Pathfinder networks (Schvaneveldt, Durso, & Dearholt, 1989) that find the minimal graph that maintains all pairwise sum-over-path distances between objects. While highlighting important structure, it retains the same similarity matrix from input to output, lacking the regularization that is important in our simulations.

While the sparse model is an important first step, it leaves out desirable features of previous connectionist and probabilistic models. The Rogers and McClelland (2004) model accounts for a rich array of phenomena from development and semantic dementia, yet to be explored with the sparse approach. Compared to structural forms, the sparse model does not learn latent nodes (compare Fig. 1c,d), which increase sparsity and could be important for learning higher-level concepts such as “mammal” or “primate” (Kemp & Tenenbaum, 2009). Future work will use the sparse approach to explore learning deeper conceptual structure with latent variables.

Acknowledgements

We thank Intel Labs for providing their 1000 objects dataset, Charles Kemp for providing code and datasets for learning structural forms, and Venkat Chandrasekaran, Ruslan Salakhutdinov, and Frank Jäkel for helpful discussions.

Abstract

When people navigate through the World Wide Web they choose their path of navigation based on their prior knowledge. This may be problematic when users have a deficient knowledge leading them to suboptimal information. In this study we examined how the externalized knowledge of social tags can be used to change navigation behavior and to trigger learning processes. In an online experiment with 531 participants we investigated the effect of the individual strength of association on navigation processes, and how the collective strength of association, visualized in tag clouds, may affect individual navigation and the strength of association. Results showed the effect of individual strength of association on navigation behavior, selection time and recognition. Furthermore, we found that the collective strength of association affects navigation behavior and triggered incidental learning processes, leading to a change of individual strength of association.

Keywords: social tagging; tag clouds; social software; information foraging; web search; incidental learning

Introduction

People frequently use the World Wide Web for information and product search. In some topic domains, Web users may only possess deficient prior knowledge and an incomplete view of relevant aspects. A user's knowledge may, however, be critical for the search process and the information which is retrieved from the Web. The Web offers enormous quantities of heterogeneous information and products, and each user will have to select between different links and keywords for finding relevant resources. When users follow navigation links based on their deficient prior knowledge these may lead to information which will confirm or even reinforce the deficient knowledge of that user. For example, users might associate the treatment of a disorder with some specific medication. Instead of considering other treatments or medications a user may quickly select a navigation path leading to information which reinforces potentially deficient knowledge saying, for instance, that a specific medication is the only reasonable treatment. This might happen when navigating to a website from a pharmaceutical company.

So, on the one hand, the mass and the diversity of resources available on the Web is combined with the risk that people might select suboptimal information or products. On the other hand, new tools may provide the opportunity to use the mass of available information on the Web to

improve individual navigation and to adjust and change the users' previously deficient prior knowledge. In this paper we address the research question how social tags, as emerging collective information, can affect the individual process of navigation and how social tags trigger learning processes during navigation. In particular, we focus on situations in which the externalized knowledge of social tags contradicts the prior knowledge of users.

The next chapter will provide a theoretical overview on Web navigation and its interrelation with spreading activation, followed by an overview on social tagging and how it may interact with cognitive processes. As a next step we will present an experimental study on the effects of social tags and the strength of association on navigation and knowledge acquisition.

Theoretical Background

Information Foraging Theory

A pivotal cognitive theory of Web navigation is the Information Foraging Theory (Pirulli, 2007; Pirulli & Card, 1999). It explains selection processes of links and navigation paths on the Web, the so-called "information foraging". Taking for granted that many search tasks on the Web require browsing activities in order to find a desired resource (Marchionini, 2006), users will have to select between different links and navigation paths. They will have to decide which link may lead to a desired – and not directly accessible – distal resource, say, a piece of information on some Web site. When navigating the Web users have to make judgments based on proximal cues (e.g., links) and assess which of these cues have the highest likelihood of leading to a desired distal resource. One of the core concepts of the Information Foraging Theory is the so-called "information scent" of links. The information scent describes the subjective usefulness of links for navigation. Links with a subjectively high probability of leading to a desired distal resource have a high information scent and are very likely to be selected in the search process. How will users estimate the information scent of links?

Spreading Activation Understanding how people evaluate the information scent of a link is closely related to models of semantic memory and spreading activation (e.g., Anderson,

1983; Collins & Loftus, 1975). Cognitive models of semantic memory assume that memory is based on a collection of cognitive structures, so-called “chunks”. These are organized as nodes in a large network in memory. Each of the chunks is connected to other chunks with a different strength of association. The strength of association derives from the respective individual’s previous learning experiences. When two chunks frequently co-occur in a meaningful context, the association between these chunks becomes stronger. For example, when Valium is often mentioned in the context of anxiety disorders, a high strength of association will be established. The strength of association is important in the process of retrieving chunks from memory. To retrieve a chunk from memory, it must be activated by other chunks. The activation spreads from one chunk to another, and the stronger the association, the higher is the likelihood of exceeding a certain level of activation for a chunk. For instance, the activation of Valium in the context of anxiety disorders is facilitated by a high strength of association.

In a search process a desired distal goal activates connected chunks in semantic memory. Based on the strength of association of connected chunks and the resulting strength of activation, users estimate the information scent of links: when a chunk receives a high spreading activation through a search goal, the corresponding link receives a high information scent, too. For example, when the chunk Valium is highly activated by a search goal, e.g., treatment for anxiety disorder, then the corresponding Web link Valium would also have a high information scent for a user.

Research on Navigation Processes Several studies have demonstrated the effect of the information scent on Web navigation (e.g., Blackmon, Polson, Kitajima & Lewis, 2002; Fu & Pirolli, 2007; Pirolli, Fu, Reeder & Card, 2002). These studies have mainly used cognitive modeling of Web navigation and validated them against actual user data.

In these studies, differences in prior knowledge were not considered for the modeling process. In some studies, for instance, the simulation of strengths of association and the resulting information scents were based on the same large text corpora and the co-occurrence of words within these texts (Fu & Pirolli, 2007; Pirolli et al., 2002). So the focus of these studies did not lie in investigating the effects of differing prior knowledge, but rather in modelling the general search process for specific search tasks. Another aspect which has not been investigated in more detail within the (non-social) context of these studies is learning processes during navigation, i.e. incidental learning as a by-product of navigation. When navigating the Web, users process information in order to assess the information scent of links. But the choice of the navigation path is not only a means to an end. It may also be of importance what happens “along the path”. Except for one study showing incidental category learning during navigation (Pirolli, 2004) it remains unclear how navigation itself could change the

strength of association of chunks through incidental learning processes.

The question of learning is particularly interesting in a social Web context, in which large numbers of other users contribute information and, in particular, in which this information can be used for navigation processes. New Web technologies, like social software tools, provide this opportunity. Social tagging systems make it possible to learn from the externalized knowledge of a community. In the next section we will give an overview on social tagging and relevant studies that have been conducted in this field of research.

Social Tags

Social tagging is the activity of annotating digital resources, e.g. bookmarks, pictures or products, with keywords, the so-called “tags”. Tags represent metadata on resources. For most applications each user can choose individual tags for stored resources. Tags reflect individual associations with resources and are based on the specific meaning or relevance to that user. At the individual level, tags will help users to structure, organize and find their own stored Web resources. In a social context, tags offer the opportunity to use other users’ navigation links for search processes. Moreover, social tagging systems can aggregate the tags of individual users. In this way, resources are described by the community in a “folksonomy”, developed in a bottom-up process of individual tagging. The aggregated tags represent an emerging collective knowledge of Web users. These aggregated tags can also be used as links for individual search processes. In a social tagging system, the community creates a network of connections between resources and tags. The connection between a resource and a tag becomes stronger when tags for that resource are used more frequently by many users. The connection between two tags becomes stronger when both tags are used together for one resource: the more often two tags co-occur with the same resources, the stronger they are related to each other. When aggregating all tags from a community, a representation of the connections between related tags and their strength of association will emerge. Typically, tag clouds visualize these associations and their specific strength: The font size of tags illustrates the strength of association of tags to a related tag or a resource (see Figure 1).

Figure 1: A tag cloud representing tags related to “red wine” (from vinorati.com). The font size visualizes the strength of association between “red wine” and the tag.

Social tagging systems may be regarded as shared external knowledge structures of communities (Fu, 2008). They can externalize the connections of tags and their specific strength of association in tag clouds. Because these associations are based on the collective tagging behavior of a community, they can also be considered to be the externalized associations of a particular community. The structure of social tagging systems even constitutes an analogy to spreading activation processes in semantic memory models, in which tags represent the nodes of a large network. When a tag is selected – or activated –, the activation spreads from this tag to others, and the related tags and their strengths of association can be visualized in tag clouds.

So far, research on social tagging has mainly focused on the description of regularities of tagging systems (e.g., Golder & Huberman, 2006) or the use of tagging systems (e.g., Millen, Yang, Whittaker & Feinberg, 2007). But, as stated by Fu (2008), surprisingly little is known about how these new technologies, like social tagging systems, may directly interact with individuals at the knowledge and cognitive level. Some studies have investigated the influence of tag clouds on visual attention, recognition and tag selection (Bateman, Gutwin & Nacenta, 2008; Rivadeneira, Gruen, Muller & Millen, 2007). But these studies focused primarily on the visual features of tag clouds and did not address aspects of collective knowledge, as it is externalized in social tagging systems and tag clouds.

A study investigating the interplay between the collective knowledge of a tagging system and the individual cognitive level was presented by Fu in 2008. He presented a rational model of social tagging and provided evidence for the interaction of social and cognitive systems. That study showed the impact of externalized knowledge structures on individual learning processes, especially the formation of mental categories, but did not focus on the effects of the representation of knowledge, externalized in the form of tag clouds, on individual navigation behavior and the strengths of associations. A further study, which also investigated the knowledge exchange within tagging systems dealt with the question of how social tags affect tag choice (Kang, Kannampallil, He & Fu, 2009). This study also showed that the externalized knowledge of social tags will influence individual behavior: users adapted their tag choice to the collective structure of the social tagging system.

Research Questions and Hypotheses

Models of Information Foraging (Pirolli, 2007) assume that processes of spreading activation are crucial for the navigation behavior of users. So the strength of association between a search goal and available links plays a critical role in the selection of navigation paths. We assume that users with deficient prior knowledge are likely to choose navigation links that lead to suboptimal resources. So we manipulated the users' prior knowledge and investigated the impact of individual strength of association on navigation processes.

The main goal of this study is to investigate how the collective knowledge of a community affects individual learning and navigation processes. Can social tags be used to change the navigation behavior of users? Will users learn from the collective knowledge during navigation, and will they improve the deficits of their prior knowledge accordingly? Apart from the variation of the users' prior knowledge we also manipulated the strength of association of tags. In our experiment we created a situation in which the individual strength of association contradicts the collective strength of association. We examined the effect of collective strength of association on the change of individual navigation and strength of association.

We expected (1) a main effect for both the individual strength of association and the collective strength of association on navigation behavior. Secondly, we expected (2) an incidental learning process and a change of individual strength of association during navigation through the collective strength of association. Thirdly, we expected that (3) in a situation of highly contradicting individual and collective strengths of association, users will perceive a conflict and process all tags more thoroughly and spend more time on their selection of tags.

Experiment

Method

Participants 531 participants (179 female, 352 male; mean age 28.94 years, $SD = 9.36$) were recruited on Amazon Mechanical Turk (mturk.com), an Internet marketplace for engaging users in online micro-tasks. The participants were paid US-\$1.20 for the experiment. The participants came from 52 different countries. Most of the subjects lived in the United States (41.1%) and India (36.7%).

Materials and Procedure In order to ensure that we could actually manipulate the prior knowledge of subjects, we selected a topic which was very likely to be mainly unfamiliar to the subjects: wine from the Asian country of Georgia, in particular from various wine regions of Georgia. The experiment was set up online and all participants could perform the task from a computer with Internet access. On average, the experiment took about 8 minutes for each user. We instructed the subjects that our aim was to receive feedback on the design of Web sites dedicated to wine. The actual goal of the task in the experimental context was not transparent to the subjects. We did not inform them before or during the task that we were actually measuring navigation and learning processes.

The task consisted of two parts. In the first part subjects had to provide feedback on design features of a wine list from "a pilot user who is a wine lover of Georgian wines". The list was presented to the subjects for 30 seconds, followed by five questions on the design of this list in order to direct attention to it. The first independent variable - the individual strength of association - was manipulated by this wine list (see Figure 2).

The second part was a navigation task. In this part, subjects were asked to use tag clouds as navigation links. The subjects were told that the tags originate “from different sources of the Internet, like online wine communities and wine retailers”. After a basic introduction to social tags, subjects were presented tag clouds and were asked to click on one tag of each tag cloud that was most appropriate to direct them to a typical Georgian wine. Overall, we presented four tag clouds. The first and the third tag cloud were used as case examples. Only the second and fourth tag cloud were relevant to the experiment. In each condition these two tag clouds were identical. These tag clouds represented related tags (wine regions) to Georgia (see Figure 3). After having clicked on a tag, it was color-marked and two seconds later the next tag cloud appeared. The next tag cloud was independent of the previous selection. Only tag clouds were presented, no corresponding resources were displayed. After the navigation task we presented tests measuring the dependent variables “decision” and recognition.

Independent Variables and Design A 5 x 4 between-subjects design was used. Subjects were randomly assigned to one of the 20 conditions. As a first independent variable we experimentally manipulated the individual strength of association by varying the content of the wine list, which was presented to the subjects in the first part of the task. We manipulated how strongly users associate the wine region “Kakheti” with Georgian wine. Users were presented a wine list with five Georgian wines. In the different conditions the number of wines coming from the region “Kakheti” was varied. The independent variable had five continuous levels: wines from the region “Kakheti” were either (1) not part of the list (see Figure 2a); or (2) one time; (3) two times; (4) three times; or (5) four times in the list (see Figure 2b).

Teliani 2005, Manavi Region: Georgia > Manavi Varietal: Saperavi, Cabernet Sauvignon Other users' tags: elegant, cherry, oak, fruity, raspberry	Teliani 2005, Kakheti Region: Georgia > Kakheti Varietal: Saperavi, Cabernet Sauvignon Other users' tags: elegant, cherry, oak, fruity, raspberry
Ninidze 2002, Gori Region: Georgia > Gori Varietal: Mtshvane, Rkatsiteli Other users' tags: balanced, peaches, fruity	Ninidze 2002, Kakheti Region: Georgia > Kakheti Varietal: Mtshvane, Rkatsiteli Other users' tags: balanced, peaches, fruity
Tbilvino 2005, Signani Region: Georgia > Signani Varietal: Mujuretsuli Other users' tags: blackberry, vanilla, oak, tannin	Tbilvino 2005, Kakheti Region: Georgia > Kakheti Varietal: Mujuretsuli Other users' tags: blackberry, vanilla, oak, tannin
Tseriteli 2006, Vani Region: Georgia > Vani Varietal: Rkatsiteli Other users' tags: floral, elegant, fruity	Tseriteli 2006, Vani Region: Georgia > Vani Varietal: Rkatsiteli Other users' tags: floral, elegant, fruity
Abuladze 1999, Terdzholia Region: Georgia > Terdzholia Varietal: Mujuretsuli, Aladasturi Other users' tags: cherry, rose, raspberry, oak	Abuladze 1999, Kakheti Region: Georgia > Kakheti Varietal: Mujuretsuli, Aladasturi Other users' tags: cherry, rose, raspberry, oak

Figure 2: Wine lists manipulating the individual strength of association for the “Kakheti” region, representing the lowest and highest levels: a) “Kakheti” is not part of the list b) 4 of the 5 wines come from “Kakheti”.

As a second independent variable we experimentally manipulated the collective strength of association by varying the tag size in the tag clouds. Except for the tag “Kakheti” none of the regions presented in the wine list reappeared in the tag clouds. We manipulated how strongly the fictitious tagging community associates the wine region “Imereti” with Georgian wine by varying the tag size of “Imereti”. The other tags did not vary in size. The independent variable had four continuous levels: (1) the tag “Imereti” had the same size as the tag “Kakheti” with both tags representing the biggest tags in the tag cloud (see Figure 3a); (2) the tag “Imereti” was 33% bigger than in the first condition; (3) the tag “Imereti” was 67% bigger than in the first condition; (4) the tag “Imereti” was 100% bigger than in the first condition (see Figure 3b).

Figure 3: Tag clouds manipulating the collective strength of association for “Imereti”, representing the lowest and highest levels: a) “Imereti” has the same size as “Kakheti” b) “Imereti” is twice as big as “Kakheti”.

Dependent Measures As dependent variables we measured the navigation behavior of users for the two relevant tag clouds (wine regions) by analyzing the logfiles. It was assessed how often users clicked the tag “Kakheti” (for which the individual strength of association was manipulated in the wine list) or the tag “Imereti” (for which the collective strength of association was manipulated in the tag cloud). Accordingly, the number of clicks for navigating the two tag clouds could range between 0 and 2 for either of the dependent variables “Navigation Kakheti” and “Navigation Imereti”. We also measured how much time users spent for the selection process. We added the time which was used for navigating each of the two tag clouds.

For the assessment of the dependent variable “decision”, users were asked which Georgian wine region they would select if they had to buy a typical wine from Georgia. They had to choose between the alternatives “Kakheti” and “Imereti”. Referring to the fluency heuristic (e.g., Schooler & Hertwig, 2005) it is assumed that if one of the two alternatives has a higher strength of association and is more fluently processed, then users will infer that this alternative has a higher value regarding to the criterion – in this case,

the decision which wine region is more typical of Georgia. We assume that the decision in favor of one of the alternatives will be based on the higher individual strength of association for that alternative. This dependent variable was coded (-1) for the selection of “Kakheti” and (1) for the selection of “Imereti”.

Another dependent variable was the recognition of tags. This measure was assessed in a multiple choice test consisting both of tags that were presented in the tag clouds (seven items) and tags which were not contained in the tag clouds (nine items). The task of the subjects was to correctly identify those tags which were presented in the tag clouds. The score was calculated as the sum of correctly identified items minus incorrectly marked items. Tags which were part of the manipulation (“Kakheti” and “Imereti”) were not considered for the recognition score.

Results

To test the impact of individual and collective strength of association on the dependent variables, multiple regression analyses were conducted with the predictors individual strength of association, collective strength of association and the individual x collective strength of association interaction, and the dependent variables as criteria. The predictor variables were centered, and the interaction term was computed by a multiplication of both variables.

It was predicted that a higher individual strength of association would lead to a higher probability of selecting a tag corresponding to this association, whereas the contradicting collective strength of association is assumed to attenuate this tendency. To test these predictions, a regression with the criterion “Navigation Kakheti” was computed. The predictions were confirmed: the individual strength of association for “Kakheti” significantly increased the selection rate of the tag “Kakheti” ($\beta = .34, p < .001$), whereas the contradicting collective strength of association significantly decreased it ($\beta = -.12, p < .01$), adjusted $R^2 = .12, F(2, 528) = 38.50, p < .001$. No significant interaction was found ($\beta = .05, p = .21$).

We also predicted that a higher collective strength of association would lead to a higher probability of selecting the corresponding tag, whereas a contradicting individual strength of association would lead to an opposite effect. To test these predictions, a regression with the criterion “Navigation Imereti” was computed. The predictions were confirmed: the collective strength of association for “Imereti” significantly increased the selection rate of the tag “Imereti” ($\beta = .24, p < .001$), whereas the contradicting individual strength of association significantly decreased it ($\beta = -.08, p < .05$), adjusted $R^2 = .06, F(2, 528) = 18.29, p < .001$. No significant interaction was found ($\beta = -.03, p = .56$).

It was assumed that users would show incidental learning when navigating through tag clouds that represent collective strengths of associations. We predicted that users would change their individual strength of association and adapt to the collective strength of association. The strength of

association for either “Kakheti” or “Imereti” was assessed in the dependent variable “decision”. On the one hand, we assumed that a higher individual strength of association for “Kakheti” would also lead to a higher probability of choosing “Kakheti”. On the other hand, we predicted that the collective strength of association for “Imereti” would increase the individual strength of association for “Imereti”, leading to a higher probability of deciding in favor of this contradicting alternative. To test these predictions, a regression with the criterion “decision” was computed. Both predictions were confirmed: The strength of association for “Kakheti” significantly increased the tendency to choose this alternative ($\beta = -.30, p < .001$). The collective strength of association for “Imereti” significantly increased the tendency to decide in favor of the contradicting alternative “Imereti” ($\beta = .24, p < .001$), adjusted $R^2 = .14, F(2, 528) = 43.38, p < .001$. No significant interaction was found ($\beta = .01, p = .82$).

Furthermore, we predicted an interaction between individual and collective strength of association for the dependent variables recognition and selection time: we assumed that for users with a high individual strength of association (e.g., for “Kakheti”) a high contradicting collective strength of association (e.g., for “Imereti”) would lead to a cognitive conflict, and that this conflict leads to a higher level of processing regarding all presented tags and to a longer duration of tag selection. To test the first of these predictions, a regression with the criterion recognition was computed. The prediction could not be confirmed: no significant interaction was found ($\beta = .00, p = .95$). What we did find, however, was that increasing individual strength of association significantly decreased performance in the recognition test ($\beta = -.12, p < .01$). The analyses did not reveal a significant effect for the collective strength of association ($\beta = .03, p = .52$), adjusted $R^2 = .01, F(2, 528) = 3.96, p < .05$. To test the second of these predictions, a regression with the criterion selection time was computed. This prediction could not be confirmed: no significant interaction was found ($\beta = -.01, p = .83$). But the individual strength of association significantly decreased the time used for the selection process: a high individual strength of association led to a faster tag selection ($\beta = -.16, p < .001$). The analyses did not reveal a significant effect for the collective strength of association ($\beta = .00, p = .96$), adjusted $R^2 = .02, F(2, 519) = 6.51, p < .01$.

Discussion

The aim of this study was to investigate the potential of emerging collective structures of the Web, such as social tags, on individual processes of navigation and learning. We addressed the research question how the collective externalized knowledge of a social tagging community could interact with individual knowledge, and if the navigation process per se – without the explicit intention to learn something – is sufficient for changing individual knowledge representations. In an experiment we investigated how the externalized representation of the

associations of a community in a tag cloud affects the individual strength of association. Through the experimental manipulation we were able to create continuous levels for each of the two independent variables, the individual and collective strengths of associations.

The results showed that both the individual and the collective strength of association affect navigation. In the context of a Web search, these results suggest that, on the one hand, a user's prior knowledge is an important factor when choosing a navigation path. On the other hand, our results suggest that the collective knowledge of other Web users may help to open up better navigation paths, especially if a user's prior knowledge is deficient or biased. The results also show that users learn from the collective strengths of associations and, in the case of contradicting knowledge, that they will change their own individual strength of association by adapting it to the collective one. In this way, users will learn incidentally how a large community evaluates the relevance of certain information or concepts, and they can change their own strengths of associations accordingly.

Furthermore, the results revealed that a high individual strength of association leads to a faster and – as far as the perception of other available links is concerned – to a less thorough selection process. When a user has a strong, but incorrect strength of association, this could lead to a fast selection of a suboptimal navigation path. Especially in this unfavorable case social tags may be helpful: if the collective knowledge of a community was able to provoke a strong cognitive conflict, this could lead to a highly improved navigation process by that user. In this study, however, we could not find any interactions that suggest effects of cognitive conflicts caused by a highly contradicting individual and collective strength of association. A possible explanation could lie in the limitations of the scenario of this experiment, e.g. the rather static and simple navigation process, the small relevance of the task to the users, or the highly unfamiliar topic domain (which had only been selected for the purpose of manipulating the prior knowledge of users). So future research could focus on larger and more dynamic scenarios, combined with a variety of topic domains with a higher degree of relevance to the respective users. In addition, it would be interesting to create a setting which combines both tags as metadata and actual information resources or products.

Abstract

We explore the role of top-down information in language processing by investigating parallel language activation in bimodal bilinguals, who are fluent users of a spoken and a signed language. In an eye-tracking study, bimodal bilinguals showed activation of their signed language while receiving input in English only. Since spoken and signed languages do not share structure, the results suggest that linguistic information can be readily transmitted across modalities, and that parallel language activation can be driven by top-down processes.

Keywords: bilingualism; ASL; language co-activation; top-down processing; eye-tracking; visual world paradigm

Introduction

The architecture of the language system is determined by the way that information flows among levels of processing. Language processing may involve both bottom-up/feed-forward and top-down/feed-back mechanisms (Rapp & Goldrick, 2000; Navarette & Costa, 2009). However, exclusively feed-forward systems may also be capable of explaining language processing *without* the aid of feed-back mechanisms (Hagoort & Levelt, 2009; Levelt, Roelofs, & Meyers, 1999; McQueen, Jesse, & Norris, 2009; Norris, 1994). Proponents of language systems that recruit top-down mechanisms face the difficulty of separating the impact of top-down information from that of bottom-up information. When both forms of information are present, it is difficult to disentangle the unique contributions each may make to language processing. To understand the role of top-down mechanisms during language processing, the influence of top-down pathways must be measured in isolation. One possible way of limiting the impact of bottom-up information is by investigating language processing in bimodal bilinguals.

Unlike unimodal bilinguals, who use two spoken languages, bimodal bilinguals are fluent in a spoken and a signed language. Research on unimodal bilinguals has revealed non-selective language effects, wherein unimodal bilinguals activate both of their languages in parallel (Blumenfeld & Marian, 2007; Marian & Spivey, 2003; Weber & Cutler, 2004). For example, when a Russian-English bilingual hears the English word “marker,” she will also make eye movements to items that are phonologically similar in the non-target language (e.g., Russian) such as “marka” (stamp), suggesting that her Russian is

simultaneously activated. This effect appears to be bottom-up in nature – as auditory input enters the language system, it non-selectively activates lexical items in both languages based on structural overlap. Critically, a dual-language bottom-up pathway cannot exist in bimodal bilinguals, as their languages do not utilize the same structural input. The cross-modal nature of bimodal bilingualism therefore allows for the direct investigation of top-down mechanisms in isolation.

If bimodal bilinguals co-activate their two languages in the absence of form overlap, it would suggest that language co-activation can be driven by top-down information, and would require a system capable of activating the non-target language via top-down or lateral connections. Models that consider exclusively bottom-up information for lexical activation or selection (such as the Shortlist Model, Norris, 1994) are unlikely to be able to explain this result, as they limit activation to items that exist in the same modality as the target. Therefore, a bimodal bilingual, when faced with single-modality input (e.g., spoken English), should not activate the signed language.

However, recent research indicates that bimodal bilinguals do co-activate their languages. For example, hearing ASL-English bilinguals produce speech and signs simultaneously (Emmorey, Borinstein, Thompson, & Gollan, 2008), deaf ASL-English bilinguals show interference from sign-language while processing written-English (Villwock, Wilkinson, Bailey, Kroll, Morford, & Piñar, 2009), and late-learning Dutch-Sign Language of the Netherlands bilinguals show interference from English while processing SLN signs (Van Hell, Ormel, van der Loop, & Hermans, 2009). In addition to clarifying the role of top-down mechanisms in language processing, language co-activation in bimodal bilinguals would suggest that linguistic information is readily transmitted across modalities, such that two unrelated languages can be activated simultaneously, even when phonological information from one of the two languages is absent.

The current study used an adapted visual world paradigm to examine parallel language processing in normal-hearing, ASL-English bilinguals. Investigating whether languages that do not share modality are co-activated in bimodal bilinguals can provide insight into the influence of top-down mechanisms on language processing and the architecture of the language system in general, as well as reveal the extent to which linguistic information is modality independent.

Method

Participants

Twenty-six participants were tested (thirteen ASL-English bilinguals, $M_{age}=33.2$, $SD=11.8$ and thirteen English monolinguals, $M_{age}=23.9$, $SD=9.8$). An additional five participants were not included in the analysis – three due to failure to display sufficient proficiency in ASL, and two due to technical error with the eye-tracker. All participants completed the *Peabody Picture Vocabulary Test* (PPVT-III; Dunn & Dunn, 1997) to assess their English vocabulary skill. No differences were found between bilinguals ($M=108.2$, $SD=9.9$) and monolinguals ($M=111.8$, $SD=9.4$; $t(24)=0.96$, $p=.35$). Information on the participants' language background was obtained via the *Language Experience and Proficiency Questionnaire* (LEAP-Q; Marian, Blumenfeld, & Kaushanskaya, 2007). On a scale of 1-10, where 10 means “fluent,” bilinguals rated their ASL abilities at 8.5 for production, and 8.8 for comprehension, indicating a high degree of ASL proficiency. All participants reported normal hearing and vision.

Materials

Twenty-two minimal sign pairs were developed by choosing two signs that matched on three of four ASL-phonological parameters – handshape, location in space, motion, and orientation of the palm (Brentari, 1998). These sign pairs represented the target and competitor items in our competitor condition. For example, the signs for “cheese” and “paper” overlapped in handshape, location, and palm orientation, but differed in the motion of the sign. Target and competitor signs did not differ significantly in English word frequency [$t(38)=-1.654$, $p=.106$] (obtained from the SubtLexus database; Brysbaert & New, 2009). In addition, twenty-two control items and 110 filler items were chosen based on their lack of phonological overlap to the target in both ASL and English. Control items were used in place of competitor items in the control condition. Control signs also did not differ from target signs in English word frequency [$t(38)=-1.027$, $p=.311$]. In the experiment, each item was represented by a black and white line drawing. In each condition, four black and white drawings were displayed on a computer screen in the corners of a 3x3 grid. The words were recorded at 44.1 Khz, 32 bits by a female, monolingual speaker of English, in sentence context as the final word in the phrase “click on the ____.” Recordings were normalized such that the carrier phrase was of equal length for all target sentences, and the onset of the target word always occurred at 600 ms post onset of the sentence. Recordings were amplitude-normalized.

Design

The current study used a 2x2 Mixed design, with group (bilingual, monolingual) as a between-subjects factor, and condition (competitor, control) as a within-subjects factor. The dependent variables include the proportion of looks (1

Competitor Trial

Figure 1: Example of a Competitor Trial. Participants eye-movements were recorded while they were instructed in English to “click on the cheese.” At the same time, a phonologically related competitor in ASL (“paper”) was present in the display.

for a look, 0 for no look) and duration of looks (percent of time per trial spent looking at an item). There were twenty-two competitor trials, containing a target, a competitor item that overlapped with the target in ASL phonology, and two fillers (Fig. 1). Every competitor trial had a corresponding control trial, in which the content and location of the target item and two filler items were identical, but where the phonologically-overlapping competitor item found in the competitor trial was replaced with an unrelated control item. This allowed for the comparison of looks to a specific location in the display as a function of the presence or absence of a phonological competitor. There were also forty-four filler trials, containing a target and three phonologically unrelated items.

Procedure

After informed consent was obtained, participants viewed a video clip displaying the experimental instructions in ASL performed by a native signer of ASL. Following the instructions, participants were fitted with an ISCAN eye-tracker to measure the location of their gaze during the eye-tracking portion of the experiment. Instructions were again provided, in both written and spoken English, followed by five practice trials meant to familiarize participants with the task. Auditory stimuli were presented over headphones and appeared synchronously with picture stimuli. Participants were told that they would hear instructions to choose a specific object in the visual display, and should click on the object that best represents the target word. Participants' eye-

movements were recorded. After the eye-tracking portion of the experiment, all participants completed the PPVT and the LEAP-Q. In addition, bilingual participants were presented with a list of words and asked to provide the American Sign Language translations. Bilinguals provided correct translations for 95.2% of the words ($M=62.8/66$, $SD=2.5$).

Results

Frequency of Looks

We measured both the proportion and duration of looks to competitor and control items. Bilinguals looked more at competitor items than at control items, and looked more at competitor items than monolingual participants. Repeated measures Analyses of Variance (ANOVAs) revealed a significant Group \times Condition interaction for both the proportion [$F(1,24)=27.284$, $p<0.001$; Fig. 2] and duration [$F(1,24)=23.285$, $p<0.001$; Fig. 3] of looks. Bilinguals looked at competitor items more than at control items [$t(12)=7.62$, $p<0.001$] and for a longer period of time [$t(12)=5.925$, $p<0.001$], signifying that bilinguals activated phonologically related competitors more than phonologically unrelated controls. No differences were found in the monolingual group for either the proportion [$t(12)=-0.95$, $p=0.362$] or duration [$t(12)=-0.16$, $p=0.87$] of looks. Bilinguals also looked at competitor items more than monolinguals [$t(24)=5.58$, $p<0.001$] and for a longer period of time [$t(24)=3.512$, $p<0.01$], while both groups looked at control items equally [proportion= $t(24)=1.18$, $p=0.248$; duration= $t(24)=-.73$, $p=0.47$], verifying that bilinguals activated phonologically related items more than monolinguals. Means and standard errors are illustrated in Table 1.

Table 1: Means and Standard Errors of the Proportion and Duration of Looks (%).

	Proportion (%)		Duration (%)	
	Comp.	Control	Comp.	Control
Bilingual	66.9 (2.8)	51.6 (3.5)	12.9 (0.8)	7.7 (0.6)
Monolingual	42.9 (3.2)	45.5 (3.8)	8.5 (0.9)	8.6 (1.0)

Time Course

Analysis of the bilingual time-course was consistent with the overall looks analysis, with bilinguals looking at competitors more than at control items. In contrast, monolinguals looked at competitor and control items equally across time. The activation curves were divided into 100 ms windows, beginning with the time window between -600 and -500 ms (which signified the first 100 ms after the onset of the picture), and ending with the window between 1900 and 2000 ms. Three-by-two repeated-

measures ANOVAs were performed on each individual window, with time (1, 2, 3) and condition (competitor, control) as within-subjects factors. Significant effects of condition were found in each of the four 100 ms time windows between 0 ms (word onset) and 400 ms, between 1000 and 1100 ms, and between 1300 and 1400 ms (all $ps<0.05$); in all cases, bilinguals showed more looks to competitor items than control items. Similar analyses performed on the monolingual activation curves revealed no

Figure 2. Proportion of Looks (%)

Figure 3. Duration of Looks (%)

Figure 4. Time-course data for Monolingual (top) and Bilingual (bottom) participants, showing activation curves for proportion of looks to target, competitor, and control items across time. The negative 600 time point represents onset of the picture stimulus, and the 0 time point represents onset of the target word. Shaded areas indicate windows where looks to competitor and control items differed at $p < 0.05$

significant effects of Condition for the monolingual group in any time window (all $ps > 0.1$), suggesting that monolinguals did not look more at competitor items than controls (see Figure 4).

It is possible that the effect seen in the late windows (1000-1100 ms and 1300-1400 ms) is a product of residual activation from the early window. To ensure that the late-window effects were not due to lingering activation from the early window, the proportion of late-window looks to competitors *with* a look to targets or competitors in the early-window was compared to late-window looks *without*

earlier target or competitor fixations. If there was a higher proportion of late-window looks when the early window contained a look to either the target or competitor than when it did not, it would suggest that late-window activation was due to residual activation from the early window. However, both instances showed the same proportion of looks, $t(12)=1.04$, $p=.377$, suggesting that the results seen in the late-windows are not due to previous activation in the early-window.

Discussion

The results of the current experiment provide evidence for a modality-independent language system that utilizes top-down pathways during processing by revealing parallel language activation in bimodal bilinguals. Specifically, bilinguals looked more to items with ASL translation equivalents that overlapped phonologically with the target item than to items with translation equivalents that did not overlap, suggesting that phonologically overlapping competitor items were more activated than unrelated controls. In turn, monolinguals looked at competitor items and unrelated control items equally. This pattern was found in the overall looks analysis and in the duration of looks analyses, as well as within specific time windows during processing. The results suggest that even though the bilingual participants received no ASL input, they nevertheless activated their sign-language during the experiment.

The finding that bimodal bilinguals coactivate their languages indicates that lexical items from two distinct languages do not require surface-level overlap in order to be simultaneously activated. Previous studies on unimodal bilinguals have relied on bottom-up information as the force behind parallel language activation – words activate phonologically similar words, regardless of language. If parallel activation is driven purely by overlap at the phonological level, then the bimodal participants should not have shown cross-linguistic activation. Instead, the connection between ASL and English likely exists at the semantic level, since the two languages do not share phonological or lexical items. Semantic representations, once activated, appear to be able to feed back to the lexical levels of *both* signed and spoken languages, resulting in parallel activation.

However, the mechanisms that underlie parallel processing in bimodal bilinguals are unclear. Examination of the time-course showed that at the moment of the onset of the target word, competitor items were activated more than control items in the bilingual group. If the target word has yet to be presented in full, how is it possible that bilinguals would show increased activation of competitor items? Prior to onset of the word, bilinguals view the display containing all four images for 600 ms. Bilinguals may automatically activate the corresponding semantic concepts due to visual input. This activation can feed back ASL lexical levels and activate phonologically similar lexical items. The phonologically related items may then continually activate one another until target selection occurs.

The process of top-down activation of the non-target language in bimodal bilinguals can also be initiated by linguistic input. The initial semantic representation could be activated by the incoming English target word, rather than by visual stimuli. When the semantic representation is activated, it feeds back to the lexical representations in both English and ASL, thereby activating phonologically similar ASL signs and their corresponding semantic representations. It is important to note that in this account, parallel activation

is still a product of top-down processes – the linguistic input should activate English only. However, bimodal bilinguals clearly activate their ASL during the task.

Coactivation may also occur via lateral links between translation equivalents. As an English word is presented, it may activate its ASL translation via direct excitatory connections at the lexical level, which may in turn activate phonologically similar ASL items. While this account does not involve top-down processes, it is also not exclusively bottom-up, and requires a system capable of interaction across languages, *within* a single level of processing. However, the strength of within-level translational connections in bimodal bilinguals is unclear. For instance, bimodal bilinguals do not show enhanced performance on executive control tasks, which has been found in unimodal bilinguals. Emmorey, Luk, Pyers, and Bialystok (2008) suggest that since a bimodal bilingual's two languages utilize separate modalities, they do not compete to the same extent as two spoken languages. Therefore there is less need for executive control of the non-target language in bimodal bilinguals. One could argue that the lack of competition between a spoken and a signed language may indicate that bimodal bilinguals do not develop cross-linguistic connections in the same manner as unimodal bilinguals. It is not yet clear whether the connections between translation equivalents, or the way in which they are processed, are similar in unimodal and bimodal bilinguals.

Regardless of whether parallel activation in bimodal bilinguals is due to top-down effects or lateral connections at the lexical level, it is clear that the processes that underlie language coactivation in bimodal bilinguals differ from those of unimodal bilinguals. While coactivation in unimodal bilinguals relies more on phonological overlap across two languages, no such overlap exists within the processing architecture of bimodal bilinguals. Therefore, the finding that bimodal bilinguals coactivate their languages implies a system where top-down or lateral processes are capable of governing cross-linguistic activation. Our results also indicate that language information may be readily transmitted across modalities, such that two highly unrelated languages can be activated simultaneously. Thus, the language system should be considered modality-independent and able to process linguistic information equally, regardless of whether it is auditory or sensorimotor in nature.

Moreover, there is reason to believe that a system of this nature is not unique to bimodal bilinguals, and may provide a window into more general language processing. Unimodal bilinguals and monolinguals have shown robust cross-modal effects as well (for a review, see Marian, 2009), and semantic-competition effects from eye-tracking provide evidence for rapid and highly robust lexical-semantic interaction (Huettig & Altmann, 2005; Yee & Sedivy, 2006). In addition, when bimodal bilinguals produce code-blends, they do so in the same fashion as unimodal bilinguals would code-switch, with the added benefit of

being able to produce speech and signs in tandem, suggesting similarities in the underlying mechanisms of production for unimodal and bimodal bilinguals (Emmorey et al., 2008). It is possible that the top-down pathways utilized by bimodal bilinguals are present in unimodal bilinguals and monolinguals as well, but are overshadowed by more immediate bottom-up effects.

The results of the current study indicate that bimodal bilinguals activate both of their languages simultaneously via a cross-linguistic lexical-semantic loop where top-down information from the conceptual level feeds back to lower levels of processing in both languages, regardless of modality. The results have further implications for the architecture and processing dynamics of the language system, bilingual and monolingual alike, suggesting that language information can be freely accessed across modalities, and that top-down mechanisms can have a strong influence on language processing.

Conditions of Directed Attention Inhibit Recognition Performance for Target-Aligned Stimuli

Abstract

Watanabe, Náñez & Sasak (2001) demonstrated that the perceptual learning of task-irrelevant items was enhanced under conditions when attentional resources were diverted away from the irrelevant stimuli. However, the current study suggests that when attention is depleted, recognition for task-irrelevant items is *impaired* in a subsequent recognition task. Participants were presented with a stream of simultaneously presented written words and line drawings, and required to respond to immediate repetitions in either the word or picture stream. A surprise recognition test measured performance for the words. When analyzing word recognition performance after attention had been directed to the pictures, words that had previously appeared when attention was most depleted (i.e., with a picture repetition in the primary task) were recognized at levels significantly *below* chance. This novel finding suggests that information that is actively ignored when appearing in conjunction with an attended stimulus is subsequently inhibited in a recognition task.

Introduction

The role of attention in human perception has been investigated extensively through the better part of experimental psychology's history (e.g., Ahissar & Hochstein, 1993; Broadbent, 1953; Cherry, 1953; James, 1890; Mack & Rock, 1998; Moray, 1954; Seitz & Watanabe, 2005; Sinnett, Costa & Soto-Faraco, 2006; Triesman, 1960). A number of findings converge on the notion that explicit perception requires, at least a certain degree of attention (Mack & Rock, 1998; Rees, Russell, Frith, & Driver, 1999). Indeed, this has been demonstrated even for cognitive processes that have been considered at one point to proceed in an obligatory or automatic fashion. For instance, written word recognition, audiovisual integration in speech perception, and motion detection have all been empirically supported to require explicit attention in order for perception to occur (Alsius, Navarra, Campbell & Soto-Faraco, 2005; Rees, Frith & Lavie, 1997; Rees et al., 1999).

Despite numerous examples suggesting that visually presented words are processed automatically (see, e.g., Lupker, 1984; Stroop, 1935), Rees et al (1999) demonstrated that when attentional reservoirs were depleted, written word perception was interrupted. In their experiment participants viewed a rapid serial visual presentation (RSVP) of written items (words or non-words), superimposed on top of a stream of pictures. The primary task was to detect immediate repetitions in either the picture or the word stream. Directly following this task, participants

were given a word recognition test for the words that had previously been presented. Behavioral findings suggested that performance was significantly better (i.e., more words were correctly recognized) after directly attending to the words. Furthermore, after attending to the picture stream, participants were just as likely to incorrectly affirm that a non-presented foil word had in fact been presented as they were to correctly identify words that had been originally presented in the repetition detection task.

While the findings of Rees et al (1999) suggest that attention plays a critical role in word recognition, one could make the claim that the words were indeed perceived, but quickly forgotten because a stable memory code could not be formed. However, the authors also compared brain activations via functional magnetic imaging (fMRI) between the presented non-words (consonant streams) and words in the repetition detection task. Importantly, and discrediting any memory based explanation, while attending to the picture stream, words and non-words failed to show different levels of activation in word processing brain areas, such as the posterior basal temporal region, an important area associated with word identification (Buchel, Price & Friston, 1998). Essentially, a string of consonants (e.g., BCRTM) was treated the same as a word (e.g., HOUSE) when attending to the picture stream (Rees et al., 1999). These results demonstrate that the processing of a written word requires that attentional resources be directed towards that word.

Rees and colleagues have also demonstrated a decrease in visual processing for motion when attentional resources were depleted (Rees et al., 1997). That is, when attention was diverted to a difficult task, a reduction in visual motion perception occurred. In this experiment participants performed linguistic judgment tasks of varying difficulty superimposed over a visual motion background while brain activity was measured with fMRI. The findings suggested that as the difficulty of the linguistic task increased, brain activity in an area associated with the processing of motion (V5; Tootell, 1995) diminished when compared to the easier task. The authors posited that as task difficulty increases, attentional resources that could otherwise be used to process task irrelevant stimuli are recruited for the more difficult task, resulting in a reduction in perception for task irrelevant events (Rees et al., 1997; see also Lavie, 1995; 2005 for a description of attentional load theory).

Despite a multitude of findings suggesting that perception levels diminish as attentional resources are depleted (see

Ahissar & Hochstein, 1993; Lavie, 2005; Mack & Rock, 1998; Rees et al., 1999; Sinnett et al., 2006), Watanabe et al. (2001; see also Seitz & Watanabe, 2003, 2005) demonstrated—in direct contrast to the results described above by Rees et al. (1997)—that the perception of irrelevant motion can actually be *increased* under situations when attentional resources are depleted. Indeed, they showed that participants' detection performance for task irrelevant motion stimuli improved under conditions when attention was directed to a separate task. Moreover, the improvement was only seen when the irrelevant motion was temporally aligned with targets occurring in the attention demanding task. This is surprising as it demonstrates a situation where improved perception is observed during moments when attention is arguably most depleted (i.e., when required to detect and respond to a target).

Watanabe et al.'s. (2001) participants took part in a series of experiments in which they were repeatedly exposed to a background motion signal that was set at either 5% or 10% coherent motion (see also Seitz & Watanabe, 2003; 2005 for further examples using the same task). When asked to determine the direction of coherent motion by choosing one of eight possible directions, participants performed at chance levels for the 5% condition, but above chance levels for the 10% motion condition (suggesting that the motion was subthreshold in the former, but not the latter, condition). The same task was also performed when engaged in a simultaneously presented attention-demanding task. An RSVP of letters was superimposed over the background motion, and participants were required to report the identity of white target letters that occurred in a sequence of black distractor letters. It is important to note that when the superimposed white target letter appeared (i.e., the task-target), the same subthreshold coherent motion direction was present every single time (i.e., the task-irrelevant target).

Upon completion of this task, participants were again shown the weak background motion signal and asked to indicate the direction of the motion by choosing from an array of eight directions (depicted as arrows). While the 5% coherent motion condition remained at chance performance before and after exposure, the 10% coherent motion condition showed significant improvements in perceptual performance for the coherent motion, but only for the specific motion that was synchronized with the presentation of the white target letter during exposure. Note, this result is surprising as it shows that an implicitly presented motion can have a later effect on behavior.

Watanabe and colleagues (2001; 2003; 2005) postulated that the improved motion perception is due to the temporal relationship between the task-relevant stimulus (presence of white letter) and the task-irrelevant stimulus (background motion). It was hypothesized that if these two stimuli were presented simultaneously, then the learning associated with attention being directed to the task-relevant features would also be applied to the task-irrelevant stimulus, despite attention being explicitly directed away from the motion

stimulus. These findings are even more surprising when one considers that significant improvements in performance only occur when irrelevant stimuli are paired with the most demanding aspect of a secondary task (i.e., when attentional reservoirs are depleted, but directed to a temporally aligned target).

The findings of Watanabe and colleagues (2001; 2003; 2005) seemingly suggest that directed attention is not a necessary condition for the perceptual learning of irrelevant targets. While the results are ostensibly robust, their conclusions stand contrary to the wealth of research that suggests that these findings would be unlikely to occur; most research would indicate that perception for irrelevant stimuli would be diminished under conditions where attention is utilized in a separate task and not explicitly directed to the irrelevant stimuli (see for example Rees et al., 1997).

The present study aimed foremost to investigate the robustness of Watanabe and colleagues' claims and expand their findings to a different type of stimulus; explicitly presented written words, using a different paradigm. Accordingly, task-relevant items (visual pictures) were temporally aligned with task-irrelevant (written words) items in a RSVP stream to see if this synchronization would lead to enhanced recognition levels of the task-irrelevant items. Based on the findings of Watanabe et al. (2001), enhanced performance would be predicted for task-irrelevant words that appear at the same time as a target picture when compared with words that do not.

Method

Participants.

Forty participants (n=40) were recruited from the University of Hawai'i at Manoa in exchange for course credit. Participants were naïve to the experiment and had normal or corrected to normal vision.

Materials.

A total of 150 pictures were selected from the Snodgrass and Vanderwart (1980) picture database. The pictures (on average 5 to 10 cm's) were randomly rotated ± 30 degrees from upright so as to ensure the difficulty of the task in each version of the experiment (see also Rees et al., 1999). Each of these pictures was combined with 150 one to two syllable, high-frequency English words (average length of 5 letters; range 4-6) selected from the MRC psycholinguistic database (Wilson, 1988). The overall average frequency of the 150 selected words was 120 per million, ranging between 28 and 686. The words were displayed in bold, capitalized letters in Arial font at a size of 24 points. Each word was superimposed over a picture and the picture-word stimuli did not exceed 10 cm horizontally or vertically. Care was taken to ensure that picture-word combinations did not have any semantic relationship.

Two streams of picture-word stimuli were created. In one stream, 50 pictures were selected from the database, 25 of which were pre-selected, duplicated and paired with their

match. These repeated pictures acted as targets as each pair occurred in the visual presentation as an immediate repetition. The remaining 25 pictures were also duplicated, but their positioning in the stream of stimuli never allowed for an immediate repetition. Together this created a block size of 100 items. A second block of 100 items was created in which the 25 pictures not immediately repeated in the first block now served as the pictures that were immediately repeated. Therefore, across both blocks, each picture was displayed a total of four times (once as a repeat and then two other times as non-repeats in the complementary block). The same principle was used when making streams of items when the words were repeated (attending to words condition). To ensure an enhanced level of randomization, three different groups of 50 words and pictures were created and randomized in the aforementioned fashion, creating six different versions of the picture-word superimposed stimuli for use in the attending to pictures condition as well as the attending to words condition.

The surprise recognition test administered after the completion of the repetition detection task, consisted of 100 words from both the previously viewed visual stream (50) as well as never seen before foil words (50). The foils were words that were used in a different version of the experiment as repeated words (fully randomized). The 50 non-foil words presented in the surprise recognition test were words that were either temporally aligned with the task-relevant target, (i.e., superimposed over the immediate repetition of a picture), or were not temporally aligned with the task-relevant target (i.e., superimposed over non-immediately repeating pictures). Words synchronized with task-relevant targets have been given the nomenclature of *target-aligned* words and those not aligned with task-relevant targets have been named *non-aligned* words (see Table 1).

Table1: Description of *Target-Aligned* and *Non-Aligned* words.

Word Type	Synchronized Temporal Pairing with Task-Target of Immediately Repeated Pictures	Synchronized Temporal Pairing with Non-Task Target of Non-Immediately Repeated Pictures
Target-Aligned	Yes	No
Non-Aligned	No	Yes

Both the repetition detection and word recognition tasks were randomized and presented on a computer screen one at a time, in bold, capitalized letters in Arial font at a size of 24 points, just as they were displayed in the previous stream.

The words in the recognition test remained on the screen until a response was made.

Procedure.

Participants were randomly assigned to one of two conditions. One group was required to attend to the picture stream (i.e., ignore the superimposed words) and respond to immediate picture repetitions, while the other group was required to respond to immediate repetitions in the word stream. Participants responded to the repetitions by using the 'G' key on the keyboard.

Each item in the picture-word presentation was presented for 350 ms with a 150-ms inter-stimulus interval (ISI; blank screen) between each item for a stimulus onset asynchrony (SOA) of 500 ms (see Figure 1). Before the first experimental block, a training block of eight trials was given and repeated until participants were familiar and comfortable with the task.

Immediately after the repetition detection task, a surprise word recognition test was administered to all participants. Words were displayed individually on the center of the screen in the same size and font as previously presented in the repetition detection task, and remained on the screen until the participant made a response. Participants were instructed to press the "B" key if they had seen the word during the repetition detection task or, instead, the "V" key if they had not seen the word before. Within each group, half of the participants (n=10) were presented with foils and target-aligned words, while the other half were presented with foils and non-aligned words.

Figure 1. Rapid Serial Visual Presentation sequence employed. Each picture-word stimulus was presented for 350 ms and was then replaced by a blank screen for 150 ms before the next stimulus. Both the word-monitoring task and the picture-monitoring tasks were performed on the same streams. Note that in the present example, the word "HOME" serves as a *target-aligned* word.

Results

Overall surprise recognition performance.

The results of the surprise recognition test were analyzed in order to compare between conditions (attending pictures vs. attending words), and also against chance levels. Overall, recognition performance was significantly better after attending to the words when compared with after attending to the pictures (59.4%, $SE=1.08$ vs. 46.7%, $SE=2.12$, $t(19)=3.94$, $p=0.001$; see Figure 2). Performance after attending to the words was significantly better than chance ($t(19)=5.19$, $p<0.001$) while performance after attending to the picture stream was not significantly better than chance ($t(19)=1.52$, $p=0.143$).

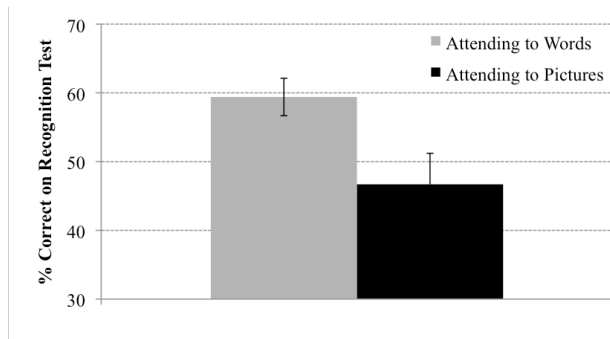

Figure 2. Overall recognition percentages and standard error bars for correct identification of words in the surprise word recognition test after attending to either the word stream (grey bar) or the picture stream (black bar).

Target-aligned word recognition.

In order to address the question at hand, that is, if performance is enhanced for words appearing with a picture repetition, recognition performance for *target-aligned* words was compared with *non-aligned* words and also against chance. When attending to words in the repetition task, subsequent recognition for *target-aligned* words (words immediately repeated) was significantly better than chance performance (59%, $t(9)=2.67$, $p=.025$), while recognition for *non-aligned* words (not immediately repeated) was not statistically different from chance (54%, $t(9)=1.35$, $p=.210$). There were no significant differences between *target-aligned* and *non-aligned* word performance after attending to the words ($t(9)=1.30$, $p=.224$; see Figure 3a). Analysis of recognition performance after attending to the picture stream demonstrated that participants were not better than chance at recognizing *non-aligned* words (50%, $t(9)=0.08$, $p=.931$). Interestingly, performance was significantly different from chance at recognizing *target-aligned* words (38%, $t(9)=4.54$, $p=.001$).

However, the direction of this significance was the opposite of what was expected, with performance significantly worse than chance (see Figure 3b). When

compared to each other, recognition for *non-aligned* words was significantly better than *target-aligned* words ($t(9)=2.34$, $p=.044$).

A.

B.

Figure 3. Recognition percentages and standard error bars for Target-Aligned (grey bar) and Non-Aligned (black bar) words in the surprise word recognition test after attending to either the word stream (A) or the picture stream (B).

An analysis was also conducted on the accuracy of the primary task of immediate target repetition detection. Overall, subjects were able to accurately detect target repetitions (75% hit rate vs. 25% miss rate, $t(9)=21.69$, $p<.001$, see also Sinnott et al. 2006 for similar hit rates using the same paradigm). In addition, a significant negative correlation was found between target detection accuracy and recognition performance for *target-aligned* words ($r(10)=-.69$, $p=.02$), further suggesting that target-aligned words are inhibited in the recognition task.

Discussion

There are three main findings for the current experiment. First, we have replicated previous findings on inattention blindness showing that word recognition is significantly better after attending directly to the word stream as opposed to attending to a distracting stream of pictures (see also Most, Simmons, Scholl, Jimenez & Chabris, 2001, Rees et al., 1999; Sinnott et al., 2006). Second, word recognition failed to be significantly better than chance levels after attending to the picture stream. That is, participants were unable to recognize the words if their attention had been placed elsewhere, suggesting that attention may be a

necessary component for word recognition (see also Rees et al., 1999; Sinnett et al., 2006). Lastly, we have shown for the first time that words that appeared with a picture repetition (i.e., target-aligned) are recognized at significantly lower than chance levels after attending to the picture stream, suggesting, perhaps, an inhibition for irrelevant information that appears simultaneously with an attended target. Furthermore, after attending to the words themselves, subsequent recognition was better than chance for words that had appeared as a target repetition (i.e., target-aligned), while at chance levels for those that had appeared elsewhere in the stream (i.e., non-target aligned). Accordingly, this suggests that words that appeared with a target repetition were either inhibited or facilitated, depending on whether attention was originally directed to the pictures or the words in repetition detection task, respectively.

The finding that there is a possible inhibition of previously viewed words that appeared with a picture target stands in direct contrast to the conclusions drawn by Watanabe and colleagues (2001; 2003; 2005). For their findings to be replicated here, an enhanced recognition performance for words synchronized with task-relevant targets should have occurred. However, while the necessary temporal synchronization between task-relevant and task-irrelevant stimuli was present, enhanced perception for task-irrelevant stimuli was not observed. In fact, the exact opposite was seen, in that there was an inhibition of performance for the recognition of words that were temporally aligned with the task-relevant target of an immediate picture detection.

The potential inhibition of the target-aligned words when attention was diverted to the picture stream is of key interest to the present findings. While it is apparent that many investigations have found that when attentional resources are depleted, unattended and irrelevant stimuli are often not perceived (Mack & Rock, 1998; Rees et al., 1999; Sinnett et al., 2006), an inhibition for these stimuli has not been observed. However, it should be noted that to the best of our knowledge, this is the first time that a distinction between irrelevant stimuli appearing with a target, or not, has been empirically investigated. When doing precisely this in the present study, an inhibition for words that appeared with repeated target pictures was observed. One possible explanation for this would be that due to focused attention being placed directly on the demanding task of detecting repetitions, thereby necessitating that the attentional system actively inhibit irrelevant information in order to facilitate goal oriented behavior.

Despite significant differences in paradigms, a possible explanation for the inhibition of *target-aligned* words after attending to pictures may be found in the inhibition of return (IOR) literature (see Klein, 2000 for a review of IOR). If a target stimulus occurring in the periphery is first cued by a salient attention grabbing event, then a facilitation is normally found for the processing of that target if the time between the cue and the target is relatively short (i.e., < 300

ms; Posner, 1980). However, if there is a longer time period between the cue and the target (i.e., after attention has been disengaged from that space), then there is a delay (i.e., inhibition) for processing of targets in the previously cued area. This might be analogous to what was observed in the present experiment: Information that was attended to is later inhibited. However, it should be noted that this comparison is difficult to make as IOR is traditionally seen in visual search paradigms and measure response latency, while the present findings result from a non-spatial paradigm measuring accuracy. Nevertheless, the present findings could be viewed as an instantiation of a non-spatial, accuracy based inhibition for ignored stimuli.

As the comparison between visual search and the present paradigms can be viewed as difficult at best, perhaps a stronger explanation for the present results can be drawn from research on negative priming (see Milliken, Joordens, Merikle, & Seiffert, 1998; Tipper, 1985; Tipper & Driver, 1988). Typically, in negative priming experiments observers are presented, for instance, with two overlapping streams of object outlines with each stream printed in a different color (i.e., green and red). Participants would be required to name items in one stream (green objects) while ignoring stimuli in the other stream (red objects). Interestingly, response latencies are slower for objects that had appeared previously in the ignored stream (i.e., the to-be- ignored color), than for objects that participants did not have to ignore previously. Accordingly, this suggests that while selecting and naming one picture, the other (simultaneously displayed but not selected) object seems to be processed as well, at least to the extent that it influences naming latencies in the following trial. The theoretical implications of this could quite obviously be supported by the present findings, as behavioral responses to the ignored items here were inhibited in the form of response accuracy.

The significant negative correlation between target detection accuracy and recognition performance for *target-aligned* words further illustrates the possibility of negative priming. That is, while there was a high level of accuracy for immediate picture repetition detection, performance was decreased for recognition of *target-aligned* words superimposed over the target pictures. Perhaps, as occurs in the aforementioned negative priming paradigms, the accurate detection of the primary target is related to decreased recognition accuracy (rather than a response latency) for the ignored *target-aligned* words.

Performance on the surprise word recognition after attending to the word stream was comparable to that of previous findings, suggesting that if attention is directed to words, they are recognized at both better than chance levels and better than after attending to the picture stream. While this is not surprising, there is one noteworthy finding: Overall better than chance performance is driven by *target-aligned* words (words immediately repeated and serving as task targets). That is, recognition performance for *non-aligned* words was not better than chance. Arguably, an increased amount of attention is allocated to target

detection, thereby potentially facilitating memory consolidation and subsequent performance in the word recognition task (see Craik & Lockhart, 1972 for a discussion on levels of processing theory). Accordingly, the present findings suggest an inhibition for target-aligned words when attention was directed to the picture stream, but a trend in the data (59% *target-aligned* vs. 54% *non-aligned*) for a facilitation of target-aligned words when attention was directed to the words themselves.

It is important to take into consideration significant procedural differences between the present study and the works by Watanabe and colleagues (2001; 2003; 2005). A detailed analysis of Watanabe et al.'s. (2001) original paradigm shows that a total of 960 trials, in which 120 consisted of the paired task-relevant and task-irrelevant stimuli, were presented daily for 20 days (i.e., nearly 100 times the amount here). In addition, the 120 paired task-relevant/-irrelevant stimuli always had the same direction in the coherent motion background. This would be equivalent to presenting only one specific word to appear with picture repetitions in the present study. Therefore, it might be possible that perception for irrelevant information paired with task-relevant information in the Watanabe et al. studies was an artifact of prolonged exposure in addition to the temporal synchronization (although this may be negated by an increased perception for the coherent motion paired with the task relevant target only). Future research could employ the paradigm from the present study to investigate prolonged exposure rates through the utilization of a larger number of trials and a smaller number of *target-aligned* words to see if perception is enhanced, rather than inhibited.

Abstract

The World Wide Web offers a lot of information that has been provided by laypersons instead of experts or professional journalists. This raises the question how Internet users perceive credibility of online authors and which information on the source influences the users' selection and processing of texts. Our study investigated the effect of self-reported expertise, community rating, and age of weblog authors. In an online laboratory experiment, information seeking behavior of 60 participants on a science weblog was analyzed. As exemplary scenario, the discussion on the effects of violent media contents on children was chosen. Results showed that authors with a high level of expertise (operationalized by the author's self-reported profession) were rated as more credible and their texts were selected for further reading more frequently. This suggests that self-reported expertise emerges as a strong cue for information selection, whereas there was only partial evidence for the importance of community ratings.

Keywords: Credibility, Selective Exposure, Persuasion, Source Cues, Information Processing.

Introduction

The Internet is today's largest source of information and communication. As Metzger (2007) points out, "more information from more sources is available and more easily accessible now than ever before" (p. 2078). Although this can definitely be seen as a major advancement, it might also lead to the problem that users get lost in the digital world and do not know how to find the content they need, e.g. when searching for information on science related issues. This phenomenon of "information overload" in the Internet (Eppler & Mengis, 2004) has brought new attention to the issue of credibility and quality of information – especially since the World Wide Web is rapidly developing in the direction of user-generated-content (Web 2.0, O'Reilly, 2005). For example, in blogs and forums "any user can say anything about any topic" (Van der Heide, 2008, p. 30). Thus, one can increasingly find information that has been provided by laypersons instead of experts or professional journalists and therefore may be less reliable.

This raises the question how Internet users perceive credibility of online authors and which information on the source influences the users' selection and processing of information in the World Wide Web. While previous

research on selective exposure focused on content features such as the relevance of the topic (e.g. Knobloch, Zillman, Gibson, & Karrh, 2002; Zillmann, Chen, Knobloch, & Callison, 2004), information on the authors has not been taken into account yet. Similarly, models of online information seeking (e.g. Pirolli & Card, 1999; Schamber & Bateman, 1996; Tombros, Ruthven, & Jose, 2005) consider factors like title, currency and layout. With respect to theoretical modelling, it can be asked whether these models have to be amended by aspects of social cognition with regard to the authors.

Against this background, we wanted to investigate the effect of source cues – self-reported expertise, community rating, and age of authors – on the perception of credibility and the selection of online science information. Who do Internet users trust? And whose information do they select? Our examination focuses on weblogs (or blogs), which can be defined as "frequently updated websites where content is posted on a regular basis and displayed in reverse chronological order" (Schmidt, 2007). These websites are popular means of science communication in the Web (e.g. www.scienceblogs.com). Therefore, they are increasingly used by laypersons for obtaining information on science-related issues. As exemplary scenario for our study, we chose the discussion on the effects of violent media contents on children and adolescents.

Credibility and Information Selection in the Web

While several studies examined the general credibility of the Internet as a medium (Stavrositu & Sundar, 2008; Metzger, Flanagin, Eyal, Lemus, & McCann, 2003) or the credibility of different web sites as a whole (e.g. Walther, Wang, & Loh, 2004), this study focuses on the credibility of authors within a certain web site, which means that the analyzed message sources here are persons. According to the theory of social information processing (Walther, 1992), impressions of persons in computer-mediated communication are formed on the basis of verbal, linguistic, and textual manipulations – even though a lot of information that would be visible in face-to-face communication is missing. These impressions, primarily based on text-based cues, accrue over time and lead to a

relatively elaborate evaluation of other persons. In this context, Walther (1996) stated that, due to the absence of other cues, basic personal information might even be more important than in face-to-face situations (hyperpersonal communication).

Van der Heide (2008) distinguishes between system generated cues (e.g. the number of posts in a forum or the number of friends on the social networking site Facebook), aggregated feedback systems (such as reputation or rating systems) and self-disclosure behaviors (e.g. self-report of profession and age) as relevant types of heuristically valuable information about computer-mediated message senders. While system generated cues and aggregated feedback systems are based on information that has been provided by other users or the computer system itself, self-disclosures are easier to manipulate by the authors themselves. This means that someone might claim to be an expert although he is not. On the other hand, self-disclosures are “an efficient, direct, and visible method of communicating one’s qualification” (Van der Heide, 2008, p. 24) and might therefore be particularly important.

As “authority is no longer a prerequisite for content provision on the Internet” (Metzger, 2007, p. 2078), it seems reasonable that people use these information on the author and his/her estimated credibility as a criterion for information selection. However, it has not been analyzed yet if these cues are a relevant factor for laypersons who are seeking information on science-related everyday issues in the Internet.

Expertise

Persuasion research in the tradition of the Yale studies (e.g. Hovland, Lumsdaine, & Sheffield, 1949) shows that messages presented by persons with a high level of expertise are more likely to influence other people (Wilson & Sherrell, 1993). Therefore, dual-models of information processing (Chaiken, 1987; Petty & Cacioppo, 1986) include expertise of the source as one major factor – which is especially relevant if the level of elaboration is low.

Expertise Communicated via Self-Report On a weblog on science-related issues, self-reports, which may consist of a short self-description and the profession of the author, are able to provide important cues on the expertise of the author. This information is able to serve as a heuristic (“experts are usually correct”). As humans are cognitive misers (Fiske & Taylor, 1991) who do not include more cues than necessary for their decisions, it seems plausible to assume that this aspect is already relevant for the selection of information. For an investigation of newsbots such as Google News, Sundar, Knobloch-Westerwick, and Hastall (2007) demonstrated that source credibility cues (name of the medium in which a certain article was found, e.g. New York Times vs. tabloid newspaper) – which can be seen as an equivalent of expertise information on the level of persons – influenced perceived message credibility and likelihood of clicking. Following these results and

considerations on persuasion research, we hypothesize that the information on the expertise of the author influences rating of the source and selective exposure to the corresponding message:

H1a: Sources with a high level of self-reported expertise will be perceived as more credible.

H1b: The texts of authors with a high level of self-reported expertise will be selected more often than the ones of the low-expertise-sources.

Expertise Attributed by Others (Community Ratings)

Next to self-reports, expertise can also be expressed through the statements of other users. Therefore, collaborative filtering, e.g. rating systems (1 to 5 stars) or popularity indications (most e-mailed, number of views), is also likely to influence information choice. As these ratings are difficult to manipulate, they provide valuable information on the qualities of the user. Walther et al. (2009) showed that comments of friends on social networking sites are even more important for impression formation than self-generated statements. Furthermore, according to Chaiken (1987), people use the heuristic that, if many agree with an opinion, the opinion is probably correct. In this line, community ratings should produce a bandwagon effect (Sundar & Nass, 2001) in that articles or elements which already have a positive rating are clicked more frequently. On the other hand, individuals sometimes seek distinctiveness from others (Brewer, 1991), which would be an explanation for the opposite effect. Previous research has supported the idea of the bandwagon effect: In an experiment on selective exposure, Knobloch-Westerwick, Sharma, Hansen, and Alter (2005) found that online articles with better explicit recommendations were read longer. Additionally, Resnick, Zeckhauser, Swanson, and Lockwood (2006) showed that sellers with a high rating at the auction website Ebay were able to sell products for higher prices than users without a positive reputation. In this context, we hypothesize that:

H2a: Authors with a high community rating are perceived as more credible than authors with a low community rating.

H2b: Texts of sources with a high community rating are more likely to be chosen.

Social Comparison (Age)

Furthermore, social comparison (Festinger, 1954) may be relevant for selection. According to Festinger’s theory, people are motivated to evaluate their opinions and abilities in comparison to similar persons, e.g. people with the same socio-demographic background (age, gender, education, etc.). The (positive or negative) results of this comparison process have been shown to influence self-evaluations and behavior (Mussweiler, 2001). In order to gain information that is relevant for social comparison, people should choose content that is connected to similar persons. In an experiment with an online news magazine, Knobloch-

Westerwick and Hastall (2006) already demonstrated that recipients more often choose news with protagonists of the same sex and that young readers prefer texts about same-age-characters. As similar effects can be expected for text authors, we hypothesize that:

H3a: Users perceive sources of similar age as more credible.

H3b: Users choose texts that were written by sources of similar age.

Method

Sample

In order to investigate these hypotheses, we created an online laboratory experiment in which 60 German participants were asked to search for information on a science weblog. As exemplary scenario, the website dealt with the controversy on the effects of violent media contents on children and adolescents. To ensure that this topic was personally relevant, participants were parents with children between the age of 2 and 18. Subjects were recruited via different channels, e.g. newspaper ads, postings in forums for parents and flyers which were distributed in schools. Participants (30 female, 30 male) were between the age of 22 and 47 ($M = 36.93$; $SD = 6.54$). 26.7 % of them had a university degree, 31.7 % finished high school with a qualification for university entrance and 41.7 % finished high school without this degree.

Stimulus Material

As stimulus material a blog platform (see figure 1) was created. On the overview page, 16 summaries of articles (with a headline, short description and information on the author) were shown. By clicking on the summary, the user was able to read the whole article – furthermore, it was possible to get more information on the author.

Independent Measures

As independent measures, the information on the author (self-reported expertise, rating, age) was systematically varied as within-subject factors. Expertise was operationalized via profession (professions with a close connection to the topic, e.g. psychologist (high) vs. professions without a connection to the topic, e.g. banker (low)). Sex, rating and age were also varied (rating: five or four stars vs. one or two stars / age: 24-27 years vs. 42-45 years). As a result, there were 16 combinations of author information that were shown below the headlines of the summaries. For every combination, a fictitious “character” was created (e.g. “Dr. Thomas Moos, 42, media scholar, community rating: 2 out of 5 stars” or “Jens Kohwall, 27, insurance broker, community rating: 5 out of 5 stars”). Headlines and texts were written in a neutral tone (e.g. “New studies on the effects of first-person shooters” or “Survey on children’s media usage”), and connections

between authors and texts were systematically rotated to avoid effects of the different topics and formulations.

Dependent Measures

As dependent measures, information selection and rating of the information and the source’s credibility were assessed. It was coded which of the texts were chosen (in which order) and how long the texts were read. Furthermore, it was assessed whether the participants decided to get more information on the author. Credibility was measured with a scale based on research by Berlo, Lemert, and Mertz (1969) and Gierl, Stich, and Strohmayer (1997), including items like “trustworthy”, “experienced” and “altruistic”.

Figure 1: Screenshot of the weblog
(Title: “Violence in the Media”)

Procedure

Data were collected in a laboratory at the University of Duisburg-Essen. First, the participants filled out an online questionnaire in which their previous knowledge on the topic, their media usage, need for cognition (Cacioppo & Petty, 1982) and self-efficacy with regard to Internet and Web skills (Eachus & Cassidy, 2006) were assessed. After that, they were told to search for information on the topic by reading the weblog. In order to create a selection situation, time was limited to four minutes. The sessions were saved with a screen-recording software. After that, the participants filled out a post-questionnaire in which they rated the credibility of the authors.

Results

Usage of the weblog

The participants of the study selected an average of 5.68 articles ($SD = 1.99$) during four minutes of reading time. Average reading time per article was 28.60 seconds ($SD = 12.52$). 25 % of the participants wanted to see further information on the author.

H1: Self-Reported Expertise

H1 predicted that authors with a high level of self-reported expertise (with a profession that has a close connection to

the topic) are perceived as more credible (*H1a*) and that their texts are selected more often (*H1b*). To test these hypotheses, we conducted an analysis of variance (ANOVA) with repeated-measures in which the values for the authors were grouped according to their level of expertise. This revealed a significant effect of self-reported expertise on credibility ratings, $F(1, 59) = 98.040, p = .000, \eta_p^2 = .624$. As table 1 shows, the credibility scores for high-expertise authors are higher than for the low-expertise sources. Therefore, *H1a* has been supported by the data.

Table 1: Descriptive statistics for the effect of self-reported expertise on credibility score, number of clicks and reading time (in seconds)

	M	SD	N
Credibility Score High Expertise	153.35	19.45	60
Credibility Score Low Expertise	115.30	24.47	60
Number of clicks High Expertise	3.13	1.44	60
Number of clicks Low Expertise	2.55	1.53	60
Reading Time (s) High Expertise	79.43	34.69	60
Reading Time (s) Low Expertise	67.67	41.32	60

For the number of clicks, ANOVA also revealed a significant effect of expertise, $F(1, 59) = 4.145, p = .046, \eta_p^2 = .066$. The mean values (see table 1) show that texts that were attached to authors with a high level of self-reported expertise were selected more often for further reading. This means that *H1b* can also be supported. However, it has to be noted that the effect size is low.

With regard to reading time, the mean values (see table 1) indicate that texts of high-expertise-authors were read longer. However, ANOVA did not show a significant effect.

H2: Community Rating

H2 predicted that the participants prefer authors with a high community rating. However, with regard to credibility evaluations, no significant result was revealed (*H2a*). For the number of clicks (*H2b*), the mean values indicate that texts of authors with a high rating were selected more often ($M = 3.07; SD = 1.52$) than texts of authors with a low rating ($M = 2.62; SD = 1.45$). However, this trend was not significant. As a result, *H2* is not supported by these data. In further exploratory analyses, we found that, if only the authors with a low level of self-reported expertise are taken into account, community rating has a positive, marginally significant effect on the number of clicks, $F(1, 59) = 3.020,$

$p = .087, \eta_p^2 = .049$: Participants selected an average of 1.40 texts of high-rating-authors ($SD = 1.01$) in comparison to an average of 1.15 texts of low-rating-authors ($SD = .88$).

H3: Social Comparison (Age)

H3 stated that the participants would perceive sources of the same age as more credible and choose their texts more often. For this analysis, the sample was separated into two age groups (from 22 to 38 years and from 39 to 47 years) via median split. With regard to credibility ratings (*H3a*), the analysis of variance revealed a significant effect of the author's age, in the group of older participants ($F(1, 29) = 14.920, p = .001, \eta_p^2 = .340$) as well as in the group of younger participants ($F(1, 29) = 8.696, p = .006, \eta_p^2 = .231$). However, in contrast to our hypothesis, mean values (see table 2) show that older authors were generally perceived as more credible in both age groups. The effect of author's age on credibility rating was significant for the whole sample, $F(1, 59) = 23.041, p = .000, \eta_p^2 = .281$. For the number of clicks (*H3b*), no significant effects emerged.

Table 2: Descriptive statistics for the effect of age on credibility score

Sample		M	SD	N
Age 22-38	Cred., Young Authors	129.43	15.94	30
	Cred., Old Authors	133.63	17.16	30
Age 39-47	Cred., Young Authors	133.10	16.34	30
	Cred., Old Authors	141.13	18.25	30
Total Sample	Cred., Young Authors	131.27	16.11	60
	Cred., Old Authors	137.38	17.96	60

Discussion

Against the background of the rise of Web 2.0 formats in which a lot of content is produced by laypersons instead of experts, we aimed to answer the question how online users perceive credibility and which factors determine their selection of online science information. For this purpose, the present study investigated the effect of expertise (as self-reports and community ratings) and age of weblog authors.

Our analysis showed that self-reported expertise has a strong influence on the perception of credibility: As hypothesized in *H1*, the participants preferred texts of

authors who had a profession with a close connection to the topic, e.g. psychologists or media scholars. Furthermore, their texts were chosen more frequently for further reading. These results are in line with studies from (offline) persuasion research (e.g. Wilson & Sherrell, 1993) and dual-models of information processing (Petty & Cacioppo, 1986; Chaiken, 1987) in which expertise of the source is one important factor. From our findings, we can conclude that expertise as heuristically valuable information is already relevant in the earlier stage of information selection: Following the heuristic that “experts are usually correct”, online users assess the credibility of the author and the estimated quality of the text before choosing an article. While Sundar et al. (2007) showed that this is true for newspaper sources, the present study indicates that expertise cues are also relevant if the message sources are persons. Therefore, it seems that online users prefer declared experts to “normal” people (who may be personally concerned with regard to the topic) even in websites that are dedicated to user-generated-content.

However, statements of other users on the expertise of the authors, expressed by community ratings (*H2*), did not have a significant effect on credibility rating and information selection. Obviously, the display of rating stars did not produce a bandwagon effect, as it was found for online articles (Knobloch-Westerwick et al., 2005) and for the credibility of Ebay sellers (Resnick et al., 2006). This is all the more astonishing as previous research on social networking sites (Walther et al., 2009) has shown that information given by other people is seen as more important than self-descriptions. The lack of impact might be due to the fact that it was not clear to the participants what exactly the ratings indicated and by whom (e.g. how many people) the evaluation had been given. The cue concerning self-reported expertise (profession of the author) has obviously been more important because the participants trusted in the correctness of these self-reports: It is also possible that they perceived it as an objective fact (possibly verified by the blog owner) rather than a subjective assessment made by the author. Furthermore, the costs and consequences of the decision to choose an article or not are smaller than e.g. when deciding to buy a product on Ebay. As a result, the considerations may be less careful, which would lead to a decreased importance of community ratings. However, if only the authors with a low self-reported expertise were taken into account, community ratings produced a marginally significant effect: Texts of authors with a high rating were selected more often than texts with a low rating. This suggests that community rating does not matter when the level of self-reported expertise is high. But if the level of expertise is low, ratings seem to make a difference in that people with a better rating are selected more often.

Our analysis for *H3* showed that the age of weblog authors has a significant influence on credibility ratings and that older authors are generally perceived as more credible. This is in contrast to our assumptions that users prefer sources of similar age, based on social comparison theory

(Festinger, 1954; Mussweiler, 2001). While Knobloch-Westerwick and Hastall (2006) found a social comparison effect on the selection of news articles according to the age of protagonists, there seems to be no such effect for blog authors. An explanation could be that users of a science weblog are mainly concentrating on the quality of information (which can e.g. be deducted from a profession with a close connection to the topic, a high rating and maybe higher age due to more professional experience) rather than seeking personal information on the author. Possibly, other websites, such as social networks in which detailed personal information and pictures are included, are more likely to foster social comparison processes (see Haferkamp & Krämer, 2010). The effect that older authors are seen as more credible may be explained by the topic of “violent media effects”, in which experiences with child-rearing are helpful. For other topics (e.g. pop music or Internet technology), the relationship between age and source credibility may be different.

In summary, self-reported expertise of the author emerges as a strong cue for the perception of online science information, whereas there is only partial evidence for the importance of community ratings and age. In line with Sundar et al. (2007), these results demonstrate that the “information scent” of articles is not restricted to its content or formal features (position or layout): Information on the author, especially expertise, must also be taken into account.

In order to achieve further insights into these processes, future research should investigate the effects of sources in combination with other variables, such as different message types and different levels of motivation of information seeking. In the present study, texts have been written in a neutral style, which might have created a slightly artificial situation that differs from the normal situation in the blogosphere. If variations of content are included, the analysis of user behavior may show the interdependencies between several important factors of information selection.

Abstract

Different representational systems permit differing degrees and forms of ambiguity and underspecification in the content they represent. Independently of this observation, a notable feature of natural language as a representational system is that it allows the same content to be expressed in different ways. In this paper, we examine the interaction of these two observations; in particular, we explore a number of linguistic forms involving underspecified content, and look at how subjects express the content of these linguistic forms both in logic and in diagrams. Our analysis demonstrates that variations in syntactic realization of the same semantic content lead to different interpretations of that content.

Keywords: logic; natural language; syntactic structure; diagrams; representations; negation.

Introduction

This paper takes as its starting point two widely-made observations. First, different representational systems permit different abstractions, and consequently, they permit underspecification on different dimensions. In particular, natural language (NL) and first-order logic (FOL) are two representational systems that permit underspecification of aspects of meaning that must be made explicit in diagrammatic representations. Direction is a case in point: consider the natural language statement *The house is adjacent to the park*; neither this sentence, nor a typical FOL rendering such as `AdjacentTo(house, park)`, specifies the direction of adjacency, but a picture or diagrammatic rendering of the sentence must make this explicit. We will say that the NL representation of the state of affairs is **underspecified with respect to** the diagrammatic representation. This makes it clear that underspecification as defined here is a relational notion; however, for convenience in the remainder of this paper we will simply refer to representations as being **underspecified** when the relatum is obvious from the context.

The second observation we take as a starting point is that natural language affords multiple ways of realizing the same semantic content. This is often exemplified by reference to the fact that active and passive sentences, such as *Fred wrote the book* and *The book was written by Fred*, describe the same state of affairs. There may be contextual, or pragmatic, reasons for choosing one realization over the other, as commonly discussed under the heading of **information packaging** (Vallduvi, 1992); but the common view is that the semantics of the two sentences, *in terms of propositional content*, is the same.

We are interested in how these two phenomena interact. Our interest is motivated by an effect found in an earlier study (Cox, Dale, Etchemendy, & Barker-Plummer, 2008), in which the specificity of participants' responses to NL sentences containing negation differed markedly between their FOL translations and their diagrammatic interpretations. Specifically, it was found that in their FOL translations of the sentence *d is not a small dodecahedron*, participants overwhelmingly treated the predicates *small* and *dodecahedron* symmetrically, whereas their diagrams of the sentence tended to make *d* a dodecahedron that isn't small, rather than a small shape other than a dodecahedron. However, contextual confounds made the source of this effect hard to establish.

In this paper, we report on an experiment which sought to elucidate the effects of different possible factors on this phenomenon. In particular, we ask: if we have a number of natural language forms that express the same *underspecified* semantic content, what happens when subjects are asked to draw diagrams that require them to be more explicit? If the NL sentences truly express the same meaning, then we might expect to see similar distributions of the possible diagrammatic renderings, regardless of the NL surface form used. Alternatively, syntax or semantics may make some diagrammatic renderings more salient or available than others. This paper sets out to determine which of these alternatives hold.

¹Center for the Study of Language and Information.

²Department of Linguistics.

Hypotheses

We explore two hypotheses in particular.

Hypothesis 1: When asked to translate from one representation into another that permits underspecification to be maintained, then in the absence of any contextual factors that encourage a more specific reading in the target representation, subjects will maintain the underspecification.

Hypothesis 2: When asked to translate from one representation into another that requires underspecification to be made specific, and there are a limited number of ways of doing this, we expect to see similar distributions across these solutions irrespective of superficial variations in the way the content is expressed in the source representation.

To test Hypothesis 1, we ask subjects to translate from NL to FOL. We make use of syntactic variations that represent the same semantic content; for example, the three sentences below all are expressions of the FOL statement $\neg(\text{Striped}(q) \wedge \text{Circ}(q))$:

- | | | |
|-----|---------------------------------------|---------|
| (1) | q is not a striped circle | PREMOD |
| (2) | q is not a circle with stripes | POSTMOD |
| (3) | q is not striped and circular | COORD |

The first two sentences are syntactically and semantically unambiguous. It is possible, with appropriate contextual cues, to encourage a more specific reading than the **wide-scoped** FOL statement above. For example, in spoken form, emphasis on either *striped* or *circle*, as in *q is not a striped circle* or *q is not a striped circle*, may encourage a **narrow-scoped** reading, corresponding to $\neg\text{Striped}(q) \wedge \text{Circ}(q)$ and $\text{Striped}(q) \wedge \neg\text{Circ}(q)$, respectively. However, in the absence of any such cues, Hypothesis 1 predicts that subjects will provide the wide-scoped reading.³

The third sentence is syntactically ambiguous (see Figure 1). Each parse corresponds to a different semantics, one of these being the wide-scoped reading, and the other the narrow-scoped-left reading. We would expect to find a distribution across these two readings in the FOL renderings.

To test Hypothesis 2, we ask subjects to translate from NL into diagrammatic realizations. We focus our analysis on those subjects who maintained underspecification in our test of Hypothesis 1, i.e., we leave aside any subjects who produce a narrow-scope reading for COORD sentences. We set up the diagram task conventions in such a way that there are only a limited number of possible ways of making the underspecified content specific. In particular, the wide-scope FOL above can be realized by three classes of diagrams:

³There is an extensive literature on scope ambiguity and its effects on human sentence processing (see, for example, (Kurtzman & MacDonald, 1993)) and on how discourse factors and lexical frequency impact on the processing of syntactic ambiguities (see, for example, (Trueswell, 1996; Spivey & Tanenhaus, 1998)); however, the focus of the former tends to be on quantifier scoping, and the latter is not obviously relevant to the kind of data we explore here. We are not aware of any existing work that looks at the processing of negated conjunctions of verbal complements, as explored here.

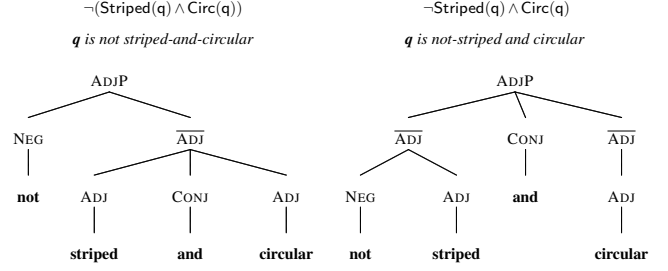

Figure 1: Two parse trees for *q is not striped and circular*

1. diagrams in which **q** is a circle that isn't striped (i.e. only the predicate *Striped* is realized-as-negated);
2. diagrams in which **q** is a striped object other than a circle (i.e. the predicate *Circ* alone is realized-as-negated); and
3. diagrams in which **q** is neither circular nor striped (i.e. both predicates are realized-as-negated).

Each of these realizations commits to some information left unspecified in the FOL sentence.

Our hypothesis predicts that the distribution of different diagrammatic realizations should be roughly similar irrespective of which surface NL form is being translated.

Methodology

The Subjects

Forty-one students enrolled in an introductory logic class at Stanford University took part. The experiment was conducted in the final weeks of the term. All of the background material necessary to complete the experimental task was presented within the first two weeks of the term. A key aim of the course is to teach the ability to distinguish the propositional content of sentences from their implicatures. The subject pool had therefore been primed to consider different possible interpretations of sentences and whether those interpretations depend on factors external to the sentence, such as common knowledge. Further, the students' knowledge of FOL allows us to test for an unambiguous reading of sentences with multiple interpretations.

The class used (Barwise, Etchemendy, Allwein, Barker-Plummer, & Liu, 1999) as the textbook, and used the Tarski's World computer program for teaching the semantics of FOL. Tarski's World presents a system similar to the diagrammatic representation used in this experiment. In general, the materials were designed to parallel the structure of materials in the course, both in terms of the diagrammatic representations that were used, and the names used to refer to the distinct activities within the experiment.

Materials Administered

Subjects were given workbooks consisting of: (a) a page of study information; (b) a sheet consisting of 18 declarative natural language sentences to be translated; (c) a page of instructions; and (d) a half-page description with illustrative ex-

Table 1: Experimental Sentences in PREMOD Formulation

d is not a large dotted object	k is not a small circle
h is not a small dotted object	l is not a striped triangle
p is not a small striped object	n is not a dotted triangle
b is not a large triangle	q is not a striped circle
c is not a large circle	

amples of the diagrammatic representation and the first-order language to be used in the task. Following these were pages describing four activities to be completed. Three of these were presented as ‘You Try It’s (YTIs), and are described further below; these would be familiar to the subjects from (Barwise et al., 1999) as activities for becoming familiar with a concept. The final page of the workbook contained a more complex exercise in translation and realization, the contents of which are not discussed here.

Subjects were asked to complete all four activities with no time-limit and with no supervision. Only data from the second and third YTIs—translating the sentences into FOL and drawing realizations, respectively—are analyzed as part of this experiment; the remaining activities were included in order to format and embed the experimental tasks within an exercise form that the participants were familiar with from (Barwise et al., 1999). More importantly, they were designed to encourage subjects to submit spontaneous, naturalistic realizations.

The Tasks

As noted, subjects were given 18 natural language sentences in English. Nine of these were **negated logical conjunctions**, expressed in a form determined by the different conditions described below. The remainder of the sentences were fillers, also varying by condition, such as *m is a triangle that’s not dotted*. The filler sentences all use the same vocabulary as the experimental sentence; some involve negation and others do not. All have unique readings.

The complete set of sentences (shown for condition PREMOD in Table 1) was counterbalanced such that each predicate is mentioned an equal number of times. In particular, of the nine experimental sentences, three mention size and pattern, three mention pattern and shape, and three mention size and shape; and each of the words *large*, *small*, *circle/circular*, *triangle/triangular*, *striped/stripes*, and *dotted/dots* are mentioned three times.

Subjects were asked to perform two tasks. The first task was to translate each sentence into a formal language of FOL, as discussed above. For the negated logical conjunctions, three FOL readings were possible, which we refer to as wide-scope, narrow-scope-left, and narrow-scope-right; for the example sentences introduced at the outset of the paper, these FOL readings are $\neg(\text{Striped}(q) \wedge \text{Circ}(q))$, $\neg\text{Striped}(q) \wedge \text{Circ}(q)$, and $\text{Striped}(q) \wedge \neg\text{Circ}(q)$ respectively.

The second task was to draw, for each sentence, a dia-

gram of a situation making the sentence true. We call these **diagrammatic realizations** of the sentences. We devised a highly constrained diagrammatic representation system in which objects have exactly three properties: shape, size, and pattern, with each of these properties having only two possible values (circle/triangle, small/large, striped/dotted). The students were asked to draw such objects in prepared spaces.⁴

Since the sentences have different readings, they may be realized in different ways, but the wide-scoped reading itself has multiple equally valid realizations. In the example above, **q** can be either a dotted circle, a striped triangle, or a dotted triangle. For such **multiply realizable** readings, each of the three possible realizations are equally valid, but the response requirement of a single diagram forces subjects to choose one.

The Conditions

The sentences of interest share the common property that they can be read as expressing the negation of a conjunction. Sentences (1)–(3), introduced earlier, are examples of such sentences. Each corresponds to one of three different conditions.

In a between-groups design, subjects were randomly allocated to one of these three conditions, named PREMOD (pre-nominal modifier, $N = 14$), POSTMOD (post-nominal modifier, $N = 11$) and COORD (coordination, $N = 16$). Subjects in each condition were presented with negated conjunctions expressed in one of these three forms.⁵ Within each condition, subjects were randomly assigned to one of three random sentence orderings in order to control for possible priming effects within the stimulus sentences.

Data Collection and Encoding

Each worksheet was encoded independently by two coders. The FOL sentences and features of the diagrams⁶ were recorded for each subject along with the condition that they were in. We also encoded which of the random sentence-orderings the subjects saw, but this information was not used for this study, as no systematic ordering effects were observed. Where they differed, the independent codings were

⁴These included guide lines for distinguishing large objects from small ones.

⁵The POSTMOD condition included an even mix of sentences with pattern expressed as a prepositional phrase (as above) and as a relative clause, as in *q is not a circle that’s striped*. In the COORD condition, the order of the predicates was varied, with some sentences of the form *q is not striped and circular* and others of the form *q is not circular and striped*. For the three sentences in the PREMOD and POSTMOD conditions which mention size and pattern but not shape, the word *object* is used as the noun (see the sentences describing **d**, **h**, and **p** in Table 1). Finally, in the POSTMOD condition, pattern is expressed post-nominally, but size is expressed as a pre-nominal adjective, as in the PREMOD condition, because the formulation *k is not a circle with small* is ungrammatical.

⁶These were encoded as large/small, striped/dotted, circle/triangle or as ‘unclear’ (if, for instance, a medium sized object were drawn), ‘unspecified’ (if, for instance, a shape were drawn with neither stripes nor dots), or ‘other’ (if, for instance, a square were drawn instead of a triangle or a circle).

Table 2: Readings: FOL scope by negation sentence condition

CONDITION	SCOPE		
	Wide	Left	Right
PREMOD ($N = 126$)	100%	0%	0%
POSTMOD ($N = 99$)	99%	1%	0%
COORD ($N = 132$)	42%	50%	0%

Table 3: Realizations of sentences with ‘negatable heads’

CONDITION	REALIZED AS NEGATED		
	Both	Head Only	Mod. Only
PREMOD ($N = 68$)	34%	25%	41%
POSTMOD ($N = 38$)	21%	21%	58%

Table 4: Realizations of modifier-only (headless) sentences

CONDITION	REALIZED AS NEGATED		
	Both	First Only	Second Only
PREMOD ($N = 32$)	47%	18%	35%
POSTMOD ($N = 18$)	50%	17%	33%
COORD ($N = 52$)	71%	14%	15%

arbitrated by a third coder, who resolved disagreements.⁷

Results

Translations into FOL

We can measure the accuracy with which subjects completed the task of translating into FOL by considering their success in expressing an expected reading of each sentence. In the case of filler sentences, there is a unique expected FOL sentence, while for experimental sentences there are three possible readings for each. 78.6% of translations were expected. 92% of unexpected sentences were produced by four of the participants. Table 2 shows the proportions of each reading obtained for the experimental sentences.

Participants in the PREMOD and POSTMOD conditions almost universally wrote wide-scoped readings: only one sentence out of 225 was translated with a narrow-scoped reading. Subjects in the COORD condition displayed markedly different behavior. Table 2 gives the breakdown by condition, but the results are interesting when broken down by subject. 43.7% of subjects produced a wide-scoped reading for all (25%) or all but one (18.7%) of the nine sentences. 50.0% of these subjects always produced a narrow-scoped reading, and all of these were narrow-scoped-left.⁸ The subjects who produced wide-scoped reading for all but one of the sentences were the only subjects to produced a mix of wide-

and narrow-scoped readings. In short, participants were systematic, with 50.0% always translating with narrow-scope-left, and 43.7% (almost) always translating with wide scope.

Thus, the results are consistent with Hypothesis 1: When subjects are asked to translate from one representation (NL) into another (FOL) that permits underspecification to be maintained, then the underspecification is indeed maintained. This is almost universally the case in the PREMOD and POSTMOD conditions, and also the case in around half of the COORD condition sentences, consistent with the fact that the latter are syntactically ambiguous, and one of the two parses is consistent with an underspecified reading.

Diagrammatic Realizations

Tables 3 and 4 show the results of encoding the realizations that students produced in the diagramming task. We recorded the predicates in the sentence that were **realized as negated** in each diagram. If the sentence is *q is not a striped circle* and the drawing was of a dotted circle, the predicate Striped is realized as negated and Circle is not.

Table 3 shows the results for sentences which are expressed syntactically with a head and modifier.⁹ This pattern only arises in conditions PREMOD (*q is a striped circle*), and POSTMOD (*q is a circle with stripes*) in which the shape predicate is the head and the other is the modifier. The columns record whether both predicates, just the head predicate, or just the modifier predicate are realized as negated.

In the PREMOD and POSTMOD conditions, the sentences which do not mention shape (such as *d is not a large, dotted object*) contain a head predicate (*object*) which cannot be realized as negated. In COORD, all of the sentences lack a ‘negatable’ head (*q is striped and circular*). We will call such sentences **headless**, although this is not literally true in the PREMOD and POSTMOD conditions. Table 4 give the results for these sentences, with the columns indicating which modifier appears lexically first in the sentence.

Correspondence between Readings and Realizations

Recall that approximately half of the subjects in the COORD condition wrote FOL sentences corresponding to the narrow-scoped-left reading of the sentences. These subjects universally drew diagrams consistent with this reading.

This suggests a strong alignment of readings with realizations, perhaps because the subjects referred to their FOL while producing the realizations, or because they arrived at the same mental representation on reading the sentence in preparation for translation into FOL and again in preparation for drawing their realization.

Similarly, subjects with wide-scoped readings in all three conditions drew diagrams consistent with this reading, although there are fewer possible incorrect realizations for these readings.¹⁰ While variation in the narrow-scoped case

⁷The workbooks for all three conditions, an exemplar subject response, and the complete encodings can be downloaded from <http://openproof.stanford.edu/readingsandrealizations>.

⁸One subject (6.3%) wrote on the packet that the sentences were ambiguous, and submitted both a narrow-scoped left translation and a wide-scoped translation for each. Data for this subject was discarded.

⁹For convenience we talk from here on of ‘sentences with heads and modifiers’, although of course this refers to the heads and modifiers used in the descriptions of the objects.

¹⁰Subjects could only incorrectly realize *q is not a striped circle*

Figure 2: Asymmetric Parse Trees for Head-Modifier Constructions

would represent error (or at least inconsistency), variation in the wide-scoped case is expected.

Realizations of Wide-Scoped Readings

Subjects who obtained wide-scoped readings of the sentences have a choice of the realization that they can draw while remaining consistent with their reading. We focus on these subjects and that variability for the remainder of the analysis. Hence, we consider only the realizations for sentences with wide-scoped readings ($N = 100$ for PREMOD, $N = 63$ for POSTMOD, and $N = 60$ for COORD).

Heads vs. Modifiers

We first discuss the sentences that have heads that could have been realized as negated. These are just those sentences in conditions PREMOD and POSTMOD that mention the shape properties *circle* and *triangle*. For these sentences, the predicate which is expressed by a modifier is significantly more likely to be realized-as-negated than the predicate expressed by the head: In the PREMOD condition, the modifier is realized as negated 75% of the time while the head is realized as negated 59% of the time ($\chi^2 = 6.752$, $p < .01$). In the POSTMOD condition the modifier is realized as negated 79% of the time while the head is realized as negated 42% of the time ($\chi^2 = 10.794$, $p < .01$). Note that in some realizations both predicates are realized as negated.

This result mirrors that reported in (Cox et al., 2008). Our sentences analogous to *d is not a small dodecahedron* are those in the PREMOD and POSTMOD conditions which do not mention pattern. In our subjects' diagrams for these sentences, size was realized as negated significantly more often than shape. In 53.4% of the realizations of the 53 readings of the three sentences of the form *b is not a large triangle*, the size alone takes the negation. By contrast, participants negated just the shape or negated both predicates in only 22.3% and 24.3% of the realizations, respectively.

Modifier Choice

We now turn our attention to those sentences that only express properties via modifiers. All sentences in the COORD condition belong in this category, as do the sentences from the other two conditions which do not mention shape (e.g. *d is not a large object with dots*).

In 57% of the 105 realizations of these sentences, both predicates are realized as negated. In the 156 realizations of by drawing a striped circle.

the other sentences (those with heads), both predicates are realized as negated only 35% of the time. This is a highly significant difference ($\chi^2 = 14.656$, $p < .001$).

It seems that when both predicates are expressed as modifiers, subjects are likely to realize them both as negated (perhaps because they must negate at least one and there is no obvious means of deciding which), while if one is expressed as a head, its identity is likely to be preserved.

It is worth noting, as well, that the tendency to realize both predicates as negated is most pronounced for sentences in the COORD formulation: both predicates are realized as negated in 71% of the realizations in this condition ($N = 52$), compared with 47% and 50% of the realizations of headless PREMOD and POSTMOD sentences, respectively. This may be because, in wide-scoped parses of a COORD formulation, the conjunction attaches to both arguments symmetrically (see Figure 1, left), so there are no structural differences whatsoever between the expressions of the two predicates.

Discussion

The results just discussed suggest that Hypothesis 2 does not hold. When subjects are asked to translate from one representation (NL) into another (a diagram) that requires underspecification to be made specific, the way in which this is done depends on the syntactic form used in the source representation. In particular, if a property is expressed via a syntactic nominal head, it is less likely to be realized as negated than when it is expressed via as a modifier.

There are other possible explanations for the observed behaviour, which we consider briefly below.

Ontological Primacy: *Perhaps shape as a concept is less readily negate-able than the other predicates.*

Since the only heads occurring in our sentences are the shape nouns *circle* and *triangle*, perhaps the phenomenon is due to some ontological primacy accorded to shape, but not to the other predicates. In our materials, shape is primarily seen as a *type* of object, whereas the other predicates are *attributes* of objects. If shape were protected because of its ontological status, rather than because of the way it is expressed, we would see these same results in conditions PREMOD and POSTMOD, since the only heads appearing in our sentences are the shape predicates. However, if it were the ontological status of shape that were protected, we would expect it to be protected in the COORD condition as well, even though in that condition shape is expressed as a modifier.

Among sentences in the COORD condition, however, shape is realized as negated 77.0% of the time ($N = 39$) (Figure 3)—just as much (more, in fact) than the other predicates. This strongly suggests that shape, as a concept, is not protected.

Surface Proximity: *Perhaps participants simply tend to negate the predicate closest to the word not.*

In sentences such as *q is not a striped circle*, *striped* is closer to *not* and perhaps this accounts for the preference for realizing this predicate as negated.

Figure 3: Among realizations of sentences which mention shape, % which negate shape (TOP) vs. % which negate the other predicate—size or pattern (BOTTOM)

Figure 4: % of realizations of sentences which mention pattern and shape in which — predicate is negated.

PREMOD	<i>q is not a striped circle</i>	<i>N</i> = 33
POSTMOD	<i>q is not a circle with stripes</i>	<i>N</i> = 24
COORD	<i>q is not striped and circular</i>	<i>N</i> = 19

Looking at the readings of the three sentences which mention the predicates pattern and shape (Figure 4), we see that students are somewhat (though not significantly) more likely to negate just pattern than just shape in the PREMOD condition, where the pattern predicate occurs closest to the word *not*. However, when phrased so that the pattern predicate occurs farthest (in the POSTMOD condition with sentences like *q is not a circle with stripes*), we find that pattern continues to take the negation—this time, 2.8 times as often as just shape (more, in fact, than when it occurs in closer proximity to *not*). The difference in likelihood to realize-as-negated just the first vs. just the second predicate across the PREMOD and POSTMOD conditions is significant ($\chi^2 = 3.979, p < .05$). Moreover, we see no tendency whatsoever toward negating the closer predicate in the COORD condition, for any sentence.¹¹

Conclusion and Future work

We set out to test two hypotheses, one of which suggested that subjects would maintain underspecification in their representations if this were possible, and a second which suggested that, if subjects had to translate into a representation that required more specificity than the source representation, then the results would be the same for semantically-equivalent source representations.

¹¹(Kroch, 1974) proposes ‘a general surface ordering principle that fixes the initial scope order of the operator words in an English sentence according to their surface order’; however, in line with our findings, this claim is refuted by (Kurtzman & MacDonald, 1993).

The evidence from our experiment supports the first hypothesis. This allowed us to go on to test our second hypothesis, where the results turned out to be surprising: we demonstrated that the same semantic content, expressed in natural language in different ways, leads to different interpretations when subjects are asked to express that information in diagrams which require them to choose a more specific representation.

This is unexpected. Of course, it is not surprising that the particular form of an utterance has an impact on how that utterance is interpreted; but such variations are usually considered to be in the realm of pragmatics, and more concerned with connotation than with denotation. The results here, however, indicate that how something is expressed has an impact not only in terms of the pragmatic aspects of interpretation, but also in terms of the state of affairs in the world the utterance is taken to describe.

If we characterize shape via a noun, then it is less likely to be negated than if it is expressed via an adjective or other modifier. It would appear that it is how things are described, or how, in Langacker’s terms (Langacker, 1991), they are **construed**, that governs our interpretation; not what they are.

Abstract

We present a connectionist model of concept learning that integrates prototype and exemplar effects and reconciles apparently conflicting findings on the development of these effects. Using sibling-descendant cascade-correlation networks, we found that prototype effects were more prominent at the beginning of training and decreased with further training. In contrast, exemplar effects steadily increased with learning. Both kinds of effects were also influenced by category structure. Well-differentiated categories encouraged prototype abstraction while poorly structured categories promoted example memorization.

Keywords: exemplar memorization; prototype abstraction; category structure; neural networks; sibling-descendant cascade-correlation.

Introduction

One of the most fundamental abilities is learning to group things into categories. This faculty allows us to classify new examples and make useful predictions concerning their properties. Two general classes of models have been proposed to account for phenomena in concept learning: prototype and exemplar models. Prototype models claim that experience with items that belong to a given category results in the formation of a summary representation of all the items observed (Posner & Keele, 1968; Reed, 1972). Subsequent categorization of a new item is then based on a comparison between the prototype and the new item. Thus, the more similar a particular instance is to the abstracted prototype, the more likely it is to be classified as a category member (Homa & Cultice, 1984; Homa, Sterling, & Trepel, 1981). In contrast, exemplar models claim that all the observed items are remembered and that the categorization of a new item involves a comparison with items that are stored in memory (Hintzman, 1986).

There is ample evidence in favor of both prototype (Homa, et al., 1981; Posner & Keele, 1968) and exemplar models (Medin & Schaffer, 1978; Palmeri & Nosofsky, 2001), suggesting that both processes are used during category learning. What is more, the relative contribution of each mechanism to categorization might vary across development, as well as during training on a novel task. Early in development, categorization seems to be based on prototype representations while exemplar representations seem to increase with age (Hayes & Taplin, 1993; Mervis & Pani, 1980). There is also evidence that people are more

likely to rely on prototypes at the beginning of a categorization task, and as training progresses they rely more on memorized exemplars (Horst, Oakes, & Madole, 2005; Minda & Smith, 2001; Smith & Minda, 1998). These studies are consistent with a shift from early prototype use to later exemplar memorization.

In addition to the amount of experience with a categorization task, category structure also influences which type of information is most used. Better-structured categories can be represented as separate clusters in psychological space, whereas poorly structured categories overlap with each other (Figure 1). Smith and Minda found that better structured categories encourage the early prototype formation, while poorly structured categories discourage it, and may even strongly disadvantage the use of prototypes (Smith & Minda, 1998). Their findings are consistent with a number of other studies (Homa, et al., 1981; Horst, et al., 2005; Reed, 1978).

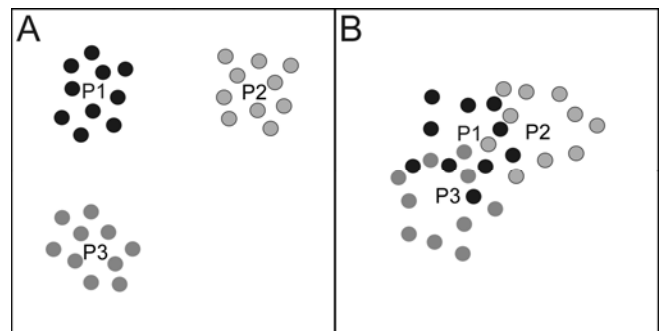

Figure 1: Hypothetical representations of three concepts. P1, P2 and P3 represent three prototypes and the circles represent examples of each concept. A: prototypes are relatively far from each other and examples are tightly clustered around their respective prototype, yielding concepts that are easy to distinguish. B: prototypes are close to each other and examples are more widely dispersed around their respective prototype, resulting in overlapping concepts that are difficult to distinguish.

The aim of this paper is to present a unified model able to simulate prototype and exemplar processes during concept learning. This unified model captures prototype and

exemplar effects with the same mechanism, as opposed to implementing two separate processes. We intend to demonstrate that it is possible for a unified mechanism to capture prototype and exemplar processes to different degrees depending on category structure and amount of training. We present here simulations with sibling-descendant cascade-correlation (SDCC) networks (Baluja & Fahlman, 1994), which offer several demonstrated advantages including automatic network construction, rapid and strong learning, and psychological and neurological plausibility (Shultz, 2003, 2006; Shultz, Mysore, & Quartz, 2007; Shultz, Thivierge, & Laurin, 2008). At the start, SDCC networks are composed of only input and output units. During training, examples were presented to the networks as specific activation patterns in the input layer. In encoder fashion, the networks gradually learned to reproduce this pattern on the output layer by changing the strength of the connections between the units and by recruiting and organizing new hidden units as needed.

In such networks, a relatively small number of units can store a large number of representations, with each representation being a specific pattern of activation across the units. These representations are relatively distributed, as opposed to being localized in single units. Because of its distributed nature, a network is likely to represent similar items as similar patterns of activations on the hidden units. The connection weights between the units reflect all trained items; thus, they represent something similar to a prototype, or an average of the trained concepts. Even if the networks are never presented with the category prototype, they are likely to falsely recognize it because it is so similar to many of the trained items. In addition, because the networks retain some specific information about the trained items, they show a familiarity effect when presented with old items, which is typical of exemplar models (Shultz, *et al.*, 2008).

The networks exhibit a prototype effect if they perform better when presented with examples that are similar to the hypothetical prototype (typical examples) than when they are presented with examples that are less similar to the prototype (atypical examples). We also tested whether the networks memorized some of the features of the trained examples. If our networks become more familiar with the trained examples and perform better when presented with old rather than new examples, regardless of distance from the prototype, then they reveal an exemplar effect.

We studied the impact of category structure and amount of training on prototype and exemplar effects. We manipulated category structure by changing the similarity between the prototypes of the trained categories and the similarity between each example and its prototype. Better-structured categories have more dissimilar prototypes and examples that are more similar to the prototype of their category (in other words, examples that are more tightly clustered around their prototype). To study the impact of training experience, networks were presented with varying numbers of training trials.

Method

As in past work (Shultz, *et al.*, 2008), we trained SDCC networks in encoder mode. Encoder networks learn to encode the input signal onto the hidden units, and then decode that hidden unit signal back onto the output units. Because error is computed as the sum-squared difference between input and output activations, this can be construed as self-supervised learning, without an externally-provided category name as target output. This type of learning occurs when people are not given information about category membership; hence, they can freely create concepts based on their observation of the examples (Homa & Cultice, 1984). In contrast, learning with category labels is much simpler and quicker. In typical encoder fashion, there were no input-output connections in our networks because such connections would have made the learning too simple.

Also as in Shultz *et al.* (2008), we trained the networks with examples belonging to four concepts. Each example varied on ten binary dimensions. A prototype was first constructed by randomly assigning values of 0.5 or -0.5 to each dimension. We refer to it as the prototype of the loner concept because it was relatively isolated from the other three concepts. Another 10-dimensional vector orthogonal to the first one was randomly selected (the normalized inner product between these two vectors was zero). From this orthogonal vector, three prototypes were created by randomly flipping one, two or four values. Flipping a value means reversing its sign. These three prototypes were much closer to each other in the 10-dimensional space than to the loner vector. We refer to them as the trio.

Nineteen examples were created from each prototype by flipping one or several values depending on the condition. Fifteen of these examples were used for training the networks, while four were used only during the test. Out of the fifteen trained examples, ten were closer to the prototype than the other five, i.e. they were created by flipping fewer values. We refer to the examples that were created through fewer flips as the close examples, and to the other ones as the far examples.

For each of the four concept prototypes, we manufactured examples by flipping 1, 2, 4, or 8 values of the prototype, randomly selected without replacement, depending on condition and subject to three additional constraints: (a) each example had a unique combination of features to flip, ensuring example uniqueness, (b) each feature was flipped in at least one example, and (c) no feature was flipped in every example. This last constraint ensured that no defining features were inadvertently created.

Out of the four examples that were used only during the test, two were close and two were far from the prototype. The networks were also tested on four of the trained examples, two that were randomly selected from the close examples, and the other two, from the far examples. Thus, testing consisted of presenting the networks with eight examples: two close trained examples, two far trained examples, two close test examples, and two far test examples. An exemplar effect is established if the networks

perform better on the trained examples than on the new test examples. Superior performance on the close examples versus the far ones demonstrates a prototype effect.

We manipulated the structure of the categories, which was determined by two factors. First, the number of flips that were applied to the vector orthogonal to the loner to create the trio was varied. Applying fewer flips means that the three concepts are closer to each other, while performing more flips means that the concepts are more distinct from one another. Second, we varied the number of flips applied to the loner and the trio to create examples. Fewer flips indicate that the examples are more tightly clustered around their prototype, while more flips imply a more dispersed distribution of the examples. These two manipulations affect the overall distinctiveness of the concepts. The concepts are more separate from one another with more prototype flips and fewer example flips.

Three levels of category structure were defined. The number of flips applied to the vector orthogonal to the loner to create the trio was 4 (Condition Easy), 2 (Condition Intermediate), or 1 (Condition Difficult). The number of flips applied to each prototype to create the close examples was 1 (Condition Easy), 2 (Condition Intermediate), or 4 (Condition Difficult). Finally, the number of flips applied to each prototype to create the far examples was 2 (Condition Easy), 4 (Condition Intermediate), or 8 (Condition Difficult).

The three conditions may be conceptualized as three levels of difficulty of a categorization task. Condition Easy was the easiest task because the examples were tightly distributed around their prototype and the concepts were well-differentiated. Condition Difficult was the hardest task because the examples were widely dispersed around their prototype and the concepts overlapped. Condition Intermediate was an easier task than Condition Difficult, but harder than Condition Easy. The concepts overlapped less than in Condition Difficult, but they were not as well differentiated as in Condition Easy.

To study the influence of training experience, the networks were trained for different numbers of epochs, varying from 5 to 700. An epoch is a training period during which a network is exposed to all trained examples once in random order. The networks were trained for 5, 10, 25, 50, 75, 100, 200, 300, 400 or 700 epochs. Twenty networks were trained for each number of epochs in each of the three conditions, for a total of 600 networks.

Results

We reserve a detailed discussion of all our findings for a longer paper and we describe here only some of the most important results. We chose network error as the dependent measure, error being defined as the sum of the squared differences between inputs and outputs. Because network error is the difference between the input and output patterns, it reflects familiarization with the examples – how well the networks recognize the examples. Thus, lower network error indicates a higher level of familiarization with the examples.

As training progressed, the mean network error decreased in all three conditions, reflecting the networks' increased familiarity with the examples. At the end of training, the mean error for the trained examples approached zero. The mean error for the new test examples was higher than the error for the trained examples, although it had decreased considerably during training. This indicates that the networks learned the trained examples very well, and at the same time generalized their acquired knowledge to the test examples never seen in training.

The most central findings of the simulations are illustrated in Figures 2 and 3. The figures show the prototype and exemplar effects in each condition as a function of the number of epochs.

Figure 2 shows the prototype effect calculated separately for the trained and for the new test examples. We calculated the prototype effect for each network by subtracting the mean error for the close examples from the mean error of the far examples. Thus, the prototype effect on the trained examples is the difference between the error for the far-train examples and the close-train examples. The prototype effect on the test examples is the error difference between the far-test and the close-test examples. A positive difference indicates a prototype effect, that is, smaller error for the examples that are more similar to the prototype.

Figure 3 illustrates the exemplar effect calculated separately for the far and the close examples. We calculated the exemplar effect by subtracting the mean error for the train examples from the mean error of the test examples. The exemplar effect on the close examples is the error difference between the close-test and the close-train examples. The exemplar effect on the far examples is the error difference between the far-test and the far-train examples. A positive difference indicates an exemplar memorization effect, which means that the error is smaller for the trained examples than for the test ones; or, in other words, that the networks are more familiar with examples that have already been encountered than with novel examples.

We performed an ANOVA on the error differences shown in Figure 2 with the within-network factor Train vs. Test Examples and the between-network factors Number of Epochs and Condition. We performed a similar ANOVA on the error differences shown in Figure 3. All main effects and interactions were reliable in both analyses, minimum $F(9, 570) = 4.54, p < .001$. We analyzed these effects separately for each condition, and found that all main effects and interactions were significant, minimum $F(9, 190) = 2.49, p = .010$, except the main effect of Epoch in Condition Difficult in Figure 2, $F < 1$. Hence, we describe the results without referring to more detailed statistical tests because all the effects we discuss are licensed by these significant main and interactive effects.

Category Structure

The difficulty of the task had a sizeable impact on the prototype effect (Figure 2). The prototype effect was quite

large in Condition Easy and somewhat smaller in Condition Intermediate. This effect was reversed in Condition Difficult as demonstrated by the negative difference scores; networks' error was higher for the close examples than for the far ones. The close examples in Condition Difficult shared a high degree of similarity, causing the networks to easily confuse them with each other. Thus, examples that

shared a high degree of similarity with their prototype no longer had an advantage over ones that did not. This finding is consistent with Smith and Minda's (1998) psychological results. They found a reversed prototype effect with poorly structured categories. Thus, the prototype effect diminished and even reversed as the difficulty of the task increased.

Figure 2: Prototype effect on the trained and the new test examples.

Figure 3: Exemplar effect on the examples that were close and those that were far from the prototype.

In contrast, the exemplar effect increased with the difficulty of the task (Figure 3), which is also consistent with psychological data (Minda & Smith, 2001; Smith & Minda, 1998). The networks relied more on exemplar memorization as the task became increasingly difficult and the prototype representation no longer provided useful information for discriminating the categories.

Amount of Training

The exemplar effect increased with the number of epochs in every condition (Figure 3), simulating Smith and Minda's psychological results (Minda & Smith, 2001; Smith & Minda, 1998). The prototype effect on the trained examples, on the other hand, decreased with the number of epochs in Conditions Easy and Intermediate, but was less affected by the number of training epochs in Condition Difficult. The decreasing prototype effect for the trained examples is consistent with Smith and Minda's results with trained examples. They did not test new examples in their experiments. Our networks make another novel prediction, namely that the prototype effect should increase with training for new test examples, especially if the categorization task is easy (left panel of Figure 2).

Networks became increasingly familiar with trained examples because they could memorize them. As training progressed, networks' recognition of trained examples relied more on individual memories, and less on their similarity to the prototype (just as with Smith and Minda). In contrast, novel examples had not been memorized. Hence, recognition of novel examples relied solely on their similarity to the prototype, and this prototype effect increased during training presumably because the prototype representation became increasingly well-defined.

Interaction Between Exemplar and Prototype Effects

The prototype effect was greater for new test examples than for old, trained ones (Figure 2). This finding seems realistic because only the trained examples could be memorized. Furthermore, the exemplar effect was stronger on the far examples than on the close examples in Conditions Easy and Intermediate (Figure 3, left and middle panels). Features of atypical instances were better remembered than those of typical instances. This presumably occurred because there was less interference between the memories of the atypical examples than between the similar memories of the typical examples. This is consistent with Light, Kayra-Stuart and

Hollander's (1979) finding that adults' recognition memory is better for atypical rather than typical faces. Similar results were found by Going and Read (1974) and Cohen and Carr (1975).

In Condition Difficult (right panel of Figure 3), however, the exemplar effect was larger on the close examples than on the far ones. The close examples were disadvantaged by their similarity to their prototype (because of the overlap between the categories); hence, these examples may have been the ones that benefited most from exemplar memorization. Reitman and Bower (1973) reported a similar effect with adult participants who were trained on an easy or a difficult categorization task. Following training, participants were given a recognition test. The results for the easy task were similar to Light *et al.*'s (1979) psychological results and our simulations in Conditions Easy and Intermediate: recognition performance was better for atypical examples. In contrast, their results for the difficult task were reversed: recognition performance was better for typical examples, matching our simulations in Condition Difficult.

Thus, prototype and exemplar effects seem to complement each other, each process having a stronger influence on the examples that are not favored by the other.

Discussion

We demonstrated that a unified model can capture both prototype and exemplar effects. The networks abstracted concept prototypes and at the same time remembered some features of the trained examples.

Networks also successfully simulated the prototype-to-exemplar trend as the learning task increased in difficulty (Minda & Smith, 2001; Smith & Minda, 1998). Our networks also showed an increase in the size of the exemplar effect from Condition Easy to Condition Difficult, as the concepts became more poorly structured. At the same time, the prototype effect substantially decreased and even reversed as difficulty level increased. For better-structured concepts (Conditions Easy and Intermediate), the exemplar effect was greater farther away from the prototype; for poorly structured concepts (Condition Difficult), the exemplar effect was greater closer to the prototype. As we mentioned earlier, this is consistent with a number of psychological studies.

The networks also exhibited a shift from prototype use to exemplar memorization during training. We observed an increase in the exemplar effect and a decrease in the prototype effect on the trained examples. Better memorization with more training makes perfect sense, as memorization depends on the amount of experience. A possible reason for the decrease in the use of prototype information for the trained examples is that it is less needed as the examples are better remembered. This is consistent with psychological studies reviewed earlier (Hayes & Taplin, 1993; Horst, *et al.*, 2005; Mervis & Pani, 1980; Minda & Smith, 2001; Smith & Minda, 1998).

Other studies, however, reported that exemplar information is used earlier in development, and the ability to abstract a prototype emerges later (Fisher & Sloutsky, 2005; Sloutsky & Fisher, 2004; Tighe, Tighe, & Schechter, 1975). Fisher and Sloutsky (2005), for instance, found that younger children's memory for trained items was significantly better than that of older children and adults, suggesting that the latter relied more on an average prototype representation.

It is important to note a key difference with these studies. The studies finding an exemplar-to-prototype shift used concepts with defining features, while those that found a prototype-to-exemplar shift did not (and neither did our simulations). Defining features are present in all examples that belong to a category, and only in those, allowing perfect categorization performance. For example, Tighe *et al.* (1975) used a word classification task in which names of animals belonged to one category, while body parts belonged to another. Following this classification task, adults were less likely to correctly recognize a previously encountered example than children. Tighe *et al.* proposed that adult participants used the defining feature as an encoding device and learned less about the other features of the words. In contrast, children are less likely to use defining features (Keil & Batterman, 1984), which may result in better memorization of the probabilistic features.

Interestingly, Shultz *et al.* (2008) successfully simulated this shift from probabilistic feature learning to the use of defining features using the same kind of networks presented here. To test the hypothesis that defining features affect exemplar memorization in the present work, we repeated the simulations for Condition Intermediate, but added two defining features to each example. Although exemplar memorization did not decrease with training (on the contrary, it increased), overall network error was higher in the simulations with defining features. These networks were less familiar with the trained examples than if they had been trained without defining features. This is consistent with Tighe *et al.*'s (1975) finding that adults, who use defining features more readily than children, exhibit poorer recognition performance. This explains why Tighe *et al.* and other researchers who also used defining features (Fisher & Sloutsky, 2005; Sloutsky & Fisher, 2004) found better memorization of exemplars in children than in adults.

To conclude, our simulations further decrease the gap between the numerous incongruent studies reported in the literature regarding the development of exemplar and prototype effects during category learning. Indeed, considering factors such as the structure of the categories and the presence of defining features, there is considerable, unexpected coherence in these mixed results. Most importantly, we have demonstrated that it is possible for a single mechanism to capture a gradual shift in concept processing depending on task difficulty and the amount of experience.

Person, place, and past influence eye movements during visual search

Abstract

What is the role of an individual's past experience in guiding gaze in familiar environments? Contemporary models of search guidance suggest high level scene context is a strong predictor of where observers search in realistic scenes. Specific associations also develop between particular places and object locations. Together, scene context and place-specific associations bias attention to informative spatial locations. At the level of eye fixations, it is not known whether a person's specific search experience influences attentional selection. Eye movements are notoriously variable: people often foveate different places when searching for the same target in the same scene. Do individual differences in fixation locations influence how a scene is subsequently examined? We introduce a method, comparative map analysis, for analyzing spatial patterns in eye movement data. Using this method, we quantified the consistency of fixated locations within the same observer and between observers during search of real world scenes. Results indicated a remarkable consistency in the locations fixated by the same observer across multiple searches of a given scene. This observer-specific guidance was shown to be distinct from general scene context information or familiarity with the scene. Accordingly, this is considered evidence for a uniquely informative role of an individual's search experience on attentional guidance in a familiar scene.

Keywords: visual search; eye movements; scene perception; learning; attentional guidance; fixation similarity

Introduction

An important feature of ecological visual search is that there are few truly novel, unfamiliar places in which a person is likely to search. Many tasks involve examining the same place repeatedly, such as the various times spent searching for a specific utensil in one's own kitchen. Locating the target in question benefits from both category based information (e.g. utensils are on countertops) and place specific information (e.g. in this kitchen, utensils hang over the stove). For any observer, there will be many sources of information that guide which scene regions are inspected during search. What influence does a person's own search experience (i.e. fixation locations) have in guiding where they are likely to look in familiar scenes?

A growing body of evidence suggests that observers use high level information, such as learned target features and global scene context, to guide their gaze when searching for an object in real world environments (Ehinger, Hidalgo-Sotelo, Torralba, & Oliva, 2009; Hwang, Higgins, Pomplun, 2009). At this level of *categorical* representation, knowledge of the basic-level scene category and target

features directs gaze to expectation-based scene regions (Eckstein, Drescher & Shimozaki, 2006; Henderson, 2003; Torralba, Oliva, Castelano, & Henderson, 2006). At the level of *scene exemplar* representations, spatial context can also be used to allocate attention preferentially to regions that have become associated with the target. In contextual cueing, for example, observers implicitly learn patterns in repeated displays that help them find a target faster in repeated configurations (Chun & Jiang, 1998). It is not well understood, however, whether a scene exemplar representation can systematically bias individual fixations.

How can "experience based" influences be distinguished from the myriad of sources that guide attention to relevant scene regions? One challenge is that attention is strongly guided by information that does *not* depend on specific experience. Figure 1 illustrates regularities in eye fixations across and within observers. In Figure 1A, fixations from 9 observers searching for a book are shown; the high fixation density along countertop surfaces illustrates how spatial layout and context guide where observers look. Systematic biases unrelated to the scene's content also influence gaze location. In Figure 1B, fixations sampled from random scenes have been projected onto the kitchen scene. Center bias in the fixation distribution is driven by oculomotor tendencies (Tatler, 2007; Tatler & Vincent, 2009) and photographer bias. A second challenge, of the opposing nature, lies in the significant variability in fixation locations across individuals. As a result, two independent observers may fixate different scene regions, even when looking for the same object in the same scene (Figure 1C). It is possible that individuals are biased by experience, but that the effects are masked by pooling over experienced observers. Given initial differences in search patterns, could systematic differences arise when an observer repeats her search of the scene? To reasonably estimate the influence of past experience, the search patterns of observers who have *never* viewed the scene must be contrasted with different observers who have *previously* searched the scene.

In this paper, eye movement data from a visual search study was analyzed using approach we have termed comparative map analysis. This analysis was used to evaluate how different sources of information contribute to attentional guidance during visual search of familiar scenes. In our experiment, observers' eyes were tracked while they looked for a book in pictures of real world scenes. On some trials, observers searched a scene that had been presented previously. Importantly, the target object and location remained unchanged in each presentation of the scene. The

main question was whether a person’s past experience (as measured by fixated locations) biases attentional selection when searching a familiar scene. Using comparative map analysis, we show that visual attention is sensitive to the influence of a person’s past experience of searching in familiar scenes.

Figure 1: Regularities in eye movements while searching for books. (A) Fixations from 9 observers searching for a book in this kitchen (green dots). Context and spatial layout constraints guide search (e.g. high density along countertop surfaces in the foreground and background). (B) Fixations sampled from random scenes and projected onto this scene (pink dots). Oculomotor and photographer bias contribute to a roughly central fixation distribution with sparse fixations in the image periphery. (C) Fixations from 2 observers who repeatedly searched this kitchen. Each row shows fixations from: the observer’s first search (Left, red dots), and the next 7 search trials (Right, blue dots). Individual differences in fixation patterns are evident, before and after learning.

Comparative Map Analysis

The approach we describe here as comparative map analysis is used to evaluate how well different distributions of fixations predict where observers will look in a scene. Critically, each fixation distribution is sampled from a different, strategically chosen, population of fixations. The resulting distributions are evaluated in regards to how well they distinguish between fixated and unfixated locations. In the present paper, this analysis was used to determine whether an observer’s experience plays a significant role in attentional selection during search.

Logic of the approach. Given the challenges outlined in the introduction, how can we isolate the bias resulting from an individual’s experience searching a *specific* scene? The solution lies in strategically identifying fixation populations relevant to the question of interest. One population, for example, includes the locations fixated by novel searchers in a given scene. A second population includes the locations fixated by a *single observer* when the same scene was repeatedly searched. While the first population represents the influence of (general) scene context on search, the second population reflects the specific influence of the observer’s own examination of the scene. Fixation maps were created for each population and used to predict fixation locations from a separate trial. If the two populations are equally informative, then there will be no significant difference in the accuracy between the predictions. The logic is analogous to established methods for determining whether fixated and control locations can be discriminated (e.g. Parkhurst & Niebur, 2003; Tatler, Baddeley, and Gilchrist, 2005). In those studies, the two distributions represent measurements of a dependent variable (e.g. visual feature content) at fixated versus unfixated locations. If the dependent variable successfully discriminates between these locations, then it is considered to inform fixation selection. Control distributions, it should be noted, can be constructed in several ways. Recent studies of attentional guidance have constructed control distributions by randomly sampling fixations from other populations (e.g. Ehinger et al, 2009; Tatler et al, 2005; Tatler & Vincent, 2009). Comparative map analysis extends this rationale by defining several control populations that vary with respect to the degree of “person,” “place,” and “past” information represented.

Broadly, we consider three *scene dependent populations* representing scene regions empirically fixated by observers when searching that specific scene: (1) Fixations made by a single observer’s repeated searches, (2) Fixations of other observers who searched the scene repeatedly; (3) Fixations of novel observers (i.e. searched the scene once). Importantly, these populations represent slightly different sources of information: self-consistency, scene familiarity and general scene context, respectively.

Control populations are crucial to assess the relative informativeness of other regularities (e.g. oculomotor biases) in predicting the same eye movements. These *scene independent populations* provide controls for different sources of information: (4) Fixations from the same observer on random scenes, (5) Fixations from different observers on random scenes. These populations reflect spatial biases in oculomotor behavior that manifest across the set of scenes (intra-observer and inter-observer biases respectively). Two simple model-based populations (as opposed to sampling from empirical fixations) serve as controls to evaluate the extent to which a central gaussian distribution (6) and uniform distribution (7) predicted observers’ fixations. The uniform distribution serves as the true measure of chance, while the widely recognized central fixation bias in human eye movements (Tatler, 2007)

suggest that a central gaussian distribution may predict fixations above chance level.

Building fixation maps. Fixation maps were created for each of the above populations using the following procedure, shown schematically in Figure 2. First, we collected a list of the locations fixated by one observer in all repeated searches of a scene; trials in which the eye was lost or the observer failed to find the target object were not included. For each repeated search trial R , a self-consistency fixation map (1) was built by excluding fixations from one search trial and using the remaining N fixations to define a prediction map. Next, the other fixation maps were created by sampling N times from the appropriate population of empirical fixations (2-5) or statistical model (6-7). This process was iterated for R repeated search trials, and the resulting fixation maps were used to predict the excluded trial's fixations (probe fixations).

Figure 2: Schematic of comparative map analysis. This illustrates the source of fixation populations (1-5) and how they are sampled to create fixation maps that represent several influences on eye guidance. The following steps are performed iteratively for each of R trials: select one search trial (i.e. first 3 fixations of one trial) from F_{self} ; use the remaining N fixations to create a prediction map for intra-observer similarity. Fixation maps for populations (2-5) are created by sampling N times from the corresponding distributions. Red (familiar observers) and blue (novel) outlines represent scene dependent populations. Dashed outlines indicate non-self fixation populations.

In the present analysis, the first 3 *search* fixations in each search trial were used to build the fixation maps. Search fixations are defined as fixations made during active exploration of the scene, thus excluding fixations landing on the target and the initial central fixation. The maps were compared in terms of how well they predicted the first 3 search fixations of the excluded trial. Given past findings that the consistency of fixation locations across observers decreases over time (Mannan, Ruddock, Wooding, 1997; Yabus, 1967), we used the first 3 search fixations because

it represented a time window appropriate for capturing the highest consistency across novel and repeated conditions.

Evaluating fixation maps. We used the Receiver Operator Characteristic to evaluate how well fixated and unfixated locations could be discriminated. The ROC curve is a common signal detection technique that represents the proportion of real fixations falling within a fixation map (detection rate) in relation to the proportion of the image area selected (false alarm rate) (e.g. Ehinger et al, 2009; Renninger, Verghese, & Coughlan 2007; Tatler et al, 2005). The area under the curve or AUC area (Green & Swets, 1966) was used to compare differences in prediction maps.

Search Experiment

In this experiment, observers searched for a book in indoor scenes (e.g. kitchens, bedrooms) while their eye movements were recorded. The original goal of this study was to investigate how time influenced the retrieval and use of scene specific associations to guide search in realistic scenes. We examined this by introducing a variable stimulus onset asynchrony (SOA) between the scene onset (observers fixating centrally) and the initial search fixation on the scene. We predicted that there would be an interaction between scene familiarity and SOA, such that longer delays would predict shorter search times on familiar, but not novel, scenes. For the present analysis, the eye movements collected from this study were collapsed across the retrieval-time manipulation since this variable was tested using a within-subject design.

Participants. Eighteen observers, ages 18-34, with normal acuity gave informed consent, passed an eyetracking calibration test, and were paid \$15/hr for their participation.

Materials. Eye movements were collected using an ISCAN RK-464 video-based eyetracker with a sampling rate of 240 Hz. The stimuli were high resolution color photographs of indoor scenes presented on a 15" LCD monitor with a resolution of 1280 x 1024 px and refresh rate of 60 Hz. The original images were cropped and resized to be presented at a resolution of 1024 x 768 px, subtending 30 x 20 deg of visual angle. Presentation of the stimuli was controlled with Matlab and Psychophysics Toolbox (Brainard, 1997; Pelli, 1997). The target prevalence in the stimuli set was 100%: all scenes contained a target and, importantly, the target location never changed in a particular scene. To make the task challenging, book targets were small (from 1 to 2°) and spatially distributed across the image periphery.

Procedure. The experiment consisted of a learning phase followed by a probe phase. In the learning phase, observers learned associations between specific scenes and a book's location in each scene. In the probe phase, observers searched following a variable SOA (200, 400, 800, or 1600 ms) on a novel or familiar scene. In both phases, observers freely explored the scene with their eyes. Each phase was comprised of 4 search blocks: 24 repeated search trials and 8 novel search trials presented randomly in each block. Scenes were counterbalanced across observers with respect

to the novel or repeated conditions. The trial sequence, similar in learning and probe phases, is as follows. Observers fixated a central fixation cross for 500 ms to begin the trial (gaze contingent). First, a scene was presented with a fixation cross superimposed over the scene; observers fixated the central cross for the duration of this interval without saccading away otherwise the trial ended. In the test phase, this was followed by a variable SOA on a gray screen. Finally, the same scene was presented again and observers actively explored the scene to find the book. Observers had a maximum of 8 s to respond via key press (learning phase) or by fixating the target for 750 ms (probe phase). Feedback was given after each trial (reaction time displayed for 750 ms) to encourage observers to search speedily throughout the experiment. The entire experiment lasted approximately 50 min.

Eyetracker calibration was critical for the gaze contingent aspects of the procedure, as well as to ensure accurate dependent measures (fixation locations). For this reason, calibration was checked at 9 locations evenly distributed across the screen after each search block; fixation position had to be within 0.75° of visual angle for all points, the experiment halted and the observer was recalibrated.

Eye movement analysis. Fixations were identified on smoothed eye position data, averaging the raw data over a moving window of eight data points (33 ms). Beginning and end positions of saccades were detected using an algorithm implementing an acceleration criterion (Araujo, Kowler, & Pavel, 2001). Specifically, the velocity was calculated for two overlapping 17 ms intervals; the onset of the second interval was 4.17 ms after the first. The acceleration threshold was a velocity change of 6 deg/s between the two intervals. Saccade onset was defined as the time when acceleration exceeded threshold and the saccade terminated when acceleration dropped below threshold. Fixations were defined as the periods between saccades. Saccades within 50 ms of each other were considered continuous.

Comparative map analysis. Forty eight scenes were searched by equal numbers of participants in the novel and repeated conditions. Search trials in the learning and probe phases, excluding block 1, were combined to yield a maximum of 7 repeated trials for each observer. The following experiment conditions correspond to each population: (1) One observer's repeated searches of a familiar scene, (2) *Other* observers' repeated searches of the same familiar scene. (3) Different observers' *novel* search of the same scene. (4) Any scene searched by the same observer. (5) Any scene searched by other novel observers.

Results

The results of comparative map analysis are shown in Figure 3. Our main finding is the evidence of experience based influences on attentional selection, specifically during the first 3 search fixations in a scene. An identical pattern of results was found when using only the *first* search fixation. We first report the results from the populations based on

scene dependent information (F_{self} , F_{group} , F_{novel}), followed by the scene independent control populations.

Role of the person

The role of a person's own search experience was evaluated by using the locations of their own fixations (F_{self}) to predict empirical fixations from the same observer on a separate search of the same image. We found that this population provided the most accurate predictions (mean AUC=0.907) relative to the other scene dependent populations F_{group} ($t(94)=5.41$, $p < 0.001$) and F_{novel} ($t(94)=6.57$, $p < 0.001$), and was significantly higher than control populations. Interestingly, observer's own population of fixations resulted in the most consistently accurate predictions across the set of images, as evident in the boxplot of figure 3.

Figure 3: Results of comparative map analysis on eye movement data from the book search experiment. Distributions shown in the boxplot show the median (red line), upper and lower quartile values (box), and outliers.

Is this influence in fact due to a person's *specific* search experience? Perhaps the experience of the individual is not unique from the experience of the group. This is a reasonable hypothesis, given that all observers have the same opportunity to learn the association between the scene's identity and the location of a book. To examine this hypothesis, we compare F_{self} and F_{group} .

Role of the past

The role of past experience was evaluated using the fixation locations from other observers who searched the same scene repeatedly (F_{group}). Interestingly, there was no significant difference between the prediction accuracy of this group and a group of novel observers (mean AUCs of 0.859 and 0.827, respectively; $t(94)=1.97$). This suggests that sampling from many individuals with past experience is not significantly more informative than sampling from the population of novel observers.

Role of the place

The role of the place is perhaps the most intuitive source of information: it represents how scene context drives consistency in fixation locations across different novel observers. We found that F_{novel} provided a significant source of guidance relative to the random scene control F_{scene} ($t(94)=11.7$, $p < 0.001$). Our finding confirms previous reports of overall high inter-observer consistency in search tasks (Ehinger et al, 2009; Torralba et al, 2006).

Scene Independent Control Populations

Two control populations were based on empirical fixations sampled from different scenes: F_{char} (same observer as F_{self}) and F_{scene} (different observers). These populations predicted fixations well above chance with mean AUCs of 0.669 and 0.666 respectively and were not significantly different from one another ($t(94)=0.11$). The overlap in these distributions is not surprising given that these populations reflect systematic oculomotor tendencies and regularities in the stimuli set (e.g. photographer bias). The two model distributions, central gaussian and uniform, were used to compare with the other populations and confirm intuitions about the results of comparative map analysis. Indeed, the central gaussian model was a better predictor of fixations than the uniform distribution ($t(94)=2.7$, $p < 0.05$).

Discussion

We have shown that the past repeats itself: a person's experience, as indexed by fixated scene locations, influences how they search familiar scenes. Although the notion of idiosyncratic gaze patterns has been previously presented (Noton & Stark, 1971), to the best of our knowledge, this is the first time observer-specific experience has been shown to influence gaze patterns in a naturalistic search task. What is the nature of the information that underlies this self-consistency effect? Is it behaviorally relevant or an incidental consequence of scene exposure? Is the encoded information object-based or spatially-based? How does self-consistency interact with other well characterized forms of search guidance (e.g. saliency)?

In order to refine our understanding of why intra-observer consistency occurs, it would be helpful to examine patterns across observers and scenes. Are certain scenes searched more consistently than others? This question can be approached in two ways. From the perspective of general

scene context constraints, scenes vary in the distribution of target-probable surfaces they contain. Looking for books in a library, for example, may present a significantly less constrained search than searching a bathroom. Still, the boxplot in figure 3 suggests the scenes are variable with respect to how consistently similar regions are selected by different viewers. From the perspective of person specific constraints, what is the relation between inter-observer and intra-observer consistency? One possibility is that scenes searched consistently by novel observers also promote self-consistency among a large proportion of familiar observers. Alternatively, high *variability* in intra-observer consistency (i.e. high F_{self} variance) may negatively correlate with inter-observer consistency. Identifying properties of the scene and task that promote self-consistency across searches remains an open question.

In the ecological psychology tradition (e.g. Gibson, 1979), our findings also raise questions about the behavioral significance of self-consistency. Are some observers more self-consistent than others? If so, what are the implications for the search task? One hypothesis is that *high* self-consistency may be associated with good search performance (e.g. fast overall reaction time). Indeed, a widely recognized feature of human memory relates to the benefit of reinstating the encoding context in retrieval (Jacoby & Craik, 1979; Tulving & Thomson, 1973). Furthermore, embodied cognition accounts suggest that a person's own movements may play a role in perceptual and cognitive performance (e.g. Knoblich & Flach, 2001). When imagining a previously viewed stimulus, for example, observers tend to make reenact patterns of eye movements from the initial viewing (Brandt & Stark, 1997; Laeng & Teodorescu, 2002; Spivey et al, 2001).

It is important to note the role of our task in driving similar patterns of viewing across observers. A number of recent studies have sought to predict where observers will look in naturalistic scenes. Many of these studies, however, deliberately employ free viewing (e.g. Bruce & Tsotsos, 2006; Itti & Koch, 2000) or a memory task (e.g. Foulsham & Underwood, 2008) so as to reduce the influence of having a common goal. Theories of visual search guidance (e.g. Wolfe, 1994) describe observers' deployment of attention as resulting from a combination of stimulus and goal driven factors. Seeing how the magnitude of self-similarity varies across tasks can serve as another approach to assessing the behavioral significance of intra-observer consistency. Recognition memory tasks, in particular, provide an opportunity to investigate the causal role of re-fixations in scene recognition. Holm & Mantyla (2007) used a remember/know paradigm to evaluate whether successful recognition was associated with similarity between an observer's fixations during study and test phases. Indeed, they found evidence that recollection ("remember" responses) were related to a high degree of study-test consistency. Recently, Underwood and colleagues (2009) investigated the roles of domain knowledge and visual saliency on fixation consistency in scene recognition. Their

findings again support the idea that observers look at scene locations that have been previously fixated and, interestingly, that the effect is stronger for individuals who were experts in the domain related to the picture.

Our experiment shows that observers have access to perceptual and memory based information that helps them locate the book in a familiar scene. What is the nature of this information? Two possibilities are that observers encoded the oculomotor movements to *spatial locations* (e.g. left side of the screen) or the *objects* (e.g. empty bookshelf) that were attended on the way to finding the target. One way to distinguish these possibilities would be compare the resulting search patterns when an observer initiates search from a familiar (e.g. center of the scene) or an unfamiliar location and comparing whether similar objects or locations were still fixated. Moreover, the speed of human eye movements (roughly 3-4 per second) suggests an automatic component to self-consistency that may not be available to conscious awareness. Although our experiment cannot speak to this issue directly, we found the same pattern of results shown in figure 3 using only observer's first fixation on the scene. This suggests that the information underlying self-consistency is rapidly available to bias eye movements.

Conclusion

Comparative map analysis, a novel approach for analyzing patterns in eye movement data, was used to evaluate the role of various sources of search guidance. We found evidence from a search study showing a uniquely informative role of an individual's experience on attentional guidance in a familiar scene

Abstract

The paper attempts to conceptualize the production and comprehension of spatial perspectives as the synchronization of intentions and contentions in a linguistic discourse. In doing so, it investigates the acts of intending and contending in invoking and instantiating the categories. The paper explains perspective setting and taking in terms of intending and contending which are crucial in shaping the conceptual route for the gradual revelation of the communicative intent. Answer to these questions, in turn, results into an understanding of what constitute the perspectivization process in a discourse.

Keywords: intention; contention; conceptual route; perspective taking; perspective setting.

Introduction

This paper investigates how spatial perspectives are represented and accessed in discourse due to the activation of linguistic expressions. We also explore how these explicitly language elements are situated and grounded. The term ‘language’ refers to the manner in which meaning potentials are invoked and realized at the time of discourse production and comprehension. The role of language in producing and/or comprehending a discourse is primarily an act of interpretation, since the emergence of meaning in a communicative situation is actually an outcome of the interpretive acts that unfold the structure of the communicative situation and the structuring capacities of the habitual attitudes of the mind (Rochberg-Halton 1982): While producing a discourse, we interpret our thought into language; whereas the discourse comprehension presumes the interpretation of language into the thought. We argue that linguistic expressions trigger two distinct cognitive functions – namely, intending and contending – while language spatial perspectives. These two cognitive functions are crucial in accommodating commonsense knowledge into the discourse interpretation through the act of language. We test our approach using spatial perspectives in *Bāṅlā* discourse, but the underlying ideas apply to the general question of how meaning is produced and comprehended in discourse.

Researchers have addressed questions related to the issues of spatial perspectives in language from different theoretical persuasions: In these studies, it has been shown that the production and comprehension of spatial descriptions presuppose the activation of asymmetries intrinsic to

conceptual categories (Clark 1973). These categories are termed as frames of reference (Levinson 1996; Landau & Hoffman 2005; Majid et al. 2004; Neggers et al. 2006). A frame of reference can function egocentrically or allocentrically. An egocentric frame of reference invokes body-based asymmetries to organize spatial coexistences. In interpreting coexistences, allocentric frames of reference employ external reference frames such as landmark based cognition.

The importance of a frame of reference, as it follows from Piaget and Inhelder (1948), lies in its capacity to mirror the invariant aspects of a category with respect to which perspectives are interpreted. Researchers – see Heine (1989), Heine et al. (1991), Levinson (1996, 2003), Gibbs (2005), Levinson and Wilkins (2006) and others – have studied the linguistic realization of frames of reference at the sub-sentential level in order to answer the following question: how does the linguistic realization of space project the underlying conceptualization of different frames of reference? The answer to this question, in turn, sheds light on old puzzles about the relation between world, language and thought. These ‘Whorfian’ concerns led researchers to explore spatial universals and their lexicalization in different languages. They are extremely useful in understanding the representation of space in language and in setting correlations between spatial language and spatial cognition.

In spite of these advances in exploring the linguistic realization of space, what remains unanswered is how the users of a language access those representations and correlations while processing a discourse. So, a further investigation of perspective *taking* is long overdue. Additionally, a shift of interest from studying sub-sentential expressions to the study of discourse, as Fauconnier (1981) stressed, will offer “a conceptually different, theoretically more promising, and empirically more broader, system of understanding natural language logic.” At the level of discourse, a static correlation between linguistic and cognitive categories is not enough. We also need to understand how these categories are grounded and situated; and, how higher order inferential judgments are integrated during the transformation of one spatial perspective into another (Karmakar 2009). The current investigation seeks to unveil the cognitive structures underlying the

perspectivization¹ process through the study of discourse. We investigate the following two questions: what cognitive functions are at work in perspectivizing space in discourse? How does the languaging of discourse manipulate these cognitive functions? These two questions will be discussed in this paper with reference to *Bāṅlā* language data.

Outline of the Approach

Spatial descriptions are perspectival, like any other linguistic communication (Mead 1938; Chakraborty 1992; Moore 1997; Coventry et al. 2009). In discourse, the descriptions of space, i.e. viewing arrangements, are languaged with respect to certain *vantage points*. A viewing arrangement, as Langacker (2008) defines it, is the ‘overall relationships between the “viewers” and the situation being “viewed”’. The process of producing and comprehending spatial viewing arrangements in discourse is termed here as *perspectivization* – that is the languaging of perspectives.

The act of perspectivization is a consequence of shared linguistic capacity (Akman 2000; Stalnaker 2002; Gibbs 2005), evolving through the generalization process (Mead 1934; Noe 2002; Kristiansen 2008; Langacker 2008) and enabling the interlocutors to understand one another’s communicative intent (Lewis 2002; Millikan 2004; Gehlbach 2004; Ganeri 2006). It is a complex phenomenon consisting of perspective setting and perspective taking (Graumann 2002).

The languaging of (spatial) viewing arrangements in discourse can be studied in terms of two cognitive functions associated with linguistic expressions that we term intending and contending. The function of an expression, while intending is to invoke the relevant conceptual category. A conceptual category is a systematic representation of interrelated knowledge systems (Laurence & Margolis 1999; Aarts 2006). For our purposes, a conceptual category is conceived as a cognitive capacitance, storing all possible perspectives of a phenomenon (Merleau-Ponty 1945/2002; Millikan 2000). As a cognitive capacitance, a category is useful in presupposing and entailing large numbers of facts associated with it, because on activation it illuminates a cluster of other categories with which it is associated (Givon 2005). However, intending alone is not enough to language a discourse, since linguistic communication is always embedded in a specific context. We need another cognitive function, whose role is to situate conceptual categories in that context (Zilberman 1938/1988; Langacker 2008). We call this act of relativization *contending*. The function of a linguistic expression, while contending, is to choose a particular perspective in a discourse context. Consider the expression, ‘table’. The act of intending, associated with ‘table’, invokes the corresponding category which includes information about its structural aspects (like shape, size, constituencies etc.)

and functional aspects (like dining table, computer table, drawing table etc.). Depending on the communicative situation, one or more of these structural and functional aspects are selected. This selection procedure is guided by the act of contending provided by an expression like ‘on’ as in ‘on the table’ in contrast to the ‘under the table’. The role of ‘on’ – while contending – is to delimit the cognitive capacity of a category to window the cognizer’s attention to a specific conceptual configuration.² Similarly, in an expression like ‘tabletop’, the categorial capacity of ‘top’ is delimited by the modifier ‘table’, when compared with an expression like ‘mountaintop’. The act of contending is a complex phenomenon: It is crucial not only in situating the categorial information in a conceptual configuration (such as when we concatenate ‘table’ with ‘top’ or ‘mountain’ with ‘top’); but also equally significant in situating the conceptual configuration in a perceptual set up (as in ‘this tabletop’, ‘that mountaintop’ etc.). This issue will be discussed later in this paper.

In our view, expressions are not the ready-made items stored in a mental inventory, but “a made-to-order product reconstructed on each occasion for use” in any linguistic construction (Hirtle 2007). The meaning construing capacity of an expression in a discourse is determined by the way underlying domains of our cognition are grounded and situated by the respective functions associated with an expression – i.e. intending and contending. This way of grounding and situating is what we call the *conceptual route* that a cognizer follows - though intuitively - in order to access the communicative intent. In fact, study of the conceptual route is an effort to explore the way conceptualization processes are structured.

Perspectivizing Space

Though the earlier investigations – as is briefed in the introductory section of this paper, led by different researchers – explore how linguistic realization of oriented space reflects its conceptual structure in different linguistic communities, very little has been done to answer how we language relevant representations and correlations at the time of perspectivizing space in discourse. At the level of discourse, puzzles about the relation between language and thought do not end with setting a correlation between linguistic and cognitive categories; we also need to answer how the above mentioned functions work together while licensing inferences that gradually reveal the conceptual route.

The mental locomotions involved in the construction of the conceptual route do not have an explicit linguistic realization. As we will see in the next two sections, the conceptual route is a combination of first-order perspectivizations that are explicitly languaged, and higher-

¹ In stead of using ‘perspectivation’ as is used by Graumann (2002), we use ‘perspectivization’ which is borrowed from Taylor (2003).

² In case of the example ‘on the table’, ‘the’ also acts as contender. However, this issue is not discussed here since it has no direct relevance in this paper.

order inferential tasks that go beyond what is available in the linguistic input alone. We argue that the formation of the conceptual route is determined by the interactions among various intendings and contendings, activated at the time of setting perspective in discourse.

Phrase level Discourse

The claim outlined above is first explored at the phrase level discourse, like (1) and (2); and then elaborated further in discourse larger than the phrase as is exemplified in (3).

- | | | | |
|-----|--------------------------------|-------|--------------|
| (1) | tomār | dān | dik-e |
| | you-of | right | direction-on |
| | On your right | | |
| (2) | tebil-er | dān | dik-e |
| | table-of | right | direction-on |
| | On the right side of the table | | |

The interpretations of (1) and (2) presume frames based on bodily asymmetries. It is worth noting that these two phrases are grounded and situated in different ways resulting in two different conceptual routes: (1) is interpreted with respect to the *addressee's* ego-centric perspective; (2) is interpreted from the *addresser's* ego-centric perspective, since the conceptual category 'table' does not have an inbuilt left/right orientation. More specifically, the right side of the table is interpreted with respect to the cognizer's understanding of his/her own physical asymmetry. Here, the intended asymmetry is extrinsic to the conceptualization of tables. In contrast, an extrinsic frame of reference is not required in interpreting a phrase like *on/under the table*, since tables have an inbuilt sense of vertical opposition. The different interpretation of (1) and (2) is a consequence of the interactions holding between intentions and contentions at the time of conceptual integration.

The act of intending associated with the expression *dān dik* invokes our background knowledge of asymmetries intrinsic to the human body. This schematic representation of the human body is an abstract and general invariant cognitive standard, applicable to a range of situations. Consequently, in every concrete situation, the abstract standard needs to be identified with a real world entity/situation in order to convey meaning. In case of (1), the body-schema is identified with the body of a person addressed by the genitive form of the second person pronominal form in *Bāṅlā*. The function associated with the genitive case marker, here in this context, is crucial in contending the relation between pronominal (*tomār*) and nominal (*dān dik*) forms. The genitive marker functions in situating the intended categorial information in a conceptual configuration, as opposed to the function of the pronoun in situating intended categorial information into a perceptual set up: Since the body indexed by the pronominal form is identified with the body-schema presupposed by the expression *dān dik*, the intended orientation in space is now referred with respect to the indexed body in the real world situation. This shows how the act of contending situates the

intended categorial information both in conceptual as well as perceptual environments. The situating of communicative intent in conceptual and perceptual worlds often follows different conceptual routes depending on the types of categories invoked by the intenders. This point will be elaborated further with a discussion of example (2).

The interpretation of *dān-dik* in (2) also requires the existence of a body in the real world with which the intended body-schema can be identified. However, unlike (1) it does not have an explicit contender whose function can provide schematic support. The function of the table as intender presupposes a frame of reference that does not support the left/right opposition. In order to satisfy the semantic expectancy activated by the expression *dān-dik* in (2), the act of contending invokes a frame of reference which has no explicit linguistic realization: This implicit reference indexes the presupposed body-schema with either addressee or addresser. In discourse, addressee and addresser are the 'last resort' to solve any problem related to the act of contending. Therefore, the act of contending first scans for a local solution which is often explicitly available in discourse; otherwise the function invokes contextualization cues as is shown in case of (2). The mechanism of last resort, as it follows from Lewis (2002), lies with "a system of concordant expectations capable of producing coordination at the salient equilibrium".

The above discussion shows how the formation of the conceptual route at the time of perspective taking (which is a part of discourse comprehension) is influenced by the way perspectives are set at the time of discourse production.

Discourse: Sequence of Connected Phrases

So far, we have discussed how the synchronization of intending and contending is crucial in languaging phrase level discourse that invokes a single frame of reference. In this section, we will investigate how different frames of reference are mapped into one another when more than one frame of reference is languaged in discourse, under the assumption that complexities arise at the level of discourse not because of the multiple perspectives set by the different intenders, but because of the inter-translatability of different perspectives.

Consider the example cited in (3), where various categories are intended, and also contended in order to describe a situation.

- | | | | | |
|-----|----------------|----------|------------------|----------|
| (3) | āmi | nadī-r | dhār | diye |
| | I | river-of | bank | through |
| | hāt-ch-i | āmār | bām-dik-e | dhān-er |
| | is walking | my | left-side-on | of-paddy |
| | kset | ār | dān-dik-e | nadī |
| | field | and | right-side-on | river |
| | sāman-e | sūrya | asta | jācche |
| | front-in | sun | setting | is going |

I am walking along the river side. The paddy fields are on my left, and the river is on the right. In front, the sun is setting.

The lexical expressions marked bold in (3) are egocentric, in the sense that they are defined in terms of asymmetries intrinsic to the cognizer's/ego's body-schema; and they produce an egocentric perspective of the landscape described by the cognizer. Further, while egocentric perspectives are the only reference frames that are explicitly languaged in the above discourse fragment, an allocentric frame of reference also plays a crucial role. In (3) the cognizer narrates that the sun is setting in front of him/her. From our commonsense knowledge we know that the sun sets in the west. This fact provides an allocentric frame of reference. Due to the interaction between egocentric and allocentric frames of reference, the following inferences are licensed about the landscape described in (3).

- (4) (a) The cognizer's motion is west-directed;
- (b) The river, which is on the left of the cognizer, is to his/her south;
- (c) The paddy field, which is on the right of the cognizer, is to his/her north;

The information enumerated in (4) is not directly stated in (3). Inferencing, on the basis of the commonsense knowledge, is a significant feature of languaging discourse; it is one way to accommodate the commonsense knowledge in discourse interpretation (Stalnaker 1998).

The inferences enumerated in (4) are drawn out of the conceptual route that emerge through the process of designed coordination among the discourse participants on the basis of the functions associated with different expressions in discourse, just in the fashion it happens in case of (1) and (2). What seems to be of significance, here, is that the inter-translatability of ego and allo-centric frames needs to be viewed as an act of contending – mapping different domains of our cognition.

Observations

Translating one perspective into another presupposes two facts: (i) the structural parallelisms intrinsic to the intended categories used in setting two different perspectives; and, (ii) a capacity to interpret the (asymmetric) configuration of one intender with respect to the other. This process of setting up a relational equivalence among different cognitive domains and facilitating higher order inferential tasks is an act of contending, which remains implicit in discourse level languaging. We will consider this type of contending as a *covert* function crucial to higher-order perspectivization.

While setting a correspondence between the ego- and allo-centric construals of space narrated in (3), the first inference (i.e. (4a)) acts as the vantage point with respect to which ego- and allo-centric references are translated into each other. The *relative salience* of (4a) over (4b) and (4c) also suggests a higher order perspectivization process.

Discussion: Perspectivization as a Process

Our analysis of (1-4) above shows that the viewing arrangement in discourse evolves due to the fixation and translation of vantage points. The translation of vantage points is governed by the relative salience that a vantage point has with respect to other vantage points. In discourse, the viewing arrangement is not a fixed arrangement of different isolated vantage points; rather it is an emergent phenomenon evolving gradually due to the shift of attention from one vantage point to other vantage point with every contention/assertion, as is also argued by Fauconnier and Turner (2002). We identify this process as *second order perspectivization*, in contrast to *first order perspectivization* triggered at the time of setting a perspective.

In brief, first order perspectivization activates the relevant frames of reference to construe the context of interpretation. First order perspectivization, then in turn, intends background information necessary for second order perspectivization; whereas, second order perspectivization contends the interactions between the conceptual categories invoked by the process of the first order perspectivization. Therefore, the viewing arrangement at the level of discourse is a consequence of a two tiered complex cognitive process.

Conclusion

The paper views the production and comprehension of spatial viewing arrangements as the synchronization of intentions and contentions in linguistic discourse. In doing so, it investigates the role of two cognitive functions, namely intending and contending (associated with a linguistic expression), in invoking and instantiating conceptual categories. These two processes underlie cognitive capacities like perspective setting and perspective taking at the level of discourse. We have argued for a bi-layered perspectivization process in order to understand the way ego- and allo- centric perspectives interact in discourse to shape the conceptual route.

Abstract

Spatial memory is supported by multiple parallel representations of the environment. Egocentric perspective (body-centered) and allocentric representations (object-centered) are integrated to allow correct interaction with the world. According to Milner and Goodale (1995, 2008), the action-related dorsal system is specialized for location of objects in space and visuo-motor integration, and uses an egocentric frame of reference. The perception-related ventral system is specialized for categorical recognition of objects and forms, and supports an allocentric frame of reference. Here we use a Distance Judgment Task to explore the use of different spatial frames in children with Cerebral Palsy (CP). Following the dorsal stream vulnerability hypothesis (Atkinson et al., 2007) children with CP might have more difficulties in egocentric judgments and in the processing of peri-personal space than controls. No significant difference emerged between CP children and controls in allocentric judgments, whereas performance was worse in egocentric judgment, indicating inefficient use of the body-centered representations. **Keywords:** Egocentric-allocentric spatial references; Distance Judgment task; Cerebral Palsy (CP).

Introduction

Humans are provided with different reference systems to code the environment and its physical attributes. For example, if we have to specify the location of an object we can make use of different frames of reference: we can define its position with respect to our body (egocentric frame) or we can refer to other objects in the environment or the environment itself (allocentric frame). Egocentric coordinates are based on the organism's position, and then linked to the specific perspective under which spatial information has been processed. Hence, these representations are particularly relevant in action planning and motor control in near space, when there is a direct interaction between body and objects. Egocentric frames have been described in relation to the different body part they are based on, such as head-centered, eye-centered, and

arm-centered (Colby, 1998). Allocentric, or object-centered frames, are external to the organism and usually centered on objects in the environment. Such coding of space has an important role in the processing of far space when objects are out of reach. Among allocentric representation, distinctions can be made when the point of reference is centered on an object of interest (object-centered) or on the environment (e.g., room-centered) (Colby, 1998). The information derived by egocentric and allocentric maps is usually integrated to allow proficient spatial processing (Burgess, 2006). However, some tasks rely more on one frame than the other. For example, pointing to a location in space within arm reach or grasping an object are likely accomplished within an egocentric framework, whereas defining the fastest route between two destinations is likely to involve an allocentric frame. Overall, selection of what spatial frame(s) of reference to use is highly action-specific.

A number of studies showed that several regions of the cerebral cortex subserved functions involved in spatial processing, having a reach network of reciprocal connections and link with subcortical structures. In the fMRI study by Zaehle et al., (2007) participants performed a spatial judgment task based on verbal instructions. They have to define the spatial relations between different objects (allocentric condition), or the position of objects with respect to the participants (egocentric condition). A fronto-parietal network was involved in both egocentric and allocentric judgments (e.g., superior occipital gyrus, medial portion of superior parietal cortex, superior frontal gyri bilaterally), but partly separated networks mediate different spatial coding strategies. While egocentric spatial coding revealed activation mainly within the medial parts of the posterior superior parietal lobe, the use of the allocentric reference frame revealed activation in right parietal lobe, bilateral ventrolateral occipito-temporal cortex and bilateral hippocampal formation. There is also increasing evidence of the critical role of connecting circuits, and the vestibular

system (Paillard, 1991). Dysfunction of egocentric frames appeared to be associated with damage in premotor cortex involving frontal eye field, whereas allocentric impairments are linked to lesions in more ventral regions near the parahippocampal gyrus (for a recent review see Grimsen, Hildebrandt, and Fahle, 2008). Patients with visual form agnosia, which is associated with ventral stream damage, have been reported to have selective impairments in allocentric judgments of spatial coding, with spared egocentric processing (Carey, Dijkerman, and Milner, 2009; Carey et al., 2006; Dijkerman, Milner, and Carey, 1998). The study from Galati et al. (2000) showed a different lateralization of spatial coding networks across the cerebral hemispheres, with body-centered frames more lateralized in the right hemisphere. In line with this evidence are the neuropsychological data from Iachini et al., (2009), were patients with right parietal lesions failed in egocentric but not allocentric distance judgments, whereas those with left parietal damages have difficulties in both frames of reference.

From a developmental point of view, the body is the primary available spatial code for the infant and allocentric references develops later in life, having a longer maturational trajectory. However, Nardini et al., (2006) suggests that object-centered coordinates and the integration between different coding systems occur earlier than previously thought. Using a task in which children have to recall the location of hidden toys within an array, they showed that spatial representations based on the environment (allocentric frames) develop between years three and six. Such experimental paradigm has been applied also to the study of spatial localization in clinical population (Nardini et al., 2008), however it might have limited application to patients with motor and deambulation deficits as one of its key components is the 'subject-move' condition.

Here we study spatial cognition in children with Cerebral Palsy exploring their use of different spatial frames of references. CP is defined as “a group of permanent disorders of the development of movement and posture, causing activity limitation, that are attributed to non progressive disturbances that occurred in the developing fetal or infant brain” (Rosenbaum et al., 2007). In the framework of visual cognition, it has been shown that the dorsal visual system (with its connections to parietal, frontal and hippocampal areas and its relations to the egocentric frame of reference) is more vulnerable to insult occurring early in life than ventral visual system. Children with hemiplegic CP (e.g., a motor deficit characterized by paralysis of the arm, leg, and trunk on the same side of the body) perform significantly worse than controls in dorsal stream tasks (e.g., motion coherence task) than ventral stream tasks (e.g., form coherence task). While a subgroup of hemiplegic children performed better than the normal median level for their age on the form coherence task, all the hemiplegic children performed close to the median level,

or worse, for their age on the motion coherence task (Gunn et al., 2002). CP children often presents with visual disorders comprising ophthalmological abnormalities and impairments in higher visuofunctional skills, which are considered a clinical manifestation of dysfunctions of visual associative areas of the dorsal visual path (Barca et al., 2010). The vulnerability of dorsal stream has been shown also in healthy children born preterm with no sign of neurological deficit, visual disturbances, or cognitive and motor deficits (Santos et al., 2008). Such findings suggest that the number of gestational weeks has an important influence on the normal development of visual cognition. Linking the vulnerability of the dorsal stream with the association of this brain regions with egocentric spatial representations, one can assume that mainly egocentric representations would be impaired in spatial processing of CP.

The aim of this study was to investigate the impact that brain injuries occurring early in life (e.g., prenatal or perinatal period) exert on the development of the different coordinate systems used for the coding of space, by studying the performance of hemiplegic CP children on a distance judgment task. Specifically, our main research question is: are egocentric (self-referred) and allocentric (object-referred) distance judgments similarly impaired? The dorsal/ventral distinction has been recently extended to spatial processing, suggesting that the dorsal circuit provides egocentric coding of space for motor control and action planning whereas the ventral circuit is tuned with allocentric coding of space (Medina et al. 2009). Hence, the dorsal stream vulnerability hypothesis would predict children with CP to have more difficulties in egocentric judgments and in the processing of peri-personal space than age matched controls. However, given the precocity of the cerebral insult, they might develop compensatory mechanisms that allow to correctly processing spatial representations, as has been shown in patients with idiopathic cervical dystonia (Ploner et al., 2005). Neuropsychological adult literature provides evidence of a link between dorsal stream lesions and impairments in egocentric judgments (Berryhill, Fendrich and Olson, 2009). However, patients with parietal damage having the opposite deficit (i.e., allocentric impairments with spared egocentric references) have also been reported (Carey et al., 2006), thus questioning the direct link between parietal lesions and body-centered perspective.

To test the prediction of a major impairment in egocentric than allocentric representations of space in children with CP, we conducted a behavioral study in which egocentric and allocentric stimulus coordinates were varied in order to individuate their contribution in making spatial judgments. The procedure of the experiment was motivated by the work of Iachini and colleagues (Iachini, et al., 2006; Iachini et al., 2009), as they were able to consistently and effectively induce a differential involvement of spatial coding systems

with such procedure. However, several changes (which will be described in the following section) have been introduced to make the task feasible for a pediatric clinical population.

Method and Materials

Participants

A group of seven children with CP participated in the study. They were 3 male and 4 female, with mean chronological age of 7 years (range 5-9 years), with no spatial neglect, language or general intellectual impairments. Four child presents with Hemiplegia, and 3 with Diplegia. A control group of 5 children with typical development was used for comparison. Children of this group had no history of visual, motor or cognitive delay, and mean chronological age of 10 years (range 8-12 years),

Neuropsychological assessment

General cognitive level was assessed with the Raven's Colored Progressive Matrices, CPM (Raven and Raven, 1986), which has been recently shown to be a valid tool in the assessment of cognitive functioning in CP (Pueyo et al., 2008). To assess visuoperceptual and visuomotor integration skills we used the Developmental Test of Visual Perception, DTVP (Hammill, Pearson, and Voress, 1994). The Corsi block-tapping task (Corsi, 1972; Milner, 1971) was used as a measure of visuospatial working memory. Parents of the controls group fulfilled the questionnaire of Houliston et al., (1999), adapted to Italian and used as a screening measure of children's neurovisual behavior (e.g., questions regards child's ability to recognize objects and faces, finding way in home, distinguishing line from steps and the perception of motion).

Experimental task

A Distance Judgment Task, adapted from Iachini et al. (Iachini et al., 2006; Iachini et al., 2009), has been used. Children were presented with triads of 3D objects in peripersonal space (within arm reach) and were asked to give egocentric and allocentric judgments. Materials comprised eighteen graspable objects divided in triads. They were geometrical shapes with different colors (e.g., cube, pyramid, and wheel), animals (e.g., duck, rabbit, and horse), vehicles (e.g., car, helicopter, and airplane) and everyday objects (i.e., key, cork and clothes-peg). Objects within triads had similar size. Each triad was spatially arranged so that distance between objects was clearly discriminable, and the amount of metric difficulty was the same for egocentric and allocentric judgments. Participants sat at 30 cm from the edge of the desk. Each triad was placed centrally on the desk and with respect to the participants' mid-sagittal plane. A white cardboard measuring 50 x 50 cm was used to arrange stimuli. Children were instructed to study and memorize the position of the objects for 30 seconds. Then the objects were covered with cups and data acquisition started. There were eight judgments for each triads: two

egocentric questions ("Which object was closer/farther to/from you?"), two allocentric questions ("Which object was closer/farther to/from the Cube (target)?"), and four distractors questions about objects' shapes and colors. For each judgment, accuracy was coded as dummy variable (1 = correct, 0 = incorrect) and the mean accuracy by subject was computed. The order of presentation of the questions was first randomized and then balanced across subjects. Before start with the session, the examiner spent some time to familiarize with the child and explained the nature of the experiment to the parents in order to have their consent.

Results

Neuropsychological assessment. CP children did not present cognitive delay as measured with the CPM (the cut-off point for clinically significant impairment was the 25th percentile) and have a visuospatial memory span adequate to their age. Although some variation emerged among patients, they did not present marked deficits in visuoperceptual and visuomotor integration skills as measured by the DTVP.

Regarding the controls group, parents' questionnaire did not report any difficulties in visuoperceptual or visuospatial behavior (e.g., problems with shapes, objects and faces recognition, simultaneous perception, perception of movement, colors perception, and orientation).

Distance Judgment task. Patients and controls performance at the Distance Judgment Task are presented in Figure 1. Chi-square test was used to evaluate significance level of observed differences.

Figure 1: Results Distance Judgment task

Overall, both groups of children made few errors in completing the task (no child exceeded the chance threshold). The task resulted more difficult for CP than controls in that they were less accurate (12% and 25% errors, respectively in controls and patients). At the group

level, controls have a Frame effect, with nearly no errors in responding to egocentric vs. 18% errors in allocentric condition (Chi-square = 5.2, $p < .05$). Differently, in CP children the egocentric-allocentric difference was less marked (20% and 30% of errors, respectively) and did not reach the significance level (Chi-square = 2, $p > .1$). A comparison between the two groups confirmed that CP children were less accurate than controls in responding to egocentric questions (Chi-square = 6.8, $p < .01$) whereas no differences emerged in allocentric questions (Chi-square < 2.4, $p > .1$).

Discussion

In the present study, children with Cerebral Palsy were asked to judge the position of graspable objects with respect to their body (egocentric condition) or with respect to landmarks (other objects) in the environment (allocentric condition). The first evidence is that such paradigm proved to be feasible to study spatial cognition in normally developing children and children with CP. Such paradigm, indeed, has been previously used with adult population (Iachini et al., 2006; Iachini et al., 2009) and this is the first time it is applied to developmental age.

Typically developing children were less accurate in recalling the position of objects using allocentric spatial coordinates than when using body-centered coordinates, confirming the predominance of egocentric coding in the developmental trend of spatial cognition (see Nardini et al., 2006). This was not the case for the group of children with CP. Indeed, they have similar performance when using egocentric or allocentric coding. Given that no differences emerged between groups with respect to the allocentric judgments, results suggest a specific deficit in using body-centered coordinates. One might argue that such difficulty reflects a deficit in visuospatial memory. However, such explanation is unlikely given that our sample of CP children have adequate score in visuo-spatial working memory task. Additionally, there is no reason to believe that (if present) a similar limitation would selectively affect egocentric vs. allocentric judgments. CP children's performance reflects preservation of categorical coding within the ventral stream, despite a loss of coordinate coding which is consistent with the hypothesis of dorsal stream vulnerability in such population (Atkinson et al., 2007; Fazzi et al., 2007). Deficits in spatial perception are usually matched with deficit in generating spatially directed actions. Patients have been described to neglect stimuli presented in peripersonal space and correctly perceive them when located in extrapersonal space, as well as the opposite pattern (Bisiach, Perani, Vallar, and Berti, 1986). Thus, information about how patients perceive the environment both in near and far space has implications in rehabilitation treatments of visuo-perceptual and visuospatial impairments. We believe that this is an important issue that needs to be further explored in impaired population in developmental age.

Findings of the study are preliminary as more participants are needed to broaden our conclusions.

The extent to which our results generalize to other aspect of spatial cognition and other types of CP are important further questions. Nico and Daprati (2009) propose a distinction between two separate egocentric mechanisms: one allowing construction of the immediate point of view and the other extracting a required perspective within a mental representation. This, for example, should be further addressed in our sample of patients. Moreover, Cerebral Palsy is an umbrella term which comprises different types of motor limitations which differently affect how children experience the external world and create internal representation of it. Children of our study can be considered 'high functional' cerebral palsied children in that they do not present language delay, general intellectual impairments and marked deficits in visuo-perceptual and visuomotor integration skills. Notwithstanding such limitations, we believe the study provides interesting findings relevant for the field of spatial cognition in impaired population in developmental age.

To summarize, children with CP were impaired in a distance judgment task: Allocentric spatial representations were present even in the context of impaired egocentric coding. Further studies are needed to tackle this issue and to understand how a unitary perception of the world is achieved from its multiple representations.

Vocabulary Spurt: Are Infants full of Zipf?

Abstract

Infants do not learn words at a constant rate. During the second year of life, a dramatic increase in the speed of word learning is observed. Different mechanisms explaining this vocabulary spurt have been proposed, either through endogenous factors such as learning capacity or exogenous factors, such as frequency of word usage. We demonstrate that occurrence statistics alone is not sufficient to explain the acceleration in vocabulary growth, discuss other potential exogenous contributions such as phonological complexity and suggest that a change in word learning capacities is necessary. A model implementing an increased ease of learning is introduced and illustrates this endogenous approach by replicating the non-linear vocabulary growth characteristics of language acquisition.

Keywords: vocabulary spurt; mathematical modelling; word learning; learning mechanisms; Zipf's law; endogenous vs. exogenous factors

Introduction

Around their first birthday infants utter their first word and by their second birthday they learn on average one new word every waking hour. Between 18 and 24 months of age, an abrupt change in the speed of word acquisition is observed, called the vocabulary spurt or naming explosion (Bloom, 1973)¹. Two types of theories have been offered to explain the vocabulary spurt. One suggests that the vocabulary spurt corresponds to representational and/or maturational changes in the infant's brain. For example, researchers have suggested that infants start acquiring words at a faster pace when they understand that words refer to things and/or that things have names. On this view, the vocabulary spurt corresponds to a *naming insight* (Dore, Franklin, Miller, & Ramer, 1976; Reznick & Goldfield, 1992; McShane, 1979; Kamhi, 1986). Alternatively, word learning occurs at a faster pace when object concepts and categories become more detailed and refined (Bates, Benigni, Bretherton, Camaioni, & Volterra, 1979; Gopnik & Meltzoff, 1987; Nazzi & Bertoncini, 2003). Other researchers have proposed that the spurt corresponds to linguistic refinements such as word segmentation (Plunkett,

1993), word retrieval capacities (Dapretto & Bjork, 2000), improvements in social cognition (Ninio, 1995) or changes in hemispheric specialisation (Mills, Coffey-Corina, & Neville, 1993). All of these hypotheses share the assumption that the vocabulary spurt reflects endogenous changes in the infant.

A second, contrasting, hypothesis has recently been introduced by McMurray (2007). He argued that under the reasonable assumptions that (i) words are learnt in parallel and (ii) some words are easier to learn than most words, a vocabulary spurt is inevitable and that "this distribution in difficulty derives from many factors, including frequency, phonology, syntax, the child's capabilities, and the contexts where words appear." (McMurray, 2007, p.631). Invoking the central limit theorem, he suggested that the individual contributions of the different factors sum to a Gaussian distribution of word difficulty. Later, using the logarithm of utterance statistics as a proxy for word difficulty, he showed that a time-to-acquisition growth curve yields a pattern of vocabulary development typical of infants during their second year. On the basis of this finding, he claimed that "acceleration in vocabulary growth could arise from occurrence statistics alone" (McMurray, 2007, p.631).

Our aim is to clarify the origin of this non-linear increase in the speed of lexical acquisition; whether this transition is the result of a change in the infant's mental representations or brain organisation (endogenous factors), or caused by the statistical nature of the input, such as phonological complexity or the frequency of word usage (exogenous factors). We show mathematically that word frequency cannot alone explain the acceleration in vocabulary growth. This demonstration also fits well with empirical findings that word frequency is not an entirely reliable proxy for word difficulty (Huttenlocher, 1991; Goodman, Dale, & Li, 2008). Instead, we suggest that changes in the infant's learning capacity are required to display the non-linear growth in the speed of word acquisition. These changes, such as the emergence of fast mapping (Carey & Bartlett, 1978), provide the basis for the unique learning capacities displayed late in the second year of human life.

Statement of the problem

For expository purposes, we make three simplifying assumptions; (i) infants only learn words when hearing them, (ii) word occurrence statistics follows Zipf's law and (iii) all words are equally difficult to learn. If these three criteria are satisfied, we demonstrate that vocabulary growth will be linear, unless a change in learning capacity takes place (as a function of time or as a function of the number of words al-

¹We will use the terminology "vocabulary spurt" throughout the manuscript in the sense of a *supra-linear lexical growth*, characterised by slow learning in early development, followed by an increase in the speed of word learning later on. Even though an increase in the speed of word learning in the first years of human life is not questioned, its mathematical description is debated; should it possess a clear inflection point or is there a more gradual increase throughout early development, as suggested by Ganger and Brent (2004)? For the scope of the present manuscript, we use the term "vocabulary spurt" in its general – and milder – interpretation, whereby infants display slow initial learning followed by a faster rate of word learning, contrasting with a linear increase in which the rate of word learning would be constant during life.

ready present in the lexicon²). In other words, a change in learning capacity is a necessary pre-requisite to drive a non-linearity in vocabulary growth. We justify this claim by both analytical considerations and through simulations. Later, we will show that (i) the assumption of online learning can be relaxed, (ii) that speech corpora used with real infants follow the same behaviour as Zipf's law and we will suggest that (iii) phonological complexity of early words do not seem to play a prominent role in shaping the vocabulary spurt. We will suggest, therefore, that a change in the infants' learning capacities is driving the naming explosion.

Let us first justify our initial assumptions. First, we argue that infants learn words when they are confronted with them and not by processing words off-line after accumulating evidence. Carey and Bartlett (1978) introduced the idea that infants are able to "fast map", whereby infants demonstrate rapid mastery of the appropriate use of labels after a limited number of learning opportunities. Evidence of the infant's ability to learn a new word after limited exposure was also explored by Woodward, Markman, and Fitzsimmons (1994), suggesting that novel words can be retained at least 24 hours after the infants have been exposed to them only 9 times, even for infants as young as 13 months of age. More recent evidence based on infant-caregiver interactions showed that the naming event needs to occur at the right moment in time when the infant is attending to the named object to be successful (Yu, Smith, & Pereira, 2008)³. These findings provide strong support for the claim that infants perform on-line word learning when exposed to them. Consequently, if infants only engage in online word learning, the raw statistics of word usage should be exploited and not, as in McMurray (2007), a logarithmic transformation of the word frequencies (a further comparison of our approach to McMurray, 2007, is discussed later). Moreover, we will show that even a relaxation of the assumption of online learning cannot explain an accelerated vocabulary growth.

Second, we adopt the perspective that infants are exposed to a distribution of word frequencies approaching Zipf's law (Zipf, 1949), which states that, from any substantial corpus, the frequency of a word is inversely proportional to its rank. For example, the most frequent word is used twice as much as the second most frequent word and three times more often than the third most frequent word. A broad range of evidence suggests that spoken language essentially follows a Zipf distribution of word usage (Miller & Chomsky, 1963; Zipf, 1935; Beier, 1965; Dahl, 1979; Altmann, 2002). We will show, in a model with constant learning capacity and exposed to a corpus of speech used with real infants, that lexical growth fails to exhibit the characteristics of a vocabulary

spurt, even when the utterance statistics deviate slightly from Zipf's law.

Analytical considerations

On average, an infant hears a word i having a frequency $f(i)$ within a time window $t(i) = 1/f(i)$. For example, a word uttered twice an hour will be heard on average every 30 minutes and a word uttered 4 times a month will be uttered every week or so. As a consequence, and to a first approximation, the time $T(i)$ to acquire a word i is inversely proportional to its frequency $T(i) \propto 1/f(i)$. The constant of proportionality depends on the number of times a word needs to be heard with respect to the threshold for learning it. Zipf's law states that, from any substantial corpus, the frequency of a word is inversely proportional to its rank: $f(i) \propto 1/i$. This predicts a linear distribution of time to acquisition; $T(i) \propto i$, which in turn predicts a linear increase in the size of the lexicon. The (constant) speed at which infants increment their lexicon size would then be proportional to their (fixed) learning capacity, as defined by the number of times they need to hear a word in order to add it to their lexicon. In real word learning situations, words do not follow Zipf's law deterministically. However, the fluctuations in everyday interactions can be modelled by drawing words probabilistically from Zipf's distribution. Since analytical calculations become increasingly complex, we simulate this process in a stochastic model.

Simulation results

Fig. 1 displays simulations using raw frequencies of word usage from Zipf's distribution. As in McMurray (2007), a knowledge level is associated with each word and is incremented with each presentation. When this crosses a threshold, the word is learnt. The model reveals a regular increase of word acquisition, the absence of an early, slow learning phase and no inflection point in word learning; in other words, the absence of a vocabulary spurt. The different curves on

Figure 1: Vocabulary size as a function of time when a model with constant learning capacity is presented with a Zipf distribution of word usage (the different curves correspond to different numbers of words uttered per epoch).

²Mitchell and McMurray (2009) have shown that leveraged learning—the fact that knowledge of some words helps with the learning of others—does not create acceleration in word learning.

³In a recent experiment, Smith and Yu (2008) showed that infants were able to use cross-situational statistics to learn novel words. It remains to be shown, however, if these effects extend to longer time windows than used in the experiment, consisting of multiple presentations of each word-referent pair over the course of 4 minutes.

Fig. 1 correspond to different (constant) learning capacities, i.e., the number of presentations needed to acquire the word in the lexicon. Steeper curves correspond to better learning capacities. Note that, in the model, the absolute number of words uttered in an epoch of exposure also modulates the slope of the learning curves. Similar curves may correspond either to a proficient learner confronted to a low number of words or to a slower learner presented with a higher number of words in any time window. All combinations of learning capacities and absolute number of words uttered per epoch lead to linear increases in the lexicon size.

As a further control we ran simulations with actual word frequencies extracted from the CHILDES Parental Corpus, made out of the following 27 corpora; Bates, Belfast, Bernstei, Bliss, Bloom, Brown, Clark, Cornell, Demetras, Fletcher, Gatherco, Hall, Higginso, Howe, Kuczaj, Macboys (MacWhinney), Macros (MacWhinney), Peters, Post, Sachs, Snow, Suppes, Valian, Vanhout, Vankleec, Warren, and Wells. The Parental Corpus consists of 2.6 million word tokens (about 24,000 word types), and is a representative sample of the speech to which children are typically exposed (MacWhinney, 1991; Li & Shirai, 2000). Fig. 2 shows that for differing numbers of presentations needed to acquire a word (different learning capacities), vocabulary growth lacks both the long latent period of slow learning and subsequent rapid increase characteristics of the vocabulary spurt. Instead, the speed of acquisition is reduced after having learnt about 100 words, and converges to a constant rate of acquisition thereafter. The number of epochs used in this simulation is greater due to the large size of the corpus. We conclude that word

Figure 2: Vocabulary acquisition in a model with constant learning capacity, when presented with parental input. No vocabulary spurt is observed. Higher curves correspond to a lower threshold of learning.

statistics alone cannot be responsible for the vocabulary spurt observed at the end of the second year of life. Rather, as many researchers have suggested, the vocabulary spurt is driven by underlying changes in learning capacity arising from changes in mental representations and/or brain organisation. We next offer a conceptual implementation of this alternative view;

that a change in learning capacity *is required* in order to display an accelerated increase in word learning.

Relaxation of the assumption of ‘online’ learning

We have demonstrated that an acceleration in vocabulary growth cannot be expected when presented with word distributions following Zipf’s law, unless a change in learning capacity is implemented in the model or further variations in word difficulties are present. We have also shown that when the occurrence statistics deviates moderately from Zipf’s law, as exemplified through simulations using the Parental Corpus, a vocabulary spurt is still absent in the model. We now show that the assumption of online learning can also be relaxed.

Let assume that upon presentation of a word, a ‘memory trace’ is initiated. This memory trace would modulate over time the value of the knowledge variable associated with that given word. Let us discuss the potential behaviour of this memory trace. We have already discussed the case for which the memory trace remains constant: It corresponds to the case in which each presentation of a word leads to an increment in the knowledge variable associated with that word, until it crosses a threshold. We have demonstrated earlier that no acceleration in vocabulary growth is observed unless an improvement of learning capacity is implemented in the model. Moreover, frequent words are learnt very early on, thereby failing to reproduce the long latency period observed in early childhood. Alternatively, the memory trace could increase over time (Vlach, Sandhofer, & Kornell, 2008), mimicking consolidation of the word form or meaning during sleep (Dumay & Gaskell, 2007) or through rehearsal of that word. However, high frequency words would be learnt even more rapidly under these conditions than with the constant memory trace, resulting, again, in the absence of the long latency period observed early in life. This account would fail to exhibit the characteristic contrast observed in infancy between a slow initial learning followed by an acceleration in lexical growth. Finally, the memory trace could decay over time, reflecting the degradation in the representations of words in absence of a new utterance, as described by Horst and Samuelson (2008). In this case, low frequency words whose memory trace decays faster than the typical interval between successive word presentations would never be learnt. Although we do not suggest that no learning take place beyond the actual presentation of a word, dynamic memory traces associated with individual presentations of the word are not the ingredient needed to explain the supra-linear vocabulary growth. Decaying memory traces as in Horst and Samuelson (2008) or reinforcement (Vlach et al., 2008; Dumay & Gaskell, 2007) would merely modulate the vocabulary spurt, not create this acceleration.

Relationship to McMurray’s account

Our approach shares a similar goal to that of McMurray (2007): understanding the cause of the sudden increase in the speed of word learning observed during the second half of the second year of life. However, our approach differs in some important respects to both the original paper (Mc-

Murray, 2007) and subsequent implementations (Mitchell & McMurray, 2008, 2009). First, if infants only engage in on-line word learning, the raw statistics of word usage should be exploited and not, as in McMurray (2007), a logarithmic transformation of the word frequencies. In addition to a lack of psychological validity, such a transformation suffers from mathematical instability: depending of the lexicon size, the sum of log-frequencies may become negative, and/or words with a very low usage (frequency smaller than 1 in the time-scale used) would have a negative log-frequency, resulting in negative probability of occurrence. Thus, the vocabulary spurt described in McMurray (2007) is driven by a distribution of word frequencies that, due to its log-sampling, do not reflect the true nature of the statistics of word occurrences. Second, Mitchell and McMurray (2008) introduce a stochastic adaptation of the original model and show that a wide range of distributions can lead to a spurt-like behaviour. Crucially, Zipf's law belongs to the class of distributions that do not lead to a vocabulary spurt.

Finally, Mitchell and McMurray (2009) study leveraged learning in word learning. They explore different metrics for relating word difficulty to word frequency. In a first case, they scale difficulty as an additive function of frequency. In order to avoid the problem of very high frequency words having negative difficulty values, they add a constant value to the difficulty score. The second case, in which word difficulty is scaled to the inverse of frequency is the approach we have chosen: For example, a word that is heard twice as often is deemed to be exactly twice as easy to learn. However, words follow Zipf's law only at a stochastic level. Our analysis, beyond initial analytical considerations, provides a stochastic account of word learning, when infants hear words drawn either from Zipf's distribution or from a corpus consisting of speech to which infants are typically exposed. Mitchell and McMurray (2009) provide a non-stochastic implementation of Zipf's distribution and Mitchell and McMurray (2008) provide a stochastic implementation of non-Zipfian distributions. The critical combination of a Zipfian distribution with a stochastic implementation is absent from their account.⁴

An alternative account

Since a Zipf distribution of word usage is insufficient to capture the vocabulary spurt, we simulate an alternative account where the capacity of learning a word is not kept constant during early life. As infants only learn words on the basis of raw exposure, the model is presented with words drawn from a Zipf distribution and, for each presentation, the model has an increasing probability of learning that word. We presented 10,000 words per "day" in the simulation⁵, out of

⁴"[...] it is important to remember that frequency is not a property of the word [...], it is an estimate of how often it occurs (stochastically) in the child's environment. Thus, our model may be limited in its ability to handle frequency, and a stochastic model may be a better approach for dealing with it (e.g., Mitchell & McMurray, 2008)" (Mitchell & McMurray, 2009, p.1519)

⁵Hart and Risley (1992) reported that, on average, 10- to 18-month-old infants hear 1275 words per hour. Assuming that this

a 40,000 word lexicon distributed with Zipf's law. Words that were presented on average less than once per day, were sampled according to their probability of occurrence within a day. The developmental time course of this probability is implemented as a non-linear function of time, in order to mimic the emergence of fast mapping and increased learning capacity, observed during the second year of life. In the model, the probability of learning a word increases with time; $p(t) = (t/20000)^3$. Any non-linear increase in the probability of learning a word would result in a non-linear developmental trajectory of word learning. Such a change in the parameters would only result in a quantitatively different path to word learning, not a qualitative change⁶. Note that this model is equivalent to a modified version of McMurray's model, in which increment size increases with time. From this perspective, many presentations of a word are needed for successful learning early in development whereas later in the second year, just a single presentation may be sufficient for learning that word, due to the emergence of fast mapping. Fig. 3 depicts the developmental trajectory simulated with the model. The curve of vocabulary acquisition possesses a clear non-linearity separating the early slow learning and the late fast learning regimes, similar to the naming explosion.

Figure 3: Acquisition in the present model, where learning capacity changes over time.

Discussion

Two contrasting hypotheses have been proposed in order to explain the rapid increase in the speed of word learning occurring in the second year of life. On the one hand, researchers have argued that the vocabulary spurt is driven by changes in the infant's learning capacities, such as the emergence of a naming insight or via maturational changes in the brain. We refer to this view as the *endogenous* hypothesis. In con-

level of exposure is maintained for 8 hours per day, then infants hear about 10,000 words a day.

⁶Since in the present simulations we did not simulate the system for more than 20000 epochs, the probability is always smaller than 1. One could alternatively choose a non-linear function of time that saturates at 1 (or close to 1) for increasing time, so as to mimic a smooth and continuous improvement in learning capacities.

trast, a second hypothesis highlights environmentally-based factors that contribute to the difficulty in learning words, such as frequency, phonological complexity, etc. On this view, the vocabulary explosion is a by-product of variability in word difficulty. We refer to this hypothesis as the *exogenous* hypothesis.

We have argued that simple analytical considerations demonstrate that a linear increase in the size of the lexicon is expected when presented with word frequencies distributed with Zipf's law. Moreover, simulations with a stochastic sampling of words following Zipf's law, as well as with samples of speech to which infants are exposed, confirmed that the type of distribution of word frequencies found in natural language would fail to induce a naming explosion. Mitchell and McMurray (2008) have shown that a wide range of mathematical distributions of word difficulties predict a non-linear growth of the infant lexicon. We have demonstrated that word occurrences following Zipf's law and speech typically heard by infants does not belong to this family of mathematical distributions.⁷

Since we have demonstrated that word frequency cannot account for the vocabulary spurt, it is reasonable to ask whether other exogenous factors that influence word difficulty could be the source of the non-linear vocabulary growth. For example, McMurray (2007) points out that phonological complexity contributes to word difficulty. It is not straightforward to measure the impact of phonological complexity during early word learning since the basis of infant's lexico-phonological representations is not yet well understood. However, as a first approximation, we might consider word length as a proxy for phonological complexity and hence word difficulty. In a recent review, Juhasz (2005) identified contributing factors in picture naming tasks. All reviewed studies (13) showed a correlation between age of acquisition and latency measures, suggesting that latency in picture naming tasks is a reliable way of determining when the word was acquired. In contrast, word length was found to be a significant variable in only 3 studies, whereas 9 studies found it to be non-significant. Phonological complexity, therefore, like frequency may not be a suitable candidate for predicting vocabulary acceleration as "an unavoidable by-product of variation in difficulty". Whereas many factors can impact the distribution of difficulty in learning a word, such as word length or word frequency, it remains to be proven that they play a primary role in determining the shape of the vocabulary spurt. Nevertheless, it is important to highlight that other exogenous factors are likely to contribute to differences in word difficulties. Many researchers would argue that words are not learnt in isolation, and the context in which they

appear may affect directly the set of potential interpretations of the words, through referential uncertainty. Computational models have shown that word learning in a sentential context can display a spurt-like pattern in the learning curve (Siskind, 1996; Fazly, Alishahi, & Stevenson, 2008) and experimental studies have shown that context diversity and within-context ambiguity can override the role of word frequency (Kachergis, Yu, & Shiffrin, 2009). Nevertheless, Hayes and Ahrens (1988) have shown that there is a positive correlation between a caregiver's mean length of utterance and the age of the infant. As a consequence, young infants are exposed frequently to words in isolation or in short motherese.

We propose, instead, that endogenous factors are primarily responsible for the vocabulary spurt. Among them, the emergence of fast mapping can explain the increase in the ease of acquisition late in the second year of life (Carey & Bartlett, 1978). Further evidence for a change in learning capacity is that word familiarity impacts the distribution of brain regions involved in word learning, reflecting an increased efficiency in the manner in which infants process familiar and novel words across the vocabulary spurt (Mills, Plunkett, Pratt, & Schafer, 2005). It is, however, important to note that neither maturational changes in the brain, nor the application of innate or domain-specific constraints are required to explain a change in learning capacity. For example, Mayor and Plunkett (2008) showed that no specialised mechanisms are needed to explain the vocabulary spurt, as a simple general learning mechanism can lead to the spontaneous emergence of fast mapping. A change in learning capacities, not mechanisms, drives the rapid onset of vocabulary acquisition observed late in the second year of life. Hence, a word that seems difficult for a 15-month-old may be acquired almost instantaneously by a 21-month-old. Is the vocabulary spurt compatible with Zipf's law? The answer is clearly "yes" provided we allow the listener to develop her learning capacities.

⁷An anonymous reviewer pointed out that a caregiver's word usage may vary over time, despite following Zipf's law at a global scale. As a result, fragments of a caregiver's speech may deviate from Zipf's law, resulting in a vocabulary spurt. The analysis of a biased stochastic sampling of words from a Zipf distribution would be an interesting avenue for further research. However, a random sampling from a Zipf distribution failed to display a spurt-like pattern of word learning.

Abstract

An experiment by Dennis and Chapman (in press) found that as the length of a categorized list of materials increased, the false alarms to unrelated distracters decreased, a finding suggesting that adults are best described by context-noise models of recognition memory. Developmental evidence demonstrating that children the age of five are more sensitive to item information suggests that children might be described by item-noise models. We tested children and adults' performance and eye movements during recognition and found that adults' usage of category context was evident in both their performance and in their eye movements. Children, however, did not give conclusive evidence in their memory performance but their eye movements did not reflect usage of category context.

Keywords: Recognition memory; Inverse list length effect; Categorization and memory; Development of memory; REM; BCDMEM; context-noise; item-noise

Introduction

Current models of recognition memory, such as the REM model (Shiffrin & Steyvers, 1997) and the BCDMEM model (Dennis & Humphreys, 2001) are capable of making accurate predictions about a number of previously problematic effects in the literature, such as the list-strength effect (Ratcliff, Clark, and Shiffrin, 1990) and the mirror effect (Glanzer and Adams, 1985). However, these models not only possess different architectures but also capture the same trends in the data using different sources of information and interference.

The REM model assumes that during the study phase, each item is stored as a separate, noisy representation. During the test phase, a probe item is compared against every item in memory and an activation value is calculated based on the degree of match between each studied item and the presented probe item. These activation values are then averaged and a mean activation value that is sufficient (exceeding a fixed criterion value) produces a yes response.

If distracters happen to have sufficient match with some of the studied items in memory, this produces a false alarm to the distracter. The REM model, as well as other global-matching type models (see Clark & Gronlund (1996) for a review), are classified as item-noise models due to the fact that interference is produced by the content and number of studied items.

BCDMEM, in contrast, assumes that during the study phase, each item isn't stored but is instead bound to the study context. During the test phase, the probe item cues all previous contexts in which the item was studied in, including learned elements of the study context. Additionally, the context of the study episode is reinstated. This reinstated context is then compared against the retrieved contexts of the item to evaluate whether or not the item was presented during the experiment, and a sufficient degree of match between the elements of the study context and matching elements in the retrieved contexts produces a yes response. If a distracter item happens to have been experienced in a large number of contexts, such as a high frequency word in the English language, then it is more likely for the retrieved context layer to spuriously contain elements of the study context and a false alarm can be produced. Consequently, this model is classified as a context-noise model because previous contexts are the principal source of interference.

Because these models account for the same effects using different sources of information and interference, determining which model is correctly representing the memory system requires looking at more current evidence in the literature. Dennis and Chapman (in press) recently found that when list length was varied between 10 and 80 items but the number of categories was kept constant (essentially varying the number of exemplars per category),

false alarms to unrelated distracter items were lower in the long list relative to the short list. This qualitative trend was dubbed the 'inverse list length effect,' which is the opposite of the predictions of the REM model. REM predicts a slight increase to unrelated distracters with increased list length, as extra study items produce additional noise during recognition. However, this effect can be handled by the BCDMEM model with the assumption that when participants are reinstating the context of the study episode, the categories learned while studying the long list become a part of the reinstated study context. These added elements of category context are then matched to the category contexts cued by the items, producing higher likelihoods of a "yes" response for matching category items and lower likelihoods of "yes" responses for mismatching category items. The authors further argue that it would be impossible for the REM model or virtually any other model that solely relies on information from individual exemplars to capture this effect.

There exist developmental evidence, however, that suggest that the source of interference may change through development. Sloutsky and Fisher (2004) conducted an experiment in which participants, which consisted of adults and children the age of five, either participated in a categorization task in which they had to induce a novel category property to animal photos, or they participated in a baseline condition in which they merely studied the photos. A surprise recognition task followed either of the two conditions, and it was found that adults experienced a sharp decrement in their ability to discriminate between studied and non-studied category items due to an increase in false alarms to related distracters. Children, in contrast, experienced no such decrement in their memory performance between the two conditions. The authors attribute this dissociation in performance between the two age groups to the fact that adults are much more sensitive to category-based information, while children are much more sensitive to item-based information.

These findings are consistent with a large number of findings from the research review performed by Brainerd, Reyna, and Ceci (2008). In this review, a number of experiments were discussed in which it was demonstrated that children are much less susceptible to false memory errors, a pattern which increases with age up until adulthood. These effects and age trends were evident in paradigms ranging from DRM type tasks to suggestibility experiments. The authors attribute these errors, particularly the decreased likelihood of recalling or falsely recognizing items highly similar to items presented at test, to children's weaker ability to spontaneously extract gist from the test materials in the same manner as adults.

We argue that if children are indeed more focused on item information and are weaker in their ability to extract gist during the study phase, then they should be deficient in their ability to extract and reinstate category context in the same manner as adults. We tested this by running both adults and children in a paradigm very similar to that used

by Dennis and Chapman (in press). If our hypothesis about children's inability to use context is correct, then they should be unable to exhibit an inverse list length effect and their performance may follow the predictions of item-noise models of recognition. Adults, in contrast, should behave consistently with previous findings and experience facilitation in their ability to reject unrelated distracters in the long list condition.

Experiment 1

Method

Participants Participants were 65 children (33 female and 32 male, $M = 4.87$ years, $SD = 0.61$ years) and 83 adults (36 women and 47 men, $M = 19.7$ years, $SD = 2.93$ years). Child participants were recruited from suburbs in Columbus, OH. Adult participants consisted of undergraduate students from The Ohio State University participating for course credit.

Figure 1: All stimulus feature possibilities in exemplar construction. For the sake of space efficiency, only left hands and left feet are presented.

Stimuli Visual stimuli consisted of artificial creatures that were composed of four different body parts: a head, a body, a pair of hands, and a pair of feet. Each body part was composed of a unique color and shape pairing. The creatures were assembled by randomly selecting a shape and a color for each component from a selection of over 16 different colors (common to all body parts) and 16 different shapes (unique to each body part). All shape and color features are detailed in Figure 1.

Figure 2: Examples of composite figures created from the sample features. *Top row*: Examples of three non-categorized exemplars. *Bottom row*: Examples of three categorized exemplars potentially seen in the long list.

For the study phase of the short list, a total of 8 exemplars were presented to the participant with unique shapes and colors for the different components (head, body, hands, and feet). For the study phase of the long list, 64 exemplars were presented and blocked into 8 categories of 8 exemplars each. Categories were defined as exemplars which shared heads of the same shape and color while the hands, feet, and body of the shared category exemplars consisted of different shape and color combinations. All categories exhibited unique, non-overlapping shape and color combinations for the heads. For the body, hands, and feet, all categories used the same colors and shapes (all randomly selected from the 16 available), no shape/color combinations were reused between categories and no shapes or colors were used for more than one exemplar within a given category. It should also be mentioned that the same number of features were used in both the short and long list conditions. Examples of possible exemplars created for short lists and long lists can be seen in Figure 2.

Distracter items in the test list were divided into two types: related distracters and unrelated distracters. Related distracters were constructed by selecting one head from

each of the 8 presented categories and using reshuffled combinations of previously presented shapes and colors for the body, hands, and feet. Unrelated distracters were constructed in the same manner as related distracters, except that the heads were not categorically related to the presented stimuli and instead were composed of new combinations of shapes and colors that were not presented at test (all remaining colors and shapes not sampled for the study items). It should be noted that all shapes and colors have an equal probability of being used in target, related distracter, and unrelated distracter items. Examples of possible distracter item composites can be seen in Figure 3.

The stimuli were presented on the center of the computer screen. All stimuli and tasks in the experiment were controlled by E-Prime 2.0 Professional software.

Figure 3: Examples of possible distracter items. *Left*: a related distracter item, featuring an identical head as the above category exemplars. *Right*: an unrelated distracter, featuring a head composed of non-presented features.

Procedure Upon arrival, participants were randomly selected into either the short list condition or the long list condition. Participants were then briefed about the stimuli they would be viewing. They were given incidental learning conditions, in that they were told to look at the stimuli and make a decision as to whether each stimulus was scary or funny, but were not told that they would be tested on their memory later in the experiment. During the study phase of the experiment, each exemplar was presented on the screen for 4500 ms while evaluating the exemplar to make the decision described above. Adult participants gave their responses by pressing keys on the keyboard while child participants gave their responses verbally to the experimenter, who then recorded the response on the keyboard. Each exemplar was preceded by a fixation cross which appeared for 500 ms.

To control for the different retention intervals between the short and long list, after completing the study phase of the experiment, both the short and long lists were followed by a distracter task that took place for 340 seconds for the short list and 60 seconds for the long list. The distracter task consisted of a rhythm game where participants listened to a sequence of 4 drumbeats and were then asked to tap out the sequence on the spacebar of the keyboard at the same tempo that the beats had played.

After completing the distracter task, participants were then instructed that they would be tested on their memory of the items from the study condition. Participants were instructed to respond “yes” if they recognized the item from the study phase, or to respond “no” if they did not recognize the item. The adult participants were instructed to give their responses on the keyboard while the children gave verbal responses to the experimenter who recorded the responses on the keyboard.

The test list consisted of 24 items: 8 of which were target items drawn from the study list, 8 of which were related distracters, and 8 of which were unrelated distracters. For the long list, each target item and related distracter was selected from each of the separate categories with no category being sampled more than once, such that all categories were represented on the test list.

Adult participants were tested in a laboratory at the university. Child participants were tested in local daycares or preschools by trained adult experimenters.

Results and Discussion

d' scores were calculated as a measure of memory sensitivity for all participants. Since we were most principally interested in the usage of the head information in making recognition judgments, only hits and false alarms to unrelated distracters were used in the calculations. Edge corrections were performed by adding 0.5 to the hit and unrelated false alarm counts and 1 to the target and unrelated distracter counts, as hit rates of 1.0 or false alarm rates of 0.0 produce infinite values for d' (Snodgrass & Corwin, 1988). Participants with d' less than or equal to 0 were excluded from the analysis (7 children and 4 adults). Hits, false alarms to related distracters, and false alarms to unrelated distracters are summarized in Table 1.

Table 1: Mean Proportions of Hits, Related False Alarms (FA), Unrelated False Alarms, and Mean d' Scores

	Adults		Children	
	Short List	Long List	Short List	Long List
Hits	0.82	0.86	0.66	0.64
Related FA	0.47	0.79	0.52	0.60
Unrelated FA	0.20	0.16	0.22	0.22

A repeated measures analysis of variance (ANOVA) was conducted on the responses for each subject, with list condition (short vs. long) and age group (adults vs. children) as between subjects factors and item type (target vs. related distracter vs. unrelated distracter) as a within subjects factor. Results indicated a significant main effect of item type, $F(2, 405) = 132.50, p < .001$, list type, $F(2, 405) = 4.28, p < .05$, as well as a significant item by age interaction, $F(2, 405) = 10.48, p < .001$, an age by list interaction, $F(1, 405) = 5.34, p < .05$, and an item by age by list interaction, $F(2, 405) = 3.09, p < .05$.

Planned post-hoc comparisons revealed a significant difference in adults' related false alarm rates across the two conditions ($t = 24.05, p < .001$), a difference which was insignificant for children ($t = 2.01, p > .05$). This replicates the findings of Sloutsky and Fisher (2004) but does not distinguish between the two models of recognition memory we're comparing against. Thus, planned post-hoc comparisons were also calculated on the differences in unrelated false alarms between the two list conditions for both adults and children, and revealed insignificant differences for both age groups (adults: $t = 1.16$, children: $t = .04, ps > .05$). Thus, neither age group revealed an inverse list length effect in their memory performance. However, there were differences in the groups' reaction times.

Table 2: Mean of Median RTs for Target Items, Related Distracters, and Unrelated Distracters

	Adults		Children	
	Short List	Long List	Short List	Long List
Target	1009	1011	3222	3126
Related	1344	1053	3130	3137
Unrelated	1198	944	2944	2859

To counteract positive skew in reaction time data, we took the median of each participant's reaction times for each of the 8 trials of every item type. The means of these median RTs can be seen in Table 2. We subjected the RTs to a repeated measures analysis of variance with list condition and age group as between subjects factors and item type as a within subjects factor. Results indicated a significant main effect of age, $F(2, 405) = 235.4, p < .001$. Planned post-hoc comparisons were also calculated on the RT differences between the two conditions for each item type and for each age. Significant differences between the two list conditions were found in adults for related distracters ($t = 2.95$) and unrelated distracters ($t = 3.75$), $ps < .01$. No significant differences in reaction times were found between the two list conditions in children, however it should be mentioned that children's responses were recorded by an experimenter and are thus difficult to interpret.

Because adults in the long list are quicker to react to unrelated distracters without receiving any decrement in accuracy, it is clear that they are in fact receiving a facilitation in rejecting unrelated distracters, which is not only contrary to the predictions of item-noise models but in accordance with the context-noise approach. However, this evidence does not give us any indication as to which model describes children's memory judgments. For this, we decided to run the same experiment in an eye tracker as a way of measuring the information that is being used in the test phase. Considering that the head is the most relevant feature of an unrelated distracter, the clearest prediction that can be made is that participants that have successfully abstracted the category context in the long list will look

significantly longer at the head relative to participants in the short list condition.

Experiment 2

Method

Participants Participants were 34 children (15 female and 19 male, $M = 5.25$ years, $SD = 0.60$ years) and 43 adults (18 female and 25 male, $M = 19.5$ years, $SD = 1.29$ years), participated in this experiment. Child participants were recruited from suburbs in Columbus, OH. Adult participants consisted of undergraduate students from The Ohio State University participating for course credit.

Apparatus Eye gazes were measured using a Tobii T60 eye tracker with a sampling rate of 60 Hz (60 data points collected per second). The device is integrated into a 17-inch monitor within a testing booth. A camera adjacent to the eye tracker provided a live feed to a trained experimenter at a nearby computer, who was able to monitor both the participant's eye movements as well as the stimuli they were viewing.

Procedure The procedure was nearly identical to that of Experiment 1 with the exception of a couple of minor adaptations to make this experiment compatible with the usage of an eye tracker. Each stimulus component (head, body, hands, and feet) was given a pre-determined area of interest (AOI) for recording eye gaze movements. To keep participants visual attention, we used a gaze-contingent fixation point between all trials in both the study phase and the test phase such that a stimulus would only be presented if participants maintained their gaze on the fixation point for a randomly calculated time interval between 300 and 700 ms. Additionally, since the stimulus appears in the center of the screen, the fixation point was randomly presented in the center of one of four quadrants on the screen to ensure that first looks were not biased by the fixation position.

All participants, including both adults and children, were run by trained adult experimenters at a nearby computer throughout the duration of the experiment. Because trials continue until a response is given, allowing adults to enter their own responses on a keyboard and having children's responses be entered by an experimenter will yield different patterns of data for the two groups. To make the data comparable between the two age groups, both adults and children gave all responses to the experimenter who entered them on a keyboard.

Results and Discussion

d' scores were calculated in the same manner as Experiment 1 and all participants with d' scores less than or equal to 0 were excluded from the analysis (2 adults and 4 children).

Because the head was the category relevant feature, all analyses were restricted to that area of interest. The

dependent measure we selected was the proportion of looks at the head, which was calculated for each item type. These results can be seen in Table 3. Because trials continued until participants gave their responses, with some trials continuing for as long as 10 seconds, the calculation was restricted from the start of the trial up until the mean reaction time (2 seconds for adults and 3 seconds for children).

Table 3: Mean Proportion of Looks at the Head for Target Items, Related Distracters, and Unrelated Distracters

	Adults		Children	
	Short List	Long List	Short List	Long List
Target	.261	.282.	.272	.247
Related	.272	.256	.276	.259
Unrelated	.261	.345	.296	.369

Considering that there is no category information in the short list (there were no repetitions of category exemplars), we interpreted looks at the head in the short list as a baseline degree of looking when only item information is available. Since the test phase is identical in both list conditions, any increase in looking at the head in the long list above that of the short list has to be due to differences in the study phase, most notably the repetitions of category exemplars. Visualizations of the looks at the head over time can be found in Figures 4 and 5.

Figure 4: Differences in proportions of looking at the head target and related distracter presentations for both children and adults recorded at each refresh rate (every 16.6 ms).

T-tests were calculated on the differences between the two list conditions for each item type to determine if the

differences in looking were significant. For adults, differences between the two lists were insignificant for both target items ($t(39) = .90, p > .05$) and related distracters ($t(39) = -.53, p > .05$). This is not surprising, considering that for both target and related distracter items, the head is not diagnostic of whether or not the item was on the list. This is not the case for unrelated distracters, where the category information (i.e.: the head) is the most relevant feature for discrimination. A t-test between the two list conditions for unrelated distracters was significant ($t(39) = 2.39, p < .05$), in that adults looked significantly longer at the head in the long list condition relative to the short list condition.

For children, differences between the two list conditions for target items ($t(28) = -.76, p > .05$), related distracters ($t(28) = -.46, p > .05$), and most importantly, unrelated distracters ($t(28) = 1.97, p > .05$) were all insignificant. Because children in the long list condition were not using the category relevant information above and beyond that of the short list, we interpret this to mean that category context information was not being accessed above and beyond that of item information. However, considering that this p-value is close to the significance margin, it is possible that there are subsets of children showing the effect that are outnumbered by children not showing the effect.

Figure 4: Differences in proportions of looking at the head unrelated distracter presentations for both children and adults recorded at each refresh rate (every 16.6 ms).

Conclusions

To summarize, for adults, increasing category length not only facilitated the rejection of non-category items but this facilitation manifested itself in a bias for category relevant features in their eye movements. For children, no such facilitation could be found in either their behavioral data or in their eye movements, implying that they may be meeting the predictions of the item-noise models of recognition memory.

We believe this is important research because despite there being a large volume of research on developmental differences in episodic memory, there has been little work connecting these differences to the components and processes of current memory models. We hope that this work as well as future work will make clear connections between the developmental literature and the modeling

literature and use them to construct a detailed theory of how memory changes with development.

Abstract

Visual search for a target is affected by visual similarity. Research on visual similarity has primarily focused on the high-level features of objects. Real-world objects are composed of low-level features that can be harder to measure and categorize. We have developed ObViS, an algorithm that measures the visual similarity of objects, based on Rao & Ballard (1995). ObViS calculates a high-dimensional vector that represents the low-level features of a real-world object. The algorithm was applied to a library of real-world object images in order to calculate the similarity of each object to every other object in the library. Two experiments evaluated the ability of our algorithm to predict the effects of visual similarity on visual search behavior.

Keywords: similarity; visual similarity; visual search.

Introduction

The visual similarity of objects in a scene is an important exogenous factor driving visual search behavior. Theories of visual search acknowledge the importance of similarity but do not specify how the visual search system uses these exogenous factors to guide search (Wolfe, 2007).

Most models of visual search, such as Treisman's Feature Integration Theory (FIT) (Treisman & Gelade, 1980), propose separate serial and parallel search mechanisms. A limited set of features such as color and size can be processed in parallel. Parallel visual search for a target that can be distinguished solely on the basis of one of those features is fast and efficient. Serial visual search for a target that is defined by multiple features is slower and requires attention to bind together the features of objects.

Six of the eight phenomena that Wolfe lists as affecting visual search response time entail some form of visual similarity: (1) target-distractor similarity, (2) distractor heterogeneity, (3) flanking/linear separability, (4) search asymmetry, (5) categorical processing, and (6) guidance (Wolfe, 2007). Each of the six types of visual similarity is specific to a low-level feature such as size, color, or orientation.

In addition to low-level features, research on visual similarity has also focused on high-level features. Approaches to the study of similarity include: geometric, feature-based, alignment-based and transformational measures of similarity (Goldstone & Son, 2005). Each of these approaches requires a form of reductionist representation of low-level properties, features, or elements.

Research on visual search has focused on issues surrounding the deployment of the serial or parallel processes. Visual search in the laboratory has used simple stimuli, manipulated set size or a few high-level features, tested search for a single feature, or the conjunction of two features, and used response time as their primary measure. Visual search in the real-world involved conjunctions of many low-level features that can be difficult to measure or categorize.

Statistical models of visual search, such as Itti & Koch (2001), have demonstrated the potential use images of real-world scenes in visual search experiments. Their mathematical model simulates the role of bottom-up saliency in guiding visual attention. It extracts low-level visual features such as color, intensity, and orientation from real-world images. The model calculates the conspicuity at every point in a scene and thus is able to provide bottom-up guidance to direct visual attention. Such models predict where the eye is attracted to in a visual scene and, thereby, have an important but limited role to play in explanations of visual search.

Top-down guidance may dominate bottom-up guidance, such as saliency, when there is a search target (Chen & Zelinsky, 2006). The goal of a visual search for a particular target is to find a location in a scene that matches the visual features of the target. The visual search system must be able to maintain a representation of the features of the target and compare those features with features at locations in the scene.

Rao & Ballard's Active Vision Architecture describes two primary visual routines: one for object identification and one for object location (Rao & Ballard, 1995). Statistical models of visual similarity, such as Rao & Ballard's, share with saliency models their reliance on low-level visual features. They differ from saliency models in that they define vectors of low-level visual features for a known target and for the locations in a scene. They then compare the similarity of the target vector with the vectors computed for locations in the scene. Top-down guidance is based on the statistical similarity of scene locations to the search target.

Cognitive architectures, such as ACT-R (Anderson & Lebiere, 1998), are used to model visual search behavior. Visual attention guidance in ACT-R suffers from the same reliance on high-level visual features that limits most theories of visual search. Statistical models of both bottom-up and top-down guidance would greatly increase the ability

of cognitive models to model real-world visual search. We have implemented a variation of Rao & Ballard’s model and applied it to the study of visual search with real-world objects.

Algorithm

Our algorithm, ObViS, is a variant of the one developed by Rao & Ballard (1995) and Rao et al (2002). The algorithm represents image patches using high dimensional feature vectors, where the computed features consist of the image response to oriented spatial frequency filters. Such filters approximate the receptive fields of simple cells in primary visual cortex, and are also similar to features obtained from the statistics of natural images (Hyvärinen, Huri, & Hoyer, 2009). In our implementation, we used 10 filters defined by the directional derivatives of a 2D Gaussian, using derivatives of up to 3rd order. The 10 combinations of Gaussian derivative order and orientation were as follows:

Table 1: Steerable basis set.

Order of derivatives	Filter orientations used (degrees)
0	0
1	0,90
2	0,60,120
3	0,45,90,135

This set of filters was chosen as it forms a steerable basis set—that is, the filter response at any orientation can be computed by a linear combination of the filter responses in the basis set (Freeman & Adelson, 1991). This property endows the feature representation with some rotation invariance, though we have not explored this property in our current work. In our implementation, the filter kernels were 9x9 pixel discretized versions of the Gaussian derivatives defined above. These 10 filters were applied to 3 color channels extracted from the original image: luminance, red–green, and blue–yellow color opponency channels. In addition, the filters were applied to these color channels at 5 spatial scales, by resampling the image to 25, 50, 100, 200, and 400% of its original size. Thus in total, each image was represented by the ObViS algorithm using a set of 150 measurements (10 filters x 3 color channels x 5 spatial scales). The use of color opponency channels was an extension to the algorithm presented by Rao et al (2002), as their implementation used only grayscale images whereas we are interested in capturing the visual similarity of color images. Finally, to determine the visual similarity between any two images, we determine the feature vector representation for two images, and then calculate the root mean square (RMS) of the difference between the images’ respective feature vectors. Images with low RMS difference are highly similar according to the ObViS measure of visual similarity.

Experiments

We conducted two visual search experiments that examined ObViS’ accuracy in predicting human visual search behavior. Subjects were asked to find target objects located in a circular array of object images from the Amsterdam Library of Object Images (ALOI) (Geusebroek, Burghouts, & Smeulders, 2005). We compared the timing, and accuracy of responses, and the number of fixations with predictions based on ObViS’ calculations of visual similarity. The two experiments differed in how similar the distractors displayed on each trial were to the target object. In experiment 1, for each trial, the distractors in the search array were all either similar, or dissimilar to the target. In experiment 2, for each trial, the distractors in the search array were approximately half similar and half dissimilar to the target.

Methods

Subjects. Thirty-four RPI undergraduates participated in the experiment 1 and twenty-seven RPI undergraduates participated in experiment 2. All subjects received course credit for their participation and signed informed consent forms. Subjects were screened for color blindness using a 10-plated Ishihara test (Ishihara, 1987).

Materials. The experiment was run on a Mac OSX computer and displayed on a 17” flat-panel LCD monitor with a screen resolution set to 1280 x 960 pixels. The software used for the experiment was written in LispWorks 5.0. The object images displayed during the experiment were 192 x 192 pixel images of real-world object from the Amsterdam Library of Object Images. A Cedrus RB-834 response pad was used to collect responses. White noise was played over headphones, using the freeware program Noise, to reduce auditory distractions. All subjects in these experiments were eye-tracked using an LC Technologies eye-tracker that recorded at a rate of 120 Hz. Subjects were asked to rest their chin on a chinrest throughout the experiment.

Design. The same 100 target objects were used as the target objects in experiments 1 and 2. The target object was present in the search array in only half of the trials. Subjects had to respond whether the target object was present, and if so, identify its location in the circular search array. Experiments 1 and 2 differed in how similar the distractors displayed on each trial were to the target object.

In experiment 1, subjects performed a visual search for a target in a search array that contained distractor objects that were either similar or dissimilar to the target. All subjects in experiment 1 saw the same 400 trials. In half of the trials, the distractor objects were all similar to the target; in the other half of the trials the distractor objects were all dissimilar to the target (Table 2).

In experiment 2, subjects performed a visual search for a target in a search array that contained approximately half similar and half dissimilar distractor objects (Table 3). The similarity of all distractor objects was based on calculations

from the ObViS algorithm. All subjects in experiment 2 saw the same 400 trials. The locations of all objects, in all trials, for all subjects, were randomized.

Table 2: Experiment 1 trials.

Trial count	Targets	Similar Distractors	Dissimilar Distractors
100	0	8	0
100	0	0	8
100	1	7	0
100	1	0	7

Table 3: Experiment 2 trials.

Trial count	Targets	Similar Distractors	Dissimilar Distractors
100	1	4	3
200	0	4	4
100	1	3	4

Procedure. Experiments 1 and 2 used the same procedures. All task instructions were presented using a Keynote presentation prior to the experiment. Subjects pressed a button on the response pad labeled “next” to begin each trial. A fixation cross, consisting of a white “+” was displayed in the center of the screen (Figure 3a). The trial did not begin until the participant had fixated on the fixation cross for 500 milliseconds. The target image was then displayed in the center of the screen for 300 milliseconds (Figure 3b). A random dot image was displayed for 300 milliseconds (Figure 3c). A circular search array was then displayed until the subject responded by pressing the “Present” or “Absent” button on the response pad (Figure 3d).

Following a response, the random dot image was displayed for another 300 milliseconds (Figure 3e). If the response indicated that the target was present, the subjects were asked to indicate the location of the target. Buttons were arranged on the screen in locations that matched the locations of objects in the search array (Figure 3f). Subjects responded by moving a mouse to and clicking on one of the buttons. Once the participant responded, a progress screen displayed the number of trials completed out of the total number of trials. Subjects pressed the response pad button labeled “next” to begin the next trial (Figure 3).

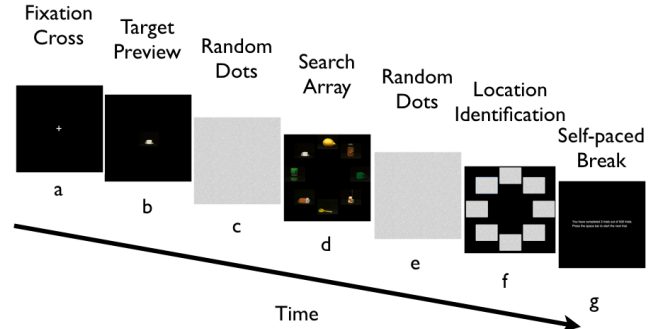

Figure 3: Experimental procedure for experiments 1 & 2.

Measures. The search array was displayed until the participant responded that the target object was either present or absent. The duration of time from the initial display of the search array until the participant responded was measured as the response time. The participant’s response was recorded and measured as target presence accuracy.

Eye-tracking data was recorded throughout the experiment. The number of fixations on distractor objects was counted for each trial.

Results

Response time was compared for trials in which the target object was present in the search array and trials in which it was absent.

In experiment 1, subjects took longer to respond on trials when the target was absent ($M = 1190.13$, $SE = 61.76$), than on trials in which the target was present ($M = 1066.22$, $SE = 34.05$), $t(129)_{\text{two-tail}} = 1.716$, $p = 0.089$, marginally significant.

Experiment 2 showed the same trend in response times: subjects took longer to respond on trials in which the target object was absent ($M = 1234.83$, $SE = 54.82$), as compared to trials when the target was present ($M = 1064.59$, $SE = 31.76$), $t(79)_{\text{two-tail}} = 2.872$, $p = 0.005$ (Figure 4).

Figure 4. Response time (ms), by target presence, in experiments 1 & 2.

In experiment 1, each trial contained distractors that were all similar or all dissimilar to the target object. Response time was significantly greater for trials with distractors that were similar to the target ($M = 1244.35$; $SE = 56.04$) than for trials with dissimilar distractors ($M = 1012.00$; $SE = 39.18$), $t(130)_{\text{two-tail}} = 1.66$, $p = 0.0009$ (Figure 5). In

experiment 2, each trials contained both similar and dissimilar distractors, so the analogous comparison was not possible.

Figure 5. Response time (ms), by distractor type, in experiment 1.

The number of fixations on distractor objects was counted for each trial. In experiment 1, when the target was absent, subjects averaged more fixations on similar distractors ($M = 2.99$; $SE = 0.22$), than on dissimilar distractors ($M = 1.76$; $SE = 0.17$). When the target was present, subjects averaged fewer fixations on distractors, but still had more fixations on similar distractors ($M = 0.88$; $SE = 0.07$), than on dissimilar distractors ($M = 0.41$; $SE = 0.04$) (figure 6). An ANOVA showed a significant main effect of target presence, ($F(1, 124) = 23.15, p < 0.001$). There was also a significant main effect of distractor type, ($F(1, 124) = 6.46, p < 0.05$). There was no significant interaction.

In experiment 2, when the target was absent, subjects averaged more fixations on similar distractors ($M = 1.96$; $SE = 0.11$), than on dissimilar distractors ($M = 0.94$; $SE = 0.07$). An ANOVA showed a significant main effect of target presence, ($F(1, 100) = 70.20, p < 0.001$). There was also a significant main effect of distractor type, ($F(1, 100) = 25.73, p < 0.001$). There was a significant interaction between the two factors ($F(1, 100) = 25.73, p < 0.001$); there was a larger difference in mean fixation count for trials with similar distractors when the target was absent. When the target was present, subjects averaged fewer fixations on distractors, but still had more fixations on similar distractors ($M = 0.54$; $SE = 0.03$), than on dissimilar distractors ($M = 0.22$; $SE = 0.02$) (Figure 7).

Figure 6. Mean number of fixations on distractor object per trial, by target present and distractor type, in experiment 1.

Figure 7. Mean number of fixations on distractor object per trial, by target present and distractor type, in experiment 2.

Target presence accuracy was a measure of the accuracy of subjects' response that the target was present or absent. Overall, subjects made few mistakes in both experiment 1 ($M = 96.32\%$; $SE = 0.36$), and experiment 2 ($M = 96.30\%$; $SE = 0.002$). In experiment 1, accuracy was significantly higher for trials in which the target was absent ($M = 97.06\%$; $SE = 0.36$), than when the target was present ($M = 95.58\%$; $SE = 0.60$), $t(130)_{two-tail} = 2.12, p = 0.018$. In experiment 2 there was no main effect of target presence on accuracy; accuracy for trials with the target absent ($M = 95.83\%$; $SE = 0.002$), was not significantly different than trials with the target present ($M = 96.54\%$; $SE = 0.003$), $t(79)_{two-tail} = 1.36, p = 0.17$. Each trial in experiment 1 had distractors that were either all similar to the target or all dissimilar to the target. Target presence accuracy was higher for trials with dissimilar distractors ($M = 97.76\%$; $SE = 0.60$), compared to trials with similar distractors ($M = 94.88\%$; $SE = 0.36$), $t(130)_{two-tail} = 4.31, p = 0.0001$.

General Discussion

We developed the ObViS algorithm in order to measure visual similarity for the top-down guidance of visual search. One of the goals of this work was to extend the study of visual search and visual similarity to real-world objects. We replicated the basic visual search phenomena. The algorithm's calculations were used to manipulate the similarity of visual search distractors. The response time data replicated phenomena typically found in laboratory search tasks using very simple stimuli; subjects took longer to find target when the distractors were similar to the target. They also made more mistakes in their responses when the distractors objects were similar to the target.

Fixation data added an additional source of information that has not typically been used in the study of similarity. Our results demonstrated that the longer response times for visual searches with similar distractors were the result of a greater number of fixations.

There are other visual search phenomena that we did not test. We did not manipulate set size, randomize locations, occlude objects, or place objects in natural scenes. All of

these phenomena could be studied in future work using our measures of visual similarity.

Conclusions

We developed a measure of the visual similarity of real-world objects based on the representation of their low-level visual features. We applied the algorithm to a library of object images. The resulting similarity calculations were used to manipulate the similarity of distractors in visual search tasks. We replicated basic findings on the effects of target presence and distractor similarity, using real-world objects. Further refinement of the ObViS algorithm could improve its ability to predict the effects of visual similarity on visual search. The algorithm could be used to create iconic representations to guide top-down visual search in computational models. ObViS could extend the study of visual search and visual similarity to real-world objects and even provide visual representations for cognitive architectures.

Learning Structured Preferences

Abstract

Learning the preferences of other people is crucial for predicting future behavior. Both children and adults make inferences about others' preferences from sparse data and in situations where the preferences have complex internal structures. We present a computational model of learning structured preferences which integrates Bayesian inference and utility-based models of preference from economics. We experimentally test this model with adult participants, and compare the model to alternative heuristic models.

Keywords: Theory of Mind; Bayesian Modeling; Preference Learning

Introduction

Children and adults are highly adept at inferring hidden mental states such as preferences from observed behavior. Work in developmental psychology has shown that by 18 months, children have learned that others have preferences which are different from their own; moreover, they can infer these preferences on the basis of observing several choices (Repacholi & Gopnik, 1997). Further work has shown that children's inferences are sensitive to the statistical properties of observed choices, so that choices which are less likely a priori are more likely to reflect strong preferences (Kushnir, Xu, & Wellman, 2008).

Despite the ease with which people appear to reason about others' preferences, such reasoning is a highly challenging computational task. An individual's preferences are never fully determined by their past choices. Moreover, people have to infer preferences on the basis of sparse data, perhaps only a few observed choices.

Our goal in this paper is to develop a computational model of preference learning on the basis of sparse observations. In the spirit of Marr's levels of explanation, we must first spell out the computational problem which has to be solved. In this case, the problem has two parts. First, what exactly has to be learned? Are an agent's preferences simply a ranking of different choices, or do they have more internal structure? Second, how can these preferences be learned on the basis of observing an agent's choices?

Previous Work

Previous computational models of preference learning have mostly focused on the second question. Central to these models is the *principle of rationality*, according to which people are rational agents whose behavior is directed towards satisfying their preferences. Crucially, these models do not claim

that the principle of rationality is descriptively true, but rather that it is assumed by people's intuitive theory of mind. These models treat the problem of preference learning as one of inverting the principle of rationality: in order to infer someone's preferences from their behavior, consider what preferences would have made this behavior rational.

In the inverse-planning model of Baker, Tenenbaum, and Saxe (2007), the task is to determine which of several candidate goals an agent desires on the basis of partial movements towards those goals. The agent is assumed to have a ranking of the goals, from best to worst, and which of the goals is desired is inferred by assuming that the agent is moving efficiently towards the desired goal. Using Bayesian inference, the model recovers a distribution over desired goals by supposing that a given goal makes efficient movement toward that goal highly likely. In this paper, there is a sophisticated link between preference and behavior, but preferences themselves have a simple structure.

Lucas et al. (2009) again use a Bayesian model for inference, but use a more sophisticated model for preferences. Instead of having preferences over outcomes, different possible object features have different utilities (are differentially preferred). Preferences over objects are given by a weighted sum over the objects' features. Agents are assumed to choose the object which gives them the maximal quantity of desirable features.

These models were not intended to capture how preferences might be learned when the goods being chosen between have complex functional relationships. Suppose, for example, that someone is choosing between a bicycle frame and bicycle wheels. It will not generally make sense to say that they prefer the frame to the wheels, or vice-versa. Rather, they most likely want an entire bicycle, meaning that whether they want the wheels will depend on whether they already have a suitable frame. Any computational model of this situation will have to account for this additional structure in the agent's preferences.

We combine the Bayesian modeling of Baker et al. and Lucas et al. with formal models of structured preferences developed by economists. We test our model experimentally by examining adult inferences in tasks that provide information about the interactions between goods. By systematically varying these interactions, we try to determine whether preference learning is sensitive to the structure of the preferences being learned.

¹The first two authors contributed equally to the paper

Modeling Structured Preferences

Economists are interested in modeling agents who are choosing between goods that can have a range of functional relationships. They are also interested in modeling agents over long spans of time, meaning that they have to account for how novel goods may interact with goods already possessed by the agent. In order to model these interactions and effects of context, economists often will not assign utilities to individual goods, but rather to bundles of goods, where the bundle (A, B) consists of A units of one good and B units of another good. Different interactions between goods in a bundle can be captured by different utility functions on these bundles.

We will be considering three kinds of interactions between goods, each of which is standard in economics (see, e.g., Mas-Colell, 1995). The first class of goods are known as *substitutes*. Two goods will be substitutes if either can be used, independent of the other, to accomplish a single goal. For example, two brands of cherry soda are substitutes for each other: if someone wants to drink cherry soda, they can satisfy that goal by drinking either brand. The second class of goods are *complements*. These goods must both be used in a specific proportion to accomplish a particular goal. Bicycle wheels and a bicycle frame must be put together in a ratio of two to one in order to accomplish the goal of building a functional bicycle. The last class of goods will be described by a *Cobb-Douglas* utility function, which is presented below. These goods perform some goal most effectively in a particular ratio, but can still perform the goal to some extent in other ratios as well. If someone wants to have a fun vacation, it may be best to spend some number of days on the beach and some number of days on a cruise, as an entire vacation on the beach might get boring. However, additional days on either the beach or the cruise will still improve the trip.

These interactions can be captured by three different utility functions on bundles of goods. If two goods are substitutes, then we can set:

$$u(A, B) = \alpha \cdot A + (1 - \alpha) \cdot B \quad (1)$$

where A is the quantity of the first good and B is the quantity of the second good. The weight α encodes how well each of the goods serves its function. This equation says that we always get the same amount of utility out of an extra unit of the first good, regardless of how much of the second good we have, and vice-versa. This is essentially the utility function used in Lucas et al., with A and B representing the quantities of two different features.

For complements, we set the utilities of the two goods to be:

$$u(A, B) = \min(\alpha \cdot A, (1 - \alpha) \cdot B) \quad (2)$$

Parameter α in this case determines the required proportions between the two goods. Once the goods are in their correct proportions, an additional unit of either good alone will not increase utility. In order to increase utility, extra units of both goods have to be added.

The Cobb-Douglas utility function is defined by:

$$u(A, B) = A^\alpha \cdot B^{1-\alpha} \quad (3)$$

As in the case of complements, the parameter α determines the optimal ratio of the two goods. Unlike in the case of complements, additional units of a single good can still increase utility without additional units of the other good. Crucially, there is diminishing marginal utility in each good, holding the other good fixed. In other words, each additional unit of a single good increases utility less and less, unless more of the other good is added.

These utility functions are often the first introduced in microeconomics textbooks, both because of their simplicity and because the structures which they encode are so common. However, the space of possible utility functions and possible interactions between goods is enormous (Mas-Colell, 1995). Though we will only be considering these three cases, our model of preference learning, which we describe next, is compatible with any parameterized utility function.

Computational Modeling

Economists have supposed that individual preferences can be represented by the utility functions above and that agents choose bundles with highest utility. By assuming that preferences have this form, predictions can be made about choice in unobserved situations, by computing the relevant utilities.

On our model of human intuitive preference inference, people's intuitive inferences use the same representation of preferences as economists—people are intuitive economists. They can represent different utility function types, corresponding to the way goods interact in a particular situation. For a given utility function type, they can represent different relations between the goods involved—e.g. that a particular ratio of one good to another is optimal. Again following economics, we propose that people employ the principle of rationality, connecting preference to choice.

In order to model reasoning about agents' choices in situations where the objects of choice interact with each other, we integrate the structured utility functions discussed above with Bayesian inference and the principle of rationality. We assume that the observed agent's preferences over a given set of objects is well-described by one of the utility functions discussed above; which of the utility functions is appropriate in a particular situation will depend on both the causal relations between the objects and the agent's goals. Whatever the utility function of the agent, we assume that she is approximately rational and softly maximizes her utility. The probability of a choice given her utility function is therefore given by the Luce-Choice rule:

$$P(c|u) \propto \exp(\beta \cdot u(c)) \quad (4)$$

where u is the agent's utility function, c is a choice, and β is a noise parameter that determines how close the agent is to rational. We set β equal to 15 throughout.

We do not attempt to model how an observer might determine, before seeing any of an agent's choices, which utility function the agent is using in a particular situation. Rather, we assume that the observer has a prior distribution $P(u)$ over the possible utility functions which apply in the situation. For example, we will not attempt to model how one might learn that bicycle wheels and bicycle frames are complements. In general, $P(u)$ will depend on the observer's prior knowledge about the relations between the goods in question. The observer is also given a prior $P(\alpha)$ for each utility function u over the parameter α of the utility function. Throughout, we assume $P(\alpha)$ follows a Beta(2,2) distribution.

These assumptions allow us to use Bayesian inference to infer an agent's utility function from her choices. Given observed choices C , the posterior over utility functions is given by:

$$P(u|C) \propto P(C|u) \cdot P(u) \quad (5)$$

where u is the utility function with parameter α . This formula inverts the generative model of the agent's behavior captured by her utility function and the Luce-Choice rule (Equation 4). From observed choices C , we can infer the probability of a novel choice c by averaging over the agent's utility functions:

$$P(c|C) = \int P(c|u)P(u|C)du \quad (6)$$

Using the Luce-Choice rule to give the likelihood $P(c|u)$, we recover the mixed multinomial logit model which is used in Lucas et al. as well as many papers in econometrics (McFadden & Train, 2000).

Experiment

In the following experiment we test the quantitative predictions of the structured preference learning model. We designed scenarios in which an agent chose between bundles of goods, with each bundle containing A amount of one good and B amount of another good. In order to distinguish our model from previous utility-based models (Baker et al., 2007; Lucas et al., 2009) we varied the functional relationship between the goods described in the scenarios in order to match the three utility function types described above. Thus we constructed three separate groups of scenarios. In the Substitutes Group, the two goods were substitutes for each other. Hence, economists would model the preferences of an agent over these goods using a substitutes utility function (Equation 1). In the Complements Group of scenarios, the goods were complements for each other and so preferences over them would be modeled by a complements utility function (Equation 2). In the Cobb-Douglas Group, the goods were related in the way described by Cobb-Douglas utility function (Equation 3).

Our experiment aims to question whether people are intuitive economists. That is, whether they recognize the functional relationship between goods in a particular scenario and model an agent's preferences with a utility function over bundles of the goods that is appropriate to that functional relationship. A key prediction of the theory from economics is

that different functional relationships will lead to different patterns of preference across bundles of the same size. For example, once you have two wheels for your bike, additional wheels are worth very little, while after two days at the beach, further days might still be very desirable. To test this, we designed scenarios for which the numerical properties of the bundles could be held fixed while the functional relationship between the goods in the bundles was varied.

Methods

Participants Participants were 480 individuals on Amazon's Mechanical Turk who received a small compensation for their time.

Materials and Procedure As noted above, we designed three groups of scenarios: Substitutes, Complements and Cobb-Douglas. Scenarios differed across the groups in how the goods being acquired related functionally, and hence in which utility function models preferences for the goods in the scenario.

An example stimulus for the Cobb-Douglas group is the following:

Last year, John and his wife took a one-week vacation in the Caribbean. When John was booking the trip he had the choice between two package deals, which both cost the same amount:

- (A) 4 days on the beach and 2 days on a cruise
- (B) 3 days on the beach and 4 days on a cruise.

John chose package (B) and thought that was the best choice given his options. This year John and his wife are planning another trip to the Caribbean. John needs to book the trip in advance. He has to decide between two package deals. Both deals cost the same amount:

- (C) 5 days on the beach and 5 days on a cruise
- (D) 8 days on the beach and 2 days on a cruise.

Which option should John take?

As this example illustrates, the scenarios consisted of three parts: (1) setup of the first choice situation, (2) the agent chooses one bundle of goods over another, and (3) the agent faces a new choice situation. Each scenario was shown in 16 numerical conditions: these were the quantities of goods in each bundle in the two choice situations. In the example above, the bundle (3,4) was chosen over the bundle (4,2), and participants were asked to choose between the bundles (5,5) and (8,2). In different numerical conditions, the quantities in these bundles were varied. In pre-testing, we found that participants were making inferences about the cost of each bundle on the basis of bundle size; as a result, we subsequently stated in each scenario that the bundles being chosen from were the same price. Because this was incompatible with one of the scenarios, it was removed from subsequent testing. This left a total of 11 scenarios: three in the Cobb-Douglas Group, four in the Substitutes Group, and four in the Complements Group. Pre-testing also suggested possible order effects in some of the numerical conditions, which were

controlled in subsequent experiments. The scenarios were crossed with the numerical conditions, for a total of 11x16 inference questions.

Participants each received five or six distinct scenarios; numerical conditions were randomized across participants.

If people are sensitive to the structure of the agents' utility functions, then identical numerical conditions should give rise to different patterns of inference, depending on the scenario group. For example, if the goods are complements, then the observer should be uncertain about the optimal proportion of one good to the other. They will take the agent's initial choice as evidence about the optimal proportion, and will subsequently choose the bundle which fits this inferred proportion as closely as possible. On the other hand, if the goods are substitutes, then they will take the initial choice as evidence about how well each good serves its function, and will subsequently choose the bundle which maximizes the weighted sum of the two goods. If both bundles have the same size, then they will choose the one with the most of the better good.

Model Predictions

In order to make model predictions, we used the multinomial logit model (Equation 6) to find the probability of taking option (C) or (D) conditional on the agent's first choice. This probability was approximated through MCMC simulations, using the Metropolis-Hastings method.

We computed these probabilities under a variety of settings for the noise parameter β in the soft-max equation (Equation 4) and for the prior distribution $\text{Beta}(\alpha, \alpha)$ over the utility functions' weight parameter. The noise parameter was set to 15 and α was set to 2 based on the fit of the model to the data over all conditions. Figure 1 shows the sensitivity of the model's predictions to the value of β . The mean squared error of the model varied between 0.04 and 0.1 as β varied between 0.1 and 20. We similarly analyzed the model's sensitivity to the value of α . We found that the mean squared error of the model varied between 0.04 and 0.1 as α varied between 1 and 10.

Our computational model predicts agent preferences by matching the appropriate utility function to the scenario. Thus, e.g. scenarios in the Complements group will be modeled with very strong prior probability on the Complements utility function and likewise for the other two groups.

In order to assess the distinctive predictions of our model, we implemented three heuristic models of preference inference. These heuristics implement rules for making preference inferences that are not based on calculations of utility. The heuristics worked as follows. The Sophisticated Ratio Heuristic was a model of ratio-matching, in which goods are selected based on how close their ratio is to an optimal ratio. The heuristic considers a range of possible optimal ratios and uses Bayesian inference to integrate over these ratios in making predictions. This differs from the complements function in being insensitive to absolute quantities of the goods. The Crude Ratio Heuristic was similar to the Sophisticated

Ratio Heuristic, except that instead of considering a range of possible ideal ratios, it treats the ratio of goods in the observed choice as ideal. The Max Heuristic assumes that one of the two goods is preferred, and that agents will always choose the bundle that contains the greatest quantity of the preferred good. This differs from the substitutes utility function in being insensitive to the quantity of the non-preferred good. These three heuristics do not assign utilities to bundles but instead simply select one outcome as the best.

Table 1: Correlations between the three different utility models and subject judgments. Scenarios 1-3 were intended to be best fit by a Cobb-Douglas utility function; scenarios 4-7 by a Substitutes utility function; and scenarios 8-11 by a Complements utility function.

Scenario	Cobb	Substitutes	Complements
1	0.79	0.83	0.50
2	0.62	0.72	0.30
3	0.80	0.70	0.80
4	0.85	0.95	0.45
5	0.69	0.83	0.32
6	0.87	0.91	0.49
7	0.81	0.93	0.36
8	0.64	0.34	0.87
9	0.63	0.41	0.86
10	0.78	0.74	0.69
11	0.46	0.23	0.87

Table 2: Correlations between the best heuristic models and participant judgments.

Scenario	Crude Ratio	Max
1	0.55	0.89
2	0.57	0.73
3	0.91	0.76
4	0.48	0.95
5	0.37	0.76
6	0.61	0.93
7	0.55	0.96
8	0.82	0.44
9	0.94	0.49
10	0.70	0.80
11	0.87	0.26

Results. We first consider the model fit when all of the weight of the prior probability distribution is placed on a particular utility function type. As noted above, scenarios were grouped based on which utility function we believed would best fit the goods in the scenario. If participants are sensitive to the functional relationship between the goods in each scenario, then their judgments should be best fit when a high prior probability is placed on the group's utility function

M

Figure 1: Sensitivity of model performance to the value of the noise parameter β .

M

Figure 2: Human judgments vs. utility model predictions (blue dots) and heuristic predictions (green triangles) for a complements scenario. Other scenarios showed a similar relationship between human judgments and the predictions of the two models.

type. In all of the Substitutes scenarios and three of the four Complements scenarios, the human data was best fit by the scenario's corresponding utility function type. Participants' judgments in two of the three Cobb-Douglas scenarios are best fit by the substitutes utility function. These results are shown in Table 1.

We next tested the fit of our heuristic models. The free parameters of the heuristics were chosen to maximize overall correlation with the human data. The Crude Ratio and Max heuristics had the highest correlations, so we restrict our attention to them. The Max Heuristic had high (above 0.7) correlations with human judgments on all of the Cobb-

Douglas and Substitutes scenarios. The Crude Ratio Heuristic had similarly high correlations on all of the Complements scenarios. These results are shown in Table 2.

Discussion

Our experiment aimed to investigate two questions. The first was whether people are sensitive to the functional relationships between goods when they make inferences about people's preferences. The second was, if people are sensitive to these functional relationships, what do they learn about others' preferences from their observations? Our results provide evidence that participants were sensitive to the func-

tional relationships between goods. In particular, participants appeared to distinguish between the Complements scenarios and the other scenarios, although we did not find evidence that they distinguish between the Cobb-Douglas and Substitutes scenarios. This is indicated by the fit of both the utility and heuristic models. A single utility model (with all of its prior weight on the substitutes utility function) and a single heuristic (the Max Heuristic) correlate well with human judgments in the Cobb-Douglas and Substitutes scenarios. On the other hand, these two models fare poorly on most of the Complements scenarios. The complements utility model and the Crude Ratio Heuristic provide better fits for these scenarios.

The performance of the Max Heuristic on a particular scenario is very well predicted by the performance of the substitutes utility function on that scenario; the same is true of the Crude Ratio Heuristic and the complements utility function. The Max Heuristic naively tracks a relationship which is important to the substitutes utility function, namely which good is favored over the other. The Crude Ratio Heuristic gives a noisy estimate of the optimal ratio between goods, which is similarly important to the complements utility function. This provides evidence that participants were sensitive to the optimal ratio of goods in the Complements scenarios, and to which was the preferred good in the other scenarios.

It is an interesting question whether the utility-based or heuristic models provides a more promising approach to modeling preference learning. The best heuristic models were able to capture the qualitative shape of participants' judgments. The heuristics were able to correctly classify bundles as more or less likely to be chosen. A representative scenario is shown in Figure 2. On the other hand, human judgments showed a gradedness that was better captured by the utility models. As predicted by the utility models, participants varied across numerical conditions in how strongly they thought one bundle should be chosen over another. This is also shown in Figure 2.

Conclusion

We have presented a computational model of structured preference learning. Our model incorporates Bayesian inference with economic models of internally complex preferences. Using a standard tool from econometrics, it can be used to model how individuals infer what someone prefers on the basis of past observations. We experimentally tested the model, and found that participants were sensitive to the functional relationships between goods in some of the ways that the model predicts. Future experiments could help to differentiate the utility-based and heuristic models. These models will make distinct predictions, for example, when the sizes of the bundles being chosen between are different. Bigger bundles will, all things being equal, be preferred by the utility-based models, while this is not always true for the heuristics.

Further work needs to be done in systematically varying the structure of the preferences being learned. This may be done by explicitly varying the causal structures of the choice

scenarios so that subjects' prior beliefs about these relations do not come into play. This suggests a further line of research: studying whether individuals can make use of more complex functional relationships than the ones that were considered here. If individuals can effectively learn others' preferences in a range of situations, then it is unlikely that these preferences will be captured by the simple functional forms studied here.

Beyond Boolean logic: exploring representation languages for learning complex concepts

Abstract

We study concept learning for semantically-motivated, set-theoretic concepts. We first present an experiment in which we show that subjects learn concepts which cannot be represented by a simple Boolean logic. We then present a computational model which is similarly capable of learning these concepts, and show that it provides a good fit to human learning curves. Additionally, we compare the performance of several potential representation languages which are richer than Boolean logic in predicting human response distributions.

Keywords: Rule-based concept learning; probabilistic model; semantics.

Introduction

Every cognitive theory requires a hypothesis about mental representation—what structures and operations form the basis for complex ideas. High-level, symbolic theories often characterize this representation using a *representation language (RL)* (Fodor 1975) that specifies primitive elements and composition laws which can be used to form complex cognitive structures. This approach has been extensively studied within two traditions in cognitive science: concept learning and linguistic semantics. In models of rule-based concept learning (Bruner, Goodnow, & Austin 1956, Shepard, Hovland, & Jenkins 1961, Feldman 2000) the representation language has typically been simple Boolean logic, which represents concepts—stable mental representations—using conjunctions, disjunctions, and negation of simple perceptual primitives. Goodman et al. (2008) presented a model of probabilistic learning for rule-based concepts that represents concepts in a simple propositional language and achieves state-of-the-art fits to experimentally-measured difficulty of learning Boolean concepts. The logical complexity of concepts appears to play a crucial role in determining how these concepts are learned: learners are biased to preferentially learn concepts with simpler representations.

However, simple Boolean concepts can capture only a very limited range of the human conceptual repertoire. People readily conceptualize context-dependent meanings such as “happiest,” and can form more complex and abstract relational concepts like “everyone with two or more siblings.” Semantic theories capture such meanings using primitive operations which manipulate and quantify over sets of objects, rather than simply features and propositional connectives. The denotation of a quantifier like “some,” for instance, is a function which takes two sets, A and B , and is true only when the intersection of $A \cap B$ is nonempty¹ (Montague 1974).

¹In a sentence like “Some boy smiled,” the set of boys would

In this paper we extend the probabilistic approach to concept induction to representation languages which manipulate sets of objects. We first describe an experiment that explores the difficulty of learning concepts that involve set-manipulation and quantification. Second, we compare human difficulty to the predictions of models with varying RLs. Our modeling work has two goals: the first is to test different RLs to see which provide the best account of people’s learning behavior. Each possible RL differs in representational power and the way in which it assigns probability to potential concepts. This means that different RLs make different predictions about people’s learning trajectories and we can therefore compare RLs by determining how well they match subjects’ empirical response distributions. The second goal of the modeling work is to provide an explicit *learning theory* for these concepts. Work on boolean concept learning has provided a probabilistic model which accounts for subjects’ behavior in acquiring boolean concepts, but there is no comparable formal theory for concepts which require a richer representation language. Such a theory would importantly extend rule-based concept learning in cognitive science to richer, linguistically-interesting semantic representations.

Behavioral experiment

The experiment we present aims to extend the rule-based concept learning paradigm to concepts which refer to sets and properties of sets of objects. To do this, we used a learning paradigm where subjects see a set of objects, guess at a labeling of the objects according to the unknown target concept, and receive feedback on their responses. Subjects used this feedback to infer the target concept.

Procedure

Amazon’s Mechanical Turk was used to run 381 subjects. Each subject was told that they had to learn the meaning of a novel word, *wudsy*, from an alien language. Subjects were told that aliens use *wudsy*, to refer to some objects in a collection of objects, and that they have to figure out what makes an object *wudsy*. Subjects were informed that what makes an object *wudsy* may depend on which other objects are present.

During the experiment subjects were shown a set of four objects which varied in size, color, shape, and background color. An example set of items is shown below:

be A and the set of things which smiled would be set B . “Some boy smiled” is true if and only if the intersection of boys and things which smiled is nonempty.

Figure 1: An example set.

After seeing a set of objects, subjects were told to guess which objects were the *wudsy* ones. For each object in the set, they were required to respond “Yes,” “No,” or “NA,” and were told to respond “NA” when it is unspecified whether an object is *wudsy*. For this example, subjects might entertain the concept is “red objects,” in which case they should respond that the second and fourth objects are in the concept and the first and third are not. However, subjects might also entertain that the meaning of *wudsy* is context-dependent, as in, for instance “unique smallest.” Similarly, the concept may also be complex, such as “same shape as the object with the darkest background.” The shape with the darkest background is a circle, so subjects should say all the circles are in the concept; if all backgrounds are the same color, subjects may respond “NA.” After responding, subjects were told what the correct answer was according to the target concept, but never given explicit instruction on the target concept. Subjects who responded incorrectly to any element of the set were penalized with a 5 second delay, during which they saw the set and the correct responses for each object.

Materials & Concepts

The meanings subjects were required to learn consisted of the concepts shown in Figure 2. These concepts include simple boolean rule-based concepts (e.g. “circles” and “circles or blue objects”), as well as more complex concepts which cannot be expressed in boolean logic (“larger than all the other objects”), and concepts which require several bound variables to express (“Same shape as the largest blue object”).

Several of the concepts we studied focus on size predicates. This is because size predicates, such as “largest” and “smallest,” are salient properties of objects in sets. They are perhaps the simplest words whose meaning is context-sensitive, and therefore not expressible with only conjunctions, disjunctions, and negation of object features. We included three simple size relations, “there exists a smaller object,” “larger than all other objects,” and “one of the largest objects.” Note that the latter two differ with respect to uniqueness: if there are two objects of the maximal size, then neither is larger than all other objects, but both are one of the largest².

Because we included these simple size predicates, it is natural to include complex concepts which are also based on size, such as “same shape as the largest object,” “same shape as the largest blue object,” and “unique largest blue object.” All three of these concepts require finding the largest object and selecting other elements based on the properties of the

largest. As such, they require answering *NA* when there is not a unique largest element³.

Results

The plots in Figure 2 show subjects’ accuracy at labeling which objects are *wudsy* (y-axis), as a function of the amount of labeled data they received (x-axis). Subjects who were more than 3 standard deviations below the mean accuracy for each concept were removed in order to exclude subjects who were not performing the task. The vertical error bars show binomial 95% confidence intervals, and the red lines show the best fitting model, which is discussed in the next section. These results reveal several interesting qualitative trends. First, subjects accuracies increase for almost all of the concepts. Importantly, even though the subjects receive labeled data, they are never explicitly instructed on the concept. This means that high accuracy can only be achieved by generalizing from the observed data, which requires inferring abstract rules for these concepts.

Two interesting exceptions to subjects’ general ability to learn these concepts are “Everything iff there is a triangle” and “Everything iff there is a single blue object.” Subject performance on these concepts does not substantially improve, and these are intuitively somewhat unnatural concepts which require all elements of a set to be selected based on what the set contains. Words do exist with similar denotations in English—for instance, a set is *contaminated* if one element of the set is bad—but subjects find these types of concepts unusually hard to learn.

Figure 2 reveals a number of places where subject performance drops temporarily for a single set—for instance at item 32 of “there exists a smaller object.” Post-hoc analysis revealed that many of these dips are caused when subjects see one of the first exceptions to a plausible alternative concept: item 32 is the first time that all objects in the set are the same size. Subjects responded *true* to objects in this item, consistent with a concept such as “not smaller than the rest,” but incorrect according to the target concept.

Analysis

We first used a regression to analyze how subjects’ learning rate varied across the 12 concepts studied⁴. In each logistic regression the outcome was whether the subject’s response to each object in a set was correct, and the independent variable was the number of items each subject had seen so far (0...70). The key prediction we tested is whether slopes (regression coefficients)—which quantify the effect of additional data on accuracy—differed between concepts.

³This makes it difficult to compare these concepts with the simple size-predicate concepts since the latter never require *NA*, which may be a difficult response for subjects to learn, independent of the concept.

⁴Because subjects typically were only run on one concept, subject effects are confounded with concept. We therefore performed a separate mixed-effect logistic regression (Gelman & Hill 2007) *within* each concept including slopes and intercepts by subjects. Regression coefficients across concepts were compared using t-tests.

²These concepts are interesting in part because it is unclear which of these meanings corresponds to the denotation of “largest” in English, and also what role pragmatics plays in understanding “largest” in normal conversation.

Figure 2: Subject accuracy (y-axis) in labeling the *wudsy* objects as a function of trial number (x-axis). Black lines show subject mean percent correct. Error bars are 95% confidence intervals. The red line shows the best-fitting model, although note that the model is fit based on agreement with the full distribution of responses, not the accuracies shown here. Numbers in the lower right show the correlation between the model and human accuracies.

Our results replicate basic effects in Boolean concept learning (Bruner, Goodnow, & Austin 1956, Shepard, Hovland, & Jenkins 1961). As is clear from Figure 2, simple concepts (“blue objects”) are easier to learn than complex concepts (“circles and blue objects”) ($t = 2.70, p < 0.01$). In addition, our results replicate that conjunctions (“circles and blue objects”) are easier to learn than disjunctions (“circles or blue objects”) ($t = 3.10, p < 0.01$). These replications provide validation for our experimental paradigm.

These effects of complexity also generalized to more complex functions than those expressible in Boolean logic. For instance, “The unique largest blue object” was easier to learn than “The same shape as the unique largest blue object” ($t = 2.71, p < 0.01$). This effect is interesting because it shows the additional difficulty associated with more complex set-theoretic concepts. The latter concept requires an additional bound variable to express in first-order logic, or a lambda abstraction to express in lambda calculus, and the effect of this complexity is reflected in subjects’ learning rates. The regression revealed no difference between uniqueness presuppositions for concepts involving the largest element of a set: “larger than all other objects” was no more difficult than “one of the largest objects” in either slopes ($t < 1.26, p > 0.20$) or intercepts ($t < 1.83, p > 0.05$).

Importantly, subjects may infer a *different* concept from

the one that was used to generate the data—high accuracy on some concepts can be achieved by inferring related concepts. To address this, we compared how well closely-related concepts predicted subjects’ responses in the last half of the experiment. For each target concept in Table 1, we looked at data points for which the target concept made a different prediction from the specified alternative hypothesis. For instance, we looked at sets for which “Largest blue object” and “blue objects” made different predictions—that is, when there are multiple blue objects, so not all of them are the largest. We then computed the percent of subjects who responded more than half the time in agreement with the target concept, as well as the overall proportion of time subjects responded with the target concept. These results show that for most of the concepts, subjects typically responded in accord with the target concept and not a close alternative. The only exception to this is the comparison between “One of the largest objects” and “size = 5” (In the items, “5” is the maximal size for objects), which showed that subjects may have been learning to identify objects based on comparing them to absolute size, rather than a context-sensitive measure of “largest”. In general, though, these results show that subject’s pattern of learning cannot be explained by simpler theories which make reference only to only individual objects’ properties. This is especially striking given that many of the alter-

Target	Alternative	Subject pct.	Response Pct.
Larger than all other objects	One of the largest objects	1.00	0.94
	Size = 5	0.81	0.67
	Size ≥ 4	1.00	0.82
	Size ≥ 3	1.00	0.88
Unique largest blue object	One of the largest objects	0.79	0.66
	Blue Objects	0.79	0.74
	Larger than all other objects	0.79	0.63
Same shape as the unique largest blue object	Same shape as the largest object	0.52	0.58
One of the largest objects	Size = 5	0.36	0.46
	Size ≥ 4	1.00	0.67
	Size ≥ 3	1.00	0.67
There exists a smaller object	Size = 5	1.00	0.67
	Size ≥ 4	1.00	0.73
	Size ≥ 3	1.00	0.91

Table 1: Comparison of subject agreement with target concepts compared to alternative concepts. *Subject pct.* shows the proportion of subjects agreeing more than 50% with the target concept, *Response Pct.* shows the overall percent agreement with the target.

native hypotheses are much simpler than the target concepts, and provides strong evidence that subjects are attending to more than simple object properties.

Computational model

The behavioral experiment shows that generally subjects are able to induce these types of set-theoretic concepts from the labeled data. Although it is important that subjects can eventually learn most of these concepts, we are also interested in whether their learning trajectory—their guesses and hypothesized concepts at each point in time—follow sensibly from the observed data. It may be rational to initially learn simpler related concepts which give approximately correct answers. There is no guarantee, for instance, that 70 items are enough to justify learning the correct form of the target concepts. We next present a computational model which can learn these types of set-theoretic concepts.

Our computational model aims to extend the *rational rules* model of Goodman et al. (2008) to a richer hypothesis space—one which is capable of representing these types of set-theoretic concepts. The probabilistic structure of the model and inference algorithm we use are neutral with respect to the RL, meaning that any potential RL can be incorporated and tested to see what distribution of responses it predicts for each object in each concept.

Each potential RL \mathcal{L} defines a hypothesis space of potential concepts corresponding to the set of all ways to compose the RL’s primitive functions in order to create functions which map objects to labels (*true*, *false*, *NA*). For instance one concept might be⁵

$$\lambda x.(\text{red } x) \wedge (\text{square } x)$$

⁵We write functions as lambda expressions, meaning that the name for the argument is preceded by λ . We also use prefix notation: a function f applied to an argument x is written $(f x)$.

This expression represents a function which checks whether its argument, x , is red and a square, and returns *true* or *false* for any object (since *red* and *square* are assumed to return *true* or *false*). We might also have concepts which take two arguments, a contextually-relevant set S and an element x :

$$\lambda S \lambda x.(\text{equal } x (\text{unique-smallest } S))$$

This function checks if x is the object which is the unique, smallest element of S .

We use a probabilistic context-free grammar (PCFG) which assigns probability to every possible composition of primitive elements. This PCFG functions as a prior over concepts and for simplicity, we assume that all PCFG expansions are equally probable⁶. In general, the PCFG assigns high probability to short or “simple” compositions of \mathcal{L} ’s primitives, and lower probability to complex rules. For instance, a function $\lambda x.(\text{red } x)$ will be higher probability a-priori than $\lambda x.(\text{red } x) \wedge ((\text{square } x) \vee (\text{circle } x))$. This captures the notion that people should be biased to prefer simple explanations of the labeled data they observe.

The second part of the model is a likelihood function which provides the probability of labels according to a hypothesized RL expression. Specifically, for any composition E of primitives in \mathcal{L} , the correct label is generated with probability α , and a label is chosen uniformly at random with probability $1 - \alpha$. However, it is also likely that memory factors come into play in remembering past labeled examples. We include this in the model by weighting the log likelihood for the n ’th data point back in time by $n^{-\beta}$, where $\beta > 0$. As $\beta \rightarrow 0$, the model has perfect memory, and as $\beta \rightarrow \infty$ the model quickly forgets past data points. This leaves us with two unknown free parameters: α , which controls how reliably set elements are labeled, and β which controls how much more recent set elements matter than past ones.

Together, the prior and likelihood specify a complete probabilistic model for any RL. Formally, we can score the probability of a hypothesized concept expression E conditioned on a collection of example sets S with corresponding labels L according to Bayes rule:

$$P(E \mid S, L, \mathcal{L}) \propto P(L \mid S, E)P(E \mid \mathcal{L}). \quad (1)$$

Here, $P(E \mid \mathcal{L})$ is the probability of E according to the PCFG for \mathcal{L} and $P(L \mid S, E)$ scores the likelihood of the labels L under the observed sets of objects S and hypothesized expression E . While Equation 1 scores the probability of any given expression E , it is a complex inference problem to actually determine what expressions are likely given the data. This problem is difficult because the space of possible expressions E is in principle infinite and difficult to search. We solved this problem using a Markov-Chain Monte-Carlo (MCMC) similar to Goodman et al (2008)’s method, which takes samples

⁶Unlike the rational-rules model, we do not integrate out the PCFG production probabilities. This is because primitives which introduce new bound variables, such as quantifiers, make this integration difficult and potentially not analytically tractable in general.

from the posterior distribution $P(E \mid S, L, \mathcal{L})$. This method takes a biased random walk around the space of hypotheses by making local changes to hypothesized expressions E , and can be shown to, in the limit, draw samples from the posterior distribution. We ran the MCMC algorithm for a range of α and β values for each amount of data, in each sequence, conditioning on the correct, observed labels for all previous sets in the sequence. This gives a distribution $P(E \mid S, L, \mathcal{L})$ on expressions E in the RL \mathcal{L} at each point during learning. These expressions can be evaluated on the next item in order to provide a model prediction of subject’s distribution of responses, conditioned on the observed labeled data. Thus, the model was run conditioned on the same labeled data human subjects were given, and—just like human subjects—was asked to make predictions about the correct labels for the next data point. Ideally, subjects’ distribution of responses at each point in time during learning should correspond to the predictions of the model, conditioned on the exact same sequence of training data.

One goal of the model is to test different representational languages to see which provide the best theory of people’s inductive biases in learning these concepts. We computed the posterior predictive distribution of responses for each representation language \mathcal{L} and saw which assigned the human responses highest likelihood⁷. We compared four different RLs with differing primitives and representational power:

Language	Primitive Operations
RESPONSE-BIASED	<i>true, false, undefined</i>
SIMPLE-BOOLEAN	<i>and, or, not, shape, size, color, background-color, equal</i>
SET-FUNCTIONS	<i>contains, filter, only, unique-largest, unique-smallest, set-of-largest, set-of-smallest, same-object</i>
QUANTIFIERS	<i>exists, forall</i>

Each RL is a *superset* of the preceding languages, except that none other than RESPONSE-BIASED contain *true*, *false*, and *na* as primitives. Here, *shape*, *color*, and *background-color* are functions which extract the corresponding properties of objects. *equal* tests if two properties are equal. *contains* returns true if a set contains an element, *filter* removes all elements in a set not satisfying a predicate, and *only* return the only element of a set and *NA* if the set has more than one element. The primitives *unique-largest* and *set-of-largest* return the unique largest element in a set (and *NA* otherwise), and the set of elements for which none are larger, respectively. *same-object* tests if two objects are identical on all dimensions. *exists* and *forall* are first-order existential and universal quantifiers.

Intuitively, the RESPONSE-BIASED language allows learners only to infer a distribution on responses, but not give responses which depend on the current objects. This serves

⁷Model predictive distributions were smoothed to give each response a minimum possible probability of 0.01, to prevent divergence.

as a baseline, and way to test if subjects are really performing the task. The SIMPLE-BOOLEAN language is one which include basic logical operations and object properties, and implements the representational system studied most in previous rule-based concept learning experiments. The SET-FUNCTIONS language extends the SIMPLE-BOOLEAN language by including primitive operation for testing if sets contain elements, extracting sets or elements with maximal or minimal properties along the size-dimension and filtering sets by elements. The QUANTIFIERS language extends the SET-FUNCTIONS language by incorporating quantification.

Results & Discussion

Table 2 shows the performance of these models in predicting the human distribution of responses across the 12 concepts studied. This shows the average log-likelihood of the human responses for the best-fitting values of α and β within each concept⁸. This table illustrates several key properties of the RLs. First, the RESPONSE-BIASED model is overall the worst predictor of human responses. This is important because it shows that subjects are performing the task, and performing nontrivial inferences about the target concepts.

In addition, this figure shows that while SIMPLE-BOOLEAN is a good predictor for the simple Boolean concepts, SET-FUNCTIONS and QUANTIFIERS provide a better account for the set-theoretic concepts that subjects are able to learn. SIMPLE-BOOLEAN provides the worst account for “same shape as the largest object” and “same shape as the unique largest blue object.” While subjects do not learn these concepts especially well, these results show that the SIMPLE-BOOLEAN does not account well for subject responses.

Overall, the best RL is QUANTIFIERS; however, the differences between QUANTIFIERS and SET-FUNCTIONS is small. Richer representation languages not only have the formal power to represent the types of set-theoretic and logical concepts required by human conceptual systems, but also provide a better account of human inductive leaning than the other RLs considered here.

As discussed above, the black line in Figure 2 shows learning curves showing percent accuracy over time for human subjects. This figure also shows a red line, corresponding to the performance of the RL QUANTIFIERS for the best-fitting α and β within each concept. We chose the best-fitting model parameters based on which parameter values assigned highest likelihood to the observed *distribution* of human responses, “true,” “false,” and “NA.” Doing this does not necessarily provide the best fit to the human learning curves in Figure 2 since the model is not fit to human *accuracy* (correct/incorrect). This means that Figure 2 shows a conservative view of the agreement between human accuracies and model accuracies. For the concepts “circles or blue objects” and “unique largest blue object” the model’s learning trajectory would increase

⁸That is, these numbers are the total log likelihood assigned to human responses, divided by the number of responses. This was necessary for cross-concept comparison since concepts may have differing numbers of subject responses.

Concept	RESPONSE-BIASED	SIMPLE-BOOLEAN	SET-FUNCTIONS	QUANTIFIERS
Blue objects	-0.66	-0.18	-0.19	-0.18
Circles	-0.73	-0.17	-0.17	-0.17
Circles or blue objects	-0.81	-0.73	-0.74	-0.74
Circles and blue objects	-0.30	-0.27	-0.27	-0.27
Everything iff there is a triangle	-0.80	-0.73	-0.73	-0.73
There exists a smaller object	-0.81	-0.51	-0.40	-0.41
Larger than all other objects	-0.58	-0.48	-0.46	-0.36
One of the largest objects	-0.80	-0.63	-0.28	-0.28
Everything iff there is a single blue object	-0.85	-0.78	-0.78	-0.78
Same shape as the largest object	-1.10	-1.75	-0.99	-0.99
Unique largest blue object	-1.05	-1.54	-1.06	-1.06
Same shape as the unique largest blue object	-1.08	-1.34	-1.06	-1.04
Mean	-0.797	-0.760	-0.594	-0.584

Table 2: Model log likelihoods *per response* for each concept. These represent the model log likelihood assigned to human responses, divided by the total number of responses in each concept to allow comparisons across concepts.

more for other values of α and β , and thus look more like subject’s accuracies, but provide a less-good fit to subjects’ overall response distribution.

This figure shows good fit between the probabilistic model and human learning. This fit appears especially remarkable for concepts which subjects have a difficult time learning, such as “Everything iff there is a triangle.” Because subjects do not learn this concept well, the best-fitting α is low and β is highly negative, meaning that the model is not penalized much for incorrect answers and down-weights old data. The model therefore responds in simple ways, such as always responding true, or responding true to only the triangles; subjects appear to use similar strategies, and thus both show similar patterns of response accuracies⁹

The model also shows more subtle agreement patterns with human subjects. First, it is capable of learning simple boolean concepts in a way similar to humans, quickly arriving at the correct meaning given the training data. This is also true for concepts like “there exists a smaller object” and the other size-predicates. The model also matches local dips and peaks in reasonably well. This is because the model, like people, may temporarily be led to a concept which is not the target concept, just as subjects (e.g. at item 32 of “there exists a smaller object”). This provides evidence that people make the same rational, statistical inferences given the same data.

Conclusion

While the SIMPLE-BOOLEAN RL provided a good fit to human response data in some cases, it is insufficient to represent some of the complex concepts that subjects learned. Subjects’ ability to learn these concepts was demonstrated by their learning curves for several context-dependent concepts. The comparison of different RLs suggests a potentially fruitful approach to discovering the precise form of semantic representations. Recently, Pietroski et al. (2009) and Hackl (2009) have used psychophysical measures to make inferences about plausible representations and computations that underlie se-

mantic meaning for words like “most.” Our work provides a complementary approach to the same problem—instead of measuring response times, we studied what RLs provide a good account of human inductive biases during learning. This method may be broadly applicable to discovering the form of semantic representations in natural language.

Of course, the RLs we study here are still incomplete with respect to the full richness of human conceptual systems; however, this work suggests that rule-based concept-learning can be extended to complex concepts which can begin to approach the complexity and context-dependence observed in human linguistic systems. Furthermore, the model provides one potential acquisition theory for semantic concepts. Children may learn semantic meanings like adults in our experiment did—by inducing concepts in a sufficiently-powerful compositional RL.

⁹The best fitting β also shows a modest negative correlation ($R = -0.55$, $p = 0.06$, $N = 12$) with response accuracies over the 12 concepts, suggesting an interaction between the target concept and the attentional or memory resources people allocate.

Encoding Sequential Information in Vector Space Models of Semantics: Comparing Holographic Reduced Representation and Random Permutation

Abstract

Encoding information about the order in which words typically appear has been shown to improve the performance of high-dimensional semantic space models. This requires an encoding operation capable of binding together vectors in an order-sensitive way, and efficient enough to scale to large text corpora. Although both circular convolution and random permutations have been enlisted for this purpose in semantic models, these operations have never been systematically compared. In Experiment 1 we compare their storage capacity and probability of correct retrieval; in Experiments 2 and 3 we compare their performance on semantic tasks when integrated into existing models. We conclude that random permutations are a scalable alternative to circular convolution with several desirable properties.

Keywords: semantic representation, semantic space models, binding, convolution, permutation, random indexing.

Introduction

Vector-space models of lexical semantics have seen considerable recent attention in the psychological literature both as automated tools to estimate semantic similarity between words, and as psychological models of how humans learn and represent word meaning from repeated contextual co-occurrences. In general, these models build semantic representations for words from statistical redundancies observed in a large corpus of text (e.g., Landauer & Dumais, 1997; Lund & Burgess, 1996). As tools, the models have provided invaluable metrics of semantic similarity for stimulus selection and control in behavioral experiments using words, sentences, and larger units of discourse. As psychological models, the vectors derived from distributional models serve as useful representations in computational models of word recognition, priming, and higher-order comprehension (Landauer et al., 2007). In addition, the abstraction algorithms themselves are often proposed as models of the cognitive mechanisms humans use to learn meaning from repeated episodic experience.

A classic example of a vector-space model is Landauer and Dumais' (1997) Latent Semantic Analysis (LSA). LSA begins with a word-by-document co-occurrence matrix representation of a text corpus. A lexical association function is applied to dampen the importance of each word proportionate to its entropy over documents. Finally, an

algorithm is applied to reduce the matrix's dimensionality; words are represented as vectors whose dimensions refer to the largest eigenvalues of the reduced representation.

Despite their successes both as tools and as psychological models, vector-space models suffer from several shortcomings. Most prominently, the models have been criticized as "bag of words" models that encode only the contexts in which words co-occur, but ignore *word-order information*. The role of word order was traditionally thought to apply only to the rules of word usage (grammar) rather than to the lexical meaning of the word itself. However, temporal information is now taking a more prominent role in the lexical representation of a word's meaning. Recently, Elman (2009) has convincingly argued that an inherent part of a word's lexical representation is information about its common temporal context, event knowledge, and habits of usage (cf. McKoon & Ratcliff, 2003; see also Hare et al., 2009).

A second issue for these models is *lack of scalability* (Recchia & Jones, 2009; Kanerva, Kristofersson, & Holst, 2000), due to reliance on computationally complex decomposition techniques to reveal the latent components in a word-by-document matrix (e.g., singular value decomposition). Not only is decomposition computationally expensive, the entire word-by-document matrix must be stored in memory during the operation. The problem is exacerbated by the fact that as the size of the corpus increases, the number of both rows and columns in the matrix increase significantly, the number of columns growing linearly with added documents, and the number of rows growing approximately in proportion to the square root of the number of tokens (Heap's law). The corpora that vector-space models like LSA are most commonly trained upon in the literature contain approximately the number of tokens that children are estimated to have experienced before age 3, not counting words that they produce during this time (Riordan & Jones, 2007; Risley & Hart, 2006). Recently, Recchia and Jones (2009) demonstrated that although simple semantic metrics such as pointwise mutual information (PMI) are outperformed by more complex models such as LSA on small corpora, PMI is capable of much better correspondence to human-derived semantic similarity judgments due to its ability to scale to large corpora. This led the authors to favor simple and scalable

algorithms to more complex non-scalable algorithms, concordant with approaches that have met with success in the computational linguistics literature (e.g. Banko & Brill, 2001).

Encoding Word Order

Two recent vector-space models that directly address the concerns of word order and scalability are Jones and Mewhort’s BEAGLE (2007) and the “random permutation” model of Sahlgren, Holst, and Kanerva (2008) (henceforth referred to as RPM). Rather than starting with a word-by-document matrix, BEAGLE and RPM maintain static, randomly generated *signal vectors* intended to represent the invariant properties of each word (such as its orthography or phonology), as well as dynamic *memory vectors* that store information about each word’s semantic representation. To represent statistical information about the word, BEAGLE and RPM bind together collections of signal vectors into *order vectors* that are added to memory vectors during training. Integrating word-order information has yielded greater success at fitting a variety of human semantic data than encoding only contextual information (e.g., Jones, Kintsch, & Mewhort, 2006; Jones & Mewhort, 2007). Because they require neither the overhead of a large word-by-document matrix nor computationally intensive matrix decomposition techniques, both models are significantly more scalable than traditional vector-space models.

Although BEAGLE and RPM differ in several ways, arguably the most important difference lies in the nature of the binding operation used to create order vectors. BEAGLE uses circular convolution, a binary operation (henceforth denoted as $*$) performed on two vectors such that every element i of $(x * y)$ is given by:

$$\sum_{j=0}^{D-1} x_j \cdot y_{(i-j) \bmod D}, \quad (1)$$

where D is the dimensionality of x and y . Circular convolution can be seen as a modulo- n variation of the tensor product of two vectors x and y such that $(x * y)$ is of the same dimensionality as x and y . Furthermore, although $(x * y)$ is dissimilar from both x and y by any distance metric, approximations of x and y can be retrieved via the inverse operation of correlation.

In contrast, RPM employs *random permutations*, henceforth referred to as RPs. True to their name, RPs are functions that map input vectors to output vectors such that the outputs are simply randomly shuffled versions of the inputs. Just as $(x * y)$ yields a vector that differs from x and y but from which approximations of x and y can be retrieved, the sum of two RPs of x and y , $\Pi x + \Pi^2 y$ (where $\Pi^2 y$ is defined as $\Pi(\Pi y)$) yields a vector dissimilar from x and y but from which approximations of the original x and y can be retrieved via the inverse permutations Π^{-1} and Π^{-2} .

Both systems offer efficient storage properties, compressing order information into a single composite vector representation, and both encoding operations are

reversible. However, RPs are much more efficient to compute. In language applications of BEAGLE, the computationally expensive convolution operation is what limits the size of a text corpus that the model can encode. As Recchia and Jones (2009) have demonstrated, scaling a semantic model to more data produces much better fits to human semantic data. Hence, both order information and magnitude of linguistic input have been demonstrated to be important factors in human semantic learning. If RPs have similar characteristics to convolution, they may afford encoding very large-scale order information, and much better approximations to human semantic structure.

This work is further motivated by the cognitive implications of circular convolution and RPs. Vector representations constructed by means of circular convolution have been frequently described as psychologically or neurally plausible (Levy, 2007; Jones & Mewhort, 2007), due to several features that they share with connectionist networks: distributed encoding, robustness to noise, affordance of generalization, error correction, pattern completion, and easy associative access (Plate, 2003). Furthermore, implementing neural networks that instantiate convolution-like operations is straightforward (Plate, 2000; but compare Pike, 1986). Similarly, RPs possess many properties relevant to human cognition. Not only have they been proposed as a particularly versatile multiplication operator for constructing vector representations that are highly distributed, tolerant of noise in the input, robust to error and component failure, and mathematically compatible with several known properties of neural circuitry (Kanerva, 2009), RPs are trivially easy to implement in connectionist terms; a RP can simply be thought of as a two-layer network connected by randomly placed one-to-one copy connections. Thus, comparing circular convolution and RPs affords us a better understanding of two psychologically plausible operations for encoding semantic information that have never been systematically compared.

We conducted three experiments intended to compare convolution and RPs as means of encoding word-order information with respect to performance and scalability. In Experiment 1, we conducted an empirical comparison of the storage capacity and the probability of correct decoding under each method. In Experiment 2, we compared RPs with convolution in the context of a simple vector accumulation model equivalent to BEAGLE’s “order space” (Jones and Mewhort, 2007) on a small battery of semantic evaluation tasks when trained on a Wikipedia corpus. The model was trained on both the full corpus and a random subset; results improved markedly when RPs are allowed to scale up to the full Wikipedia corpus, which proved to be intractable for the convolution-based model. Finally, in Experiment 3, we specifically compared BEAGLE to RPM, which differs from BEAGLE in several important ways other than its binding operation, to assess whether using RPs in the context of RPM improves their performance further. We conclude that random permutations are a promising and scalable alternative to circular convolution.

Experiment 1

Plate (2003) made a compelling case for circular convolution in the context of holographic reduced representation, demonstrating its utility in constructing distributed representations with high storage capacity and high probability of correct retrieval. However, the storage capacity and probability of correct retrieval with RPs has not been closely investigated. This experiment compared the probability of correct retrieval of RPs with circular convolution under varying dimensionality and number of vectors stored.

Method

As a test of the capacity of convolution-based associative memory traces, Plate (2003, Appendix D) describes a simple paired-associative retrieval task in which the algorithm must select, from set E of m possible random vectors, the vector x_i that is bound to its associate y_i . The retrieval algorithm is provided with a trace vector of the form $t = (x_1 * y_1) + (x_2 * y_2) + (x_3 * y_3) + \dots$ that stores a total of k vectors. All vectors are of dimensionality D , and each x_i and y_i is a vector with elements independently drawn from $N(0, 1/D)$. The retrieval algorithm is provided with the trace t and the probe y_i , and works by first calculating $a = (y_i \# t)$, where $\#$ is the *correlation operator* described in detail in Plate (2003, pp. 94-97). It then retrieves the vector in the “clean-up memory” set E that is the most similar to a . This is accomplished by calculating the cosine between a and each vector in the set E , and retrieving the vector from E for which the cosine is highest. If this vector is not equal to x_i , this counts as a retrieval error. We replicated Plate’s method to empirically derive retrieval accuracies for a variety of choices of k and D , keeping m fixed at 1,000.

Sahlgren et al. (2008) essentially bind signal vectors to positions by means of successive self-composition of a permutation function Π , and construct trace vectors by superposing the results. Because the signal vectors are random, any permutation function that maps each element of the input onto a different element of the output will do; we adopt Sahlgren et al.’s suggestion of using rotation of a vector by one position for Π for the sake of simplicity. We also use their notation of $\Pi^n x$ to mean “ Π composed with itself n times;” thus, $\Pi^2 x = \Pi(\Pi x)$, $\Pi^3(x) = \Pi(\Pi^2 x)$, and so forth. The notion of a trace vector of paired associations can then be recast in RP terms as follows:

$$t = (\Pi y_1 + \Pi^2 x_1) + (\Pi^3 y_2 + \Pi^4 x_2) + (\Pi^5 y_3 + \Pi^6 x_3) + \dots$$

where the task again is to retrieve some y_i ’s associate x_i when presented only with y_i and t . A retrieval algorithm for accomplishing this can be described as follows: Given a probe vector y_i , the algorithm applies the inverse of the initial permutation to trace vector t , yielding $\Pi^{-1}t$. Next, the cosine between $\Pi^{-1}t$ and the probe vector y_i is calculated, yielding a value that represents the similarity between y_i and $\Pi^{-1}t$. These steps are then iterated: the algorithm calculates

the cosine between y_i and $\Pi^{-2}t$, between y_i and $\Pi^{-3}t$, etc., until this similarity value exceeds some high threshold; this indicates that the algorithm has probably “found” y_i in the trace. At that point, t is permuted one more time, yielding x' , a noisy approximation of y_i ’s associate x_i . This approximation x' can then be compared with clean-up memory to retrieve the original associate x_i .

Alternatively, rather than selecting a threshold, t may be permuted some finite number of times¹ and its cosine similarity to y_i calculated for each permutation. Let n indicate the inverse permutation for which $\cos(\Pi^{-n}t, y_i)$ is the highest. We can permute one more time to get $\Pi^{-n-1}t$, that is, our noisy approximation x' . This method is appropriate if we always want our algorithm to return an answer (rather than, say, timing out before the threshold is exceeded), and is the method we used for this experiment.

The final clean-up memory step is identical to that used by Plate (2003): we calculate the cosine between x' and each vector in the clean-up memory E , and retrieve the vector in E for which this cosine is highest. As when evaluating convolution, we keep m (the number of vectors in E) fixed at 1,000 while varying the number of stored vectors k and the dimensionality D .

Results

Figure 1 reports retrieval accuracies for convolution-based associative memory traces, while Figure 2 reports retrieval accuracies for the RP formulation of the task. 500 vector pairs were sampled randomly from a pool of 1,000 possible random vectors with replacement and the proportion of correct retrievals was computed. All 1,000 vectors in the pool were potential candidates; thus, an accuracy of 0.1% would represent chance performance. The horizontal axes of all figures indicate the total number of pairs stored in the trace (i.e., half the total number of vectors in the trace).

Figure 1. Retrieval accuracies for convolution-based associative traces.

¹ In Plate’s (2003, p. 252) demonstration of the capacity of convolution-based associative memories, the maximal number of pairs stored in a single trace was 14; we likewise restrict the maximal number of pairs in a single trace to 14 (28 items total).

Figure 2. Retrieval accuracies for RP-based associative traces.

Discussion

Circular convolution has an impressive storage capacity and excellent probability of correct retrieval at high dimensionalities; the results were comparable to those reported by Plate (2003, p. 252) in his test of convolution-based associative memories. However, RPs seem to share these desirable properties as well. In fact, the storage capacity of RPs seems to drop off significantly more slowly than does the storage capacity of convolution as dimensionality is reduced.

This information capacity is particularly interesting given that, with respect to basic encoding and decoding operations, RP is computationally more efficient than convolution. Encoding n -dimensional bindings with circular convolution using equation (1) is a very slow $O(n^2)$ operation. This can be sped to $O(n)$ by means of the Fast Fourier transform (Jones, 2007; Plate, 2003). The algorithm to bind two vectors a and b in $O(n)$ time involves calculating discrete Fourier transforms of a and b , multiplying them pointwise to yield a new vector c , and calculating the inverse discrete Fourier transform of c . Encoding with RPs can also be accomplished in $O(n)$ time, but with steps that are not as computationally expensive. To bind two vectors a and b , the elements of a are permuted by directly copying them into a new vector, but with the mapping of their indices determined by the permutation function. For example, if the permutation function were chosen to be *rotation by one position* and vectors were of dimensionality D , each value at index i in the vector a would be copied to index $(i + 1) \bmod D$ in the new vector. The vector b is permuted in the same way, but using a different permutation function (e.g., $(i + 2) \bmod D$). Finally, a and b are added to yield a final binding c .

Noisy decoding—the retrieval of a noisy version of one or more bound associates from a trace (which may then be passed to clean-up memory to unambiguously determine the identity of the associate)—also operates in $O(n)$ time in both representations. As with encoding, the operation is $O(n)$, but fewer operations are required (a single permutation decodes one associate, rather than an involution + two discrete Fourier transforms + an elementwise multiplication + one inverse discrete Fourier transform).

Experiment 2

In order to move from the paired-associates problem of Experiment 1 to a real language task, we evaluated how a simple vector accumulation model akin to Jones & Mewhort’s (2007) encoding of order-only information in BEAGLE would perform on a set of semantic tasks if RPs were used in place of circular convolution. In Experiment 2, we replaced the circular convolution component of BEAGLE with RPs so that we could quantify the impact that the choice of operation alone had on the results. Due to the computational efficiency of RPs, we were able to scale them to a larger version of the same textbase, and simultaneously explore the effect of scalability on order.

Method

Order information was trained using both the BEAGLE model and a modified implementation of BEAGLE in which the circular convolution operation was replaced with RPs as they are described in Sahlgren et al. (2008). A brief example will illustrate how this replacement changes the algorithm. Recall that in BEAGLE, each word w is assigned a static “environmental” signal vector e_w as well as a dynamic memory vector m_w that is updated during training. Recall also that the memory vector of a word w is updated by adding the sum of the convolutions of all n -grams (up to some maximum length λ) containing w . Upon encountering the phrase “one two three” in a corpus, the memory vector for “one” would normally be updated as follows:

$$m_{\text{one}} = m_{\text{one}} + (\Phi * e_{\text{two}}) + (\Phi * e_{\text{two}} * e_{\text{three}})$$

where Φ is a placeholder signal vector that represents the word whose representation is being updated. In the modified BEAGLE implementation used in this experiment, the memory vector for “one” would instead be updated as:

$$m_{\text{one}} = m_{\text{one}} + \Pi e_{\text{two}} + \Pi^2 e_{\text{three}}$$

The modified BEAGLE implementation was trained on a 2.33 GB corpus (418 million tokens) of documents from Wikipedia. Training on a corpus this large proved intractable for the slower convolution-based approach. Hence, we also trained both models on a 35 MB, six-million-token subset of this corpus constructed by sampling random 10-sentence documents from the larger corpus without replacement. Accuracy was evaluated on two synonymy tests: the English as a Second Language (ESL) and the Test of English as a Foreign Language (TOEFL) synonymy assessments. Rank correlations to human judgments of the semantic similarity of word pairs were calculated using the similarity judgments obtained from Rubenstein and Goodenough (G, 1965), Miller and Charles (M&C, 1991), Resnik (R, 1995), and Finkelstein et al. (F&al, 2002). A description of these measures can be found in Recchia and Jones (2009).

Results and Discussion

Table 3 provides a comparison of two variants of the BEAGLE model, each trained on order information only.

“Convolution” refers to the original BEAGLE as described in Jones & Mewhort, while “Random Permutations” refers to a version in which order information is encoded using RPs rather than circular convolution. Three points about these results merit special attention. First, there are no significant differences between the performance of convolution and RPs on the small corpus. Both performed high-identically on F and TOEFL; neither showed any significant correlations with human data on R&G, M&C, R, nor performed better than chance on ESL.

Table 3. Comparisons of variants of BEAGLE that differ by binding operation. Accuracy scores are reported for ESL & TOEFL; remaining tasks are Spearman rank correlations.

Criterion	Wikipedia subset		Full Wikipedia
	Convolution	Random Permutations	Random Permutations
ESL	.20	.26	.32
TOEFL	.46 [†]	.46 [†]	.63 [†]
R&G	.07	-.06	.32*
M&C	.08	-.01	.33*
R	.06	-.04	.35*
F&al	.13*	.12*	.33*

*Significant correlation, $p < .05$, one-tailed.

[†]Accuracy score differs significantly from chance, $p < .05$, one-tailed.

Second, both models performed the best by far on the TOEFL synonymy test, supporting Sahlgren’s et al. (2008) claim that order information may indeed be more useful for synonymy tests than tests of semantic relatedness, as paradigmatic rather than syntagmatic information sources are most useful for the former. However, it is unclear exactly why neither model did particularly well on ESL², as many models have achieved scores on it comparable to their scores on TOEFL (Recchia & Jones, 2009). Finally, only RPs were able to scale up to the full Wikipedia corpus, and doing so yielded extreme benefits for every task. This is a very strong point in favor of RPs, and suggests that sequential information can even be useful for tasks that involve semantic relatedness but not synonymy per se (R&G, M&C, R, F), provided that the model is trained at a sufficiently large scale.

Experiment 3

In Experiment 2 we saw that importing RPs into BEAGLE yielded comparable results on a small corpus and considerable improvement in scalability. Here we compare BEAGLE to the original model of Sahlgren et al., which we

² Note that the absolute performance of these models is irrelevant to the important comparisons. Many factors (e.g., frequency thresholding, morphological normalization, corpus size/type) are known to improve performance on synonymy tests; we held these constant, which produced poor absolute performance (but see Sahlgren et al., 2008). The key comparisons are the consistency of the operations on the same textbase, and the relative performance boost when data are scaled up.

have been referring to as RPM. In many ways the two are similar: Like BEAGLE, RPM can construct a semantic space by (1) adding only order vectors to memory vectors during training, yielding an “order space,” and (2) by adding order vectors *as well as* “context vectors,” yielding a “composite space.” Besides using RPs in place of circular convolution, the specific implementation of RPM reported by Sahlgren et al. differs from BEAGLE in several ways (signal-vector representation, window size, lexicon size, and the stoplist). This experiment aims to assess RPM’s performance with another corpus and on other semantic tasks besides TOEFL, and to determine if performance improves under RPM parameter settings (compared to the BEAGLE settings in Experiment 2).

Method

The same evaluation method was applied as in Experiment 2, but with BEAGLE being compared directly to RPM. Both models were trained in order and composite space.

Results and Discussion

Table 4 reports the results of BEAGLE and RPM trained in order space, while Table 5 reports results in composite space (context + order information). As in Experiment 2, RPs but not convolution proved capable of scaling up to the full Wikipedia corpus. We replicated Sahlgren et al.’s (2008) performance on TOEFL in order space at this dimensionality, but this Wikipedia implementation of RPM fell short of the $\sim .73$ accuracy they reported on TOEFL at a dimensionality of 2000 in composite space; the difference is most likely due to the different corpora used in the two evaluations. On the small corpus, switching from order space to composite space did not yield significant differences for either model when contrasted with the use of order space alone. On the large corpus, however, when contrasted with RPs in Experiment 2 (Table 3), RPM performed far better on several evaluations, most notably the correlations to the R&G, M&C, and R similarity judgments. It is intriguing that the version of RPM trained on the full Wikipedia in order space was able to perform well on several tasks that are typically conceived of as tests of associative relatedness and not tests of synonymy per se—for example, .70 on the Miller & Charles pairs (Table 4).

Table 4. BEAGLE and RPM in order space.

General Discussion

Experiment 1 demonstrates that RPs are capable of high retrieval accuracy even when many paired associates are stored in a single trace, and their storage capacity appears to be slightly better than that of circular convolution for low dimensionalities. Experiments 2 and 3 reveal that both methods achieve approximately equal performance on a battery of semantic tasks when trained on a small corpus, but that RPs are ultimately capable of achieving superior performance due to their higher scalability. In all, these results suggest that RPs are worthy of further study both as encoders of sequential information in word space models and as operators capable of storing associative information more generally. It should be noted that Sahlgren et al. (2008) found better synonymy performance when RPs were trained on “direction” vectors rather than order vectors; direction vectors simply encode whether words appear before or after a word in the temporal stream, but ignore the order chain. Given the computational efficiency of this approach, future work should explore the effects of scaling to large-scale data on RP direction vectors.

Both convolutions and RPs are naturally derived from properties of the human cognitive system, namely groups of neurons connected with a certain degree of randomness (see Plate, 2003 for convolution and Kanerva, 2009 for RPs; also see Howard et al. [in press] for a related model using neural properties of temporal context encoding). The current work demonstrates that when a model is able to apply these associative learning mechanisms across a large amount of episodic experience with linguistic structure, it produces much better approximations of human semantic structure. As Elman (2009) has argued, the encoding of large-scale order information is a core component of a word’s lexical representation that is often overlooked. Future work needs to explore application of large-scale RP encoding to more complex semantic and linguistic tasks.

Abstract

A deep problem in cognitive science is to explain the acquisition of abstract semantic relations, such as antonymy and synonymy. Are such relations necessarily part of an innate representational endowment provided to humans? Or, is it possible for a learning system to acquire abstract relations from non-relational inputs of realistic complexity (avoiding hand-coding)? We present a series of computational experiments using Bayesian methods in an effort to learn and generalize abstract semantic relations, using as inputs pairs of specific concepts represented by feature vectors created by Latent Semantic Analysis.

Keywords: Bayesian inference; induction; generalization; abstract relations; machine learning; LSA

Introduction

An intelligent human adult can recognize that the concepts *day* and *night* are related in much the same way as *hot* and *cold*, but not in the same way as *day* and *hour*. This ability to appreciate abstract semantic relations is fundamental to analogical reasoning, and is arguably a core component of what is special about the human mind (Penn, Holyoak & Povinelli, 2007). But how are such abstract relations acquired? If they are learned, how this could be achieved is far from obvious. On the face of it, no perceptual or other features seem to be available to represent such abstract relations as antonymy, synonymy, or superordination. Almost by default, it might be assumed that abstract relations must be innate (Fodor, 1975).

Research on cognitive development has clearly established the phenomenon of a *relational shift* (Gentner & Rattermann, 1991), such that children process relations more effectively with increasing age. In particular, children move from a focus on global similarities of objects to similarities defined by specific dimensions, such as size or color (Smith, 1989; Smith & Sera, 1992). Less is known about the development of abstract relations that seem yet further divorced from perceptual similarity (see Halford, 1993). Analyses of corpora of child speech have identified systematic use of antonyms by children aged 2-5 years (Jones & Murphy, 2005). Children aged 6-7 years are more accurate in detecting the falsity of sentences such as *Some valleys are mountains* as compared to *Some valleys are*

lakes, where the former sentence type contains an antonymous pair (Glass, Holyoak & Kossan, 1977), suggesting that some sense of antonymy is available prior to any formal instruction about this concept.

The Problem of Relation Learning

Regardless of whether abstract relations are learned or mature over the course of development, there is no doubt that adults can distinguish among instances of relations such as antonymy versus synonymy. In the present paper we pose the following computational problem: Given as inputs a modest number of pairs of concepts that instantiate an abstract relation (e.g., *day-night* and *hot-cold*, which instantiate antonymy), is it possible to extract a representation of the abstract relation that may then be used to accurately classify novel instantiations (e.g., *valley-mountain*)?

Most recent connectionist models of relation learning (e.g., Rogers & McClelland, 2008) have focused on the acquisition of small numbers of specific input-output pairs (e.g., “canary” + “can” → “fly”), but have not demonstrated the capacity to generalize to novel inputs dissimilar to the training items. In contrast, achieving such generalization is the central aim of our project. Moreover, an important constraint we imposed is that inputs to the learning system could not be hand-coded, as has been commonplace in the literature on computational models of analogy and relation learning. For example, Dumas, Hummel, and Sandhofer (2008) showed how structured relations corresponding to relative adjectives such as *bigger-than* can be extracted by bottom-up mechanisms given inputs consisting of unstructured feature vectors of objects. However, the modelers ensured that “size” features were present among the relatively small feature set defining the inputs, setting the stage for selecting these size features to form a part of the to-be-learned relational predicate. While perceptual relations may indeed be derived from the perceptual features of objects, this assumption is unwarranted for more abstract relations, for which hand-coding of features is even more problematic. In addition, realistic semantic representations would seem to require very large numbers of features, raising all the difficulties associated with search in a large

representational space. Learning models that are developed for small, hand-tailored inputs at best postpone the challenges of “scaling up”. Another approach to learning relations is to combine statistical techniques with structured representations. For example, Kemp and Tenenbaum (2008) showed how Bayesian techniques can operate on relational structures to learn relational systems such as hierarchies and linear orderings. The relational structures are provided to the system by including a grammar that generates possible structures. Although this approach may be appropriate for relations that have a well-defined logical structure known to the modeler, it is not clear that it can readily be extended to the full range of “messy” semantic relations. In addition, since the postulated grammar of relations is not itself learned, rather strong nativist assumptions remain.

Learning Relations from Unstructured Inputs

In this project, we have taken the tack of attempting to model the learning of abstract relations through essentially data-driven statistical learning, using Bayesian algorithms applied to large, unstructured input representations that we the modelers did not create. The raw inputs are vector representations of words, derived by Latent Semantic Analysis (LSA; Landauer & Dumais, 1997). Such vectors, the product of singular value decomposition applied to lexical co-occurrence data from a large corpus of text, have proved extremely useful in many applications, often serving as good measures of semantic similarity of concepts (Wolf & Goldman, 2003). However, LSA vectors do not provide any direct basis for identifying abstract relations between concepts (although some modest success has been achieved by exploiting LSA vectors for relation words, such as *opposite*; Mangalath, Quesada & Kintsch, 2004). Related machine-learning algorithms have had some success in solving relational analogies by working directly from co-occurrence data for word combinations found in a large corpus of text (Turney & Littman, 2005). However, our goal is different in that we aim to model learning of relational representations from the LSA vectors for a small (< 20) set of word pairs that instantiate each abstract relation. The task of learning relations from representations of simpler concepts bears at least some resemblance to the task a child might face in acquiring an abstract relation from a modest-sized set of examples that instantiate it.

For our present purpose, we do not assume that LSA provides anything like an optimal psychological representation of concepts (indeed, it has well-known and serious limitations, notably problems dealing with lexical ambiguity). However, by using LSA inputs we ensure that we have in no way tailored the inputs so as to “hand hold” the learning algorithms we test. Moreover, we do not assume that it is in fact possible to acquire human-like representations of abstract relations solely by data-driven learning. Rather, by pressing the limits of data-driven approaches, we may be able to identify more clearly what nativist assumptions may ultimately prove essential.

A General Framework for Relation Learning

Here we report a preliminary investigation of relation learning based on two variants of the same basic framework. Our goal is to learn an explicit representation of a relation from a training set, \mathbf{S} , consisting of pairs of concepts that each instantiate the relation. We assume that a decision regarding whether a pair of concepts instantiates a particular relation R is determined by a representation that includes both the basic features of the input concepts and additional features that the model automatically derives from the basic features. The full input representation is comprised of the basic features of two concepts, \mathbf{A} and \mathbf{B} , which are represented by LSA vectors, and of derived features $\Phi(\mathbf{A}, \mathbf{B})$ computed from \mathbf{A} and \mathbf{B} (see Fig. 1). In this study the derived features included two types, product features $\mathbf{AB} = [A_1B_1 \ A_2B_2 \ \cdots \ A_dB_d]$ and absolute difference features $|\mathbf{A} - \mathbf{B}| = [|A_1 - B_1| \ |A_2 - B_2| \ \cdots \ |A_d - B_d|]$, both defined across corresponding positions in the \mathbf{A} and \mathbf{B} vectors. The length of each type of derived vector is thus equal to the length of each basic vector, so that the total size of the input vector scales linearly with the number of basic features.

If we let \mathbf{X} denote the full vector including basic and derived features, $\mathbf{X} = [\mathbf{A}, \mathbf{B}, \Phi(\mathbf{A}, \mathbf{B})]$, then the computational goal of relation learning is to estimate the distribution of a corresponding weight vector \mathbf{w} from a set of training pairs that share the same relation. That is, we calculate $P(\mathbf{w} | \mathbf{X}_S, \mathbf{R}_S = 1)$, where the subscript \mathbf{S} indicates the set of training examples (the source) and \mathbf{R}_S is a set of binary indicators, each of which (denoted by R) indicates whether a particular pair of concepts instantiates the relation or not. The vector \mathbf{w} constitutes the learned relational representation, which can be interpreted as attention weights reflecting the importance of the corresponding features in \mathbf{X} . To test generalization of the learned relational representation, we test on new transfer pairs, denoted by the subscript \mathbf{T} . The inference step needs to estimate the probability that a target pair shares the same relation as the training pairs, $P(R_T = 1 | \mathbf{X}_T, \mathbf{X}_S, \mathbf{R}_S = 1)$.

Figure 1: Graphical representation of the general framework. \mathbf{A} and \mathbf{B} denote two vectors of concept features (LSA inputs); $\Phi(\mathbf{A}, \mathbf{B})$ denotes derived features based on the two concepts, i.e., product features \mathbf{AB} and absolute difference features $|\mathbf{A} - \mathbf{B}|$. Vector \mathbf{w} represents the unknown relational weights that define R , and is learned using the training set of examples instantiating R .

The models we consider are both based on Bayesian logistic regression, as described by Silva, Airolidi and Heller (2007) and Silva, Heller and Ghahramani (2007). Given a small set of word-pairs \mathbf{S} that all instantiate a given abstract relation R , both models compute the posterior probability that $(\mathbf{A}_T, \mathbf{B}_T)$ is an example of the same relation,

$$P(R_T = 1 | \mathbf{X}_T, \mathbf{X}_S, \mathbf{R}_S = 1) = \int_{\mathbf{w}} P(R_T = 1 | \mathbf{X}_T, \mathbf{w}) P(\mathbf{w} | \mathbf{X}_S, \mathbf{R}_S = 1) \quad (1)$$

where the likelihood is assessed using a logistic regression function to predict the probability of a word-pair instantiating a given relation,

$$P(R = 1 | \mathbf{X}, \mathbf{w}) = \text{logistic}(\mathbf{w}^T \mathbf{X}) \quad (2)$$

where $\text{logistic}(x) = (1 + e^{-x})^{-1}$.

For the first model we consider (based directly on Silva et al., 2007), the posterior distribution for \mathbf{w} is found by applying Bayes' rule using the prior distribution for \mathbf{w} and the training word-pairs:

$$P(\mathbf{w} | \mathbf{X}_S, \mathbf{R}_S = 1) = \frac{P(\mathbf{R}_S = 1 | \mathbf{w}, \mathbf{X}_S) P(\mathbf{w})}{\int_{\mathbf{w}} P(\mathbf{R}_S = 1 | \mathbf{w}, \mathbf{X}_S) P(\mathbf{w})} \quad (3)$$

Because of the high dimensionality of the learning problem we are tackling, the choice of a good prior $P(\mathbf{w})$ is essential to the performance of any model. We investigated two kinds of priors, a simple empirical prior proposed by Silva and colleagues, and our own hierarchical model.

The Empirical Prior

Intuitively, our simple empirical prior distinguishes word-pairs that instantiate *any* of the to-be-learned relations from unrelated word-pairs. The empirical prior takes the form $P(\mathbf{w}) = N(\mathbf{w}; \hat{\mathbf{w}}, \hat{\Sigma})$, in which the sample mean estimate $\hat{\mathbf{w}}$ is found by fitting a logistic regression classifier using maximum-likelihood estimation on a relatively small set of related word pairs (positive examples), and a larger set of unrelated word pairs (negative examples), reflecting the fact that most pairs of actual concepts do not instantiate any abstract relation. The covariance matrix $\hat{\Sigma}$ for this empirical prior is calculated by

$$(\hat{\Sigma}^{-1}) = c \cdot (\mathbf{X}^T \mathbf{M} \mathbf{X}) / N \quad (4)$$

where c is a user-defined smoothing parameter set to twice the number of related pairs in the training samples, N is the total number of word pairs in the training set, and \mathbf{X} is a matrix containing the features of all (related and unrelated) word pairs in the training set. \mathbf{M} is a diagonal matrix with each entry defined as

$$(\mathbf{M})_{ii} = \hat{p}(i)(1 - \hat{p}(i)) \quad (5)$$

where $\hat{p}(i)$ is the MLE predicted probability of the i th word pair being related, given by Eq. (2).

The Hierarchical Prior

The above model computes its prior based on the observed data. This empirical prior uses all related pairs as members

Figure 2: Graphical representation of hierarchical model. Distribution of α is determined by the hyperparameters that model the variance of the relational weight vector \mathbf{w} . The other notations are the same as in Figure 1.

of the set of positive training cases, and numerous unrelated pairs as negative cases. An alternative empirical prior could be computed by considering pairs of a specific relation as positive examples and pairs instantiating other relations as negative examples. Although empirical priors are a sensible choice to facilitate inference in the high-dimensional space, the question of how the best data set for learning an empirical prior could be constructed remains unresolved.

Here we explored a different approach, specifying a hierarchical prior on the distribution of the weight vector \mathbf{w} (see Fig. 2). Specifically, the posterior distribution of \mathbf{w} learned from training data is derived (replacing Eq. 3) by

$$P(\mathbf{w} | \mathbf{X}_S, \mathbf{R}_S = 1) = \int_{\alpha} P(\mathbf{w} | \alpha, \mathbf{X}_S, \mathbf{R}_S = 1) P(\alpha) \quad (6)$$

where vector $\alpha = [\alpha_1, \alpha_2, \dots]$ determines the precision (the inverse variance) of each element of the weight vector \mathbf{w} . We use a conjugate prior distribution in the form of a Gamma distribution for α_i with two hyperparameters a_0 and b_0 :

$$P(\alpha_i) \sim \text{Gamma}(\alpha; a_0, b_0) \quad (7)$$

The individual prior for each element in vector \mathbf{w} is assigned in the form of a normal distribution:

$$P(w_i | \alpha_i) \sim N(w_i; 0, \alpha_i) \quad (8)$$

This normal distribution imposes a general prior that the value of w_i is centered at 0 (i.e., the i th feature dimension is not expected to be relevant in predicting whether a certain relation exists between the two words). However, the value of α_i controls the certainty about this prior belief. A low precision value makes the prior belief uninformative, whereas a high precision value imposes a strong bias that w_i is most likely 0. Accordingly, the hyperparameters play an important role in determining the relevance of feature dimensions in predicting the existence of a relation.

The other term in Eq. (6) can be derived by applying Bayes rule directly,

$$P(\mathbf{w} | \alpha, \mathbf{X}_S, \mathbf{R}_S = 1) = \frac{P(\mathbf{R}_S = 1 | \mathbf{w}, \mathbf{X}_S) P(\mathbf{w} | \alpha)}{\int_{\mathbf{w}} P(\mathbf{R}_S = 1 | \mathbf{w}, \mathbf{X}_S) P(\mathbf{w} | \alpha)} \quad (9)$$

The Inference Algorithm

Although the general framework of the relation learning models is straightforward, the inference step is non-trivial because the calculation of the normalization terms in Eqs. (3) and (9) and integrals in Eq. (6) are intractable, lacking analytic solutions. A sampling approach is impractical for dealing with high feature dimensionality. We therefore employed variational methods developed by Jaakkola and Jordan (2000) to obtain a closed-form approximation to the posterior distribution. Specifically, the variational method updates the mean of vector \mathbf{w} and its covariance matrix \mathbf{V} iteratively:

$$\begin{aligned}\mathbf{V}^{-1} &= \mathbf{a} / \mathbf{b} + 2 \sum \lambda(\xi_n) \mathbf{x}_n \mathbf{x}_n^T, \\ \mathbf{w} &= \mathbf{V} \sum_n \mathbf{x}_n / 2, \\ \mathbf{a} &= a_0 + 1 / 2, \\ \mathbf{b} &= b_0 + \mathbf{E}_w(\mathbf{w} \mathbf{w}^T) / 2, \\ \xi^2 &= \mathbf{x}^T (\mathbf{V} + \mathbf{w} \mathbf{w}^T) \mathbf{x}.\end{aligned}\tag{10}$$

Computational Experiments

The Training Set and Generalization Test

Table 1 shows some examples of pairs of concepts that we used to train and test the two models. We used four different relations: function, synonyms, linear ordering, and antonyms. For each relation, we chose 15-20 pairs that were examples of that relation to use as the training set. We will refer to pairs used for training as AB pairs. All pairs were selected from experimental materials used previously to form four-term verbal analogy problems, and for which LSA vectors (derived using the tasaALL corpus) were available. We selected pairs for which the cosine similarity between the words (based on their LSA vectors) was at least 0.1, aiming to exclude pairs that included highly ambiguous words (e.g., *gift-present* as an example of synonyms).

After learning representations of the abstract relations based on the AB pairs, the model was tested on a two-alternative forced-choice generalization task. For each test item, the model was asked to choose which of two alternative pairs instantiated a specified relation. We will refer to correct and incorrect options as CD and CD', respectively. For example, one item required the models to decide which pair instantiated antonymy, *shallow-deep* (CD) or *shallow-depth* (CD'). As this example suggests, the discrimination was quite subtle, as the C term was common to both options and the CD' pair also instantiated an abstract relation (but not the relation being queried). The words used in this generalization test did not overlap at all with the AB pairs used in training, but were selected according to the same general criteria. For each test problem, the models calculated the probability of CD and of CD' being examples of the relation, respectively, according to Eq. (1), and chose the pair with the higher probability as the answer. The percentage of test questions that each model answered correctly for each relation was calculated.

Table 1: Examples of word pairs used in the training sets and generalization tests (correct option on left).

Training pairs	Testing pairs
Function	
door-open	rabbit-hop vs. rabbit-bunny
sun-warm	cup-drink vs. cup-mug
zoo-animals	smile-happy vs. smile-frown
Synonyms	
liberty-freedom	car-auto vs. car-bus
huge-enormous	weak-feeble vs. weak-strong
forest-woods	sad-unhappy vs. sad-sadder
Linear ordering	
worse-worst	inch-foot vs. inch-length
kitten-cat	rain-downpour vs. rain-fall
tap-strike	pebble-rock vs. rock-mineral
Antonyms	
weak-strong	shallow-deep vs. shallow-depth
start-finish	float-sink vs. float-boat
slowly-quickly	find-lose vs. find-search

Simulation Details

Inputs for each word were LSA vectors of length 300. The LSA algorithm orders its features from highest to lowest in terms of their predictive power. Preliminary tests indicated that most of the information useful for our learning models was encoded in the first ten features of the LSA vectors. Accordingly, we used just these first ten features for each word as inputs. The full vector for a word pair included the basic and derived features, $\mathbf{X} = [\mathbf{A}, \mathbf{B}, \mathbf{AB}, |\mathbf{A} - \mathbf{B}|]$, with a total length of 40 features.

In the implementation of the model by Silva et al. (2007), the dataset for computing the empirical prior included all AB word pairs plus a large number (>3500) of unrelated word pairs. Each unrelated word pair was weighted by approximately the ratio of the total population of unrelated word pairs to the number of unrelated word pairs that were sampled. After obtaining the prior, the model employed variational methods to compute the posterior distribution for \mathbf{w} using the AB training pairs for each relation separately.

In the simulation of our hierarchical model, the values of hyperparameters (a_0 , b_0) were searched separately for each relation to maximize generalization performance.

To provide baselines for evaluating the two Bayesian learning models, we applied three simpler methods of judging the correct relational alternative. First, we calculated the mean cosine distances of the correct alternative and its foil to the training set using “raw” LSA vectors, i.e., using only the basic features $[\mathbf{A}, \mathbf{B}]$ over all 300 dimensions of the LSA vector for each word in a pair (yielding 600 features total). Specifically, we computed the average of cosine distances between a CD pair and all AB

pairs in the training set, and for the corresponding CD' pair and all AB pairs. The baseline decision for the discrimination task was determined by which pair yielded the closer cosine distance. The performance of this method informs us about the amount of information that “raw” LSA vectors provide for the four abstract relations of interest.

Second, we used an additional cosine distance measure defined over the same feature vectors as those used by the Bayesian models, i.e., the \mathbf{X} vectors, which included the first ten features of the LSA vector for each word, plus the corresponding derived features.

Third, we examined the performance of simple logistic regression (which obtains the relational representation \mathbf{w} through maximum-likelihood estimation) using the first ten LSA dimensions and the full set of derived features.

Results and Discussion

The five modeling methods were evaluated on nine different sets of training pairs and testing pairs. Each set was randomly chosen from the analogy problems available to us. Mean proportion correct over the nine different training/test sets for each of the methods described above is shown in Fig. 3. Overall, the Bayesian model incorporating the hierarchical prior yielded the best generalization performance for all four relations, and in each case was reliably more successful than any of the three baseline models. The proportions correct for the hierarchical model were .78 for function, .72 for synonyms, .86 for linear ordering, and .66 for antonyms. In general, the generalization performance for the Bayesian models was best for linear ordering and weakest for antonymy. It should be noted that the linear ordering relation can be viewed as a generalization of the type of specific comparative relation (e.g., “larger than”) to which the learning model proposed by Dumas et al. (2007) has been applied.

The Importance of the Prior

The improvement in generalization performance of the Bayesian models over the MLE logistic regression model illustrates the importance of the prior distribution on the relational weights \mathbf{w} . This result suggests the possibility that children may also benefit from prior knowledge, either innate or acquired through previous experience, when learning new abstract relations. They may, for example, first learn to distinguish related or generally similar concepts from unrelated concepts before discriminating among more specific relations. Future experiments could explore the kinds of prior training that best aid human learning of new abstract relations, and compare the results with model performance using different priors.

The superior generalization of the Bayesian model using the hierarchical prior compared with the model using the empirical prior indicates that learning can be further improved by introducing a more effective prior. Using the general prior knowledge obtained by contrasting related and unrelated relations is a sensible choice in the applications on which Silver et. al. (2007) focused. However, this empirical prior may not be sufficient to provide informative guidance for inferences in the high dimensional space created using LSA inputs. Adopting a hierarchical prior increases learning power by incorporating soft constraints on the relational representation, \mathbf{w} , and its associated uncertainty.

Why are Antonyms so Hard?

The fact that the Bayesian models performed relatively poorly on antonyms warrants further analysis. It should be noted that for antonyms only, the cosine distance method based on 300 LSA dimensions (with basic features only) outperformed cosine distance based on 10 LSA dimensions and the full set of derived features. This finding raises the possibility that finding a good representation for antonymy

Figure 3: Simulation results. Prediction accuracy for generalization of relations in the two-alternative forced-choice relation-discrimination task. Error bars represent 1 standard error of the mean, based on 9 random samples of training/test items.

may require attention to more feature dimensions than is the case for the other relations. Another possible reason for their greater difficulty is that antonyms are usually very similar concepts that are dissimilar in only a few aspects (e.g., both *love* and *hate* can be used as a noun as well as a verb, and are strong emotions that one sentient being can have about another). Moreover, the aspects or dimensions on which antonymous concepts differ vary from one pair to another (e.g., *love-hate* vs. *black-white*). The shifting relevance of features makes learning a good representation for antonyms challenging, especially using a method that learns weight distributions over a fixed set of features.

Conclusions

We investigated the possibility that abstract semantic relations can be learned at least in part by purely data-driven statistical techniques applied to concept pairs represented by unstructured feature vectors. By using LSA vectors as inputs we avoided any hand-coding of semantics or relational structure, while assuring that inputs were of realistic complexity. Compared to baseline performance (inference based on cosine similarity of test options to the training set and MLE logistic regression), two models of relation learning based on Bayesian logistic regression achieved higher overall performance on a transfer test requiring discrimination between learned relations instantiated entirely by new concepts. The more successful of the two models incorporated hierarchical priors.

Neither model approached perfect performance on transfer problems. However, considering the small size of the training set (less than 20 examples of each relation), the total absence of overlap between training and test items, and the relatively subtle discrimination of relations required on the generalization test, these preliminary findings are encouraging. Further exploration of statistical approaches to learning abstract semantic relations appears to be warranted.

Acknowledgments

We thank Walter Kintsch, Tom Landauer and Praful Mangalath at the University of Colorado Institute of Cognitive Science for kindly providing us with LSA vectors. This research was funded by a University Fellowship and a Chancellor's Prize from the Graduate Division at the University of California, Los Angeles, and by ONR grant N000140810186.

Abstract

Recent Semantic Space Models (SSMs) are now integrating perceptual information with linguistic statistics into a unified mental space, offering a solution to the criticism that SSMs are disembodied. However, these new models introduce the problem of illusory feature migrations. When the word *dog* is perceived, its perceptual features should migrate to *hyena*, so the system can infer the perceptual features for a non-perceived word (hyenas have fur). In doing so, however, the models are unable to avoid migrating the features for *dog* to syntagmatically related words, such as *bone*. As a result, the models incorrectly infer that bones have fur. We argue that the problems of perceptual grounding and word order are not independent—a model of word order information is needed to correctly infer how features should migrate in mental space. We introduce a multiplicative binding framework that allows all information sources to be stored in a composite mental space, but features will only migrate to words that share sufficient order information with directly perceived words.

Keywords: semantic space models, symbol grounding problem, perceptual integration, embodied cognition.

Introduction

Semantic Space Models (SSMs) have seen remarkable success in recent years as models of how humans learn the meanings of words from repeated episodic experience, and for how lexical semantics are represented in mental space. Many types of SSMs now exist, with several modifications to better approximate human semantic cognition.¹ In general, these models all create semantic representations from statistical regularities in large linguistic corpora, building on Harris' (1970) *distributional hypothesis* of lexical semantics: the more similar the contexts in which words are experienced, the more similar their meanings. SSMs have successfully accounted for a wide variety of human semantic data, ranging from semantic priming and free association, up to high-level discourse processing by applying compositional algorithms to SSM representations.

Despite their successes, SSMs have been heavily criticized as implausible psychological models on a number of grounds. Firstly, most of these models have been criticized as “bag-of-words” models, in that they simply consider the context in which the word occurs, but ignore the statistical information inherent in word transitions. Recent solutions to the word-order problem use binding operations to learn a blended semantic space in which a word's representations reflects its history of co-occurrence

with, and position relative to, other words (e.g., Jones & Mewhort, 2007). Further, these models are able to retrieve plausible n-gram information (coarse grammaticality) directly from the blended space, without the need for explicit rules of grammaticality. The integration of word order information has been shown to give a much better fit to human data in a variety of semantic tasks.

Secondly, SSMs have been criticized as “disembodied” in that they learn from only linguistic information but are not grounded in perception and action (see de Vega, Graesser, & Glenberg, 2008 for a workshop on the issue). The lack of grounding in SSMs is in direct contrast to the recent literature on embodied cognition, demonstrating that a word's meaning is grounded in sensorimotor experience. Sensorimotor information is an inherent part of the semantic organization of the human lexicon, but much of this information cannot be learned from statistics in a text corpus—it must be learned from multisensory experience (but see Riordan & Jones, in press). In addition, current models have a symbol-reference problem: there is no way to link a word's internal representation back to its referent in the real world.

We are now seeing the emergence of the first perceptually grounded SSMs. As a proxy for sensorimotor experience, these models use norms of human-generated features (such as the norms of McRae et al., 2005). These norms represent aggregate human productions of the physical properties, appearance, sounds, smells, functional properties, etc. for concrete nouns and event verbs based on multisensory experience. For example, the feature <has_4_legs> will have a high probability for *dog* and *cow*, but a low probability for *centipede*, and a zero probability for *strawberry*. However <is_red> is a highly salient feature of *strawberry* and not for *dog*.

Most of the new grounded SSMs simultaneously consider the distribution of words across contexts in a text corpus and the distribution of words across perceptual features, allowing them to extract joint information between the two data sources. This allows the models to make implicit inferences across the two information sources: if the model learns from perceptual experience that *sparrows* have beaks, and from linguistic experience that *sparrows* and *mockingbirds* are used in a similar distributional fashion, it naturally makes the inference that *mockingbirds* have beaks. The inference chain works in the opposite direction as well. Most impressive, given a novel word most of these models can retrieve an accurate representation of the perceptual features of the novel word's referent. Simulations have

¹ For recent advances in SSMs, see the upcoming issue of *Topics in Cognitive Science* edited by Danielle McNamara.

demonstrated that the blended linguistic/perceptual mental space may yield a superior approximation of human data.

However, a major issue common to all of these new grounded models is that they have no way to discriminate between syntagmatic relationships (e.g., the relationship between *bee* and *honey*) and category-based paradigmatic relationships (e.g., *bee* and *wasp*). The linguistic abstraction phase of these models will learn to position the vectors for *car*, *automobile*, and *road* close in semantic space. This produces the problem that the model cannot distinguish which regions of space may adopt features that migrate from a perceptually grounded word during the feature inference phase. The result is that the model correctly infers that *automobile* <has_wheels>, but it also incorrectly infers that *road* <has_wheels>. We refer to these errors as *illusory feature migrations*, and argue that errors of migration are much more common in semantic space than are correct migrations, which can severely pollute the resulting semantic space relative to a human representation that would not contain this type of error.

One reason these models fail to discriminate between context-based syntagmatic vs. category-based paradigmatic relationships is that they ignore word order information, which is a powerful cue for category membership (Jones & Mewhort, 2007). That is, words that are flanked by similar n-grams tend to belong to the same conceptual categories. Extensive study in the field of category-based inference has investigated the ways in which category structure constrains feature generalization (for reviews, see Heit, 2000; Rips, 2001). To ignore word information is to ignore a very salient cue to category membership at an SSM's disposal.

To be clear at the outset, we strongly commend the authors of these perceptually grounded models for taking a huge step in the right direction towards our understanding of human semantic representation. However, a plausible model must also be able to filter components of this representation so that perceptual information may generalize to paradigmatically but not syntagmatically similar words (i.e., from *car* to *automobile* but not *road*). Here we explore the utility of a formal binding framework based on ideas from signal processing and Jones and Mewhort's (2007) BEAGLE model that has these desiderata.

Grounding Semantics in Perception and Action

Recent attempts to ground SSMs in perception and action can be placed into one of two classes: post-hoc inference models, and ad-hoc inference models. Both types can be trained on the same text corpus and feature representations (e.g., TASA and McRae et al., 2005).

Post-hoc inference models begin with the abstraction of a text corpus into a reduced vector space (a traditional SSM), and then attempt to bind these linguistic vector representations to the feature norms. For example, Durda, Buchanan, and Caron (2009) train a feedforward neural network to associate linguistic vectors with their corresponding activation of features. Given the linguistic representation for *dog*, the output feature <has_fur> should

be activated but the output feature for <made_of_metal> should be inhibited. After iterative training with backprop, the model can infer the correct pattern of perceptual properties for words that did not have a perceptual feature vector. At its core, this technique simply maps similar linguistic vectors to similar output vectors, as with other pattern generalization applications of feedforward networks.

Ad-hoc inference models typically begin with a raw word-by-document matrix of a text corpus and a word-by-feature matrix of a feature database. During learning, the model attempts to learn a word's representation by simultaneously considering inference across documents and features. An excellent example of an ad-hoc model is presented in Andrews, Vigliocco, and Vinson (2009). Andrews et al., use a Bayesian framework to infer the joint distributional information for a word between linguistic and perceptual data. It is important to note that their technique is *joint inference*: it squeezes more information out of the data than simply adding perception to linguistic experience. Andrews et al. convincingly demonstrate that their joint model gives better fits to word association data than a model that considers only one data source, or the simple addition of the two sources.

Illusory Feature Migrations

A major problem with both post-hoc and ad-hoc inference models is that they must exhibit illusory feature migrations as a consequence of their architecture. An illusory feature migration occurs when a non-perceived word adopts erroneous features from a linguistically related word simply because they are proximal in semantic space. This is a common issue in the aforementioned models because they do not have order information to discern between syntagmatic and paradigmatic word relations. If the models are optimized on free-association data (which is strongly dominated by syntagmatic productions), then they must position syntagmatically related words like *bee* and *honey* close in space, as well as paradigmatically related words like *bee* and *wasp*. As a result, the inference mechanism simply sees both *honey* and *wasp* as similar patterns to *bee*, and naturally makes the inference that *honey* can fly and has wings.

Note that the "migration" described need not be a dichotomous on/off feature. It is simply the case that the inferred distribution over possible features for *honey* has some correlation with that of *bee* simply because their distributional structure in language has overlap. This overlap introduces error in the labeling of novel referents (e.g., a novel object that looks like an insect will activate words like *honey* as potential labels). Furthermore, this inference error will introduce noise to the overall semantic organization, which will lead to a poorer account of human semantic data compared to a human who will not make these inference errors. The aforementioned models demonstrated examples of correct feature generalizations in their papers; what was not illustrated is the larger number of incorrect feature generalizations.

Presumably, humans use word-order information to constrain the inference of features in mental space. This information allows a model to distinguish what types of words may adopt features given a perceived target word. Rather than making this a terse rule-based model, we choose to adopt a graded feature migration framework—words adopt the aggregate features of proximal words that have features, weighted by their similarity in order space. However, it is also important to keep the sources (context, order, perception) blended to account for the wide range of embodied semantic data. This requires a model that can create a blended semantic representation, but that can know what part of the semantic signal to use in computing similarity for feature migration. We next describe a simple framework towards this type of integrated model, test its behavior on an artificial language paradigm, and then scale it up to a real language corpus to see how the properties are maintained at a large scale.

A Feature-Binding Framework

Our goal was to build an SSM with two key properties. First, context, order, and feature information should be represented as patterns in high-dimensional vectors. Even though these three sources of information should be blended within a single vector, it should be possible to determine the degree of similarity between two words in context space, order space, or feature space alone. Because context, order, and feature information is distributed, computing a vector cosine between two vectors reflects their similarity when all three sources of information are taken into account.

Second, feature migration should occur, but features should only migrate to words with which they share order information (i.e., words that are commonly flanked by similar n-grams). For example, *food* and *table* will share primarily context information, whereas *table* and *countertop* will share primarily order information; therefore, features should migrate from *table* to *countertop*, but not from *table* to *food*.

Encoding. Our model is similar to other SSMs that represent both context and order information with fixed-length high-dimensional vectors (Jones & Mewhort, 2007; Sahlgren et al., 2008). When a word w is encountered in the input text for the first time, it is assigned an initial “environmental” vector e_w —a random vector whose elements are randomly selected from a Gaussian distribution of mean 0 and variance 1. Environmental vectors are intended to represent the static properties of a word’s surface form, such as its orthography and phonology, and are not updated during processing. The new word is also assigned an initially empty memory vector m_w to represent its semantics. When the model encounters a new sentence in the input corpus, m_w is modified according to the update rule:

$$m_w = m_w + (C_l \odot \text{context}) + (O_l \odot \text{order}) + (F_l \odot \text{features}_w)$$

where the circumpunct “ \odot ” denotes elementwise vector multiplication, one of a class of multiplication-like operators

that vector symbolic architectures employ to combine vectors in a neurally plausible manner (Levy & Gayler, 2009; Kanerva, 2009). C_l , O_l , and F_l are *indicator vectors*—unchanging vectors that are bound with vectors representing context, order, and feature information, respectively. They serve to “tag” the source of the information signal (context, order, or perception). They may be initialized either as random vectors, or as binary vectors of ones and zeros sharing little or no overlap with each other.

As in Jones & Mewhort (2007) and Sahlgren et al. (2008), the *context* vector represents co-occurrence information: it is the sum of all environmental vectors of words occurring in the same sentence as w . The *order* vector is the sum of all n-grams surrounding w up to some fixed window size, where an n-gram is represented by binding the environmental vectors of all the words comprising the n-gram via elementwise multiplication. In the experiments presented here, only bigrams directly to the left and right of w are considered. As in Sahlgren et al. (2008), words to the right and left are distinguished by rotating the environmental vectors by one unit in a positive or negative direction, respectively. Finally, the *features* vector represents information about sensorimotor features of words. Each of 2,526 features taken from the feature norms of McRae, et al. (2005) was assigned a unique random vector. If w is the word for one of the 541 concepts for which feature norms were collected, features_w is the sum of the five vectors that correspond to the five features that were attributed to w by the greatest number of participants. If w is not among the concepts in the McRae et al. feature norms, features_w is initialized as a vector of zeroes (and only acquires nonzero values during training, when vectors are added to m_w via the update rule). The fact that features_w has a w subscript while *context* and *order* do not reflects the fact that features_w is derived from information about w in the feature norms, while *context* and *order* represent information about the sentence currently being processed.

Retrieval. After training, the cosine between every pair of memory vectors is calculated to determine the model’s estimate of the semantic similarity between words. These similarity scores can be thought of as distances between points in a high-dimensional space, which we refer to as the *composite space*. In addition to having a lower computational complexity than circular convolution, one benefit of using elementwise vector multiplication for binding the information source tag is that the operation serves as its own approximate inverse when vector elements are sampled from a z-distribution, hence:

$$X \approx (X \odot Y) \odot Y \quad (1)$$

This allows vectors to be elementwise multiplied with the aforementioned context indicator vector C_l before calculating their cosines. The operation serves to ‘unbind’ the $C_l * \text{context}$ binding, yielding a *context space* in which two words’ distance from each other reflects the amount of context information they share (but is not heavily influenced

by shared order or feature information). Similarly, unbinding via elementwise multiplication with O_I yields an *order space* in which cosine similarity reflects the amount of shared order information; unbinding with F_I yields a *feature space* where feature information is paramount.

Experiment 1

The objective of Experiment 1 was to determine whether the binding model we outlined does in fact possess the desired property of representing context, order, and feature information in a separable fashion, and whether it behaves appropriately with respect to feature migration. Demonstrating this required training the model on a corpus in which the amount of context, order, and feature information that words share is known, which is best accomplished using a corpus of an artificial language. Strictly controlling the input allows us to determine conclusively whether the model at least exhibits the desired properties in the simplest case and lets us more clearly observe how the inclusion or exclusion of different types of information affects the similarity space.

Method

Input corpus. The model was trained on a corpus of 1,000 sentences from a simple artificial language. This language was designed such that it would contain some word pairs that shared context information but not order information, some pairs that shared order information but not context information, and some words that shared context as well as order information. The language used is described by the following context-free grammar (symbols in bold are terminal symbols):

$S \rightarrow A \text{ Aux } B \text{ Num } Cs \mid D \text{ Aux } E \text{ Num } Fs$
 $Aux \rightarrow \text{can} \mid \text{should} \mid \text{would} \mid \text{could} \mid \text{does}$
 $Num \rightarrow \text{two} \mid \text{three} \mid \text{four} \mid \text{five} \mid \text{six}$

Sentences of the corpus were generated randomly, with each possible transition of equal probability. Thus, it consisted of sentences such as “A can B three Cs”, “A would B four Cs”, “D should E three Fs”, and so forth. In this corpus, *A*, *B*, and *Cs* each share context information, as they always co-occur, but they do not share order information. If this were a real language, one could think of *A*, *B*, and *Cs* as fillers for three different grammatical roles. Similarly, *D*, *E*, and *Fs* share context, but not order, information. In contrast, the members of pairs {*A*, *D*}, {*B*, *E*}, and {*Cs*, *Fs*} each share order information, but significantly less context information. The auxiliary verbs {can, should, would, could, does} and numbers {two, three, four, five, six} share significant amounts of order information with each other. They also share context information: even though the grammar allows auxiliaries and numbers to co-occur with any of *A*, *B*, *Cs*, *D*, *E*, or *Fs*, each auxiliary always co-occurs with some number.

Procedure. Two simulations were conducted. In Simulation 1, no feature information was included. In Simulation 2, we

retrained the model with the full update rule $m_w = m_w + (C_I \odot context) + (O_I \odot order) + (F_I \odot features_w)$, adding five vectors corresponding to five features for the word “strawberry” from the McRae et al. norms to the concept for the word *A* (*a_fruit*, *grows_on_plants*, *grows_in_fields*, *grows_on_bushes*, and *has_green_leaves*). We compared the model under three conditions: context, composite, and order. In each condition, feature migration proceeded by unbinding $m_w \odot F_I$ to retrieve an approximation $features'_w$ of $features_w$, and adding this approximation to every other memory vector m_i in proportion to the strength of their similarity in the relevant space (context space, composite space, or order space, depending on condition). That is, features tend to be more likely to migrate in the order condition between two words that share a large amount of order information than between two words that do not. Because we are interested in migrating features not merely to words that are “close” to the perceived word but rather to words that are similar to *w* in terms of their relationships to other words, the similarity between words w_1 and w_2 is obtained by correlating a vector of w_1 ’s cosine with each word in the lexicon with a vector of w_2 ’s cosine with each word in the lexicon. However, using just the cosine of w_1 and w_2 yields largely similar results.

Simulation 1.1. Tables 1 and 2 illustrate the most similar words to *A*, *B*, *Cs*, *D*, *E*, *Fs*, *can*, and *two* in context and order space, respectively, after training using the update rule $m_w = m_w + (C_I \odot context) + (O_I \odot order)$; no feature information was included in this simulation. In the absence of feature information, context and order information are separable in this model, despite the fact that both information sources are fully distributed across vector elements. Appropriately, the members of {*A*, *B*, *Cs*} cluster together in context space, as do the members of {*D*, *E*, *Fs*}. Additionally, pairs {*A*, *D*}, {*B*, *E*}, and {*Cs*, *Fs*} cluster together in order space. Although they do not appear in the tables, auxiliaries and numbers also cluster together.

Table 1. Z-scores of cosines of the most similar words to *A*, *B*, *Cs*, and *D* in context space, Simulation 1.

A		B		Cs		D	
A	3.6	B	3.6	Cs	3.6	D	3.6
B	.20	Cs	.20	B	.21	E	.18
Cs	.16	A	.16	A	.13	Fs	.15
five	-.08	two	.01	two	-.07	three	-.06
two	-.09	five	-.01	five	-.09	could	-.09

Table 2. Z-scores of cosines of the most similar words to *A*, *B*, *Cs*, and *D* in order space, Simulation 1.

A		B		Cs		D	
A	3.5	B	3.7	Cs	3.5	D	3.5
D	1.2	E	.32	Fs	1.1	A	1.2
B	-.10	A	-.03	B	-.15	Fs	-.14
Cs	-.13	Cs	-.04	A	-.17	E	-.17
can	-.24	can	-.22	can	-.24	can	-.30

Simulation 1.2. Table 3 illustrates the standardized correlations of vector cosines of the four most similar words to A under each migration condition. Because the migration rule transfers feature information in direct proportion to these values, the higher the value of a word, the more feature information that word receives from A. The important pattern in Table 3 is the reversal of B and D: in context space, the syntagmatic relation between A and B is much more salient, but in the order space the paradigmatic relation between A and D is emphasized. In the overall composite space, these relations are mixed (our desired blending in full lexical space), but the information required for correct feature migration is still implicitly represented.

Table 3. Standardized correlations of vector cosines of the four most similar words to A under the context, composite and order conditions, Simulation 2.

context		composite		order	
A	3.5	A	3.2	A	3.4
B	.63	B	.06	D	1.2
Cs	.55	D	.04	B	.05
does	-.17	Cs	.00	Cs	-.03

Thus, it appears that only the *order* condition minimizes opportunity for illusory feature migrations while preserving the appropriate migration to D, which is paradigmatically similar to A in this corpus. Furthermore, when feature information is added, the separability between context and order space is maintained, (allowing features to appropriately migrate from A to D) and individual features can be successfully retrieved.

Experiment 2

The objective of Experiment 2 was to explore whether the proposed binding framework continues to yield distributions that inhibit illusory feature migrations (i.e., migrations to syntagmatically similar words) while facilitating appropriate feature migrations to paradigmatically similar words when scaled up to a corpus of natural language. We therefore designed a version of Experiment 1 trained on a real corpus, the TASA corpus of high-school level English text. Two simulations were conducted: The first to examine the similarity of the decoded context and order spaces to paradigmatic and syntagmatic relations, and the second to demonstrate feature migrations to category co-ordinates vs. non-categorical associates of a target word. Both simulations were identical to Experiment 1’s Simulation 2 in terms of the update rule, the conditions (context, order and composite), and the feature migration rule.

Simulation 2.1. For each word, its feature vector $features_w$ was generated by summing the five vectors corresponding to the five features from the McRae et al. norms attributed to w by the greatest number of participants. As test items, we extracted 1075 word pairs from the word association norms of Nelson, McEvoy, & Schreiber (1998) for which both the first word of the pair (the cue) and the second word

of the pair (the target) were members of the McRae et al. feature norms². For each pair, we determined the category membership of each word, using the categories employed by Cree & McRae (2003, Appendix B): weapons, vehicles, foods, and so forth. Cree & McRae explicitly list which normed words belong in which categories, allowing us to code whether the cue was a member of the same conceptual category as the target. The 690 pairs in which both words shared a category were interpreted as being paradigmatically related (e.g., *apple-pear*), while the 385 paired words not sharing a category were interpreted as being syntagmatically related (e.g., *apple-crab*). The fact that two words are associates and do not appear in the same category does not guarantee syntagmatic similarity nor does it preclude phrasal association, however, informal observation suggests that many word pairs in the latter condition tend to appear in collocations or other classic syntagmatic relationships for which feature migration would be inappropriate. Indeed, the cosine similarity scores from the McRae et al. (2005) feature vectors for the word pairs were significantly higher for our paradigmatically related words than for syntagmatically related ones, $t(1073) = 24.66, p < .001$.

Motivated by the results of Experiment 1, we predicted that words sharing paradigmatic relationships would be closer in order space than in context space. This pattern of results would suggest that attending to order information facilitates more feature migrations among paradigmatically related words than among syntagmatically related ones, while attending to context information does just the opposite. For paradigmatically related words, the model’s cosine similarities were significantly higher in order space than in context space, $t(689) = 2.96, p < .01$. That is, words in paradigmatically related pairs were gauged to be more similar to each other in order space than in context space. In contrast, for syntagmatically related pairs, the model’s cosine similarities were significantly higher in context space than in order space, $t(384) = 4.371, p < .001$.

Simulation 2.2. To briefly demonstrate how illusory feature migrations may be corrected by incorporating order information, we selected 25 “triples” from Simulation 1, each consisting of a target **T** that existed in the McRae et al. norms, a category coordinate **CC** of **T**, and a syntagmatically related word **R** that had an associative relationship with **T** but was not a member of the same category. An example triple is <T:freezer, CC: refrigerator, R:ice>. *Freezer* and *refrigerator* each share a common class (kitchen appliances); *freezer* and *ice* are certainly related as well, but not by virtue of a category relationship. Intuitively, one would like features to migrate more strongly from **T** to **CC** than from **T** to **R**, given that categories for concrete words are defined at least partly on the basis of feature overlap. For example, the most popular features of *freezer* are *used_for_storage*, and *has_an_inside*, features that are

² We excluded the 24 concept words that the McRae et al. norms explicitly identify as having ambiguous meanings, such as “mouse_(animal)” and “mouse_(computer).”

much more applicable to kitchen appliances than they are to related non-category members (ice, frozen waffles, etc.). If a particular feature migrated more strongly from T to R than from T to CC, this was coded as an illusory feature migration. Otherwise, it was coded as an appropriate feature migration.

The (incorrect) migration of feature information from T to R was much stronger in the context condition than the order condition, and the (correct) migration of feature information from T to CC was stronger in the order condition than the context condition. By our coding scheme, 56% of the triples exhibited at least one illusory feature migration in the context condition (recall that this means the migration was stronger from T to R than it was from T to CC). In contrast, only 40% of the triples exhibited at least one illusory feature migration in the order condition. Most notable is that *all* illusory feature migrations that took place in the order condition also took place in the composite condition, and *all* illusory feature migrations taking place in the composite condition also took place in the context condition. In other words, some illusory feature migrations that took place in the context and composite conditions were avoided in the order space. Hence, emphasizing order information by unbinding with O_I (order space) yielded equal or better results for every triple when compared with emphasizing context information by unbinding with C_I (context space) or not unbinding at all (composite space). Table 4 presents four triples that differed by condition as to whether CC or R was deemed a better candidate for feature migration from T by the model. In each case, a feature migration error was committed in the context condition, but was avoided in the order condition.

Table 4. Example feature migration errors in context space that were corrected in the order space. Cases in which the related word was the stronger attractor were considered illusory feature migrations. Target word is bold.

Triple	Features most strongly attributed to target by participants in McRae et al. (2005)	Competitor that <i>features_w</i> Migrated More Strongly To, By Condition		
		context	comp	order
bottle CC: jar R: fill	used_for_holding_things made_of_glass used_for_holding_liquids made_of_plastic has_a_lid	fill	jar	jar

motorcycle CC: car R: wheels	has_wheels has_2_wheels is_dangerous has_an_engine is_fast	wheels	car	car

General Discussion

Integration of sensorimotor information is an important next step in the development of SSMs. While human-generated feature norms are admittedly an intermediary step, it is important to understand the cognitive mechanisms that humans might use to integrate perception/action and linguistic structure to organize meaning in memory for when perceptual models (e.g., computer vision) are sophisticated enough to directly represent environmental information to integrate with linguistic distributional structure (see Roy, 2008 for a discussion).

While early attempts at integrating perception and language in SSMs have shown much promise, our work here indicates that a model must have a mechanism to encode temporal linguistic information to know how perceptual information may be generalized in the mental space. The binding framework presented here shows the basic property of storing all information sources in a blended composite space (as is suggested by the literature in embodied cognition). However, the model is able to identify which components of the composite signal perceptual information should be allowed to migrate to. While this scheme needs more testing at a large scale, we believe it has promise for accounting for a wide range of semantic and embodied data, and is a step toward addressing criticisms of SSMs being ungrounded.

Abstract

A major part of learning a language is learning to map spoken words onto objects in the environment. An open question concerns the consequence this learning has for cognition and perception. We show that hearing common words (e.g., dog) activates visual information more than equally informative non-linguistic information (e.g., a dog bark). The main results show that (1) pictures were verified more quickly after hearing a word than after hearing a nonverbal sound, even after hundreds of trials of practice. (2) Verbal labels activated visual information more effectively than nonverbal sounds as tested by a simple visual discrimination task that required minimal semantic processing. (3) The advantage of the verbal modality did not arise simply due to greater familiarity of verbal labels: when experience with novel labels and sounds was equated, verbal labels continued to activate the associated visual information more reliably than the equally well-learned nonverbal sounds. These results inform the understanding of how human cognition is shaped by language and hint at effects that different patterns of naming can have on individuals' conceptual structure.

Introduction

Two hallmarks of human development are the development of conceptual categories—learning that things with feathers tend to fly, that animals possessing certain features are dogs, and that foods of a certain color and shape are edible (Carey, 1987; Keil, 1992; Rogers & McClelland, 2004), and learning *names* for those categories. The latter achievement is unique to humans. While many have commented on the transformative power of names (Clark, 1998; Dennett, 1994; Harnad, 2005; James, 1890; Vygotsky, 1962), it is only recently that the interplay between verbal labels and concepts has become a subject of rigorous empirical study.

The learning of categories is, in principle, separable from the learning of language. A child can have a conceptual category of “dog” without having a verbal label associated with the category. However, in practice the two processes are intimately linked. Not only does conceptual development shape linguistic development (Snedeker & Gleitman, 2004), but linguistic development—specifically learning words—impacts conceptual development (Casasola, 2005; Lupyan, Rakison, & McClelland, 2007; Gentner & Goldin-Meadow, 2003; Spelke, 2003; Spelke & Tsivkin, 2001; Waxman & Markow, 1995; Yoshida & Smith, 2005). The effects of words on nonverbal cognition only begin at word-learning. The learned associations between words and their referents appear to continue to influence cognitive processes

such as visual recognition memory (e.g., Lupyan, 2008a) and even visual processing (Gilbert, Regier, Kay, & Ivry, 2006; Lupyan, 2008b; Winawer et al., 2007). For example, hearing a verbal label such as “chair” facilitates the visual processing of the named category compared to trials on which participants know the relevant object category but do not actually hear its name (Lupyan, 2007, 2008b; Lupyan & Spivey, 2010). Hearing a label can even make an invisible object, visible (Lupyan & Spivey, 2008). One way to think about such results is that processing a verbal label preactivates the sensory and higher-level representations of objects denoted by the label—over and above activation caused by just thinking about the object category.

The present work addresses the question of how special words are in evoking visual information. Is a highly familiar concept accessed equivalently through verbal and nonverbal means with words being a merely convenient way to activate conceptual information? Or, do words evoke conceptual representations in a special way? We focus here on visual representations and compare the power of verbal and nonverbal cues to evoke visual information of both familiar and novel categories.

It has been long known that a response to a visual stimulus can be altered by a cue presented prior to the target stimulus. These cues can be nonverbal (Egley, Driver, & Rafal, 1994; Eriksen & Hoffman, 1972; Posner, Snyder, & Davidson, 1980) as well as verbal. For example, verbal cues in the form of words like “left” and “right” produce automatic shifts of attention just as reliably as nonverbal cues such as directional arrows even when the words are entirely non-predictive of the target's location (e.g., Hommel, Pratt, Colzato, & Godijn, 2001). Words related to motion, e.g., “float,” have been shown to affect visual motion processing (Meteyard, Bahrami, & Vigliocco, 2007). Several studies have also shown visual object processing can be altered by verbal cues (Puri & Wojciulik, 2008; Vickery, King, & Jiang, 2005). Such effects of cues on visual processing have been linked to increases in category-specific cortical activity. For example, after seeing the word “face,” participants are not only better at making a gender judgment of faces embedded in visual noise, but this enhanced discrimination correlates with activity in the fusiform face area (Esterman & Yantis, 2009). These experiments have typically used verbal labels as cues, as language is a natural way to convey information about objects. It is at present unknown whether a verbal label should be thought of as merely a convenient method of cuing—it is a primary function of language to convey information not presently in view—or whether there

is something special in the way language activates visual information. In other words, is the type of visual activation produced by hearing the word “cow” somehow special or can it be achieved by nonverbal cues similarly associated with the concept of cows, e.g., a mooing sound. Although both “cow” and the sound of a cow mooing are associated with cows, only the former is treated (in the normal course of things) as referring to a cow.

We present six experiments comparing the powers of verbal and nonverbal cues to evoke visual information. Experiments 1a-1c contrast verbal and nonverbal cues in a series of picture-verification tasks. Experiments 2a-2b contrast verbal and nonverbal cues in a visual discrimination task that requires minimal semantic processing. Experiment 3 tests whether the verbal advantage arises due to participants’ greater familiarity with the verbal cues or whether the verbal advantage in evoking visual information is due specifically to the referential status of words.

Experiments 1a-1b

Experiments 1a-b comprised picture verification tasks in which participants heard an auditory cue (a label or a nonverbal sound), and then saw a matching or mismatching picture. If verbal labels activate visual information more reliably than do nonverbal cues, participants should be able to respond more quickly after hearing a label than a nonverbal sound.

Participants

A total of 116 University of Pennsylvania undergraduates volunteered in the experiments in exchange for course credit: 18 in Exp. 1a, 15 in Exp. 1b, 20 in Exp. 1c, 18 in Exp. 2a, 25 in Exp. 2b, and 20 in Exp. 3.

Materials

We selected 10 objects that were easily nameable and that had characteristic sounds (cat, car, dog, frog, gun, motorcycle, rooster, train, cow, whistle). Each category was instantiated by 5 images: a normed color drawing (Rossion & Pourtois, 2004), 3 photographs obtained from online image collections, and 1 “cartoon” image (e.g., a drawing of a cartoon dog). We used several instances of each category to introduce some visual heterogeneity. Spoken labels comprised basic-level names (listed above). Nonverbal sounds were obtained from online environmental sound libraries and judged to be unambiguously related to the target categories through piloting. All sounds were volume and length-normalized.

Procedure

On each trial participants heard a label or nonverbal sound followed by a picture, which, with equal probability, either matched the cue or did not. In the latter case, the picture was randomly selected from among the non-matching category images. Participants responded by pressing a “match” or “does not match” key on a keyboard. Immediately following

their response, auditory feedback in the form of a buzz or bleep indicated whether the response was correct. Exps. 1a and 1b differed in one respect: in Exp. 1a the delay between cue offset and picture onset was 400 ms. In Exp. 1b this was increased to 1 s—a common delay used in verification tasks (Stadthagen-Gonzalez, et. al.2009). The rationale for this long delay is that it gives plenty of time for the word or sound to be encoded thoroughly by the time the picture appears. Thus, the verification RTs will be largely determined by the time it takes to recognize the picture rather than reflecting residual processing of the label or sound cue.

All factors were within-subjects and each participants completed 400 verification trials: 10 categories \times 5 category exemplars \times 2 levels of congruence \times 2 cue-types (sound vs. label) \times 2 repeats.

Results and Discussion

The data were analyzed using a mixed-effects ANOVA with all factors as within-subject effects. Only correct RTs were included. RTs less than 200 ms or greater than 1500 ms were excluded (1.9% of all trials). An analysis of RTs revealed a highly reliable validity advantage, $M_{\text{valid}}=552$ ms, $M_{\text{invalid}}=600$ ms, $F(1,18)=35.72$, $p<.0005$ and a strong advantage for label trials, $M_{\text{label}}=563$ ms, $M_{\text{sound}}=588$ ms, $F(1,18)=24.77$, $p<.0005$ (Figure 1A). This advantage was also observed in accuracy, $M_{\text{label}}=96.2\%$, $M_{\text{sound}}=95.2\%$, $F(1,18)=6.38$, $p=.02$. There were no reliable cue-type \times validity interactions.

Experiment 1b likewise revealed a validity advantage for RTs, $F(1,14)=20.80$, $p<.0005$, and a strong label advantage, $M_{\text{label}}=583$ ms, $M_{\text{sound}}=620$ ms, $F(1,14)=26.80$, $p<.0005$ (Figure 1B). The label advantage was also observed in accuracy, $M_{\text{label}}=97.8\%$, $M_{\text{sound}}=96.0\%$, $F(1,14)=13.11$, $p=.003$. There was no significant prime-type \times item interaction, $F<1$. A replication of Exp. 1b with a 1.5 s delay yielded virtually identical results.

It is conceivable that the advantage of labels is short-lived, owing its existence to the initial unfamiliarity of the sound cues. If so, the advantage should vanish or be diminished with practice. We divided each participant’s data into four equal blocks and ran an ANCOVA with block as a covariate. Although participants became faster, and more accurate over time ($F_s > 10$), there were no hints of an interaction between block and cue-type for either RT or accuracy in either experiment, $F_s < 1$.

Experiments 1a-1b show that hearing a verbal label compared to a nonverbal sound affords a quicker identification of a subsequent picture most likely by pre-activating visual information associated with the label allowing for quicker and more accurate acceptance of a congruent picture and a quicker rejection of an incongruent picture.

Experiment 1c

The results from Exps. 1a-1b suggest that labels may play a special role in evoking visual representations owing to their referential nature (see below for discussion). Alternatively,

participants may have simply been more familiar with verbal labels than the sounds we used. This latter account predicts that, in a verification context, participants should, on seeing an image, be faster to activate a label than its nonverbal sound. Experiment 1c tested this possibility by reversing the order of the label/sound and picture. Participants now saw a picture first and had to judge a subsequently presented auditory label or nonverbal sound as either matching the picture or not. A finding of a continued advantage of labels would support the familiarity account (but would not necessarily contradict the reference-based account). A disappearance of the label advantage would provide evidence against the familiarity-based account.

Materials and Procedure

Materials were identical to Experiments 1a-1b. The procedure was identical except for the reversal of cue and target identities. On each trial, participants saw a picture for 1 s. One additional second after it disappeared, a verbal label or nonverbal sound was played and the participants task was, as quickly as possible, to press the appropriate key indicating whether the sound matched the picture (valid trial) or not (invalid trial). Participants could start responding at any time after the onset of the target label or sound, although responses generally occurred after the offset of the label or sound. Accuracy feedback was provided immediately after the response.

Results and Discussion

The data were analyzed identically to Exps. 1a-1b. There was a significant validity advantage in RTs, $F(1,19)=17.45$, $p=.001$: $M_{\text{valid}}=575$ ms, $M_{\text{invalid}}=614$ ms. There was no significant difference between label and sound trials, $F(1,19)=2.62$, $p=.12$, with a trend for slower responses times to label trials than to sound trials, $M_{\text{label}}=502$ ms, $M_{\text{sound}}=587$ ms. An analysis of accuracy also failed to find a difference between label and sound cues, $M_{\text{label}}=94.6\%$, $M_{\text{sound}}=94.9\%$, $F<1$, further demonstrating that the nonverbal sounds were as recognizable as the labels. Comparing Exps. 1b and 1c revealed a highly reliable experiment \times cue-condition interaction, $F(1,33)=24.19$, $p<.0005$.

If the label advantage observed in experiments 1a-1b was a simple consequence of participants' greater familiarity with labels, it was expected that a label advantage would be observed in the present study because viewing the picture would activate the stronger associate—the label—more quickly than the weaker associate—the nonverbal sound. However, that is not what we observed. Rather, the label advantage appears to be asymmetric, occurring when visual information is to be activated by a label cue, but not when a label needs to be activated by a visual cue. An alternative explanation is that lexical items are more complex than environmental sounds and thus require additional processing time. On this account, however, it is unclear why, if labels required greater processing time, we found a reliable verification advantage in Exps. 1a-1b.

Experiments 2a-2b

A limitation of Experiments 1a-1c is that the response requires the participants to semantically classify the image. It is thus unclear whether the label advantage derives from a faster activation of associated visual information (which facilitates subsequent recognition) or if it arises from faster activation of a semantic category itself. To tease apart these accounts, we use a task with a response that depends on visual processing, but only minimally dependent on semantic processing: discriminating an upright image from an upside-down one. The task is similar to one used by Puri and Wojciulik (2008) to examine effects of general and specific cues on visual processing.

Materials

The verbal and nonverbal sounds were identical to Experiments 1a-1c. In addition, a non-informative cue was created consisting of white noise of the same length and volume as the other auditory cues. For the pictures, only the standardized and normed instances of each category were used (Rossion & Pourtois, 2004).

Procedure

On each trial, participants saw two pictures for 200 ms. presented simultaneously to the left and right of a fixation cross. These pictures were identical except one was upside-down (flipped about the x-axis). Participants' task was simply to indicate which side of the screen contained the upright picture by pressing the 'z' key with their left index finger if it was the picture on the left, and the '/' key with their right index finger if it was the picture on the right. It was stressed that it did not matter what object was shown in the picture. The pictures were preceded by an auditory cue. The trials were evenly divided into label cues, sound cues, and uninformative noise cues. The label and sound cues validly cued the upcoming picture on 80% of the trials. On the remaining 20% the cue was invalid, for example, participants would hear "cow" (or hear a mooing sound) but then see a car. This allowed us to measure both the advantage of a valid cue relative to a noise cue (are people faster to locate the upright cow after hearing "cow"/a moo sound?) and the cost of an invalid cue relative to a noise cue baseline (are people slower to identify the upright cow after hearing "car"/a car-starting sound?) And, critically, we can compare these benefits and costs for label and sound cues.

Exps. 2a and 2b differed in only one respect: in Exp. 2a the delay between the offset of the cue and onset of the pictures was 400 ms. In Exp. 2b it was lengthened to 1 s to determine whether the results observed in Exp. 2a were due to insufficient time to process the nonverbal sound. There were 20 practice and 300 real trials.

Results and Discussion

RTs were analyzed by mixed-effects ANOVAs followed by directed t-tests. The first analysis included validity and cue-type (sound vs. label) as fixed factors (validity is undefined

for noise cue trials) and subject as a random factor. Results are shown in Figure 1. We found a highly reliable effect of validity, with valid trials being reliably faster than invalid trials, $F(1,17)=39.72$, $p<.0005$. There was a significant validity \times cue-type interaction with label cues showing a larger cuing effect than sound cues, $F(1,17)=8.23$, $p=.011$. Relative to the no-cue baseline, valid sound cues improved performance by a significant amount, $t(17)=2.84$, $p=.03$. Label cues also improved performance, $t(17)=5.01$, $p<.0005$, and this improvement was significantly greater than the improvement due to sounds, $t(17)=2.93$, $p=.009$. Conversely, relative to the no-cue baseline, invalid label cues significantly slowed responses, $t(17)=4.38$, $p<.0005$; sounds cues did not, $t(17)=1.19$, $p>.2$. There was a significant difference between the cost of invalid labels and the cost of invalid sounds, $t(17)=2.12$, $p=.048$. Accuracy was very high ($M=97.8\%$) and did not vary between conditions.

Figure 1: Results of Exps 2a-2b. Error bars show ± 1 SE of the difference between noise cues and the condition closest to its mean. The mean of the noise cue trials is plotted twice for ease of comparison.

Did the label advantage result from a lack of time to process the sound cue? This was unlikely given the results of Exp. 1c, but nevertheless, we conducted a replication of Exp. 2a with a longer (1 s) delay between cue offset and picture onset. As shown in Figure 2b, valid labels helped relative to baseline, $t(24)=2.45$, $p=.022$, while sounds did not, $t(24)=1.13$, $p>.2$, though the interaction was not significant. Invalid sounds now hurt performance relative to baseline (although not as much as labels). In sum, labels continued to function as more effective cues than sounds.

With a longer time to process the cue, the nonverbal cues start to act more like verbal cues, quite possibly because participants may explicitly label the nonverbal sounds.

Experiment 3

The studies thus far examined effects of words/sounds on visual processing of objects with which participants have had extensive prior experience. We had no way of knowing whether and what types of differences in experience may have produced the label advantage observed in Exps 1-2. The label advantage is unlikely to be a product of a simple familiarity difference between labels and sounds (see Exp. 1c), but it is possible that labels have a greater power to evoke visual information because they have been more frequently encountered in the context of the visual referent. In Exp. 3, we exerted complete control over by training different groups of participants to associate either novel labels or nonverbal sounds with novel stimuli. A finding of a label advantage in this context would lend support to the idea that words have a special power to evoke visual information.

Materials

The learning set consisted of 6 novel 3D objects (Figure 2). There were 3 variants of each object to increase visual heterogeneity. These variants involved changes in viewpoint and slight changes in feature configuration. Each category was paired with a novel label (shonk, whelph, scaif, crelch, foove, and streil). Each of these nonce words was designed to have approximately equal bigram and trigram statistics and similar real-world lexical neighborhoods. We also created 6 nonverbal sounds: one for each category. These were created by modifying and combining environmental and animal sounds to create 6 sounds that were not readily nameable, as judged by pilot testing.

Figure 2: Materials used in the learning task for Exp 3.

Procedure

Participants were randomly assigned into *label* and *sound* groups. There were 3 parts to the experiment presented in immediate succession. In the first part, participants passively viewed 12 trials during which all three exemplars of each category were presented together with a recording, e.g., “These are all shonks” (for the label condition), or “These all make the sound___” (for the sound condition).

Part 2 consisted of a verification task. Participants saw two exemplars from different categories followed by a prompt, e.g., “Which one’s the streil?” or “Which one makes the sound ____”) and had to select whether the left or right stimulus matched. There were 180 training trials.

The last part was a replication of Experiment 2b with the novel stimuli. That is, participants judged whether the left or right picture was upright (i.e., in the familiar orientation) after hearing a sound or label cue (now without a sentential context). The images were presented for 200 ms after a 1 s delay which was timed to the offset of the auditory cue.

Results and Discussion

Participants were remarkably adept at learning the 6 categories. After Part I—just two exposures to each category—participants could correctly perform the 2AFC task of Part II with ~95% accuracy. The label group was slightly less accurate and slower than the sound group, $p=.08$, and there were no reliable condition \times block interactions. By block 5 both groups were performing at 99%, demonstrating that learning names for novel categories is no more or less difficult than learning what sounds they make.

Figure 3: Cuing effects in Experiment 3. Left: $RT_{invalid} - RT_{valid}$. Middle: $RT_{no-cue} - RT_{valid}$. Right: $RT_{invalid} - RT_{no-cue}$. Error bars show $\pm SE$ of the mean difference score.

The critical part of the experiment was subsequent orientation judgment task. Having ruled out entirely differences in familiarity and association strength between labels and sounds, would labels continue to evoke visual activations in a more robust way than sounds? Indeed, that is what we found. As shown in Figure 3, there was a significant validity advantage, $F(1,18)=49.55$, $p<.0005$, but this advantage was significantly larger for label than sound cues, $F(1,14)=6.14$, $p=.023$. The valid cue also benefited RTs relative to the uninformative noise cue, $F(1,18)=38.34$, $p<.0005$, and this benefit was larger for the label than sound trials, $F(1,18)=10.73$, $p=.004$. Finally, there was a significant cost of hearing an invalid cue relative to no cue, $F(1,18)=8.08$, $p=.011$, but this cost was not reliably different for the two groups, $F<1$. An identical pattern of results was found when we used proportions instead of RT differences.

The two groups did not differ in overall response times, $M_{label}=433$ ms, $M_{sound}=389$ ms, $F(1,18)=1.70$, $p>.2$, or accu-

racy, $M_{label}=96.4\%$, $M_{sound}=95.7\%$, $F<1$.

In Experiment 3 we had complete control over participants’ exposure to the pictorial stimuli, labels, and sounds. We could thereby ensure that they were equally familiar with the labels and nonverbal sounds. Participants were equally proficient in learning to associate the novel categories with labels or sounds. After only about 10 minutes of training, hearing a label or sound activated the corresponding visual form, as revealed by an RT advantage on valid trials and an RT cost on invalid trials. This in itself is quite remarkable. Critically for our thesis, the label cues were more reliable in activating the corresponding visual form than the sound cues, confirming that even when familiarity and experience with verbal and nonverbal associates is fully equated, verbal cues activate visual information more reliably than nonverbal cues.

General Discussion

Humans learn an elaborate system of sounds (or gestures in case of sign language) that refer, in a largely arbitrary way, to objects, actions, and relations. Beyond enabling linguistic communication, does the acquisition and use of the system confer certain cognitive and perceptual abilities?

In this work, we have investigated whether information communicated verbally (through words denoting concrete objects) and nonverbally (through sounds associated with those objects) activates visual information in the same way. We found that it does not. Cuing categories by using words is more effective than cuing them using nonverbal cues. Verbal cues, more than nonverbal cues appear to preactivate a visual representation of the cued category, helping when the cue is valid and hurting performance when the cue is invalid. This phenomenon is robust, being observed in virtually every subject. A number of control experiments rule out the possibility that this effect is due to different levels of familiarity with verbal versus nonverbal cues.

These findings contradict the popular view that language simply activates nonverbal concepts (Gleitman & Papafragou, 2005; e.g., Li, Dunham, & Carey, 2009; Snedeker & Gleitman, 2004) because presumably such concepts should have been activated in the same way by equally well-learned nonverbal information (as in Exp. 3), but they were not. The finding that representations of very familiar categories (e.g., dogs, cats, and cars) can be evoked more reliably by labels than by sounds, even a full second after cue offset hints at the powerful effects of language on visual activation.

How do words come to have such evocative powers? We believe it is unlikely that there is innately privileged access to vision from the verbal modality (indeed, it is unclear what an innate verbal modality would entail). Rather, the special status of words may derive from accumulated experience of treating them in a referential way (Waxman, 1999), although what exactly this entails vis-à-vis a neural mechanism remains unknown. The present results show that verbal labels serve as powerful cues (Elman, 2004; Rumelhart, 1979), invoking associated concepts and percepts in a unique way, even when the concept in question is a highly

familiar one such as [dog]. The finding that after only ~10 minutes of experience, labels affect representations of new concepts (Exp. 3), hints that long-term differences in linguistic experience can have significant effects on the ease of activating specific mental states. Rather than being simple constituent feature of the concept with which it is associated, a name appears to offer a particularly efficient route to the activation of visual and perhaps other information. Although the verbal activation of conceptual information can be deemed a human universal—perhaps the defining feature of language—the present results hint that the substantial differences in lexicalization patterns between languages may translate to cross-linguistic differences in how particular mental states can be evoked.

Abstract

Prepositions in natural languages often appear to be governed by arbitrary conventionalized idiomatic uses (e.g., *I was born in May, I will see you on Sunday*). We present empirical evidence that such prepositional uses are not entirely arbitrary, as they activate image-schematic perceptual simulations during language processing.

In Experiment 1, native speakers of English were prompted to think about either the date or the month of their birthday, and then select one of four calendar diagrams, two foils, one flat calendar and one box-like calendar diagram designed to invoke perceptual simulations of support and containment respectively. There was a significant relationship between the question prompt (implicitly eliciting *in* or *on*) and the type of calendar chosen (containment or support). Thus, spatial schemas can be spontaneously activated when thinking about time even for non-literal, idiomatic uses.

Prepositional uses are notoriously difficult for English L2 learners. We surmised that improper prepositional uses may be linked to improper underlying perceptual simulations. This was confirmed in Experiment 2 where Japanese-speaking students of English were presented the same task as Experiment 1. Here, results indicate no relation between the date or month question and calendar choice. The experiments offer both theoretical and practical insights into how prepositions are processed by individuals with varying levels of language knowledge.

Keywords: Perceptual simulations; prepositions; second language learning; embodied cognition.

Introduction
